The purpose of our study was to examine the association between maternal age and chromosome 21 nondisjunction (NDJ) by the origin of the meiotic error. We analyzed data from two population-based, case-control studies: Atlanta Down Syndrome Project (1989-1999) and National Down Syndrome Project (2001-2004). Cases were live born infants with trisomy 21 or mosaic trisomy 21 and controls were live born infants without trisomy 21 delivered in the same geographical regions. Of the eligible 1881 cases and 2293 controls, we enrolled 1215 case and 1375 control families (64.6% and 60.0% participation, respectively). Chromosome 21 DNA markers were used to classify the NDJ error. There were four primary findings from this study. First, the significant association between advanced maternal age and chromosome 21 NDJ was restricted to meiotic errors in the egg; the association was not observed in sperm or in mitotic errors. Second, advanced maternal age was significantly associated with errors occurring in both stages of meiosis. For example, compared to mothers of controls, mothers of infants with trisomy 21 due to meiosis I (MI) NDJ were 8.5 times more likely to be 40 years old than 20-24 years old at the birth of the index case (95% CI= 5.6-12.9). Where NDJ occurred in meiosis II (MII), mothers were 15.1 times more likely to be 40 years (95% CI=8.4-27.3). Third, the ratio of MI to MII errors differed by maternal age. The ratio was lower among women 19 years of age and those 40 years (2.1, 2.3, respectively) and higher in the middle age group (3.6). Lastly, there was no evidence found for a grandmaternal age effect for the risk for maternal NDJ. This study emphasizes the complex association between advanced maternal age and NDJ of chromosome 21 during oogenesis.

Association analysis of the interleukin 17A (*IL17A*) gene in Rheumatoid Arthritis patients from Norway and New Zealand. *G. B. N. Nordang[1], M. K. Viken[1], J. E. Hollis-Moffatt[2], T. R. Merriman[2], O. T. Forre[3], K. Helgetveit[4], T. K. Kvien[5], B. A. Lie[1]* 1) Institute of Immunology, Rikshospitalet University Hospital, Oslo, Norway; 2) Department of Biochemistry, University of Otago, Dunedin, New Zealand; 3) Department of Rheumatology, Rikshospitalet University Hospital, Oslo, Norway; 4) Martina Hansens Hospital, Sandvika, Norway; 5) Department of Rheumatology, Diakonhjemmet Hospital, Oslo, Norway.

Objective: Elevated levels of interleukin 17A (IL-17A) have been detected in the inflamed synovium of rheumatoid arthritis (RA) patients, and murine arthritis models that are *IL17A* deficient demonstrate reduced inflammation. A possible indirect effect during osteoclatsogenesis has been revealed by IL-17A-mediated induction of receptor activator of NF-B ligand (RANKL) on osteoblastic cells (Sato K et al. 2006). Based on the likely role of IL-17A in inflammation and bone destruction in RA, the aim of this study was to investigate *IL17A* as a candidate gene for RA. **Method:** Five single nucleotide polymorphisms (SNP) were selected to tag the genetic variability of the IL17A region. Genotyping was performed by TaqMan technology on 950 RA cases and 933 random controls from Norway. In addition, 652 RA patients and 562 controls from New Zealand were used as a replication data set. **Results:** We found a weakly significant association between RA and the promoter SNP rs2275913 (OR=1.17; 95% CI [1.02 - 1.34]; *P*=0.02) in the Norwegian population. This association was not replicated in the RA cohort from New Zealand (OR=1.01; 95% CI [0.93 - 1.10]; *P*=0.8). However, combining the two data sets demonstrates a weak association (OR= 1.20; 95% CI [1.03 - 1.39]; *P*=0.02). **Conclusion:** Modest evidence of an association with *IL17A* in Norwegian RA patients was observed. Although, our findings were not replicated in an independent RA cohort from New Zealand, a significant common risk estimate indicated that *IL17A* warrants further investigation in RA before any definite conclusions can be drawn.

A small in-frame deletion in the seventh immunoglobulin-like repeat of filamin C is a cause of myofibrillar myopathy. *A. Shatunov[1], M. Olivé[2], Z. Odgerel[1], C. Stadelmann-Nessler[3], K. Irlbacher[4], M. Bayarsaikhan[5], H.-S. Lee[1], I. Ferrer[2], M. C. Dalakas[6], N. Sambuughin[5], H. H. Goebel[7], L. G. Goldfarb[1]* 1) National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, Maryland, U.S.A; 2) Institut de Neuropatologia, Ciutat Sanitària i Universitària de Bellvitge, Hospitalet de Llobregat, Barcelona, Spain; 3) Universitätsmedizin der Georg-August-Universität Göttingen, 37075 Göttingen, Germany; 4) Charité - Universitätsmedizin Berlin, Germany; 5) Uniformed Services University of the Health Sciences, Bethesda, Maryland, U.S.A; 6) Thomas Jefferson University, Philadelphia, PA, U.S.A; 7) Mainz University Medical Center, Mainz, Germany.

We studied an International cohort of 39 families with myopathologically confirmed myofibrillar myopathies, in which DES, CRYAB, MYOT, and ZASP mutations have been excluded. In an unrelated German family a 12-nucleotide deletion (c.2997_3008del) in FLNC resulting in a predicted in-frame 4-residue deletion (p.Val930_Thr933del) in the 7th repeat of filamin C was identified. Both affected family members, mother and daughter, carried the mutation. Size-fragment analysis of FLNC exon 18 in 241 unrelated individuals of European ancestry failed to uncover defects in exon 18, suggesting that p.V930_T933del was the candidate mutation associated with myofibrillar myopathy in this family. Ultrastructural examination revealed major myofibrillar abnormalities, including accumulation of debris of Z-disc origin, granular and filamentous material and the presence of a large number of nemaline rods. In addition, there were tubulofilamentous profiles and large autophagic vacuoles containing myelin-like figures and cellular debris. V930_T933del deletion in FLNC can cause damage in the cytoskeletal architecture and most likely is a structural basis for deficient flexibility of actin networks. Molecular analysis of the novel filamin C mutation adds to the characterization of the diverse forms of myofibrillar myopathies and permits a more precise molecular diagnosis.

Genetic association with retinopathy in a large cohort of American families with type 1 diabetes. *C. Monti[1,3], R. Montross[2], B. Corso[3], J. Lonsdale[2], C. Montmoli[3], D. Greenberg[1]* 1) Division of Statistical Genetics, Department of Biostatistics, Columbia University, New York, NY; 2) Genetics Division (HBDI), National Disease Research Interchange, Philadelphia, PA; 3) Section of Medical Statistics and Epidemiology, Department of Health Sciences, University of Pavia, Pavia, Italy.

We conducted a case-control analysis to test for association of diabetic retinopathy with single nucleotide polymorphisms (SNPs) found in type 1 diabetes (T1D) candidate loci. All subjects had T1D; cases had the complication of retinopathy, controls did not. Phenotypic data came from the Human Biological Data Interchange (HBDI) family collection of the National Disease Research Interchange (Phila., PA). SNP data was from the Type 1 Diabetes Genetics Consortium, sponsored by NIDDK, NIAID, NHGRI, NICHD and JDRFI. Of the 6000 available SNPs, we focused on SNPs known to be in T1D-related genes. The phenotype (presence or absence of retinopathy) was rigorously assessed. Cases had clearly-diagnosed retinopathy. Controls had T1D for 20 years or more without retinopathy and had no first-degree relative family history of retinopathy. We compared the frequency of alleles in 118 retinopathy T1D probands (cases) with the frequencies in 143 non-retinopathy T1D probands (controls). The SNPs that yielded strong association evidence for retinopathy susceptibility ($p<0.001$, $OR > 1.7$) were: rs540652 (NOSTRIN gene), rs1991537 (ADAM23 gene), and rs1483457 (LOC389676 gene). Two SNPs showed a significant ($p<0.001$, $OR <0.5$) protective effect: rs9740 (CASR gene) and rs3740892 (PKNOX2 gene). These results provide strong preliminary evidence for genetic association with diabetic retinopathy. Our results suggest that genes predisposing to T1D may also be involved in increased risk for complications, although some may provide protective alleles.

DSS1, Abraxas and RAP80: an analysis of three genes coding for BRCA1 or BRCA2 interacting proteins in hereditary breast cancer families. *D. J. Novak[1, 2], N. Sabbaghian[2], R. Kyle[2], P. Maillet[3], P. O. Chappuis[3], M. Tischkowitz[1,2], W. D. Foulkes[1,2]* 1) Depts of Medicine and Human Genetics, McGill University, Montreal , Canada; 2) Program in Cancer Genetics, McGill University, Montreal , Canada; 3) Service of Oncology and Med Gen, Geneva University Hospitals, Geneva, Switzerland.

Background: Germ-line mutations in the two major breast cancer (BrCa) susceptibility genes, BRCA1/2, in addition to minor susceptibility genes such as CHEK2, P53, ATM, PTEN, BRIP1 and PALB2 currently account for 30-50% of the familial BrCa risk. Most of these genes encode proteins implicated in the preservation of genomic integrity, interacting either directly or indirectly with one of the BRCA genes. Three genes with similar functional interactions are DSS1, RAP80 and Abraxas. DSS1 is known to interact with BRCA2, and is implicated in BRCA2 DNA repair of DSBs, in addition to DNA foci formation of RAD51. Abraxas has been shown to directly interact with BRCA1, allowing for the indirect interaction between BRCA1 and RAP80. Together, the BRCA1-Abraxas-RAP80 complex is required for loading BRCA1 to sites of DNA damage and its associated response. Mutations in any of these three genes may account for unattributed familial BrCa risk.

Methods: One hundred and forty seven BRCA1/2 negative women with BrCa, selected for a strong family history of multiple BrCa cases, were sequenced for variants within the 3 exons of DSS1. Sequencing data was analyzed as an entire set as well as according to ethnic background. Similarly, ninety-five women with BrCa were sequenced for variants within the 14 exons of RAP80 and 9 exons of Abraxas.

Results: In DSS1, one silent variant was identified. In Abraxas, we have identified nine intronic, two untranslated and two previously identified missense variants. Finally, seven intronic, three silent, three known and one novel missense, in addition to three variants in the UTRs of RAP80, have been identified.

Conclusions: Overall, it appears unlikely that highly penetrant alleles exist in either of the DSS1, RAP80 or Abraxas genes.

Towards protein expression quantitative trait loci (peQTL): Initial analysis of variability in protein expression levels and development of a 2D gel spot-map for human lymphoblastoid cells. *M. K. Bunger[1], M. D. Rowland[1], H. Pan[2]* 1) Biomarkers and Systems Biology Center, RTI International, Research Triangle Park, NC; 2) Research Computing Division, RTI International, Research Triangle Park, NC.

Population-based variability in protein expression patterns are often observed, but poorly understood. Recent literature describing population-based mRNA expression implies that variability in mRNA levels behaves as a heritable quantitative trait. Several QTL associated with mRNA expression levels have been mapped in both *cis* and *trans* relative to expressed genes using genome wide association methods in multiple organisms. However, little is known about the genetics driving protein expression and whether the same QTL will be associated with both protein expression and mRNA expression variability. We have performed a small pilot study using quantitative fluorescence difference gel electrophoresis (DIGE) on proteins from 24 lymphoblastoid cell lines (LCLs) derived from the CEPH; Utah collection (CEU). On average, 1500 spots were detected on each gel and 560 spots were detected on all gels. Expression levels were determined relative to a pooled internal standard and population variability of each protein was calculated. Population variance among these proteins ranged from 0.006 to 36.2 demonstrating that a large dynamic range of variation is detectable using DIGE. Regression analysis of expression variation with cell doubling time revealed only a minor contribution with R^2 values above 0.5 for only 5 proteins. Identification of proteins from spots from 3 unrelated experiments was carried out using high resolution MALDI MS/MS incorporating both peptide mass fingerprinting and MS/MS analysis searching against the latest human protein database from IPI. To date 283 proteins have been identified from at least one gel. Among the 283 proteins, 58 were represented by at least two spots. Multiple spots per protein often occur as a result of post-translational modifications (PTMs) which can shift both the pI and molecular weight of any given protein, resulting in spot trains. Thus, using DIGE allows for quantitative analysis of both proteins and their post-translational modifications independently.

Identification of Genetic Variants Associated with Capecitabine toxicity through Gene Expression. *A. Stark[1], B. E. McIlwee[2], E. O. Kistner[3], M. E. Dolan[2]* 1) Dept Human Gen, Univ Chicago, Chicago, IL. USA; 2) Section of Hematology/Oncology, Dept Medicine, Univ Chicago, Chicago, IL USA; 3) Dept Health Studies, Univ Chicago, Chicago, IL USA.

Capecitabine is a prodrug of 5-fluorouracil used to treat colorectal and breast cancer. Human variation in the degree of chemotherapeutic-induced toxicity and response can be based on a number of functional mechanisms. In an attempt to elucidate these mechanisms we investigated the relationship between baseline gene expression levels and capecitabine-induced cytotoxicity in HapMap lymphoblastoid cell lines derived from the Phase I populations: Yorubans from Ibadan, Nigeria, Japanese from Tokyo, Japan, Han Chinese from Beijing, China, and CEPH from Utah. Due to insufficient cytidine deaminase expression, we used an activated form of capecitabine (5-DFUR). Inter-ethnic differences in sensitivity to capecitabine were observed with the Yoruban population displaying the most sensitivity. Using the Affymetrix Gene Chip Human Exon 1.0 Array, we correlated the baseline gene expression with cytotoxicity measured in the Yoruban and CEPH cell lines. Using this genome-wide approach, we discovered unique and common genes correlating with cytotoxicity in the two populations. At a permissive p-value cutoff of $p < 0.005$, there are 196 unique CEPH genes and 31 unique Yoruban genes and 4 genes that overlap: WIG1, DMXL2, FMNL3, and TNFAIP2. Baseline expression for both WIG1 and FMNL3 are significantly associated with the same SNP on chromosome one (rs161110). The most significantly associated gene, found in the CEPH population, is hemochromatosis, HFE, ($p = 7.06$ x 10-6) a gene that encodes a transmembrane protein regulating transferrin receptor. HFE expression is associated with a SNP on chromosome five (rs10040947), a possible trans regulator ($p < 0.00001$). Genes with baseline expression correlated with cytotoxicity of capecitabine provide evidence for these candidate genes to be evaluated for regulatory architecture.

A novel locus for autosomal dominant retinitis pigmentosa (ADRP) maps to chromosome 7p15. *J. S. Friedman[1], M. Brooks[1], R. Khanna[2], E. H. Trager[2], K. E. Branham[2], V. Ponjavic[3], L. Gränse[3], G. R. Abecasis[4], S. Andréasson[3], A. Swaroop[1,2]* 1) NIH/NEI/NNRL, NIH, Bethesda, MD; 2) Department of Ophthalmology, University of Michigan, Ann Arbor MI; 3) Department of Ophthalmology, Lund University Hospital, Lund, Sweden; 4) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Retinitis Pigmentosa (RP) constitutes a group of genetic eye diseases in which the photoreceptor cells in the retina degenerate, leading to irreversible vision loss. To date, 17 genes have been identified to cause autosomal dominant retinitis pigmentosa (RetNet). We are studying a large Scandinavian family with a slower than average progression rate and apparent autosomal dominant pattern of inheritance. We performed linkage analysis using the data obtained by hybridiziation of affected individual DNAs to 250K gene chip SNP arrays from Affymetrix. SNP data was examined using standard methods (Pedstats, GRR etc), and linkage was performed using Merlin. We identified a peak lod score of 5.0 on chromosome 7p15. No mutations were identified in a previously-reported RP9 gene, Pim-1 kinase associated protein, at 7p14. We have initiated a screen of genes in the minimal region as determined through haplotype analysis. The identification of this ADRP gene will assist in the better understanding of the mechanisms underlying RP and could lead to targeted therapies to alleviate this disease.

A novel mutation (Ser186Leu) in rhodopsin is associated with an autosomal dominant form of congenital stationary night blindness (adCSNB) in a Chinese family. *Y. Jiang[1], S. Hu[1], X. Liu[2], S.-H. Chen[3]* 1) Beijing Genomics Institute, Beijing, China; 2) School of Optometry and Ophthalmology, Wenzhou Medical college, Wenzhou, Zhejiang, China; 3) Department of Pediatrics, University of Washington, Seattle , WA98195.

The autosomal dominant form of CSNB is a group of rare eye disorders characterized by non-progressive deficiency of night vision under dim illumination with normal fundus, abnormal dark adaptation curves and severe attenuation of electroretinogram (ERG) a and b waves. Molecular studies of families with adCSNB have identified six missense mutations in 3 different genes. They are: G90D, A292E, T94I of RHO; H258D of PDE6B; and G38D and Q200E of GNAT1. We have studied a large Chinese adCSNB family with over 34 affected individuals in 11 generations. A novel mutation, Ser186Leu of RHO was found to associate with the adCSNB in this family. Peripheral blood samples were obtained from 15 affected individuals, 2 toddles of unknown phenotype and 12 unaffected family members. Genomic DNA was isolated from leucocytes. Six segments of the RHO gene were amplified by a standard PCR method. Sequencing was performed in Beijing using an ABI prim 3730x1 Sequencer. Using Polyphred (Phred/Phrap/Consed software package), a mutation was identified in each of 15 affected family members and 2 toddles but not in the 12 unaffected individuals of the family or in 100 controls. The phenotype of adCSNB is co-segregating with the heterozygotes in the family. The mutation is a C to T missense mutation in codon 186.2 (TCG) of the RHO gene resulting in Serine (TCG) to Leucine (TTG) change at amino acid 186 of rhodopsin protein. The affected individuals and the 2 toddles are heterozygous (Serine/Leucine) for the locus, while the unaffected individuals are homozygous (Serine/Serine).

European individual ancestry (IA) is associated with subclinical cardiovascular disease phenotypes in African-Americans (AFA) and Hispanics from the Multi-ethnic Study of Atherosclerosis (MESA). *C. L. Wassel[1], J. S. Pankow[1], S. Choudhry[2], C. A. Peralta[2], M. F. Seldin[3], D. K. Arnett[4]* 1) University of Minnesota, Minneapolis, MN; 2) University of California, San Francisco, CA; 3) University of California, Davis, CA; 4) University of Alabama, Birmingham, AL.

Coronary artery calcium (CAC) and common carotid intima media thickness (cIMT) are subclinical measures of atherosclerosis that differ by ethnicity, with AFA in general having larger cIMT but less CAC compared to Caucasians. IA can be an important tool for identifying traits for admixture mapping as well as controlling for population stratification in genetic association studies. Thus, we examined the association of IA with CAC and cIMT among MESA AFA and Hispanics. In 2847 ethnically diverse men and women aged 45-84 from 6 sites in the US, we studied associations of IA with CAC and cIMT using log-binomial and linear regression models, respectively, controlling for confounders. Splines were used to assess the appropriate functional form of IA with CAC and cIMT. CAC and cIMT were measured at baseline with computed tomography and ultrasound, respectively. IA was estimated using STRUCTURE V2.2, which employs Markov Chain Monte Carlo approach. Genotype data was available for 199 ancestry informative markers, and 712 MESA Caucasians, 60 Yoruban Nigerians from HapMap, and 345 Native Americans were used as pseudo-ancestral populations. Among AFA, a standard deviation increase in European IA was associated with an 8% higher CAC prevalence, p=0.02 and a 2% lower cIMT, p=0.008. Average European IA ranged from 15% at the New York site to 25% at the Chicago site. Among Hispanics, the highest tertile of European IA (48.4%) was associated with a 33% higher CAC prevalence compared to the lowest tertile, p=0.02. Average African IA ranged from 4% to 28% across sites, while average Native American IA ranged from 30% to 59% across sites. Higher European IA was associated with CAC and cIMT among AFA and CAC among Hispanics. This suggests that CAC and cIMT may be good candidates for admixture mapping. The variation in IA by site illustrates the importance of controlling for population stratification in genetic association studies.

Bayesian block clustering for multi-trait genome-wide association studies. *M. Gupta[1], Y. H. Hsu[2], S. Demissie[1], L. A. Cupples[1], P. Sebastiani[1], D. P. Kiel[2,3], D. E. Karasik[2,3]* 1) Boston University, Boston, MA; 2) Institute for Aging Research, Hebrew SeniorLife, Boston, MA; 3) Harvard Medical School, Boston, MA.

Many common diseases including diabetes, cardiovascular disease, and osteoporosis are characterized by complex traits, which are determined by the interplay of numerous genetic variants and their interaction with environmental factors. Although genetic and phenotypic data may contain the information to decipher complex diseases, building global models that can associate complex traits with the appropriate genetic profile leads to several formidable statistical and computational challenges. We have developed a novel Bayesian framework for a block clustering model and an efficient Monte Carlo-based computational methodology geared towards identifying sets of candidate genes associated with traits for different diseases, and for prioritizing subsets of candidate genes/SNPs for further evaluation. Our method is suitable for large genetic data sets, and is more appropriate to use than standard clustering techniques when (i) small sets of SNPs are believed to influence a phenotype of interest, or (ii) a single SNP may affect multiple phenotypes that may or may not be influential in all other phenotypic measurements. Application of our method to data from the Framingham Osteoporosis Study shows several interesting SNP-phenotype connections, which illustrate underlying characteristics of bone aging. The data set consisted of 2,005 women and 1,496 men (with a mean age of 62.5 years), members of two generations of Framingham, who were measured for bone mineral density (hip and spine), heel ultrasound, hip and metacarpal geometry. Heritability estimates for all bone health related phenotypes were 30-66%, and some of the phenotypes displayed high genetic correlations.

tRNA splicing endonuclease mutations cause pontocerebellar hypoplasia. *B. S. Budde[1], Y. Namavar[2,3], P. G. Barth[3], B. T. Poll-The[3], P. Nuernberg[1], F. Baas[2]* 1) Cologne Center for Genomics, University of Cologne, Cologne, Germany; 2) Department of Neurogenetics, Academic Medical Center, University of Amsterdam, The Netherlands; 3) Division of Pedriatric Neurology, Emma Childrens Hospital/Academic Medical Center, Amsterdam, The Netherlands.

Pontocerebellar hypoplasias (PCH) represent a group of neurodegenerative autosomal recessive disorders with prenatal onset, atrophy/hypoplasia of the cerebellum, hypoplasia of the ventral pons, microcephaly, variable neocortical atrophy and severe mental and motor impairments. To identify the locus responsible for PCH type 2 we performed a genome-wide scan in two families from the Volendam region in the Netherlands using 10K SNP arrays (Affymetrix). We found linkage to chromosome 17q25 with a maximum LOD score of 5.81. By finemapping using microsatellite markers we narrowed the PCH2 locus to an interval of 3.4 cM between markers D17S1301 and D17S751. We prioritized the genes in this region based on expression pattern and function and sequenced 19 genes. One variant in the tRNA splicing endonuclease homolog 54 gene (c.919G>T) was exclusively homozygous in 47 of 52 analyzed PCH2 cases, all of European descent, but not in the control samples. By genotyping 31 of those PCH2 patients being homozygous for the c.919G>T mutation we found a common SNP haplotype of 285 kb shared by all of them suggesting a founder effect dating at least 11 generations back. Further evidence for a causative role was obtained by extending the TSEN54 mutation screening to our PCH4 patients. In all three patients the c.919G>T variant was found in one of them homozygous while two of them were compound heterozygous carrying a nonsense mutation on the other chromosome. Furthermore we identified mutations in two other of the four different subunits of the tRNA-splicing endonuclease complex in two of the remaining PCH2 cases without the common mutation. Expression analysis of TSEN54 revealed a high level of TSEN54 mRNA in the developing pons, dentate and olive nuclei, which is in line with the PCH2 phenotype. Our findings point to RNA processing as a new basic cellular impairment in neurological disorders.

Genotyping quality of Affymetrix GeneChip Human Mapping 500K Array Set. *G. Zhang[1,2], G. Kennedy[3], J. Schumm[4], R. Chakraborty[1]* 1) Center for Genome Information, Department of Environmental Health, University of Cincinnati, OH; 2) Department of Family Medicine, University of Cincinnati, OH; 3) Genomics Collaborations, Affymetrix Inc, CA; 4) The Bode Technology Group, VA.

The Affymetrix GeneChip Human Mapping 500K Array Set enables high throughput genome-wide SNP analysis and has been widely used in genome-wide association and population genomics studies. It has been shown that even moderate genotyping error rates can have serious affects on haplotype or LD measure inferences and in turn inflate the type I error rate of a study. Therefore, it is important to learn whether the 500K Array Set will provide accurate and robust genotyping calls for DNA samples in practice, which may have large variations in quality and quantity. To answer this question, we analyzed the genotyping quality of the 500K Array Set using the genotype data of 43 forensic samples as well as the data of the 270 HapMap samples. The experimental procedures of the GeneChip Assay generally involve two steps: 1) whole genome sampling analysis (WGSA) by restriction fragmentation and PCR amplification and 2) SNP allele discrimination by probe hybridization. Accordingly, we investigated the impacts of length and Tm of restriction fragments and probe specificity on the genotyping quality of 500K markers, using the observed call rate and confidence score as quality measures. Our results indicate that both length and Tm of restriction fragments could influence the genotyping quality to a certain degree (especially in forensic samples). Also, probe specificity characteristics (i.e. additional homologous hits, known CNV or variation in probe target region) significantly deteriorate genotyping quality. In addition, genotyping quality substantially decreases for markers with low minor allele frequencies. These observations suggest that a subset of Mapping 500K markers with undesirable properties could be pre-filtered from genome-wide data analysis and some marker-specific features should be considered in future SNP array design.

***CFTR* Val470 allele is associated with higher reproductive rates and larger families in the absence of IVS8 5T allele in fertile men.** *G. Kosova[1], C. Ober[1,2,3]* 1) Commitee on Genetics; 2) Dept. of Human Genetics; 3) Dept. of OBGYN, University of Chicago, Chicago, IL.

Congenital bilateral absence of the vas deferens (CBAVD), resulting in male infertility, is considered a primarily genital form of cystic fibrosis, due to the high frequency of cystic fibrosis transmembrane regulator (*CFTR*) mutations in men with CBAVD. The most common mutation leading to CBAVD is the 5T variant at the 3 splice acceptor site of intron 8, which induces alternative splicing of exon 9 and reduced expression of CFTR mRNA. However, linkage disequilibrium between the 5T allele and the Val allele at the Met470Val SNP in CBAVD men, but not in controls, suggests a contribution of Val470 to disease penetrance of CBAVD. On the other hand, the derived Val470 allele resides on an extended haplotype (Pompei et al., EJHG 2006; 14:85-93) and occurs at high frequency only outside of Africa (F_{st} = 0.44 between HapMap CEPH and Yoruba populations), suggesting recent positive selection. Here, we examined fitness effects of the Met470Val polymorphism in fertile couples by considering two measures of fertility, family size and reproductive rate (calculated as 1/mean interbirth interval), in 142 Hutterite men and 157 Hutterite women. The Hutterites, a founder population of European descent, proscribe contraception and desire large families. As a result, mean family size is 7.07 and reproductive rates are among the highest observed in humans. Using an association test that accounts for the relatedness between all pairs of Hutterites, we found that Hutterite men carrying one or two copies of the Val470 have significantly higher reproductive rates (P = 0.00017) and larger family sizes (P = 0.0020), consistent with a selective advantage conferred by this allele. There was no association in women. Furthermore, the IVS8 5T locus allele is absent in the Hutterites and neither the 7T nor 9T alleles was associated with either fertility trait (P 0.10). We suggest, therefore, that the Val470 allele increases male fitness on genetic backgrounds that lack the 5T allele but may act as a modifier to increase the penetrance of the 5T allele in CBAVD. Supported by NIH grant HD21244.

Impact of analyzing multiple contingency tables per SNP on the type I error rate and power in GWAS. *A. G. Matthews[1], J. Ott[1,2]* 1) Ott Lab, Box 192, Rockefeller Univ, New York, NY; 2) Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing, China.

One common approach to the analysis of genome-wide association studies is to consider multiple contingency tables for each SNP. For example, computing the genotype-based test and allele-based test, then reporting the test with the smallest p-value. Alternatively, one may report the test with the smallest p-value over three genetic models: dominant, recessive or heterozygotic susceptibility. We demonstrate via simulation that these two approaches inflate the type I error rates to over 10% in some cases. The power of these methods are also compared indicating that, for most genetic models, once the false positive rate is controlled at 5%, these two methods are as or more powerful than use of the genotype- or allele-based tests alone. Further we apply these methods to a genome-wide association study of Parkinsons disease (Fung et al. 2006) to illustrate the effects of not accounting for the inflation of the type I error rate.

Approaches and Considerations for Applying Random Forests to Genome Wide Data. *B. A. Goldstein[1], A. Hubbard[1], A. Cutler[2], P. P. Ramsey[3], L. F. Barcellos[3], International Multiple Sclerosis Genetics Consortium* 1) Division of Biostatistics, Univ California, Berkeley, Berkeley, CA; 2) Department of Mathematics and Statistics, Utah State University. Logan, Utah; 3) Division of Epidemiology, Univ California, Berkeley, Berkeley, CA.

As computational power improves, the application of more advanced machine learning techniques for the analysis of large genome wide datasets becomes possible. While most traditional statistical methods of analysis can only elucidate potential main effects of genetic variants on disease risk, machine learning approaches are particularly suited to discover interactions and higher order effects. One such approach is the Random Forests (RF) algorithm. Recent years have shown a growth in utilization of RF for SNP discovery in complex disease studies. However, most work has focused on small or simulated datasets which are limited. Using 500K SNP genotypes comprised of 931 multiple sclerosis (MS) cases and controls matched on gender, we outline an approach for optimally tuning RF parameters based on empirical analyses. Our results indicate that the out-of-bag error derived from a small number of trees (~50) can be used to pre-select the optimal number of SNPs to choose at a given node. We also present considerations for addressing issues such as low minor SNP allele frequency and high linkage disequilibrium; both can bias RF analyses. Finally, we show that while RF detects those SNPs with the largest marginal chi-square statistics (top 10), there is considerable lack of overlap between those identified by both RF and a chi-square test among the top 100 (~33%-50%). These results suggest that novel interactions among SNPs may be contributing to MS susceptibility. We also discuss approaches for fully characterizing these potential gene-gene interactions. Acknowledgments: International MS Genetics Consortium (MS case data) and National Institute of Mental Health (control data).

Genetic profiles of various gene-associated subtypes of Myofibrillar myopathies in an International cohort of MFM patients. *H. Lee[1], A. Shatunov[1], M. Olive[2], B. Goudeau[3], N. Sambuughin[4], Z. Odgerel[1], M. Dalakas[5], P. Vicart[3], L. Goldfarb[1], The international MFM Collaborative Group* 1) NINDS, NIH, Bethesda, MD; 2) Ciutat Sanitària i Universitària de Bellvitge, Barcelona, Spain; 3) Université Paris 7, Denis Diderot, Paris, France; 4) Uniformed Services University of the Health Sciences, Bethesda, Maryland; 5) Thomas Jefferson University, Philadelphia, PA.

Myofibrillar myopathies (MFMs)is a group of heterogenic disorders having in common myopathological features of disintegration of myofibrils and accumulation of degradation products in inclusions containing desmin and other myofibrillar and ectopic proteins. A strong feature that brings these disorders into a single disease entity is the fact that the myofibrillar disintegration begins at the Z disc of the sarcomere. Mutations in genes encoding Z disc associated proteins DES, CRYAB, MYOT, ZASP, and FLNC cause MFM. Accumulating data suggest some gene-dependent clinical and myopathological differences between the MFM subtypes. We studied 207 patients from 135 families originating from 22 countries. Patients with MFM were systematically identified, studied and documented at regional referral centers specialized in neuromuscular disorders. Sequence analysis of the above five genes led to the identification of a causative mutation in 91 affected families (67%). DES mutations were detected in 59 (44%), CRYAB mutation in one (0.7%), MYOT in 26 (19%), ZASP in 4 (3%), and FLNC in one (0.7%). Negative screening results in 44 MFM families (33%) suggest the possibility that other genes are involved in MFM. Our results also show the necessity of population specific genetic screening strategy as different sets of genes are involved in different countries: the absolute majority of MFM affected families in Spain show MYOT mutations suggesting existence of a founder effect in the region.

Ethical, Societal, and Policy Implications of Research: Do Geneticists Views Differ from Other Scientists? *J. McCormick, A. Boyce, M. Cho* Stanford Ctr Biomedical Ethics, Palo Alto, CA.

Genetics is an area of scientific inquiry that is viewed to have tremendous impact on society, with the potential to raise complex ethical, legal, and social issues. It has been nearly 20 years since the establishment of the Ethical, Legal, and Social Implications (ELSI) program of the Human Genome Project, in which philosophers, lawyers, social scientists, and others helped to identify and study ethical issues in genetic research. However, we know little about the views of geneticists on the broader ethical, societal, and policy implications of their research. What considerations do they give to these issues, and how do they view the relationships between science and society? Are geneticists more interested in talking about ESP issues than other scientists? To the public? To policymakers? We conducted a mixed methods study, including 16 phone interviews and 5 focus groups with researchers from one institution and survey of 2000 researchers at 7 US institutions. Our sample included researchers from range of positions and departments, including genetics. Geneticists in general share the views of other life scientists. 46% are at least moderately interested in having more opportunities to discuss ethical and societal issues and 16% agree that scientific papers should include a discussion of the ethical and societal implications of the reported data. 25% agree that they have sufficient opportunities to communicate with the public while over 75% agree that it would be better for science if researchers communicated more with the public. The response is mixed on whether involvement of scientists in partisan politics harms the credibility of science. A majority agree that it would be beneficial to science if researchers learned more about the policy-making process and that better science policy would be formed if they interacted more with policymakers. Our data suggest that most researchers recognize the importance of incorporating ELSI considerations in research and participating in discussions about these issues with the public. Furthermore, our findings suggest that there is a role for the ELSI and bioethics community in facilitating these discussions.

Comparison of Family Healthware and Physicians' Family History Documentation Among 1124 Patients. *S. M. O'Neill, E. J. Starzyk, R. A. Kattezham, W. S. Rubinstein* Dept Medical Genetics, Evanston NW Healthcare, Evanston, IL.

Background: Family Healthware (FH) is a web-based tool created by the CDC that collects family history (FHx) of 6 diseases, Coronary Heart Disease (CHD), Stroke (CVA), Diabetes (DM), and Colorectal (CRC), Breast (BC) and Ovarian (OC) cancers and generates family history-based risk assessments and risk-based prevention messages. The Family Healthware Impact Trial (FHITr) is assessing its clinical utility in primary care. Method: In a subset of 1124 patients enrolled at Evanston Northwestern Healthcare, we compared the FHx they entered directly into the FH tool with existing documentation in their medical charts. FH records relationship, disease status, and age of onset for first and second degree relatives. We reviewed charts for the same information. If adequate information was present (at least one affected relative or notation of no family history), it was entered into FH to produce a chart-based risk assessment (CRA). We then assessed the agreement between the direct and CRA risk levels. Results: There was no FHx documentation or insufficient information to perform a CRA in many of the charts: CHD (37.5%), CVA (37.5%), DM (63.5%), CRC (47.7%), BC (51.2%), and OC (40.2%). Of these participants unable to be assessed by chart review, 23% had a moderate or strong risk for one of the diseases when they entered their FHx in FH themselves. For those with chart documentation sufficient to generate a CRA, agreements between risks are: CHD (percent agreement=53%, weighted kappa= 0.399), CVA (60%, 0.338), DM (71%, 0.563), CRC (92%, 0.740), BC (84%, 0.666), and OC (91%, 0.531) ($p<0.04$). FHx recorded directly by participants resulted in higher risk levels ($p<0.05$), with more affected first and second degree relatives and more ages of onset than the FHx documented in their charts. Conclusion: Primary care physicians are not systematically documenting FHx of the 6 common diseases included in the Family Healthware tool. Incorporation of automated family history-based risk assessment tools into clinical practice may increase the opportunity to identify those individuals who would benefit from enhanced surveillance and prevention measures.

3-Methylglutaconic (3MGC) Aciduria in Smith-Lemli-Opitz Syndrome (SLOS). *J.-B. Roullet, L. Merkens, A. Pappu, M. Jacobs, W. Connor, R. Steiner* Oregon Health & Science University, Portland, OR.

SLOS is an autosomal recessive multiple malformation/mental retardation syndrome caused by deficiency in 7-dehydrocholesterol reductase (DHCR7), the last enzyme in cholesterol synthesis. The pathophysiology of SLOS is incompletely understood and there is no proven treatment. In SLOS, cholesterol is reduced while 7DHC accumulates. In addition the urinary excretion of non-sterol isoprenoids (e.g. Coenzyme Q, CoQ) is elevated while that of mevalonic acid (UMVA), the early precursor of cholesterol is unaltered. We hypothesized that due to the distal block in cholesterol synthesis, MVA is diverted toward other pathways including synthesis of 3MGC via the Popjak shunt. We also hypothesized that dietary cholesterol supplementation would decrease U3MGC via decreased MVA synthesis. In 1995, Kelley *et al.* reported that plasma 3MGC is elevated in SLOS, but urine excretion may give a more accurate estimate of diversion. To further explore MVA diversion, we measured 24-hr urinary excretion of 3MGC by GC-MS in 10 SLOS patients on low (LC) or high (HC) cholesterol diet, and in 18 controls (Ctrl). UMVA and UCoQ were also measured (radio-enzymatic assay & HPLC). U3MGC (mol/mol creatinine) was increased in SLOS compared to Ctrl (LC: 173; Ctrl: 9.51.4; $p<0.015$), but was not affected by cholesterol intake (HC: 13.01.7; NS vs. LC). Similarly UCoQ was increased in SLOS (LC: 25.717.1; Ctrl: 3.01.8; $p<0.045$) and not affected by cholesterol intake. UMVA was similar in all groups. There was no correlation between U3MGC and any of the following: plasma cholesterol, 7DHC, 7DHC/Chol ratio, UCoQ or severity score. However, U3MGC was positively correlated with age (r=0.54; $p<0.003$), body weight (r=0.47; $p<0.01$) and UMVA (r=0.65; $p<0.001$). These results demonstrate that SLOS is associated with 3MGC aciduria. The lack of effect of diet on U3MGC and absence of correlation between U3MGC and UCoQ excretion suggests that increased U3MGC in SLOS is not caused by increased shunt activity but by a derangement of mitochondrial energy metabolism, the other known cause for 3MGC aciduria. Such possibility will need to be explored in the future as it may have important treatment implications.

Exact Power Calculations when testing Hardy-Weinberg Equilibrium in Small Samples. *S. Venkatesan, R. Chakraborty, M. Rao* Center for Genome Information, University of Cincinnati, Cincinnati, OH.

The genotype probability distribution for a biallelic marker is generally represented by a 2 X 2 symmetric matrix with identical marginal row and column probabilities. There are many tests available to test Hardy-Weinberg equilibrium (i.e., alleles independently combining to form genotypes). The power of these tests has been examined extensively in literature for large samples. We present a novel approach to calculate power in small samples. The set of all 2 X 2 symmetric distributions with fixed marginals is a compact convex set. This set has precisely two extreme points. The exact distribution of any test statistic under products of extreme points can be determined reasonably well. We demonstrate the calculation of power by cobbling these exact distributions. A comparison of several test statistics in terms of power is made.

ZNF217 is associated with coronary artery disease in multiple samples. *T. Wang[1], B. S. Sutton[1], S. Nelson[1], D. R. Crosslin[1], S. G. Watson[1], D. Seo[3], S. H. Shah[1,2], P. Goldschmidt-Clermont[3], S. G. Gregory[1], W. E. Kraus[1], E. R. Hauser[1]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Division of Cardiovascular Medicine, Duke University Medical Center, Durham, NC; 3) Miller School of Medicine, University of Miami, Miami, FL.

Zinc finger protein 217 (ZNF217) locates to the linkage peak on chromosome 20q13 from our family based linkage study (GENECARD) of early-onset coronary artery disease (CAD). Additionally, a study of gene expression signatures from human aortas identified ZNF217 to be differentially expressed in aortas with and without atherosclerosis. ZNF217 is known to repress the transcription of many genes and is associated with cell proliferation, survival, and invasion. We investigated the role of ZNF217 as a candidate gene for CAD in three independent CAD samples: GENECARD families (n= 1,101 families, 2,934 individuals), CATHGEN case-control samples (cases = 912 and controls = 401), and human donor aorta samples (n = 193). We genotyped 18 single nucleotide polymorphisms (SNPs) based on their linkage disequilibrium (LD), function and tagging potential. Single SNP analysis using logistic regression identified seven SNPs that were significantly associated with CAD in at least one dataset (p-values 0.005 - 0.04). Four of these SNPs are coding (C133C, A342A, I739V, and G899D), including two of the most significantly associated SNPs (A342A and G899D). To further test the potential functional impact of the SNPs, we evaluated allele-specific expression in the aorta samples adjusted for sex, race and age. The results indicated that seven SNPs were significantly associated with the level of ZNF217 expression (p-values 0.004 - 0.04). Two of these SNPs (A342A and I739V) were also significantly associated with CAD in CATHGEN sample. These combined results from independent genome-wide linkage, association, and gene expression studies suggest that ZNF217 is a novel susceptibility gene for CAD. We are currently studying the genes specific contribution to heart disease through the identification of its target genes.

Variants in CAST, the gene encoding Calpastatin, associate with variation in lung disease severity in cystic fibrosis (CF). *V. K. Doshi[1], L. Vanscoy[1], S. M. Blackman[3,1], J. M. Collaco[2,1], L. Bremer[1], G. R. Cutting[1]* 1) Inst of Genetic Medicine, JHMI, Baltimore, MD; 2) Pediatrics Pulmonary Dept, JHMI, Baltimore, MD; 3) Pediatric Endocrinology Dept, JHMI, Baltimore, MD.

Studies of CF twins and CF siblings indicate that genetic modifiers make a substantial contribution to variability in lung disease. Linkage analysis performed using 345 affected sibpairs from 299 families with at least one lung function measurement identified two loci for both cross-sectional and longitudinal lung function measures on chromosome 5 (93 cM and 196 cM). Adjustment of lung function measurements for variation in nutritional status demonstrated that linkage to the locus at 93 cM was influenced by body mass. To determine if variants in a specific gene were responsible for the variation in lung function and BMI, we selected tagged SNPs from 22 candidate genes within the linkage locus on chromosome 5 (~80-100cM). We then analyzed for association between individual SNPs and patterns of SNPs (i.e. haplotypes) in 562 patient-parent-parent trios using family based association testing (FBAT). Two SNPs (rs27654 and rs27980) demonstrated association for cross-sectional and longitudinal measures of lung function (p values ranging 0.04-0.0004). These SNPs were located in the 3 region of CAST, the gene that encodes calpastatin. The two SNPs demonstrate linkage disequilibrium with each other and haplotypes constructed of these SNPs fall into two major classes accounting for 66% and 33% of genetic diversity in CAST. The common haplotype is associated with lower lung function (AvgFEV1CF%, Z=-3.4, p=0.0007) while the minor haplotype is equally associated with improved lung function (AvgFEV1CF%, Z= 3.4, p=0.0007). Genotype analysis of these CAST variants show that mean lung function measures of homozygotes for the minor alleles of either SNP differ from those homozygous for the major alleles (e.g. rs27980: AvgFEV1CF% 0.47 vs. 0.22, p=0.015). Intriguingly, genetic variation in CAST has been associated in several mammalian species with differences in skeletal muscle mass and repair. These analyses support CAST as the first genetic modifier of CF identified using positional methods.

Candidate genes in antisocial personality disorder (ASPD), an association study with variants in genes involved in both dopaminergic and serotoninergic system in prison population in Antioquia. Colombia. *M. Cuartas[1,2], C. Palacio Acosta[2], Y. Garcia Valencia[1,2], C. Mejia[2], G. Montoya[2], C. Lopez Jaramillo[2], J. Arango[2], Y. Caicedo Petrovich[1], P. Montoya[2], G. Bedoya Berrio[1],* *GRANT 1115-04-16373 COLCIENCIAS* 1) Molecular Genetics Group (GENMOL), Biology Institute, Antioquia Univ, Medellin, Colombia; 2) Dept Psychiatry, Medicine School. Antioquia Univ. Medellin, Colombia.

Background: many studies haves implicated the dopamine and serotonin neurotransmission in psychiatric disease. Several genetic association studies have been published, but so far, no DNA variants have been unequivocally demonstrated as contributing to ASPD susceptibility. Dopamine and serotonin related gene loci have been implicated; however, each of these may influence the liability of ASPD to a small degree. Notably, all are involved in signal transduction at the neuronal synapse. In this propose, we investigate as candidate genes for ASPD, DNA polymorphisms at dopamine and serotonin receptors, and genes known to be involved in both systems. Methods: a case-control study,530 individuals, male population from prison population in Antioquia, Colombia. The clinical evaluation used: semi structure clinical interview, DSM IV criteria, DIGS and PCL (Check list). We genotyped eight snps and five VNTRs strongly associated in previous researches. Results: The present study strongly supports disequilibrium linkage in HTTLPR, TPH1 and HTR2A; moreover, the COMT was significantly associated with ASPD. The markers DRD4, DRD2 and DAT1 were related with spectrum disorder such as drugs, addiction and alcoholism. Conclusions: despite the limited sample size, these results promote the notion that genotype and psychosocial factors interact to precipitate male adult criminal behavior; and show implications for the design of future association studies of personality disorders, including the likely sample sizes that will be required to achieve sufficient power and the potential role of moderating variables like as cognitive endophenotypes.

The DNA replication FoSTeS mechanism can cause human genomic, genic, and exon shuffling rearrangements.

F. Zhang[1], M. Khajavi[1], J. R. Lupski[1,2,3] 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030; 3) Texas Childrens Hospital, Houston, TX 77030.

We recently proposed a DNA replication based mechanism of Fork Stalling and Template Switching (FoSTeS) to explain the complex rearrangements associated with Pelizaeus-Merzbacher disease (PMD), an X-linked dysmyelinating central nervous system disorder. The hallmarks of FoSTeS are complex rearrangements that result from template driven juxtaposition of sequences from different genomic locations with DNA sequence microhomology at the join point(s). Here we provide further evidence for human genomic rearrangements generated by FoSTeS and the involvement of autosomal loci in which such rearrangements convey genomic disorders including Potocki-Lupski syndrome (PTLS) and Charcot-Marie-Tooth disease type 1A (CMT1A). We now show by oligonucleotide array CGH and breakpoint sequencing that 8/14 nonrecurrent PTLS associated duplications are complex and occur by FoSTeS. Furthermore, we show that >99% of CMT1A duplications/HNPP deletions occur by NAHR, but the majority of nonrecurrent rearrangements (6/7) appear to occur by FoSTeS. Our data suggest FoSTeS may be a major mechanism for generating structural variation of the human genome. Furthermore, we show that this mechanism can also apply to both genic and single exon rearrangements indicating a link to gene evolution and potentially the mechanism for the long postulated exon shuffling.

Phenotype /Genotype Correlation and Prevalence determination of Spondylothoracic Dysostosis/ Jarcho-Levin Syndrome. *A. S. Cornier[1], S. Carlo[1], N. Ramirez[2], N. Arciniegas[3], J. Flynn[2]* 1) Dept. of Molecular Medicine, La Concepcion Hospital, San Germán, PR; 2) Dept. of Orthopeadics, La Concepcion Hospital, San Germnán, PR, PR; 3) Dept.of Pediatrics, La Concepcion Hospital, San Germán, PR.

Spondylothoracic Dysostosis (STD) also know as Jarcho-Levin syndrome (JLS), is an autosomal recessive disorder characterized by abnormal vertebral segmentation and formation defects affecting the spine with complete bilateral fusion of the ribs at the costovertebral junction. The shortened spine and trunk may severely affect respiratory function in early childhood. Although STD is prevalent in the Puerto Rican population it is a pan-ethnic disorder. Recently mutations in the MESP2 gene were identified as responsible for the STD phenotype. Molecular characterization of the disease has been achieved in over 35 patients with the disorder including identification of non-sense, missense and deletions within the MESP2 gene. Genotype/phenotype characterization has provided important correlations regarding the severity of the disease for specific mutations. These findings extend the range of abnormal vertebral and rib malformation phenotypes, clinical complications in neonatal period, ventilatory parameters, management, mortality and morbidity for specific mutations in the MESP2 gene. We have performed MESP2 mutation screening in 450 newborn samples and determined a prevalence of the disease of 1 in 6,800 live births. With such a high prevalence we are studying possible beneficial effects for heterozygotes of MESP2 gene mutations. This new molecular, clinical and epidemiological information may prove to be useful for medical management and genetic counseling in Spondylothoracic Dysostosis.

Human Cognition is Related to STX1A Gene Expression. *M. Gao[1,2,3], U. Bellugi[4], L. Dai[7], D. Mills[5], E. Sobel[3], K. Lange[3,6], J. Korenberg[7]* 1) Dept Med Gen, Cedars-Sinai, Los Angeles, CA; 2) Dept. of Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) Dept. of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 4) Laboratory of Cognitive Neuroscience, The Salk Institute for Biological Studies, La Jolla, CA; 5) Dept. of Psychology, Emory University, Atlanta, GA; 6) Dept. of Biomathematics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 7) The Brain Institute at the University of Utah, Salt Lake City, UT.

Although genetics is the most significant known determinant of human intelligence, specific gene contributions are largely unknown. To accelerate gene discovery, we have studied the relation between gene expression and IQ in a cohort of 67 patients with Williams syndrome, a mental retardation syndrome caused by a 1.5Mb deletion on chromosome 7q11.23. We find that variation in the brain gene STX1A correlates significantly with intelligence $r = 0.40$ ($p = 0.0005$) in WS patients, accounting for 14.9% of variation in the first principal component of the standard Wechsler Adult Intelligence Scale-Revised intelligence test. These results suggest that syntaxin 1A, a neuronal regulator of presynaptic vesicle release, is a component of the cellular pathway determining human intelligence.

Involvement of pathogens in recurrent hydatidiform moles caused by *NLRP7* mutations. *E. Bukhari[1,2], C. Deveault[1,2], J. Qian[1,2,5], A. Mehio[3], L. Gilbert[2], M. Seoud[4], x. Xie[5], R. Slim[1,2]* 1) Human Genetics Department, McGill University Health Center, Montreal, Quebec, Canada; 2) Dept of Obstetrics and Gynecology,McGill University Health Center, Montreal, Quebec, Canada; 3) Dept of Pathology, McGill University Health Center, Montreal, Quebec, Canada; 4) Dept of Obstetrics and Gynecology American University of Beirut, Beirut, Lebanon; 5) Womens Reproductive Health Laboratory, Womens Hospital, Zhejiang University School of Medicine, Hangzhou, China.

Hydatidiform mole (HM) is an abnormal human pregnancy characterized by the absence of, or abnormal, embryonic development and hydropic degeneration of the chorionic villi. Recently, *NLRP7* has been found responsible for recurrent hydatidiform moles (RHM) by the identification of 11 mutations in this gene (Murdoch et al., 2006; Kou et al, 2008). In this study, we investigated the presence of microorganisms in several molar tissues from several patients with NLRP7 mutations by microscopy screening of sectioned tissues stained with Gram and Grocotts methenamine silver and by PCR amplification with universal bacterial and fungal primers followed by cloning and DNA sequencing. Microscopy screening revealed Gram-positive (G+) cocci, Gram-negative (G-) bacilli, yeast cells and filamentous fungi, in most tissues from the patients, while only 10% of control tissues from elective first trimester abortions had a few G+ bacilli and G+ cocci. PCR amplification with universal bacterial and fungal primers followed by cloning and DNA sequencing confirmed the presence of several microorganisms in the patients and the pathogenic nature of some of them. Our data demonstrate the involvement of pathogens in RHMs caused by NLRP7 mutations and will have great impact on our current understanding of the pathology of moles and reproductive wastage.

New testing strategy for first trimester prenatal diagnosis by CVS. *V. Cirigliano[1,2], G. Voglino[3], E. Ordoñez[1,2], A. Marongiu[3], L. Rueda[1,2], C. Mediano[4], C. Fuster[2]* 1) General Lab, Barcelona; 2) Universitat Autonoma de Barcelona; 3) Cytogenetics Lab Promea ,Turin; 4) Hospital Vall dHebron, Barcelona.

Prenatal diagnosis in CVSs usually implies sequential karyotyping cytotrophoblastic cells (STC) and long term cultures (LTC). Main drawbacks of this approach are possible discordance between results obtained on different cell populations, confined placental mosaicism (CPM) and maternal contamination. The great majority of chromosome abnormalities can readily be detected by QF-PCR analysis of microsatellites. However, when applied on CVSs, STRs may also provide valuable information about the presence of different cell lines in mosaic or contaminated samples and the origin of extra chromosomes in trisomic cases. We analysed 3696 consecutive CVSs by QF-PCR and karyotyping; following an initial evaluation on 500 samples, QF-PCR fully replaced the STC. QF-PCR was performed on a single villus within 24 hours from sampling, abnormal results were confirmed on a second independent frond. In alternative, DNA extraction was performed on the cellular pool obtained after digestion prior to cell culture. A total of 201 cytogenetic abnormalities were observed, 98% were detected by QF-PCR with 100% PPV and 98.7% NPV. Five CPM cases could be detected by QF-PCR because of trisomic diallelic patterns observed for all informative markers in single tissue fronds. Six true mosaic fetuses were detected by QF-PCR with STR patterns clearly confirming the meiotic origin of the extra chromosome. Maternal cell overgrowth in 2 LTC could be revealed by the discrepancy with the QF-PCR result of normal male. LTC failed in 3% of cases because of poor sample quality or amount, QF-PCR analysis was always possible and in several cases a second invasive procedure could be avoided. The QF-PCR test coupled with LTC is a robust diagnostic approach. The molecular assay allowed discriminating true fetal abnormalities from CPM in several cases thus avoiding further investigations by amniotic fluid sampling. This testing strategy proved to be efficient and reliable also if applied on samples of limited size and quality and its routine application resulted in a significant reduction of costs, hands on and reporting time.

Cystinuria in Australian Cattle Dogs: A Model of Non-Type I Cystinuria. *P. Henthorn[1], J. Liu[1], A. Shearin[1], J. Westropp[2], A. Huff[1], U. Giger[1]* 1) Section Medical Genetics, Univ PA Sch Veterinary Med, Philadelphia, PA; 2) Dept. of Medicine and Epidemiology, College of Veterinary Med, Univ CA-Davis, Davis CA.

Cystinuria is an inherited transport defect in the proximal renal tubules associated with reduced reabsorption of cystine and other dibasic amino acids and has been documented in > 60 dog breeds. Because cystine at high concentrations precipitates in acidic urine, cystinuria may lead to formation of urinary cystine crystals and calculi that could lead to urinary obstruction. Mutations in the SLC3A1 and SLC7A9 genes, which encode a dibasic dimeric amino acid transporter, are responsible for cystinuria in humans, where the disease is classified clinically as Type I or non-Type I cystinuria based on cystine and dibasic aminoaciduria in obligate heterozygotes. Aminoaciduria is present in obligate carriers of non-type I cystinuria, as is urolithiasis in a small proportion of individuals. Therefore, in humans, Type I cystinuria is inherited as an autosomal recessive trait, while the inheritance pattern of non-Type I cystinuria is best described as autosomal dominant, with incomplete penetrance. In our ongoing study of dogs from different breeds ascertained by formation of cystine calculi or by unusually high urinary cystine levels, we previously characterized cystinuria in Newfoundland and Labrador retriever dogs at the clinical and molecular levels, identifying Type I cystinuria with early onset of calculi formation due to homozygosity of different mutations in the SLC3A1 gene in each breed. Here we report the results of studies of cystinuric male Australian cattle dogs. We sequenced the SLC3A1 gene and found a six bp (two amino acid) deletion in an exon of the SLC3A1 gene in three dogs. Two dogs with stone formation before age one year were homozygous for the deletion, while the dog with later onset of stone formation was heterozygous. There are no amino acid length differences in this exon among diverse species, from zebrafish to man, suggesting that this deletion may have deleterious effects. Therefore, this six bp deletion appears to be analogous to an allele for non-Type I cystinuria in humans, where stone formation can occur in obligate carriers.

Ambroxol as a potential enzyme-enhancement therapy for Gaucher disease. *G. H. B. Maegawa[1,2], M. B. Tropak[1], J. Buttner[1], G. Kornhaber[3], B. Rigat[2], J. T. R. Clarke[1,2], D. J. Mahuran[2]* 1) Div Clin Metab Genet - Peds, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Research Institute, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Exsar Inc., Monmouth Junction, NJ, USA.

Gaucher disease, currently treated by enzyme replacement therapy (ERT), is caused by a deficiency of lysosomal -glucosidase (GCase). The disadvantages of ERT include its high cost, its ineffectiveness in treating the CNS or other organ compartments and its failure to prevent the unfolded protein response in cells. Small molecule-based enzyme enhancement therapy (EET) is a promising approach that can potentially be used alone or in combination with ERT to address these deficiencies. Clinical trials of isofagomine, an inhibitor of GCase (IC50~0.04 M), as an EET-agent are being initiated. In order to accelerate the process of obtaining IND-status for new EET-agents we have screened the NINDS library of FDA-approved drugs for compounds that inhibit and/or stabilize the target enzyme towards heat denaturation. Using GCase as the target we identified ambroxol, an expectorant, as a candidate EET-agent. Despite ambroxol being only a weak inhibitor of GCase, IC50 ~ 27 M, at higher concentrations it compared favorably with isofagomine in its ability to rescue mutant N370S GCase in patients fibroblast and lymphoblast cell lines. However, it was not as effective at rescuing F213I mutant GCase. Cells with wild-type GCase also show a mild enhancement in activity. Hydrogen-deuterium exchange mass spectrometry (H/D-Ex) was used to compare the regions in GCase that were stabilized by these compounds. Isofagomine has been shown through co-crystallization to stabilize a loop structure at GCase311-319. Both compounds were equally effective in stabilizing two additional loop regions at the mouth of the active site, GCase243-249 and 386-400, suggesting its importance as a target for EET-agents.

Improved survival among people with mosaic trisomy 21 compared to standard trisomy 21 and Robertsonian translocations. *C. Svaerke[1], S. A. Rasmussen[2], J. M. Friedman[3], D. Schendel[2], H. Hasle[4], A. Correa[2], P. Thorsen[1]* 1) University of Aarhus, Aarhus, Denmark; 2) Centers for Disease Control and Prevention, Atlanta, GA; 3) University of British Columbia, Vancouver, BC, Canada; 4) Aarhus University Hospital Skejby, Aarhus, Denmark.

Health outcomes among persons with mosaic trisomy 21 have not been well documented. The purpose of this study is to compare mortality rates among people with Down syndrome by karyotype using the population-based Danish registries. People with Down syndrome diagnosed by chromosomal analysis from 1961 through 2007 were identified through the Danish Cytogenetic Central Register. The study cohort was born between 1902 and 2007 and was observed from April 1968 or birth (if born later) until death, emigration, or the end of follow-up (May 2008). Dates of death or emigration were retrieved from the Danish Central Person Register. Mortality rate ratio [MRR] was estimated for mosaic trisomy 21 and Down syndrome associated with Robertsonian translocations using Cox regression, with standard trisomy 21 as the reference group. Year of birth and sex were treated as potential confounders. Among the 3,551 people with Down syndrome identified, 3,287 had standard trisomy 21 (921 deaths), 151 had Robertsonian translocations (38 deaths), and 113 had mosaic trisomy 21 (29 deaths). The MRRs for people with mosaic trisomy 21 were 0.55 (95% confidence interval [CI]: 0.39-0.79) for the full cohort and 0.43 (95% CI: 0.21-0.92) for the cohort born in 1968 or later (a group followed since birth). In contrast, for people with Robertsonian translocations, the MRRs were 1.03 (95% CI: 0.75-1.42) for the full cohort and 0.88 (95% CI 0.56-1.37) for the cohort born in 1968 or later. In conclusion, survival among persons with mosaic trisomy 21 is significant greater than that for persons with standard trisomy 21 or Robertsonian translocations. If this finding is replicated in future studies, this information could be useful to clinicians counselling affected families.

Chromosome 17q21.31 microdeletion in a patient with autism. *C. Betancur[1], D. Moreno De Luca[1], A. Gennetier[1], F. Devillard[2], V. Ginchat[2], B. Assouline[3], C. Gillberg[4], M. Leboyer[5]* 1) INSERM U513, Paris, France; 2) Grenoble University Hospital, Grenoble, France; 3) Centre Alpin de Diagnostic Précoce de lAutisme, Saint Egrève, France; 4) Dept. Child and Adolescent Psychiatry, Goteborg University, Goteborg, Sweden; 5) Dept. Psychiatry, Albert Chenevier Hospital, Créteil, France.

Recent findings suggest that microdeletions/microduplications involved in mental retardation also play an important role in autism. A new 17q21.31 microdeletion syndrome, caused by non-homologous recombination between low copy repeats, was recently described in 11 individuals. The subjects had overlapping deletions of 500-650 kb, developmental delay, hypotonia and characteristic facial features. The purpose of this study was to ascertain the involvement of 17q21.31 deletions in autism. A total of 410 patients with autism spectrum disorders recruited by the PARIS study were screened for deletions and duplications associated with mental retardation syndromes using multiplex ligation-dependent probe amplification (MLPA). We identified one patient with a deletion at 17q21.31. Characterization of the breakpoints with qPCR showed that the deletion was about 900 kb and comprised nine genes, including MAPT and CRHR1. The deletion was not present in the mother; the father was deceased and no DNA was available. Analysis of polymorphisms in the MAPT gene showed that the deletion arose from the H2 haplotype inherited from the father. The H2 haplotype comprises a 900 kb inversion polymorphism which makes it susceptible to rearrangements, and is the origin of all of the deletions described to date. The girl had delayed motor and speech development, as well as mild dysmorphic features similar to the ones described previously, including long face, blepharophimosis, bulbous nasal tip, broad chin and long fingers. At 11 years of age, she fulfilled diagnostic criteria for autistic disorder and had a global IQ of 40. In conclusion, this is the first report of a 17q21.31 microdeletion associated with autism. Although the prevalence appears to be low, this observation adds to the increasing list of genomic disorders involved in the etiology of autism.

Prenatal diagnosis of marker chromosome 4: A report of two cases with outcomes. *D. Myles Reid[1], K. Chong[1], E. Kolomietz[2], R. Hopkin[3], A. Bedard[3], J. Kogan[3]* 1) Prenatal Diagnosis and Medical Genetics, Mount Sinai Hosp, Toronto, ON, Canada; 2) Pathology and Laboratory Medicine, Mount Sinai Hosp, Toronto, ON, Canada; 3) Division of Human Genetics, Cincinnati Children's Hosp Medical Center, Cincinnati, OH.

Marker chromosomes are small pieces of chromosomal material that vary in size and are self-replicating. They commonly contain heterochromatic regions but may contain euchromatin with normal or rearranged structure. We report 2 cases of marker chromosome 4 diagnosed prenatally. Case 1 presented with a positive first trimester screen and amniocentesis to rule out chromosomal abnormalities. Concurrently, chromosome analysis completed on the father due to a family history of MR revealed a mosaic karyotype, 47,XY,+mar[8].ish der(4)/46,XY[32]. Fetal chromosome analysis also revealed a mosaic female karyotype, 47,XX,+mar[11]/46,XX[5]. Microarray analysis on the father and fetus showed an identical marker derived from the pericentromeric region of the short and long arms of chromosome 4. Detailed fetal ultrasound was normal and the remainder of the pregnancy was uncomplicated. Case 2 presented for amniocentesis for advanced maternal age and the results revealed a mosaic karyotype, 47,XX,+mar[15]/46,XX[7]. Microarray analysis performed to better define the marker identified the marker as derived from chromosome 4. The marker was shown to be de novo as parental studies were normal. Detailed fetal ultrasound showed choroid plexus cysts, IUGR and oligohydramnios. Fetal echo and fetal MRI were normal. The markers in Case 1 and Case 2 show significant overlap and are both derived from the pericentromeric region of chromosome 4. Both cases resulted in the delivery of healthy newborns. Postnatal follow up has shown no medical or neurological problems for either infant. These are the first reported cases of prenatally detected marker chromosome 4 with normal postnatal outcomes to date. Interestingly, these cases highlight that various parts of the genome even in large imbalance may not significantly impact normal development in humans.

Genome-wide association confirms variants in *SLC2A9* are associated with serum uric acid in Mexican Americans. *VS. Voruganti[1], JW. Kent Jr.[1], SA. Cole[1], M. Carless[1], JE. Curran[1], MP. Johnson[1], HH. Goring[1], L. Almasy[1], TD. Dyer[1], NH. Arar[2], R. Bauer[2], JW. MacCluer[1], HE. Abboud[2], AG. Comuzzie[1], EK. Moses[1], J. Blangero[1]* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) University of Texas Health Science Center at San Antonio, San Antonio, TX.

Increased serum uric acid (SUA) is a risk factor for gout, renal and cardiovascular disease and is known to aggregate in families. Variation in SUA is controlled by both genetic and environmental factors. The purpose of this study was to identify genetic factors that affect the variation in SUA levels in Mexican Americans of the San Antonio Family Heart Study. We used a linear regression-based association test under an additive model of allelic effect, while accounting for the non-independence of family members via a kinship variance component. All analyses were performed in SOLAR. In 848 subjects with SUA measures, mean SE age was 47.87 14.8y. SUA levels were higher in men (6.11.7 mg/dl; n= 313) than in women (4.941.6 mg/dl; n=535). SUA was significantly heritable (h^2 = 0.39 0.07, p=2.3 x 10^{-8}). A genome-wide association (GWA) analysis was performed in 605 subjects using the Illumina Human Hap 550K single nucleotide polymorphism (SNP) chip. SNP rs6832439 within the solute carrier family 2, member 9 (*SLC2A9*) gene was associated with SUA levels at genome-wide significance (p = 7.2 x 10^{-8}). The minor allele of this SNP had frequency of 35.5% and was associated with decreasing SUA levels. The *SLC2A9* gene encodes a urate transporter that has significant influence on SUA levels. Three additional SNPs rs737267 rs6449213 and rs13131257 showed suggestive association (p < $6.8x10^{-7}$) with SUA levels. Suggestive associations were also found in *DRD5* (~ 200kb from *SLC2A9*) and in *ACTL8* on chromosome 1. Our finding replicates a reported association of SUA with this gene in European populations in Germany, Austria, Scotland, Croatia, Sardinia and the United Kingdom. SNPs rs6832439 and rs737267 are in intron 7, the location of the previously reported associations. SNPs rs6449213 and rs13131257 are in introns 4 and 5, respectively. In summary, we have replicated the association of *SLC2A9* with SUA in a Mexican American cohort.

***PPP1R3B* as a Candidate Gene for Congenital Diaphragmatic Hernia.** *N. D. LopezJimenez[1], A. Moshrefi[1], G. Shaw[2], A. M. Slavotinek[1]* 1) Pediatrics, UCSF, San Francisco, CA; 2) C.H.O.R.I., Oakland, CA.

Congenital diaphragmatic hernia (CDH) is a common, life threatening birth defect. A 5-6 Mb chromosome region required for diaphragm formation has been mapped to 8p23.1, between D8S1706 at 6.83 Mb and RP11-252C15 at 12.59 Mb (Shimokawa et al., Am J Med Genet 2005;136:49; Slavotinek et al., J Med Genet 42:730). This region contains the *PPP1R3B* gene which we selected for further study because *in vitro* studies in L6 rat skeletal muscle cells depleted for PP-1G, the encoded protein, show an inability to differentiate (Ragolia et al., J Biol Chem 2000;275:26102). Sequencing of *PPP1R3B* in 96 CDH patients revealed c.481delG in an Hispanic male with left CDH, pectus excavatum and cryptorchidism. This substitution predicts a premature stop at amino acid 162 in the CBM_21 domain of the protein, suggesting haploinsufficiency. The variant was not found in more than 100 Hispanic control chromosomes. However, it was present in the probands normal mother. In-situ hybridization studies with murine sections did not confirm *Ppp1r3b* expression in the diaphragm and we also could not detect expression in proliferating or differentiating C2C12 myoblasts. We therefore did not establish a relationship between this gene and CDH. However, *PPP1R3B* is known to enhance the rate at which PP-1G activates glycogen synthase, and homozygous null mice for *Ppp1r3b* have impaired glycogen accumulation in muscle. Linkage to chromosome 8p23 has been described in both MODY and type II diabetes and PPP1R3B has also been sequenced in 13 predominantly Caucasian families with type 2 diabetes or MODY linked to 8p, but no pathogenic variants were observed (Dunn et al., Ann Genet 2005;70:587). It is therefore interesting to speculate that the c.481delG mutation could cause metabolic effects relating to impaired glycogen synthase. The maternal grandmother had type 2 diabetes in her sixth decade, but DNA was not available. The proband also had significant feeding difficulties with failure to thrive at 34 months, requiring a G-tube. However, further studies are needed to determine if this *PPP1R3B* sequence variant can induce significant metabolic effects.

Amplification Distortion Test: A Method to Fine Map Selection in Tumors. *N. Dewal[1], M. Freedman[2], T. LaFramboise[3], I. Pe'er[1]* 1) Columbia University, New York, NY; 2) Dana Farber Cancer Institute, Harvard Medical School, Boston, MA; 3) Case Western Reserve University, Cleveland, OH.

Selection of amplified genomic segments in particular somatic cellular lineages drives tumor development. However, pinpointing genes under such selection has been difficult due to these regions large sizes. We propose a new method, called the Amplification Distortion Test (ADT), that identifies specific nucleotide alleles that confer better survival for tumor cells when somatically amplified. ADT draws upon the Transmission Disequilibrium Test from statistical genetics and is extended to evaluate and localize distortion on haplotypes in addition to single markers. It is optimized for performance and includes computational techniques to address the intricate challenges of discerning true biological signals from technology-induced artifacts in data. ADT is used to analyze our pioneering dataset, containing 700 tumor samples from lung cancer patients that are typed for copy number variation and 240K SNPs genome-wide. We detect candidate single-SNP and haplotype distortion signals on multiple chromosomes, thus revealing prime target regions for fine mapping. We propose that this novel mode of genome scanning via ADT constitutes a new paradigm for mapping oncogenes. Analogous datasets currently being accumulated by other organizations, such as the Cancer Genome Atlas, provide compelling avenues for further investigation and application of this new methodology.

A functional missense variant in glutamate transporter EAAT1 in Tourette syndrome. *A. Adamczyk[1], C. D. Gause[2], R. Sattler[3], S. Vidensky[3], J. D. Rothstein[2,3], H. Singer[2,3], T. Wang[1,2]* 1) Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Dept. of Pediatrics, Johns Hopkins Univ, Baltimore, MD; 3) Dept. of Neurology, Johns Hopkins Univ, Baltimore, MD.

Tourette syndrome (TS) is a neuropsychiatric disorder characterized by the presence of involuntary motor and phonic tics. TS has an estimated prevalence of about 1% in school age children. A genetic etiology is supported by large family and twin studies, although the specific genetic abnormality remains undetermined. Pathophysiologically, evidence suggests an abnormality localized within cortico-striatal-thalamo-cortical pathways and possibly an abnormality of dopamine neurotransmission. Glutamate is the major excitatory neurotransmitter in the CNS and has wide interactions with dopaminergic pathways. Glutamate levels are tightly regulated in the synaptic cleft by Na+-dependent glutamate transporters. The goal of this study was to explore the genetic contribution of glutamate signaling in the pathogenesis of TS. DNA sequence variants in EAAT1, which encodes the main glutamate transporter in astrocytes, was evaluated in a well-characterized cohort of TS patients (n=250; TS-only, 106; TS plus ADHD, 148) and controls (n=217) (Yoon et al, 2007). All exon-containing regions of EAAT1 were screened using CE-SSCP and sequenced. A missense variant, E219D, was identified in 11 heterozygous individuals with TS and 4 controls. Allele frequency for E219D was 2.4 and 3.1 times higher in the total TS (0.022) and TS-only (0.028) cohorts, respectively, as compared to controls (0.009). E219 is a residue that is highly conserved from human to x-tropicalis. In order to pursue a functional association with the presence of the E219D variant, a 3H-glutamate-uptake assay was performed in transfected HEK293 cells. Results showed that E219D conveys a significant increase in the EAAT1-mediated glutamate uptake as compared to the wt control. These results raise the possibility that the E219D variant and its alteration of glutamate uptake may have a pathogenic role in a small number of individuals with Tourette syndrome. The role of glutamate signaling in Tourette syndrome warrants further investigation.

Extent of Copy Number Variation in an isolated population of European descent. *H. Xi[1], G. Sun[1], S. R. Indugula[1], G. Zhang[1], P. Rudan[2], R. Chakraborty[1], R. Deka[1]* 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Institute for Anthropological Research, Zagreb, Croatia.

Copy Number Variation (CNV) has emerged as an important class of genetic variation influencing genetic traits. However, the extent of CNV in worldwide populations has yet to be fully ascertained. We have constructed a CNV map based on data from 235 individuals from a relatively isolated island population from the eastern Adriatic coast of Croatia. Primarily of Slavic origin, the population migrated to the Adriatic islands in the 15th century. DNA samples were genotyped using the Affymetrix SNP Array 5.0 that includes ~500K SNPs and 420K non-polymorphic probes for detection of CNVs. We used two packages for data normalization and copy number segment identification - Copy Number Variation Module (CNAM) of Golden HelixTree and Bengtssons R-package aroma.affymetrix. Our results show ~10% of the genome is covered by CNVs; average length of CNV regions is 45.1Kb with a median length of 1.4Kb. Additional data on >600 samples are currently being analyzed for a finer resolution of CNVs in this population. Supported by grant R01DK069845.

Canine Models of Ichthyosis. *M. L. Casal[1], E. A. Mauldin[2]* 1) Sect Medical Genetics, Univ Pennsylvania, Philadelphia, PA; 2) Dept Pathobiology, Univ Pennsylvania, Philadelphia PA.

Ichthyoses are characterized by faulty formation of the outer layer of the epidermis, the stratum corneum, with resultant scaling and include a heterogeneous group of hereditary and congenital diseases in humans. In dogs, relatively few ichthyosiform disorders have been documented and most are reported as single cases. Here we present two forms of non-epidermolytic ichthyosis in the golden retriever and the American bulldog. The golden retriever disease is characterized by mild to moderate, generalized, nonpruritic scaling (large, loosely-adherent, soft, white to gray scales) with clinical lesions becoming apparent between 8 weeks and 2 years of age. American bulldogs typically have a more severe phenotype with lesions evident at birth or shortly thereafter. The scaling is generalized with large, light brown, plate-like, adherent scale on the ventral thorax and abdomen. The puppies may develop chronic pruritus that coincides with the onset of secondary malassezial infections. Histopathologic findings are similar in both disorders: laminar orthokeratotic hyperkeratosis with an absence of epidermal hyperplasia and dermal inflammation. Ultrastructural analysis using a ruthenium tetroxide fixation method revealed retained and convoluted membranes with crystalline structures in the stratum corneum in both breeds of dogs. Scattered keratinocytes in the granular cell layer had prominent, clear, membrane bound, cytoplasmic vacuoles. Pedigree analyses in both breeds are highly suggestive of an autosomal recessive trait. Molecular characterization is underway for both forms. In humans, many forms of ichthyosis can be debilitating and require lifelong treatment which is only symptomatic. Here we offer a large animal model for treatment trials that will hopefully lead to curative therapies for humans affected with ichthyosis.

A family with Rapp-Hodgkin-like syndrome with intellectual disability and a microdeletion at 13q31.3 that includes the *GPC5* gene. *R. Aul[1], P. Eydoux[2], D. Chai[3], M. I. Van Allen[1]* 1) Medical Genetics; 2) Pathology & Laboratory Medicine; 3) Canadian Molecular Cytogenetics Network, University of British Columbia, Vancouver, BC.

Rapp-Hodgkin syndrome (RHS) is an autosomal dominant condition with anhydrotic ectodermal dysplasia, cleft lip and palate and a specific facies. There is a great deal of clinical overlap with other ectodermal dysplasias including Hay-Wells syndrome and EEC syndrome. These conditions are allelic to mutations in *TP63* gene, the only gene shown thus far to be associated with RHS. We are reporting a family of three siblings and their mother, who have autosomal dominant inheritance of microcephaly, developmental delay, and ectodermal dysplasia features consistent with RHS. The proband is a 13 year old boy with microcephaly and moderate developmental delay. The features of ectodermal dysplasia in him include hypodontia with conical-shaped teeth, enamel hypoplasia, anhydrosis, fine hair, weak nails and abnormal clavicles. In addition, he was born with a cleft lip/palate suggesting a diagnosis of RHS. His mother had a history of learning disabilities as well as anhydrosis, hypodontia, conical teeth, enamel hypoplasia, sparse hair and weak nails. The proband has two older siblings also presenting with microcephaly, learning disabilities and similar ectodermal abnormalities. No mutation was identified in *TP63* gene. Chromosomal microarray analysis showed a 2.1 Mb deletion within chromosome region 13q31.3 in the proband and his mother; results in the other family members are pending. This deletion includes the *GPC5* gene, a highly conserved member of the glypican family of cell surface proteoglycans. The function of *GPC5* is unknown although it is expressed in a tissue-specific manner during development. *GPC5* likely plays a role in cell division as it has been shown to be amplified in follicular lymphoma and rhabdomyosarcoma; suggesting a sensitivity to copy number changes. To our knowledge, there have been no previous reports of individuals with mutations or deletions of this gene. Given the features of ectodermal dysplasia plus microcephaly and intellectual disability this may comprise a new syndrome.

Pathological studies and therapeutic testing of isofagomine in a viable mouse model of neuronopathic Gaucher disease. *Y. Sun[1], K. Kitatani[4], H. Ran[1], B. Liou[1], M. Zamzow[1], D. P. Witte[3], M. R. Skelton[2], M. T. Williams[2], C. V. Vorhees[2], Y. A. Hannun[4], G. A. Grabowski[1]* 1) Div Human Genetics, CCHMC, Cincinnati, OH; 2) Div of Neurology, CCHMC, Cincinnati, OH; 3) Div of Ped Pathology, CCHMC, Cincinnati, OH; 4) Dept of Biochemistry and Mol Biology, Med U of SC, Charleston, SC.

Gaucher disease is the most common lysosomal storage disease caused by defective acid -glucosidase (GCase) function. To develop a model for therapeutic studies in Gaucher disease, we generated mice of subacute neuronopathic type Gaucher disease by crossing the point mutated GCase (V394L/V394L) mice with saposin C deficient mice (C-/-). Saposin C is a lysosomal protein needed for optimal GCase activity. The resultant mice (4L;C*) began to exhibit CNS abnormalities at ~30 days. Death occurred ~48 days due to neurological deficits. Axonal degeneration was evident in brain stem, spinal cord and white matter of cerebellum accompanied by increasing infiltration of CD68 positive microglial cells and activation of astrocytes in the brain stem, basal ganglion, thalamus and hindbrain regions. Electron microscopy showed inclusion bodies in neuronal processes. Relative to V394L/V394L mice, 4L;C* mice had diminished GCase protein and activity. Marked increases (20-30 fold) of glucosylsphingosine (GS) and moderate elevation (1.5-3 fold) of glucosylceramide (GC) were detected in the brain. In contrast to the CNS, increase of GC and GS in the liver and lung did not develop storage cells. Neuronal cells in the hippocampus from 4L;C* mice had significantly attenuated long-term potentiation than WT mice. The 4L;C* mice mimic the CNS phenotype and biochemistry of some type 3, neuronopathic variants of Gaucher disease. The treatment of isofagomine tartrate, a selective chaperone for GCase, in 4L;C* mice increased GCase activity by 1.6-5.3 fold. Importantly, the treated mice showed delayed onset and significant extension of their life span by ~25%. Those results demonstrated that 4L;C* mouse is a unique and viable model suitable for testing chaperone and substrate reduction therapies, and investigating the mechanisms for neuronopathic Gaucher disease.

A variance components method to test for QTL heterogeneity among multiple ethnic groups. *T. Kippola[1], K. Edwards[2], S. Santorico[3]* 1) Department of Statistics, Oklahoma State University, Stillwater, OK; 2) Department of Epidemiology and the Institute for Public Health Genetics, School of Public Health and Community Medicine, University of Washington , Seattle, Washington; 3) Department of Mathematical and Statistical Sciences, University of Colorado, Denver, Colorado.

Findings from the Third National Health and Nutrition Examination Survey suggest that as many as 1 in 4 Americans may be affected by metabolic syndrome (Ford et al. 2002). As with many diseases, the prevalence of metabolic syndrome varies greatly among ethnic groups (Park et al. 2003). We wish to simultaneously investigate the etiology of metabolic syndrome among multiple ethnic groups using quantitative trait linkage methods. Numerous methods exist for conducting linkage analysis for a quantitative trait locus (QTL); however, these methods do not allow for heterogeneity that may arise when testing for linkage using multiple families from different ethnic groups, countries or geographic locations. We propose a method, which is an extension of the variance components method suggested by Almasy and Blangero (1998). Our method can determine if there exists statistically significant linkage while allowing for heterogeneity among different ethnic groups, countries or geographic locations. We also propose a test for determining if heterogeneity exists. Our method can incorporate group specific non-genetic differences via covariates and varying levels of polygenic and environmental variability prior to assessing whether the variability due to potentially common QTLs is the same. Additionally our method allows for each group to use a different marker map. Both tests are based on likelihood ratio test statistics and will be applied to an existing data set consisting of genotype and metabolic syndrome phenotype data for 69 Caucasian, 53 Mexican-American, 65 African-American and 15 Japanese-American extended kindreds. Simulation results of various statistical properties, such as power and Type I error rate, of our proposed method will be presented.

Novel Enzyme Replacement Therapy for Gaucher Disease: On Going Phase III Clinical Trial with Recombinant Human Glucocerebrosidase Expressed in Plant Cells. *D. Aviezer[1], E. Almon-Brill[1], Y. Shaaltiel[1], G. Galili[4], R. Chertkoff[1], S. Hashmueli[1], E. Galun[3], A. Zimran[2]* 1) Protalix Biotherapeutics, Karmiel, Israel; 2) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, IsraeL; 3) Goldyne Savad Institute of Gene Therapy, Hadassah Hebrew University Hospital, Jerusalem,Israel; 4) Plant Sciences, Weizmann Institute of Science, Rehovot, Israel.

Gaucher Disease, characterized by glucocerebrosidase (hGCD) deficiency, provokes glucosylceramide accumulation in cellular lysosomes. Disease clinical pathology includes anemia, thrombocytopenia splenomegaly, skeletal pathology and pulmonary hypertension/infiltration. Current therapy uses mammalian based production of recombinant glucocerebrosidase for enzyme replacement therapy (ERT) that involves post-expression glycan remodeling for exposing mannose structures, required for intake by Macrophages. Protalix has developed a propriety plant cell expressed active form of rh-glucocerebrosidase (prGCD). The unique protalix technology permits control of glycosylation pattern and consistency through targeting to specific plant cell organelles. Hence, prGCD has intrinsic exposed mannose residues and demonstrates batch to batch consistency. prGCD exhibits similar crystal structure and biological activity to that of the currently used CHO expressed Cerezyme using in-vitro assays. Preclinical toxicology studies showed no treatment-related adverse events, no neutralizing antibodies and no clinical findings. Phase I safety clinical trial showed that prGCD administered intravenously in sequential doses (15, 30 and 60 units/kg) was well tolerated, all tests being within normal ranges, with no treatment related adverse events. Pharmacokinetic analysis demonstrated a prolonged half life. All immunological specific tests were within normal ranges. An international multi-center Phase III Pivotal trial is currently ongoing under FDA Special Protocol Assessment approval where 30 untreated patients will be administered with 30U/kg or 60U/kg per infusion over a period of 9 months. Following completion of the protocol, patients are offered to enter an Extension study. In addition, a switch-over study to prGCD is to begin soon.

Amplification of the BP1 homeobox gene in breast cancer. *L. Cavalli[1], Y.-G. Man[2], A. Schwartz[3], I. Cavalli[4], P. Berg[5], B. Haddad[1]* 1) Georgetown University, Lombardi Comprehensive Cancer Center, LL S165A, Washington, DC; 2) Armed Forces Institute of Pathology, Department of Gynecologic and Breast Pathology, Washington DC; 3) George Washington University Medical Center, Dept. of Pathology, Washington, DC; 4) Federal University of Parana, Department of Genetics, Curitiba, PR, Brazil; 5) George Washington University Medical Center, Dept. of Biochemistry and Molecular Biology, Washington, D.C.

The BP1 gene, mapped to 17q21.33, is a homeobox gene that has been implicated in breast tumorigenesis. Studies have shown BP1 mRNA overexpression in 80% of infiltrating ductal carcinoma and its correlation with cancer progression and invasion. A central question is the mechanism(s) of activation of the BP1 gene these tumors. Our main objective was to assess the copy number status of the BP1 gene in primary breast tumors (PBT) and sentinel lymph node (SLN) metastasis to determine whether BP1 protein expression is caused by gene amplification. Formalin-fixed, paraffin-embedded sections of 36 breast cancer lesions, including 12 cases of PBT and 12 pairs of PBT with corresponding SLN metastasis, were analyzed by Fluorescent in situ Hybridization (FISH) using a BP1 probe. In 20 of these cases FISH analysis was also performed for the HER2/NEU gene (localized at 17q21). The results were correlated with immunohistochemistry (IHC) data for BP1 and HER2/NEU proteins. Increased BP1 copy number was observed in 33% of the cases, with a frequency of 36% and 29% in the PBT and SLN metastasis, respectively. BP1 protein was expressed in 91% of the samples: in all of the PBT with increased BP1 copy number and 78.6% of PBT with normal copy number. HER2/NEU amplification was detected in 22% of the cases. Concordance between BP1 and HER2/NEU copy numbers was found in 68% of the PBT and 90% of the SLN metastasis We have shown that the BP1 homeobox gene is amplified in primary and metastatic breast tumors, with a significant correlation with HER2/NEU amplification. Considering that BP1 expression was observed in cases with both increased and normal BP1 copy number, we conclude that other mechanisms in addition to gene amplification play a role in BP1 protein expression.

A new phenotype in the Stickler/Marshall continuum: COL11A1 mutations and growth deficiency in childhood.

L. Sloper[1], B. F. Griswold[1], R. M. Liberfarb[2], C. A. Francomano[3], M. Mannikko[4], L. Ala-Kokko[4], N. B. McDonnell[1] 1) Clinical Research Branch, NIA/NIH, Baltimore, MD; 2) Massachusetts General Hospital, Boston, MA; 3) Greater Baltimore Medical Center, Towson, MD; 4) University of Oolu, Finland.

Stickler Syndrome is an autosomal dominant disorder caused by mutations in the collagen genes including COL2A1, COL11A1, and COL11A2. Manifestations include facial dysmorphisms, cleft palate, vitreoretinal abnormalities, hearing loss, spondyloepiphyseal dysplasia, joint laxity and premature osteoarthritis. COL11A1 mutations are also implicated in Marshall syndrome, in which additional features include frontal bossing, short upturned nose, persistence of flat facies into adulthood, and relatively shorter final stature. We have recently identified three probands born with cleft palate, hearing loss and high myopia, with splice site mutations in COL11A1, who presented with an additional complication of growth deficiency in childhood despite adequate nutritional intake. All patients (age range 3-9) were pre-pubertal children with height <3 centile; with delayed bone age, low IGF-1, and were being considered for growth hormone replacement. Additional features noted included frontal bossing, short nose, and large eyes. Brain MRI of one of the children showed a short clivus and basilar invagination of the odontoid process. We analyzed final heights and growth curves of patients with Stickler Syndrome with known mutations who were seen at the NIH. It was noted amongst eight probands and family members with COL2A1 mutations, the final stature was consistently above average. Three probands with COL11A1 mutations, now adults, were noted to have final stature in the 5-15 centile with no history of growth deficiency. This cohort of three young patients suggests that there is a newly defined phenotype that includes growth deficiency in the Stickler/Marshall continuum associated with COL11A1 mutations. The availability of growth hormone treatment represents a new challenge in the management of this syndrome. Given a general lack of success with other skeletal dysplasias, it is difficult to endorse such an intervention at this time.

Identification of susceptibility genes for complex diseases using pooling-based genome-wide association scans. *Y. Bosse[1], F. Bacot[2], A. Montpetit[2], J. Rung[2], H. Q. Qu[3], C. Polychronakos[3], T. J. Hudson[4], P. Froguel[5], R. Sladek[2,3], M. Desrosiers[3,6]* 1) Laval University, Quebec, PQ, Canada; 2) McGill University and Genome Quebec Innovation Center, Montreal, PQ, Canada; 3) McGill University, Montreal, PQ, Canada; 4) The Ontario Institute for Cancer Research, Toronto, ON, Canada; 5) CNRS 8090-Institute of Biology, Pasteur Institute, Lille, France; 6) Montreal University, Montreal, PQ, Canada.

The success of whole genome association studies (GWAS) to identify risk loci of complex diseases is now well-established. One persistent major hurdle is the cost of these studies. Performing GWAS on pools of DNA samples may be a cost-effective alternative. In this study, we performed pooling-based GWAS with more than 550,000 SNPs in two case-control cohorts consisting of patients with Type II diabetes (T2DM) and with chronic rhinosinusitis (CRS). In the T2DM cohort, the results of the pooling experiment were compared to individual genotypes obtained from a previously published GWAS. SNPs associated with T2DM by traditional GWAS were among the top ranked SNPs in the pooling experiment. For example, two of the five susceptibility genes identified in the original publication (TCF7L2 and HHEX) had SNPs among the top 10 allelotyping results (top 10 out of 555,175 SNPs). In the CRS cohort, the top 1536 SNPs were validated by individual genotyping. Forty-one percent of SNPs (598 out of the 1457 SNPs that passed quality control) were associated with CRS at a nominal p value of 0.05, confirming the potential of pooling-based GWAS to identify SNPs that differ in allele frequencies between two groups of subjects. These results demonstrate that the pooling experiment on high-density genotyping arrays can produce a list of top ranked SNPs that is overrepresented by true genetic associations. It also suggests that a pooling approach combined with selection of a limited number of SNPs for individual validation can substantially lower the cost of GWAS that are conventionally too expensive for diseases with limited access for funding. The low cost associated with a pooling-based GWAS clearly justifies its use in screening for major genetic determinants of complex diseases.

A Novel Base-Pair Mutation of the CSPG2 Gene in a Family with Wagner Syndrome. *E. Burner[1,2], S. Ronan[1], K. Tran-Viet[2], C. Toth[1], T. Young[1,2]* 1) Duke University Eye Center, Durham, NC; 2) Center for Human Genetics, Durham, NC.

Purpose: Wagner syndrome (OMIM 143200) is an autosomal dominant vitreoretinopathy characterized by an optically empty vitreous cavity with fibrillary condensations, a preretinal avascular membrane, retinal perivascular sheathing, chorioretinal dystrophy, lattice degeneration, and high myopia, with a predisposition to retinal detachment and cataracts. Wagner syndrome has significant phenotypic overlap with other conditions, such as ocular Stickler syndrome type 1 (OMIM 609508). Stickler syndrome type 1 maps to chromosome 12q13.11-13.2, with associated COL2A1 gene mutations. Wagner syndrome maps to chromosome 5q13-q14 (WGN1 locus), with previously reported mutations in the CSPG2 gene confirming that this is a distinct syndrome. We report a three-generation Caucasian family with 6 affected individuals clinically diagnosed with Wagner syndrome, and screening for sequence variants in the COL2A1 and CSPG2 genes. Methods: Genomic DNA samples derived from venous blood were collected from 9 total family members. Complete sequencing of COL2A1 was performed on the proband. Direct sequencing of CSPG2 was performed on all family member samples. Primers for PCR and sequencing were designed to cover all exons and intron-exon boundaries. Results: No detectable COL2A1 mutations were noted, making the diagnosis of ocular Stickler syndrome highly unlikely for this family. A unique base-pair substitution (GT) in intron 8 cosegregating with disease status was identified. This mutation occurs in a highly conserved previously reported splice site with a similar base-pair substitution (GA). Direct sequencing of this splice site mutation in 107 unrelated external controls revealed no variants, supporting the rarity of this base-pair change and its causation in Wagner syndrome. Conclusions: CSPG2 encodes versican, a proteoglycan and component of human vitreous. This novel base-pair substitution is thought to cause deletion of exon 8 and formation of a truncated protein product as previously reported. Further mutation screening of CSPG2 in additional Wagner syndrome families is important for functional characterization.

Role of X-inactivation in females with heterozygous mutations of *ARX*. *J. Sudi[1], G. Mancini[2], A. Toutain[3], M. I. Van Allen[4], S. L. Christian[1], W. B. Dobyns[1]* 1) Dept. Human Genetics, Univ Chicago, Chicago, IL; 2) Dept. Clinical Genetics, Erasmus Univ Medical Center, Rotterdam, The Netherlands; 3) Service de Génétique et Service de Neuropédiatrie, Centre Hospitalier Universitaire de Tours, Tours, France; 4) Dept. Medical Genetics, Univ British Columbia, Vancouver, B.C, Canada.

Mutations in *ARX* have been associated with X-linked lissencephaly with abnormal genitalia, infantile spasms, and less severe phenotypes in males. We have recently shown that a majority of females with severe *ARX* mutations (protein truncations or missense mutations in the homeobox) have an abnormal phenotype, excluding mothers of affected males to remove ascertainment bias (Sudi *et al*., ASHG 2007). To explain the phenotypic variability among heterozygous females, we developed a novel X-inactivation assay using a polymorphic marker (AFM260YE5) located 1.4Mb upstream of *ARX*, that contains a restriction site for the methylation-sensitive enzyme, *Aci*I. We performed X-inactivation (Xi) analysis in 21 heterozygous females including 3 probands, 13 mothers of males with XLAG, and 5 other female relatives. Overall, we detected skewing of Xi greater than 80:20 in only 1/21 females (4.7%), which is similar to the studies of control females using the *AR* assay (Amos-Landgraf *et al*., 2006) suggesting that skewing of X-inactivation is not the major cause of disease expression in heterozygous females. We next evaluated four families with two or three heterozygous females informative at the AFM locus to examine whether variations in direction of Xi less than 80:20 (mild skewing) could impact the phenotype. Here we assume that no crossovers occurred in the 1.4 Mb between the Xi locus and the *ARX* gene. In two families, the affected and normal females had mild skewing in opposite directions, while in two others the affected and normal females had mild skewing in the same direction. These results do not support a major role for mild skewing of Xi in producing the *ARX* female phenotype, although mild skewing could still be a modifying factor in some individuals. Our data suggests that other genetic factors contribute to phenotypic variability in females.

Clinical implementation of a high-resolution oligonucleotide based array-CGH platform for the detection of deletions and duplication in Dystrophin (*DMD*) and neighboring genes on Xp21. *D. del Gaudio[1], J. A. Lee[1], E. S. Schmitt[1], H. Pham[1], E. Spiegel[2], R. J. Wapner[2], L. Groome[3], C. M. Eng[1]* 1) Dept.of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, USA; 2) Dept. of OB/GYN, Columbia University Medical Center, New York, NY, USA; 3) Dept. of OB/GYN, LSU Health Sciences Center, Shreveport, LA, USA.

Duchenne and Becker muscular dystrophies (DMD/BMD) are X-linked recessive dystrophinopathies caused by mutations in the dystrophin gene (*DMD*). Approximately 70% of mutations are intragenic deletions or duplications. We report our experience with the clinical implementation of a high-resolution oligonucleotide array-CGH platform for the identification of copy-number changes in the *DMD* gene. The analysis was performed on a total of 940 samples submitted to our clinical laboratory from August 2007 to May 2008. The initial 302 samples were analyzed on version 1.0 (4X44K) of the array, and the subsequent 638 cases were analyzed on version 2.0 (8X15K) with expanded coverage in the *DMD* exons and neighboring genes on Xp21. Array-CGH detected *DMD* copy-number changes in 277 cases. Of these, 223 were deletions, 48 duplications, and 6 complex rearrangements. One case with a 191-bp deletion within exon 19 was missed on the version 1.0 array but was subsequently correctly identified on the version 2.0 array. The ability of array-CGH analysis to clarify unique clinical scenarios is illustrated by the detection of two complex rearrangements involving *DMD* and neighboring genes on Xp21: an interrupted duplication involving *DMD* exons 58 through 60 and the entire *DAX1* gene distal to *DMD* in a male fetus, and an unusual rearrangement composed of a deletion of *DMD* exons 1 through 7 and a duplication of the *XK* and *CYBB* genes identified in a male fetus and in his carrier mother. Our results highlight the utility of high-resolution array-CGH in detecting copy-number changes in the *DMD* gene in affected males and carrier females. In addition, this analysis allows improved identification and interpretation of complex rearrangements involving *DMD* and the neighboring genes on Xp21 maximizing genotype-phenotype correlations and improving patient counseling.

Sex-specific gene flow between Pygmy and non-Pygmy populations. *T. S. Simonson[1], W. S. Watkins[1], Y. Zhang[1], M. J. Bamshad[2], L. B. Jorde[1]* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Department of Genome Sciences, University of Washington, Seattle, WA.

Cultural traditions and preferences may drive sex-specific gene flow among human populations. We have examined sex-specific gene flow between Mbuti Pygmies, a hunter-gather population, and surrounding agriculturist groups, the Alur, Hema, and Nande, which all reside in Central Africa. We used 18 lineage-defining Y chromosome SNPs and HVS1 mitochondrial DNA sequence information to examine patterns of gene flow among these groups. Mbuti Pygmy males have more diverse Y chromosome lineages (Mbuti Pygmy [n = 28]: = 0.229; Alur [n = 10]: 0.193; Hema [n = 18]: 0.178; Nande [n = 15]: 0.090) and slightly less mtDNA diversity than neighboring groups (0.020, 0.023, 0.025, 0.022 in Mbuti Pygmy, Alur, Hema, and Nande groups, respectively). The majority of Mbuti Pygmy males have a Y haplotype characteristic of Mbuti Pygmies (B2b); however, more than 30% of Pygmy males exhibit Y haplotypes associated with Bantu-speaking agricultural populations (E3a lineage). Conversely, no agriculturist males exhibit Y haplogroups associated with Mbuti Pygmy populations but instead have derived Y haplogroups characteristic of Bantu agriculturalists (E2, E3a). Pairwise F_{ST} was calculated among all populations using Y haplogroup frequency and HVS1 mtDNA sequence data. YDNA and mtDNA F_{ST} values between Mbuti Pygmy and non-Pygmy groups (Alur, Hema, and Nande) were 0.278, 0.355, and 0.217 (for YDNA) and 0.088, 0.239 and 0.217 (for mtDNA), respectively. A Mantel test between pairwise F_{ST} matrices showed no significant correlation ((r = 0.27; p 0.35), which indicates that patterns of genetic differentiation differ between Y chromosome SNPs and mtDNA sequence patterns. These results also suggest no emigration of Mbuti Pygmy Y chromosomes into surrounding groups but immigration of non-Mbuti Pygmy Y chromosomes into the Mbuti Pygmy population.

Control of population stratification by correlation-selected principal components. *S. Lee[1], F. Zou[1,2,3], F. A. Wright[1,2,3]* 1) Departments of Biostatistics, University of North Carolina, Chapel Hill, NC; 2) Carolina Center for Genome Sciences, University of North Carolina at Chapel Hill, NC; 3) Center for Environmental Bioinformatics, University of North Carolina at Chapel Hill, NC.

In genome-wide association studies, population stratification is recognized as inflating Type I error by producing overdispersion of test statistics. Principal component-based methods applied to genotypes provide information about population structure, but the precise relationship between principal components and the over-dispersion of test statistics has not been established. We have identified a relationship between principal components and over-dispersion of association test statistics that provides precise guidance on the selection of principal components to use in adjusted test statistics. While methods such as Eigenstrat use the eigenvalues alone to determine which principal components to employ, in our approach the principal components are selected based on both eigenvalues and the relationship of the principal components to the disease phenotype. Our analytic results provide a direct connection among genomic control methods, principal component methods, and more recent approaches which attempt to use the relationship between markers and disease phenotype in obtaining adjusted test statistics. For real data analysis, our approach selects a much smaller number of principal components than that suggested by Tracy-Widom statistics, providing substantial computational savings in genome scans.

Toward the delineation of the clinical diagnostic criteria for the early onset seizure variant of Rett syndrome. *M. Maria Antonietta[1], R. Artuso[1], R. Polli[2], S. Sartori[2], F. Ariani[1], M. Pollazzon[1], A. Marozza[1], M. R. Cilio[3], F. Vigevano[3], M. Vecchi[2], C. Boniver[2], B. Dalla Bernardina[4], A. Parmeggiani[5], S. Buoni[6], J. Hayek[6], F. Mari[1], A. Renieri[1], A. Murgia[2]* 1) Medical Genetics, University of Siena; 2) Pediatric Neurology Unit, University of Padua; 3) Division of Neurology, Bambino Gesù Childrens Hospital, Rome; 4) Servizio Neuropsichiatria Infantile, Università di Verona; 5) Child Neurology and Psychiatry Unit, University of Bologna; 6) Child Neuropsychiatry, Azienda Ospedaliera Senese, Siena, Italy.

We report a detailed clinical investigation of 9 girls with CDKL5 mutations to delineate the specific clinical diagnostic criteria of the Hanefeld variant of Rett syndrome. Four subjects were previously reported (Scala et al. J Med Genet 2005; Mari et al. Hum Mol Genet 2005) and 5 are new cases (p.R178W, p.Q347X, p.N71D, pV132G, p.E203D). Patients range from 14 months to 9 years. All present epilepsy with variable onset from 10 days to 3 months. Girls experience different seizures at onset and during the whole course of the disease; multiple seizure types may occur as well. After the antiepileptic treatment patients may have a short free period but epilepsy progressively relapses. Patients do not show a classic regression period due to the very early onset of the seizures. Even if an apparently normal perinatal period is referred, the girls were described as irritable, easy to cry, drowsy and poor sucking. Typical stereotypic hand movements severely affecting ability to grasp are showed. Psychomotor development is severely impaired. In all girls the head circumference was and is within the normal range, indicating that head growth should be considered among minor diagnostic criteria. Each patient was classified using a severity score through the evaluation of 22 different clinical signs (Renieri et al Brain Dev in press). Results were compared with 128 classic and 25 PSV MECP2-mutated patients, all evaluated by the same clinical geneticists. Both the statistical and the descriptive approach have been used to delineate clinical diagnostic criteria for the Hanefeld variant.

Safety and tolerability of miglustat (Zavesca) in patients with infantile onset GM2 gangliosidosis. *C. Tifft[1], S. Yang[1], C. Morgan[1], A. Vanderver[2], T. Lateef[2], B. Moorjani[2], P. Glass[2], B. Brooks[3]* 1) Div Genetics & Metabolism, Children's Natl Medical Ctr, Washington, DC; 2) Center for Neuroscience & Behavioral Medicine, Children's Natl Medical Ctr, Washington, DC; 3) Opthalmic Genetics Branch,National Eye Institute, NIH, Bethesda, MD.

Miglustat, a competitive inhibitor of the first step in ganglioside synthesis, has been shown to decrease GM2 storage and improve clinical outcome in Sandhoff disease mice. The drug is approved for the treatment of Gaucher disease in adults, but experience with miglustat in very young children is limited. In this open-label study 6 patients with infantile GM2 gangliosidosis were treated with miglustat for 26 weeks at an equivalent adult dose of 200 mg/kg/day. Pharmacokinetics were assessed after a single dose and at steady state at weeks 1 and 13 respectively. Side effects were monitored and disease progression assessed using EEG, evoked response (VER, BAER), developmental and neurological evaluations, and biomarkers in cerebrospinal fluid (CSF) including chitotriosidase, CCL18, and GM2 quantitation by tandem mass spectrometry.

Our results show that miglustat is well-tolerated with fewer gastrointestinal side effects than adult patients. At baseline, GM2 ganglioside was markedly elevated in patient vs. control CSF and did not change significantly over the 26-week treatment period. Chitotriosidase, a measure of activated macrophage/microglial cell burden, was 54-fold elevated ($p<0.001$) and macrophage marker CCL18 was 4-fold elevated over control CSF ($p<0.01$). There was no significant change in these biomarkers during the study. All patients showed variable rates of clinical decline. Evoked response testing suggests that vision declines more rapidly than hearing. Interestingly, the Sandhoff disease patient showed near complete clearance of PAS positive inclusions in conjunctival cells. We conclude that although well-tolerated, miglustat cannot prevent the relentless decline in patients with infantile GM2 gangliosidosis. However, we have identified several surrogate biomarkers and clinical tools that may be useful in monitoring disease progression in the future.

The ribosomal biogenesis protein EMG1 is mutated in Bowen-Conradi Syndrome. *J. Armistead[1], S. Khatkar[1], B. Meyer[2], P. Koetter[2], E. Nylen[1], S. Liu[1], G. Coghlan[1], K. Wrogemann[1], C. Greenberg[1], KD. Entian[2], T. Zelinski[1], B. Triggs-Raine[1]* 1) Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, Manitoba, Canada; 2) Center of Excellence, Macromolecular Complexes, Institute of Molecular Biosciences, Johann Wolfgang Goethe-University, Frankfurt, Germany.

Bowen-Conradi syndrome (BCS) is an autosomal recessive disorder characterized by severely impaired prenatal and postnatal growth, profound psychomotor retardation, and death in early childhood. BCS is of major concern to the Hutterites of the Canadian Prairies and the United States Great Plains because of its morbidity, mortality, and high birth prevalence (1/355). We previously mapped the BCS gene to a 1.9 Mbp interval on human chromosome 12p13.3 between *F8VWF* and *D12S397*. The 59 genes in this interval were ranked as candidates for BCS and 36 of the best candidates were sequenced. Numerous variants were identified, but only an A to G mutation causing an Asp to Gly substitution in the 18S ribosome assembly protein EMG1 was a good candidate to cause BCS. This mutation segregated with disease, was not found in 207 non-Hutterite controls, and affected an amino acid conserved in all identified homologues. *EMG1* mRNA was found in most adult tissues and its levels did not differ between BCS patient and control fibroblasts. To investigate the effect of the mutation on the EMG1 protein, vectors encoding HA-tagged wild type and mutant EMG1 were constructed and expressed in mammalian cells. The level of detectable soluble mutant EMG1 was significantly reduced compared to the wild type protein. Metabolic labeling with ^{35}S-Cys/Met showed that the Asp to Gly mutation did not reduce the rate of EMG1 synthesis, but instead led to its sequestration in a detergent-insoluble compartment. Fluorescence microscopy in mammalian cells did not differentiate the sub-cellular localization of mutant and wild type EMG1. In yeast, EMG1, also known as NEP1, is an essential gene and EMG1 harbouring the Asp to Gly mutation interfered with RNA binding as well as dimerization and cellular localization of the protein. These findings strongly support our conclusion that the Asp to Gly mutation disrupts the normal function of EMG1 resulting in BCS.

Regulation of Direct-to-Consumer Genetic Tests. *L. Geddes, T. Caulfield, R. Hyde-Lay* Health Law Institute, Law Centre, University of Alberta, Edmonton AB, T6G 2H5.

The completion of the Human Genome Project has given rise to a plethora of genetic tests for everything from cancer to personalized diet plans. Although these tests seem to offer a new age of personalized medicine, some are concerned that it is too soon to be offering these tests, especially directly to the public. Internet companies have been springing up rapidly, offering these tests directly to the consumer and often without the involvement of a physician or genetic counselor. Regulation of these tests can be difficult; the Internet spans national and state boundaries, attempts to restrict advertising may be challenged by freedom of speech jurisprudence, and the distribution of authority to regulate tests is often unclear. For example, in the United States the FDA has jurisdiction over the pre-market review of genetic tests only when they are sold as a test kit as opposed to tests that are developed in house by clinical laboratories and marketed as a service. The majority of genetic tests available are developed in house and are therefore not subject to pre-market review. Similar uncertainty exists in Canada, where in-house testing services do not seem to be captured by existing legislation covering medical devices. This abstract provides an overview of recommendations for regulation being made in the literature as well as by the media. Preliminary observations show that recommendations frequently include the involvement of a trained professional in the testing process, the regulation of information provided in advertisements and on company websites, and the provision of educational resources to medical professionals and consumers. Further, media portrayals of genetic tests show a mix of caution and excitement, and often recommend that the consumer be cautious when purchasing a genetic test. The availability of genetic tests directly to consumers creates an interesting regulatory problem for policy makers. An overview of these problems and existing recommendations may help paint a clearer picture of what regulations are currently needed.

Genome-wide Association Analysis of Multiple-Drug Severe Adverse Events. *Y. Shen[1], B. Jagla[1], A. Floratos[1], M. Nelson[3], S. John[4], E. Lai[3], Q. Li[5], A. Califano[1], A. Holden[6], I. Pe'er[1,2]* 1) Center for Computational Biology and Bioinformatics, Columbia University, New York, NY; 2) Department of Computer Science, Columbia University; 3) Pharmacogenetics, GlaxoSmithKline, NC; 4) Pfizer Inc; 5) Johnson and Johnson; 6) Severe Adverse Effects Consortium, LTD.

Severe adverse events (SAEs) due to drug treatment are usually rare but acute, potentially life threatening occurrences that not only pose a serious public health concern, but also can limit or even eliminate the use of otherwise beneficial agents. Pharmacogenetics seeks to identify strong risk alleles for SAEs, facilitating a molecular-level understanding of biological mechanisms and potentially develop predictive tests to focus safety concerns on carriers. In contrast to common diseases, there is expectation of large effects. The International SAE Consortium (SAEC) set out to systematically scan for genetic SAE risk factors by pulling together samples and resources from more than a dozen pharmaceutical, government, and academic partners, with aggressive sharing policy of raw data and analysis results (http://www.saeconsortium.org). We present the first genome-wide association study by the SAEC focused on serious skin rash, which includes stevens-Johnson syndrome and toxic epidermal necrolysis, widespread burn-like reactions to a variety of drugs that can be lethal. We genotyped 72 cases and 135 matched controls with the Illumina 1M chip, a study powered to identify large genetic risk factors with potential predictive utility. We further improved the power of this study by inclusion of up to 1934 additional control samples from publicly available datasets. We detail methodological demography and quality control pitfalls in this procedure of aggregating controls, along with approaches to overcome such issues. Our results highlight several genomic regions that may play a role in SSR risk for several drugs, including confirmation of the HLA locus. Furthermore, these results support the absence of highly penetrant common genetic risk factors that could be responsible for most SSR events. SAEC is committed to continue and tackle this and other adverse events, with several projects already being planned and structured.

Detecting rare variants for complex traits using linkage and association analysis. *X. Zhu, T. Feng, Q. Lu, R. Elston*
Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH.

Large genome-wide association studies have been evident to detect common genetic variants involved in common diseases. However most of the variants account for only a small portion of a trait variance. Candidate gene based resequencing approach also suggests that many rare genetic variants contribute to a trait variance. Here we proposed two designs: sibpair and unrelated case designs to detect rare genetic variants in candidate gene based analysis or genome-wide association. We show first that we are able to classify the rare risk haplotypes together using a small portion of sample and have power to test association in the remaining sample. This method can be straightforwardly applied to resequencing data. We next applied the method to WTCCC hypertension data, which is the only trait no genome-wide association evidence was reported in the original study, and identified one interesting gene associated with hypertension at genome-wide significance level. These results suggest that searching rare genetic variants is feasible and can fruitful in current genome-wide association studies, candidate gene studies or resequencing studies.

Clinical implementation of a high-resolution oligonucleotide based array-CGH platform for the detection of deletions and duplications of *MECP2* and neighboring genes on Xq28. *J. Lee, P. Fang, C. Eng, D. del Gaudio*
Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Mutations in *MECP2* cause Rett syndrome, a progressive neurodevelopmental disorder that affects ~1:10,000 females. *MECP2* mutations have been detected in females and males with a wide spectrum of neurodevelopmental phenotypes. Diagnostic sequencing of the *MECP2* coding region detects ~86% of mutations in classic Rett syndrome. We previously implemented dosage-sensitive Southern analysis to identify copy-number changes in *MECP2*, which account for an additional ~10% of cases. To augment the detection of these rearrangements, particularly heterozygous duplications in females, we had developed a real-time PCR assay and also utilized MLPA for confirmation by a second methodology. In an effort to explore new technologies that would enable higher resolution copy-number analysis of *MECP2* and the surrounding genes, we recently designed an oligonucleotide comparative genomic hybridization array (array-CGH). This array includes ~700 oligonucleotide probes covering *MECP2* (introns and exons) with an average spacing of ~1 probe per 100 bp; this version of the array also contains probes covering the neighboring genes at a similar density. On this platform we tested 7 blinded control samples (6 females, 1 male) that were previously analyzed by Southern and MLPA analyses and showed a spectrum of rearrangement sizes. Our array-CGH assay correctly detected *MECP2* partial gene deletions in 3 females (exon 1 deletion, exons 1 and 2 deletion, and exon 4 partial deletion), whole gene duplications in 1 female and 1 male that extended beyond the *MECP2* gene, and no copy-number change in 1 female. For one female patient, an exon 3 partial deletion (c.205_c.377+287del460) was detected by a single probe loss. Our data demonstrate the potential utility of array-CGH analysis in detecting *MECP2* rearrangements, particularly duplications in females and rearrangements extending beyond *MECP2*, with high sensitivity, and highlight the value of covering the entire *MECP2* gene, the neighboring genes, and flanking intergenic sequences to delineate most accurately these rearrangements in a clinical diagnostic setting.

Performance of genome-wide association studies for the identification of genes with known genetic association with asthma. *A. J. Rogers[1], B. A. Raby[1], J. A. Lasky-Su[1], A. Murphy[1], R. Lazarus[1], C. Lange[2], E. K. Silverman[1], S. T. Weiss[1]* 1) Channing Laboratory, Brigham & Women's Hosp, Boston, MA; 2) Harvard School of Public Health, Boston MA.

Rationale: GWAS studies promise to detect common disease susceptibility genetic variation. However, it is unclear whether this study design will overtake candidate gene based studies given the burden of correction for multiple comparisons imposed by this design and the inter-locus variability of coverage of common variation. Using genotype data from a GWAS in asthma, we assessed whether we could detect associations to replicated asthma-susceptibility candidates. **Methods**: GWAS was performed in 422 white asthmatic children and their parents, using the Illumina HumanHap 550v3 array. We identified replicated (2 populations) asthma-associated candidate genes through review of published literature. We performed family-based association testing assuming an additive genetic model using FBAT. **Results**: Review of literature identified 42 genes (163 SNP) with evidence of reproducible association with asthma. The sample size of our cohort was larger than >90% of studies, suggesting adequate power to detect marginal associations for the majority of loci. Genotype data was available for 892 SNP mapping within 50kb of these loci, including 31 SNPs previously associated with asthma. In our dataset, SNP associations ($p<0.05$) were observed for 63 SNP in 15 of the candidate genes, including 3 of 5 positional candidates (PHF11, GPR-154, and DPP10). The most significant associations were with DPP10 ($p=0.0008$). None of the observed associations were significant after correction for multiple comparisons. Importantly, we did not observe association for the 31 SNPs previously associated with asthma. **Conclusions**: The majority of SNP previously associated with asthma were poorly represented in this study. While we showed marginal replication of several of the genetic loci, SNP-level replication was not achieved. Despite the value of GWAS in identifying novel biology, their role in assessing replicated candidate genes remains questionable. U01 HL075419, U01 HL65899, P01 HL083069, R01 HL 086601, and T32 HL07427.

Mechanisms of JAG1 missense mutations in Alagille Syndrome and Cardiac Disease. *R. C. Bauer[1,2], A. O. Laney[1], E. Goldmuntz[1,2], N. B. Spinner[1,2]* 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, Philadelphia, PA.

Mutations in JAG1, a ligand in the Notch signaling pathway, cause autosomal dominant Alagille Syndrome (AGS), which is characterized by liver, cardiac, skeletal and ocular symptoms. JAG1 mutations have also been reported in individuals with apparently isolated cardiac disease. The cause of this variable expressivity is not completely understood. Over 45 unique missense mutations have been identified in AGS patients and an additional 4 mutations have been reported in patients with isolated cardiac disease. We analyzed 12 AGS missense mutations distributed throughout the various domains of the JAG1 protein as well as the 4 cardiac mutations. We assessed subcellular localization, post-translational modification and ability to signal via the Notch receptors. We found 3 classes of mutations. In the first class are 8 mutations that cause improper glycosylation and improper trafficking (C78S, C92Y, Y181N, C229Y, C234Y, C693Y, P810L, C902S). These mutant proteins are retained intracellularly and therefore cannot interact with the Notch receptors. The second class contains 4 mutations that are leaky in that 2 species of proteins are observed: one that is trafficked to the cell surface and one that is retained intracellularly (C271R, G274D, C284F, C438F). The protein that does make it to the cell surface still cannot activate the Notch signaling pathway. The third class of mutants is also leaky, however, in this group the proteins present at the cell surface are able signal through the Notch receptor (C664S, C714Y, C740R, C911Y). The clustering of mutations in classes 2 and 3 suggests clues for functional characteristics of specific protein regions. Examples of mutations that fit into each of these classes have been identified in both patients with classic features of AGS and in patients with apparently isolated cardiac defects. This suggests that the variable expressivity seen in these patients is not caused by intrinsic properties of the mutations, as previously thought, but rather by additional modifying factors, which could be genetic, environmental or stochastic.

Combined genomewide linkage and association study of ocular refraction in the Framingham Eye Study. *R. Wojciechowski[1], D. Stambolian[2], L. D. Atwood[3], J. E. Bailey-Wilson[1]* 1) IDRB, NHGRI, Baltimore, MD; 2) Ophthalmology & Genetics, Un of Pennsylvania, Philadelphia, PA; 3) Dept of Biostatistics, Boston University, Boston, MA.

Purpose: Refractive disorders are the most common causes of visual impairment worldwide. Previous studies have reported linkage of myopia or ocular refraction to a number of loci, but no genomewide association results have been published. We report results of genomewide linkage and association scans in Framingham Eye Study (FES) families. Methods: Eye exams were conducted on 2,540 FES participants in 293 families. We performed quantitative trait linkage and association analyses on ocular refraction, defined as the spherical equivalent refractive error. Genotypes were available for 1,240 individuals at ~113,000 SNP markers. Variance-components (VC) linkage analysis was performed with the Merlin package using a subset of ~18,000 SNPs. Family-based association statistics were estimated using FBAT and Merlin-assoc. FBAT was performed under additive genetic models for single SNPs and haplotypes using a 3-SNP sliding window. Results: VC linkage analyses yielded a peak LOD score of 4.16 (p=0.00001) at 124 cM on chr. 2q14.3. The strongest association in the FBAT haplotype analysis was found in the chr. 2 linkage region (p=0.0009 at ~80.96 Mb or 103 cM) . Merlin-assoc statistics yielded the strongest evidence of association with rs1049467 (p=8.2 x 10e-7; chr1q31.2, ~190Mb or 210 cM). There was suggestive evidence of linkage to that region (LOD=1.42, p=0.005 at 232cM). Conclusions: We found significant linkage of ocular refraction to a region on chr.2q. Though not genomewide significant after Bonferroni correction, association results are consistent with the presence of loci influencing ocular refraction on chromosomes 1 and 2. Nearby genes have not previously been reported as functional candidates for ocular phenotypes. Further investigation of these regions with a denser SNP map is warranted.

Founder mutations in the *PMS2* gene. *L. Senter-Jamieson[1], M. Clendenning[1], S. Sun[2], J. Panescu[1], S. Gallinger[3], J. Mackay[4], J. Larsen Haidle[5], M. Greenblatt[6], J. Young[7], A. de la Chapelle[1]* 1) Human Cancer Genetics Program, Ohio State Univ, Columbus, OH; 2) Mathematical Biosciences Institute, Ohio State Univ, Columbus, OH; 3) Mt Sinai Hosp, Toronto, ON, CA; 4) Dept of Biology, Univ College London, UK; 5) Univ of Iowa Hosp and Clinics, Iowa City, IA; 6) Univ of Vermont, Burlington, VT; 7) Queensland Inst of Med Res, Brisbane, AUS.

Germline mutations in the mismatch repair (MMR) gene, *PMS2,* are associated with Lynch syndrome. We recently published a series of *PMS2* gene mutations, 11 of which occurred in multiple unrelated probands. We previously characterized one such mutation in exon 7 (c.736_741del6ins11) that occurred in 12 unrelated probands. A shared ancestral haplotype was found, indicating that this is a prevalent mutation with reduced penetrance. Likewise, a missense mutation (c.137GT; S46I) was observed in 7 unrelated probands of European descent. Six probands had colorectal cancer and 1 had cancer of the small intestine. All tumors demonstrated absence of PMS2 only by IHC. Haplotype analysis was possible in 5 probands, and DNA from informative relatives was obtained for 4 of the families. All available individuals were typed at 6 microsatellite and 10 SNP loci, which span the *PMS2* region. In 3 of these families, a common haplotype was found which was shared by 2 affected individuals in each family, but not by unaffecteds. This haplotype spans ~98.5-356Kb and was not observed among 96 control haplotypes. In the fourth family, a smaller haplotype was shared. We also identified an exon 10 deletion in 3 unrelated probands from Australia, and confirmed the same breakpoints (c.989-296_144+706del1158) as two cases reported by others. No haplotype data have been obtained from these individuals to date given paucity available of DNA. Both the c.137GT mutation and the exon 10 deletion in *PMS2* likely represent additional founder mutations in the *PMS2* gene while founder mutations in *MLH1*, *MSH2*, and *MSH6* are less common. This could be due, in part, to the reduced penetrance of *PMS2*-associated disease in comparison to the other MMR genes and could explain why more than 20 cases of biallelic *PMS2* mutation carriers have been reported in the literature.

Toward Delineation of the clinical Syndrome associated with the 17q21.31 Microdeletion. *J. Leroy[1], F. Faes[2], B. Loeys[1], R. Van Coster[2], F. Speleman[1], A. De Paepe[1], A. Gijsbers[3], C. Ruivenkamp[3], E. De Baere[1], B. Menten[1]* 1) Dept Med Genetics, Ghent Univ Medical Sch, Ghent, Belgium; 2) Division of Pediatric neurology, Dept Pediatr, Ghent Univ Medical Sch, Ghent, Belgium; 3) LUMC, The Netherlands.

Recently the recurrent microdeletion 17q21.31 was identified in some individuals with syndromic mental retardation by use of array comparative genomic hybridization. The detection of this deletion in three independently ascertained mental retardation patients prompted attention to their mutual clinical similarity. Our patients were born at or slightly post term in 1990 (Pt.1, female), 1999 (Pt. 2, male) and 2006 (Pt. 3, male) respectively following an uncomplicated pregnancy and vertex delivery in Pts 2 and 3. Because of fetal bradycardia, emergency caesarian section was required in Pt 1. Anthropometric data at birth were within normal limits and have been throughout. All had significant motor and slow cognitive development, but no signs of regression. Hypotonia has remained significant throughout childhood in Pts 1 and 2, but is milder in Pt 3, who achieved sitting unaided at 9 months, whereas this milestone was not reached before 15 months in the former two. Walking started at 20 months in the boys, but not until 28 months in the girl. Although onset occurred after age two, speech development progressed well subsequently in all. Dysmorphic facial features included prominent, tall forehead and oblong facial configuration, enlarged intercanthal distances, broad nose with bulky tip (not evident in Pt 3), eyelid ptosis in Pt 2, upslanting palpebral fissures and convergent squint. All had marked joint hypermobility. All belong to the mildly retarded, have a pleasant disposition and benefit effectively from special education classes. MRI of the CNS in Pt 1 revealed nearly complete absence of the corpus callosum and syringomyelia in segments D7-D10. The microdeletion 17q21.31, *de novo* in the three patients causes a recognizable clinical syndrome. Work is ongoing in order to establish the potential causal role played by the inversion polymorphism frequently observed precisely in this chromosomal region.

Gaucher Disease Diagnostic Dilemma: When the Molecular Analysis and Clinical Presentation Disagree - The N370S/L444P Allele. *M. Balwani, M. E. Grace, R. J. Desnick* Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY.

The diagnosis of Type I Gaucher Disease (GD) was made by prenatal carrier screening of the acid -glucosidase (GBA) gene in a 31 year old Ashkenazi Jewish (AJ) woman who had the common mild N370S allele and the more severe L444P mutation. GD patients with N370S/L444P typically manifest symptoms at a mean age of 16.9 years, with mean splenic and hepatic volumes of ~22x and 2x normal, and early-onset bone involvement (Sibille et al 1993). Follow-up evaluation at our Center found the proband to be essentially asymptomatic: a normal physical examination, no organomegaly, and normal blood counts (Hgb=13.3 g/dL, WBC=8.2x 103/cm3, Platelets=344,000/cm3). Leukocyte GBA activity was in the low normal range (2.9 U/mg, nl: 1.6 - 8.5 U/mg). Clinical laboratory studies and plasma biomarkers for GD were normal, including chitotriosidase (20 U/ml, nl: 300U/ml). The patient declined MRI studies; however a skeletal survey and bone density were normal. To investigate this quandary, cDNAs from this individual, obtained by RT-PCR amplification, were sequenced. Of the 10 cDNAs sequenced, 50% were negative for the N370S and L444P alleles. The remaining cDNAs carried both mutations. Thus, this individual was heterozygous for GD, having a very rare allele with the two most common GD mutations. Family studies revealed that the p.[N370S; L444P] allele was inherited from her 63 year old asymptomatic mother who had normal leukocyte GBA activity (2.0 U/mg) and plasma chitotriosidase (72 U/ml). The N370S allele is present at a frequency of ~ 1 in 17 in AJ individuals, and occurs in ~70% of AJ GD patients, while the L444P occurs infrequently (<3%) in AJ GD patients (Grabowski, 1997). Thus, the mechanisms for the p.[N370S; L444P] allele include crossing-over, or gene conversion with the pseudogene, or less likely, a second independent mutation (Beutler et al 2000). This unique mutation emphasizes the limitations of only molecular studies for the diagnosis of this disease.

Using Exon Skipping to Rescue Common Mutations in Hermansky-Pudlak Syndrome Type 1. *L. M. Vincent, R. Hess, W. Westbroek, W. A. Gahl, M. Huizing* MGB, NHGRI/NIH, Bethesda, MD.

Hermansky-Pudlak syndrome (HPS) is characterized by oculocutaneous albinism, a bleeding diathesis, and other systemic complications, including granulomatous colitis and fatal pulmonary fibrosis, due to defects in intracellular vesicle trafficking. The most common subtype, HPS-1, occurs primarily among Puerto-Ricans and results from a 16-bp duplication in exon 15 of the *HPS1* gene. Little is known about the function and structure of *HPS1*, making directed therapy difficult. In view of successful advances in therapeutic exon skipping (e.g., Duchenne Muscular Dystrophy), we utilized anti-sense morpholino oligonucleotides (MOs) to induce in-frame exon skipping of exons carrying deleterious *HPS1* mutations, specifically those in exons 12, 13, 15, and 16. Normal melanocytes positively transfected with MOs were selected using FACS analysis and observed over time. We utilized RT-PCR analysis to validate the effect of each MO on the *HPS1* transcript and immunofluroescence (IF) staining against the melanosome-specific protein TYRP1 to detect abnormal melanosomal trafficking patterns (i.e. lack of accumulation in dendritic tips). Exon 12 MO, ille12, effectively removed exon 12 in ~75% of *HPS1* transcripts. IF analysis revealed a decrease in the accumulation of melanosomes at the dendritic tips; however, it is unknown if this was due to partial activity of the mutant HPS1 protein or residual normal HPS1. Exon 13 MO, e13i13, removed exon 13 in ~95% of *HPS1* transcripts and likewise showed reduced, but not abolished, trafficking of melanosomes to the dendritic tips. We are currently administering these corresponding mutation-specific MOs to patient melanocytes in order to determine if we can rescue the HPS-1 phenotype. Interestingly, co-transfection of i11e12 and e13i13 removed both exon 12 and exon 13 in 100% of HPS1 transcripts and trafficking of melanosomes to the dendritic tips was abolished suggesting the resultant mutant product lacks HPS1 function. Further investigation into targeted exon skipping could result in clinical applications for the treatment of the fatal pulmonary fibrosis associated with HPS-1.

Linkage analysis of candidate genes in Carribean Hispanic families affected with Dementia with Lewy Bodies. *C. Reitz[1,2], J. Lee[1,2,3,6], A. Nervi[1], E. Katz[1], R. Mayeux[1,2,4,6], L. N. Clark[2,5,6]* 1) G.H. Sergievsky Center, Columbia University, New York, NY; 2) Taub Institute for Alzheimer Disease and Aging Research; 3) Department of Epidemiology; 4) Department of Neurology; 5) Department of Pathology; 6) Center for Human Genetics.

Background: Mutations in several Parkinson and Alzheimer disease genes including alpha-Synuclein, beta- Synuclein, Leucine Rich Repeat Kinase 2, Glucocerebrosidase, Presenilin 1 and Presenilin 2 have been identified in patients with dementia with Lewy bodies (DLB). Although the majority of patients with DLB are thought to be sporadic, families have also been described suggesting a genetic component. Objective: To explore chromosomal regions harboring DLB candidate genes in nine multiplex Caribbean Hispanic families with multiple members affected with DLB using 264 microsatellite markers (average intermarker distance of 9.3 cM). Results: Significant LOD scores >1.0 suggestive for genetic linkage were obtained for several markers and in several chromosomal regions. Chromosomal regions harboring known DLB genes and related pathways in addition to other chromosomal regions with significant LOD scores were further analyzed. One such region of interest was 1q21.3. At an average intermarker distance of 9.3 cM, marker D1S1679 which maps to region 1q21.3 and is 7cM apart from Glucocerebrosidase (GBA) at 1q22, showed significant genetic linkage with the DLB phenotype (LOD=0.87, p= 0.03). Conclusions: Here we describe the results of linkage analysis for exploration of DLB candidate genes in nine Caribbean Hispanic families with multiple family members affected with DLB. Several chromosomal regions including, locus 1q21.3 which is close to the chromosomal region harboring GBA, were significantly linked with the DLB phenotype. Our findings highlight these regions for further genetic exploration in DLB research.

Characterization of UGTs active against Suberoylanilide Hydroxamic Acid (SAHA). Variations in SAHA glucuronidation associated with UGT genetic variants. *R. M. Balliet, G. Chen, R. W. Dellinger, C. J. Gallagher, D. Sun, P. Lazarus* Penn State University College of Medicine, Hershey, PA.

SAHA is a histone deacetylase inhibitor that has been FDA approved to treat cutaneous T-cell lymphoma and is currently being used in 47 clinical trials to treat various cancers. A major mode of SAHA metabolism is via glucuronidation. The goal of the present study was to characterize the SAHA glucuronidation pathway and identify genetic factors within this pathway that could play a role in overall response to SAHA. As determined by ultra-pressure liquid chromatography and confirmed by sensitivity to treatment with -glucuronidase and LC-MS, UGTs 1A1, 1A3, 1A4, 1A6, 1A7, 1A8, 1A9, 1A10, 2B7 and 2B17 all exhibited glucuronidation activity against SAHA *in vitro*, with the hepatic UGT2B17 and the extra-hepatic UGTs 1A8 and 1A10 exhibiting the highest overall V_{max}/K_Ms after normalization for UGT protein expression by Western blotting (16, 33 and 24 $nL.min^{-1}.g$ over-expressed UGT $protein^{-1}$, respectively). The $UGT1A8^{173Gly277Cys}$ variant exhibited a significant ($P<0.03$) 3-fold decrease in glucuronidation activity as compared to wild-type UGT1A8; the $UGT1A8^{173Ala277Tyr}$ and $UGT1A10^{139Lys}$ variants exhibited no glucuronidation activity against SAHA *in vitro*. HLM from male subjects who were homozygous for the UGT2B17 whole-gene deletion exhibited a significant ($P<0.001$) 50% decrease in glucuronidation activity as compared to HLM from individuals with at least one UGT2B17 allele; no association between UGT2B17 genotype and HLM glucuronidation phenotype was observed in females. This gender-specific association between UGT2B17 genotype and glucuronidation activity was correlated ($R^2 = 0.30$) with UGT2B17 expression in the same liver specimens as determined by real-time PCR. These results suggest that several UGTs may play an important role in the metabolism of SAHA and that the presence of one or more variant UTGs could significantly alter SAHA clearance rates and potentially play an important role on overall patient response to SAHA. These data further suggest that there are gender-specific differences in hepatic UGT2B17 expression and activity that may affect drug clearance.

Morphometric Analysis of the Posterior Fossa and Spinal Cord in patients with Hereditary Disorders of Connective Tissue. *J. C. Quo[1,2], L. Sloper[1], R. Raza[2], N. B. McDonnell[1]* 1) Clinical Research Branch, NIA, NIH, Baltimore, MD; 2) Harbor Hospital Center, Baltimore, MD.

Patients with hereditary disorders of connective tissue (HDCT) have increased incidence of Chiari I malformation, however, abnormalities of the posterior fossa or the spinal cord has not been systematically evaluated to date. We retrospectively evaluated midline sagittal brain, midline sagittal lumbar spine, and axial lumbar magnetic resonance imaging (MRI) of 94 subjects with HDCT (70 Female, 24 Male, aged 12-71) and 209 age matched controls (138 Female, 71 Males). HDCT subjects included those with diagnoses of Ehlers-Danlos syndrome (EDS), Marfan syndrome, and Fibromuscular Dysplasia with connective tissue features (FMD). The MRI images were obtained on a 1.5 Tesla MRI machine (Philips Interna, USA) with system 11.1 software. The measurement that showed significant differences between the subjects and the controls included the basiocciput measurement ($p=0.0115$), foramen magnum distance ($p=0.0101$), opisthion to internal occipital protuberance (IOP) ($p=0.0188$), dorsa sella to IOP ($p=0.0176$), tonsillar herniation ($p<0.0001$), fourth ventricle height ($p=0.0020$), brainstem length to the craniocervical junction ($p<0.0001$), brainstem length to the inferior portion of the gracile tubercle ($p=0.0016$), tentorium slope ($p=0.0109$), tentorium slope to the twining line ($p=0.0044$), height of cerebellum ($p<0.0001$), conus medullaris level ($p=0.0383$), and filum terminale thickness ($p<0.0001$). Measurements that were not statistically significant included the basisphenoid length, ponto-medullary height, medullary height, and odontoid angle. The significant p value observed in 13 of the 17 measurements suggests that there are consistent morphometric differences that are seen in HDCT patients that can contribute to increased incidence of clinical abnormalities such as Chiari I malformation, tethered cord syndrome and related complaints.

Identification of TP53 mutations in Mexican Li Fraumeni families. *S. Vidal[1], L. Taja-Chayeb[1], O. Gutierrez-Hernandez[1], A. Duenas-Gonzalez[1,2]* 1) Dept Clinical Research, Inst Nacional de Cancerol, Mexico City, Mexico; 2) Unidad de Investigación Biomédica en Cáncer.Instituto de Investigaciones Biomédicas, UNAM/Instituto Nacional de Cancerología.

Li Fraumeni syndrome (LFS) is a rare disease characterized by early tumor onset, multiple tumors in individuals and multiple affected family members; most cases (70%) are associated with dominant germline mutations in the tumor suppressor TP53. There are no known germline mutations at TP53 for the Mexican mestizo population. The purposes of this work were to determine the mutation frequency of TP53 gene, and to analyse what kind of mutations are present in our LFS patients. This study was carried on through denaturing high performance liquid chromatography (DHPLC) analysis. Any abnormal DHPLC profile that suggested a mutation was corroborated by direct sequencing. Those families with mutations will be follow up for early detection, and will receive genetic counseling. 15 LFS patients were included; DNA was obtained from peripheral leukocytes, and was amplified for the coding regions as well as the adjacent intronic sequences. 7 pairs of primers were used to analyse exons 2 to 11. Of the 15 families studied, we found deleterious mutations in 4, two missense mutations in exon 5 and 8, one splicing mutation that affect exon 5 and results in a stop codon (187), and one novel insertion of seven nucleotides in codons 329-330 which has never been reported. Besides, several polymorphisms were detected. Until now, 26.7% of our population has mutation in TP53 gene. Mutation negative families are currently being studied with different sets of primers to corroborate the absence of mutations.

Mouse Mutants as Models for Human Developmental Malformations: The *Extra-Toes Spotting (Xs)* Mouse. *D. Gildea[1,2], S. Loftus[1], Y. Yang[1], W. Pavan[1], L. Biesecker[1]* 1) GDRB, NIH/NHGRI, Bethesda, MD; 2) Genetics, GWU, Washington, DC.

Greig cephalopolysyndactyly syndrome (GCPS) is a malformation syndrome that includes limb anomalies, specifically polydactyly and syndactyly. GCPS is caused by mutations in *Glioma-associated oncogene-3 (GLI3)*, which is part of Sonic hedgehog (SHH) signaling. The GLI3/SHH pathway regulates many developmental processes, including limb patterning. Dysregulation of this pathway due to mutations in *GLI3* can result in limb malformation. The Extra-toes ($Gli3^{Xt}$) mouse is an animal model for GCPS. Like the human phenotype, $Gli3^{Xt}$ mice exhibit preaxial polydactyly. Another mouse, Extra-toes spotting (*Xs*), shares a similar phenotype with $Gli3^{Xt}$. *Xs* mice exhibit preaxial polydactyly, coat hypopigmentation, limb length asymmetry, and microphthalmia. Previous mapping excluded mouse *Gli3* as the gene mutated in Xs^J (Jackson allele) mice, and the gene and Xs^J mutation remain unknown. To identify the gene, we are performing recombination mapping in Xs^J mice. We maintain our Xs^J mice on a B6C3FeF1/J background, where penetrance of the phenotype is 82%. For mapping, it was necessary to outbreed Xs^J mice to castaneus mice to introduce a distinct chromosomal background, as we encountered substantial homozygosity in the candidate interval. Offspring from this outcross do not exhibit the Xs^J phenotype. When breeding offspring from the castaneus outcross to B6C3FeF1/J mice, we experienced a penetrance of 39%. These data show variable penetrance of the Xs^J phenotype that is dependent upon mouse genetic background. Here we present our genetic analysis, phenotypic characterization, mapping data, and developmental analysis of the Xs^J animal. We mapped the Xs^J locus to a 322 kb region on mouse chromosome 7 and are evaluating candidate genes. Since the $Gli3^{Xt}$ and *Xs* phenotypes overlap, we hypothesize that the gene mutated in Xs^J mice is a gene in the Gli3/Shh pathway. To test this hypothesis, we used *in situ* hybridization to evaluate in Xs^J embryos the expression of genes in the Shh/Gli3 pathway. Data show misexpression of Shh members in Xs^J embryos, suggesting that the gene mutated in Xs^J mice is in the Shh pathway.

Searching for rare mutations in autism spectrum disorders, from SLC6A4 to novel candidate genes. *T. Sakurai, G. Cai, E. Hoffman, J. D. Buxbaum* Dept Psychiatry, Mount Sinai Sch Medicine, New York, NY.

It has long been recognized that autism can result from inherited and de novo chromosomal abnormalities and single gene mutations. However, for any given chromosomal abnormality or single gene mutation, the prevalence in individuals with autism is typically below 1 percent. With the development of methods of molecular cytogenetics and high-throughput sequencing, the capacity to identify such variants has improved markedly. We have undertaken deep re-sequencing of candidate genes as a means of identifying previously unidentified causes of autism. To do this we have evaluate several screening methods (including methods such as high-resolution melting curve analysis and additional novel methods). One such method was previously applied to a cohort of ca. 800 individuals with nearly equal numbers of cases with autism spectrum disorders and controls, to evaluate the role of rare variants in the 2q37 region in autism. We examined more than 1000 amplicons. Using this same method, we have examined the candidate gene SLC6A4 in the same cohort. We have begun sequencing genes that fall within regions of recurrent deletions in autism, including such regions on chromosomes 2 and 16. We sequence 300-400 unrelated subjects with an autism spectrum diagnosis (giving us > 95% power to detect a variant occurring in 1 percent of cases) and typically search for de novo mutations as the most compelling evidence for a causal relationship with the disorder. To date we have found no de novo mutations in brain-expressed candidate genes in the 2q or 16p region, but additional genes are now being evaluated. Our data demonstrate that rare variants in SLC6A4 are not associated with autism or with specific behaviors within autism (as defined by factors within the ADI-R).

Combination of acid -glucosidase D409H and saposin C deficiency in mice leads to visceral glucosylceramide accumulation. *G. A. Grabowski[1], K. Kitatani[2], S. Barnes[1], H. Ran[1], J. Brandewie[1], Y. A. Hannun[2], Y. Sun[1]* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center and Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH; 2) Department of Biochemistry and Molecular Biology, Medical University of South Carolina, Charleston, SC.

The defective lysosomal hydrolysis of glucosylceramide (GC) in Gaucher disease is caused by mutations in the gene encoding acid -glucosidase (GCase). Saposin C is a lysosomal protein having unique activation and proteolytic protective functions for GCase. To develop an additional model of Gaucher disease and to explore the in vivo effects of saposin C deficiency on GCase function, the point mutated GCase (D409H/D409H) mice were backcrossed to saposin C deficiency (C-/-) mice. The resultant mice, 9H;C*, developed visceral storage cells in the liver and lung that were identified as macrophages by positive CD68 staining. 9H;C* mice showed similar GCase activity as D409H/D409H mice. LC/MS analysis revealed 4-10 fold increased GC levels in 9H;C* liver and lung while brain GC levels remained at wild type levels. Life span, neurological phenotype, and CNS pathology in 9H*C mice were not distinct from C-/- mice. In contrast to 4L;C* mice (V394L/V394L;C-/-), a neuronopathic Gaucher disease model, 9H;C* mice presented primarily visceral involvement of GC accumulation. These models provide insights into potential interaction of saposin C with GCase mutations leading to a tissue-specific disease phenotype. This mouse model will be useful for evaluating therapeutic intervention and understanding the interaction of saposin C and GCase in vivo, and will greatly contribute to advancing our knowledge of glycosphingolipid storage diseases.

Treatment With Enzyme Replacement Therapy in a Severely Affected Individual With Hunter Syndrome (MPS II). *N. Arciniegas[1], A. S. Cornier[2], C. Burgos[2], N. Ramirez[3], J. Flynn[3], S. Carlo[2,4]* 1) La Concepcion Hospital, Dept. of Pediatrics, San German, PR; 2) La Concepcion Hospital, Molecular Medicine Dept., San German, PR; 3) La Concepcion Hospital, Dept. of Orthopaedics, San German, PR; 4) Ponce School of Medicine, Dept. of Biochemistry, Ponce, PR.

Hunter Syndrome (MPS II) is caused by the absence of the enzyme iduronate sulfatase.The deficiency of this enzyme gives rise to lysosomal accumulation of heparan and dermatan sulfate. The accumulation of these mucopolysaccharides in the connective tissue affects multiple systems including the musculoskeletal, cardiovascular, pulmonary and ocular systems. It is the only type of mucopolysaccharidosis with X-linked recessive transmission. We are presenting the case of a 16 year old male patients with MPS II , who was on enzyme replacement therapy (ERT) for the last 12 months of his life. The patient was evaluated before enzyme replacement therapy. The evaluation included physical examination, cell blood count, urine GAGS levels and abdominal sonogram. Patient had monthly follow up visits for evaluation. Weekly intravenous enzyme infusion was performed using the recommended doses for age and weight. Initial physical examination and determination of urinary levels of GAGS were elevated, abdominal sonogram presented hepatomegaly, brain magnetic resonance reported communicating hydrocephaly and cell blood count showed thrombocytopenia. After nine months of treatment patient had normal levels of urinary GAGS and hepatomegaly had disappeared, platelet count was within normal limits. At physical examination the patient displayed the typical dysmorphic features of MPS II, purulent nasal secretions and limitation of range of movement of the joints, manifestations have improved considerably after the treatment, including allergies and sinusitis. Patient died of complications of the disease after one year of treatment. ERT is beneficial for short and long term treatment of patients with lysosomal storage diseases. Majority of symptoms improve with the treatment making the quality of life of patient and family members improve considerably.

A High-Resolution Smaller Insertion and Deletion Map of a Human Genome by Next-Generation, High-Throughput Paired-End Sequencing. *E. F. Tsung[1], H. E. Peckham[1], Z. Zhang[2], S. S. Ranade[2], C. C. Lee[1], C. R. Clouser[1], J. M. Manning[1], C. L. Hendrickson[1], L. Zhang[1], E. T. Dimalanta[1], T. D. Sokolsky[1], J. K. Ichikawa[1], F. C. Hyland[2], J. M. Kidd[3], C. Alkan[3], J. A. Malek[4], F. M. De La Vega[2], G. L. Costa[1], E. E. Eichler[3], K. J. McKernan[1]* 1) Applied Biosystems, Beverly, MA, 01915; 2) Applied Biosystems, Foster City, CA 94404; 3) Dept. of Genome Sciences, HHMI, University of Washington, Seattle, WA; 4) Weill Cornell Medical College in Qatar, Doha, Qatar.

Hybridization microarrays and fosmid-end sequencing reveal that structural variants (SVs) including insertions and deletions are common and extensive. Microarray methods, however, lack resolution and are blind to unbalanced events, while clone-based end-sequencing is time consuming and expensive. Here, we present a high-resolution survey of insertion and deletion SVs from a human genome, a HapMap Yoruba sample (NA18507), by ultra-high throughput sequencing of paired-end libraries with the Applied Biosystems SOLiD System. We have sequenced a variety of 2x25-bp paired-end libraries with insert sizes ranging from 600bp to 3.5kb (SD 10-23%) as well as several longer read length paired-end libraries. The paired-end libraries provide over 178x physical (clone) coverage and over 6x sequence coverage from uniquely placeable mate pairs derived from unique molecules.

The variety of insert sizes and the high physical coverage reached delivers an unprecedented level of resolution which allows the detection of very small indels within single tags (1 to 11 bp), as well as larger indels in the range of 20 bp to over 100 kb, thus closing the gap of the detectable indel sizes. Approximately 90,000 small indels including 24,000 one base pair insertions and 22,000 one base pair deletions have been detected with high specificity. Also, the sensitivity approaches fosmid-sequencing in regions of high sequence coverage. Overall, our results provide a comprehensive assessment of the requirements to discover insertion and deletion variants in large-scale studies of genetic variation in human populations and human diseases with next-generation sequencing.

PHYLO-GENETICS VARIATION IN EUROPEAN PERCIDS. *A. Islam[1], O. Gorshkov[2], V. Chernov[2], V. Kuznetsov[3]* 1) Dept Ophthalmology, Schepens Eye Res Inst, Harvard University Medical School, Boston, MA 02114, USA; 2) Kazan Institute of Biochemistry and Biophysics, Russian Academy of Sciences, Kazan, Russia 420111; 3) Dept Vertebrate Zoology, Kazan State University, Kazan, Russia 420008.

The genetics variation of Percids of Russian Kuibyshev lake evolved compact phylo-evolutionary relationship bond among the populations. Pikeperches (*Stizostedion lucioperca* and *S. volgense*), river perch (*Perca fluviatilis*) and ruffe (*Gymnocephalus cernuus*) are the most ancient species of this reservoir, which have the same external appearances with different sizes and shapes. The declining tendency of pikeperches in this reservoir urges us to investigate their genetics relationship. The genetics variation and rapidly amplified DNA polymorphism between the exploited fish populations, a product of past evolution in relation to the ecology is an essential initiative to increase the overall chances that depleted population will regain and persist over the long period of time. Two microsatellites DNA from walleye (*S. vitreum*) were used as primers for this study. Each of the DNA markers (Svi-4 and Svi-18) resolved to 4-6 alleles with a size range of 102-124 bp. The DNA analysis revealed diversified polymorphism in different Percid populations. The PCR products of *S. volgense* have amplification of 100-1200 bp with rapidly amplified polymorphic DNAs. Most of the dominant DNA bands of pikeperches existed in the size range of 100-600 bp in both of the primers treatments. *S. lucioperca* had diversified DNA amplifications with a size range of 100-400 bp where 2-3 dominant DNA bands were located at 100-250 bp. River perch had only one band at 100 bp and ruffe had two DNA amplification signals at 100 and 180 bp. The rapidly amplified DNA polymorphism of different Percids showed a specific size range of the DNA amplifications. *S. lucioperca* and *S. volgense* revealed as closely related species. The phylo-evolutionary genetics variation of these species established that over-fishing, geographical, temporal and reproductive isolations are the primary barriers that produce changes in populations and genetics compositions. These analyses could help us further to understand the human phylo-genetics variation as well.

Chromosome 9p21 Polymorphisms Confer Risk of Myocardial Infarction in the INTERHEART Study. *R. Do[1], C. Xie[2], J. Kimberly Haladyn[2], S. D. Bailey[1], A. Belisle[3], A. Montpetit[3], S. Yusuf[2], J. C. Engert[1], S. S. Anand[2] on behalf of the INTERHEART Genetics Investigators* 1) Department of Human Genetics, McGill University, Montreal, QC; 2) Population Health Research Institute, McMaster University, Hamilton, ON; 3) McGill University and Genome Quebec Innovation Center, McGill University, Montreal, QC.

Genome-wide association (GWA) studies have identified genetic variants in the chromosome 9p21 locus that influence the risk of coronary heart disease (CHD)/myocardial infarction (MI) and type 2 diabetes (T2D) in several European populations. To date, the findings for CHD/MI have been studied in two non-European populations, with replication found in East Asians but not African Americans. In the present study, we investigated the effect of chromosome 9p21 variants on MI in 1,867 South Asians from the INTERHEART study. Six SNPs identified from GWA studies of CHD/MI and T2D were selected. Minor allele frequencies (MAF) for the T2D SNPs, rs564398 and rs10811661, were 0.25 and 0.15 respectively, while MI SNPs (rs10757274, rs2383206, rs10757278, rs1333049) ranged from 0.43 to 0.47. The T2D SNP, rs10811661, was in low linkage disequilibrium (LD) with all other SNPs ($0 < D < 0.11$). There was strong LD between all four MI SNPs ($D > 0.95$), with decreasing LD between MI SNPs and the other T2D SNP (rs564398; $0.73 < D < 0.78$). After adjusting for age and sex, five of the six SNPs were associated with MI (all $p<0.01$), with the strongest result being rs10757274 ($p=0.0004$). In addition, the most common haplotype (MAF=0.49) was associated with an increased incidence of MI ($p=0.0004$). Conditional haplotype tests that adjusted for the nine risk factors for MI shown previously in the INTERHEART study (diabetes, apoB/apoA1, waist/hip, current smoking, hypertension, alcohol consumption, fruit and vegetable consumption, psychosocial factors and physical activity) yielded the strongest result ($p=0.00005$). These results suggest that chromosome 9p21 variants are a strong risk factor for MI in South Asians and this effect is independent of nine risk factors for MI. Further assessment of these variants is required in other ethnicities.

Tethered Spinal Cord in Patients with Vascular Ehlers-Danlos Syndrome. *S. Bangura[1], B. F. Griswold[2], L. Sloper[2], R. Raza[2], N. B. McDonnell[3]* 1) Laboratory of Clinical Investigation, National Institute on Aging, NIH, Baltimore, MD; 2) Clinical Research Branch, National Institute on Aging, NIH, Baltimore, MD; 3) Harbor Hospital, National Institute on Aging, Intramural Research Program, NIH, Baltimore, MD.

Tethered Spinal Cord Syndrome (TSC) is a progressive neurological disorder caused by fatty tissue attachment that limits the movement of the spinal cord within the spinal column, causing an abnormal stretching of the spinal cord. Symptomatology includes urinary and bowel dysfunction, lower extremity pain, numbness or weakness, scoliosis, foot deformities and abnormal reflexes. Here we report two female patients (age 14 and 43) out of 16 consecutive probands with the vascular form of Ehlers Danlos Syndrome (VEDS)who were discovered to have TSC by Magnetic Resonance Imaging (MRI) of the lumbar spine. Patient #1 (Age 14) had a glycine substitution mutation, c.3563 G>A (G1021E) and had excessive bruising, abnormal scarring and wound healing problems, but no vascular events to date. Patient #2 had a 108 bp deletion in COL3A1 (exons 26 and 27) and had vascular complications including rupture of the abdominal aorta and multiple aneurysms in the splenic artery. Patient #2's MRI revealed open spina bifida and tethered cord at the level of L5. She had previous surgery for bladder incontinence, and currently suffers from urinary retention, which are not known complications of VEDS and likely related to TSC. Patient #1 had spinal cord tethered at the level of L3. She has chronic constipation, which is often seen in VEDS patients, but can also be a manifestation of TSC. Both patients had lower extremity weakness and pain. Physical findings included scoliosis, genu vera and pes planus, which can be seen in both TSC and VEDS. Patient #1 had abnormal lower extremity reflexes. This study describes the first reported case series of TCS in the setting of VEDS. Some findings, such as the lower extremity and spine deformities can be caused by both TSC and VEDS. A lumber spine MRI is indicated in the setting of VEDS if suspicious signs and symptoms of TSC are present.

Fine Mapping of a Myopia Susceptibility Locus on Chromosome 22q12. *D. Stambolian[1], R. Spielman[2], G. Ibay[3], K. Gogolin Ewens[2], R. Wojciechowski[3], J. Bailey-Wilson[3]* 1) Dept Ophthamology, Univ Pennsylvania, Philadelphia, PA; 2) Dept. Genetics, Univ Pennsylvania, Philadelphia, Pa; 3) NHGRI, NIH, Baltimore, MD.

Myopia is an increasingly common disease caused by an inability to focus images on the retina. Currently, there are 14 known loci but no genes are known to cause myopia. In an effort to delineate the genetic susceptibility to myopia, we have previously performed a genome-wide screen in a Jewish population of 56 families ascertained by a proband with myopia. The genomic region with the strongest evidence for linkage with myopia was located on chromosome 22q12 (HLOD=4.73). We have recently constructed a high-density SNP map of this 35 Mb region in the Jewish population, utilizing LD data available from the International HapMap Project. A total of 1386 SNPs were genotyped with minor allele frequencies of >0.10 in this Jewish population. Eleven SNPs were not informative in the analysis. Association analyses were performed with common myopia (-1D or worse) in extended pedigrees using FBAT. Nine SNPs clustered around 30 Mb had p-values <0.001. Most of these SNPS were positioned in the intergenic regions of PISD, SFI1 and EIFENIF1. One SNP remained statistically significant after adjustment for multiple testing using the Bonferroni correction and is located in the 3 UTR of PISD. Additional work is in progress to replicate and confirm these findings in independent multi-ethnic populations and to determine the overall relevance of these SNPs in myopia susceptibility.

APOE Testing for Alzheimers Disease (AD) Risk Assessment: the Potential for Underestimating Risk. *S. Hiraki[1], J. S. Roberts[4], C. A. Chen[3], R. C. Green[1,2]* 1) Dept of Neurology, Boston Univ School of Medicine; 2) Dept of Medicine (Genet), Boston Univ School of Medicine; 3) Data Coord Center, Boston Univ School of Public Health (1-3 Boston, MA); 4) Dept of Health Behavior and Health Education, Univ of Michigan School of Public Health; Ann Arbor, MI.

Genetic test results are usually presented in binary terms while the implications of these results may be expressed as a risk. Much attention has focused on the potential negative effects of testing positive for a disease mutation while less consideration has been given to the potential for false reassurance from negative results. The REVEAL Study is a randomized controlled trial to evaluate the impact of providing a genetic risk assessment for AD on unaffected first-degree relatives of AD patients. Participants were randomized to receive APOE-based risk assessment either through a traditional education/counseling protocol or a highly condensed protocol. In this sub-study, we explored the association between APOE result (4+ vs. 4-) and underestimating risk, defined as perceiving ones risk as lower or equal to someone who does not have a family history of AD (ie. 10-15% risk). Participants (n=220) were given a lifetime AD risk estimate between 18 and 75%. Those who tested 4- (mean lifetime risk = 31%) were significantly more likely than those who were 4+ (mean lifetime risk = 50%) to underestimate their risk by rating it as the same or lower than someone without a family history of AD (35% vs. 6%, $p<0.001$). This relationship was also demonstrated in our multivariate logistic regression (OR=7.3, $p<0.001$) after controlling for age, sex, race, income, education, number of affected relatives, and randomization arm. Those testing 4- were also more likely to classify their risk as very low/low (29% vs. 7%, $p<0.001$) and to disagree with a statement of concern about developing AD (24% vs. 8%, $p=0.003$). In providing genetic risk assessment for common disease, the probabilistic nature of the information in contrast to the all-or-none result may lead to misinterpretation. Improved methods of communication of genetic susceptibility test results are needed to ensure adequate understanding of this complex information.

MCTP2 plays an important role in left ventricular outflow tract development. *S. R. Lalani[1], S. M. Ware[4], X. Wang[1], L. Potocki[1], G. Zapata[1], M. Bray[1], A. C. Chinault[1], B. A. Boggs[1], E. K. Brundage[1], J. A. Towbin[3], A. Patel[1], S. D. Fernbach[1], M. Baker[2], S. L. Hamilton[2], K. L. McBride[5], J. W. Belmont[1]* 1) Dept of Molecular and Human Genetics; 2) Dept of Molecular Physiology and Biophysics; 3) Dept of Cardiology, Baylor College of Medicine, Houston, TX; 4) Division of Molecular Cardiovascular Biology, Cincinnati Children's Hospital, Cincinnati, OH; 5) Nationwide Childrens Hospital, Columbus, OH.

Left ventricular outflow tract obstruction (LVOTO) defects have been reported in individuals with terminal deletions of 15q26. Using array-comparative genomic hybridization (CGH), we identified two half-siblings with coarctation of the aorta (CoA) and dysmorphic features, with 2.1 Mb microdeletion of 15q26.2, involving a single gene, MCTP2 (multiple C2 domain and transmembrane region protein). Their mother was found to be mosaic for this deletion which was not identified in 14,200 individuals subjected to the clinical array CGH. Targeted array CGH analysis of MCTP2 identified a de novo 40 kb duplication from intron 10 to intron 21 within the MCTP2 gene, in an individual with non syndromic CoA and hypoplastic left heart, which, if fully spliced, would predict a frameshift and premature termination at F697X. We then sequenced MCTP2 gene in 142 patients with LVOTO and found five missense variants, each one inherited from a parent and not found in 200 ethnically matched controls. To further investigate the role of MCTP2 in cardiac development, we carried out loss of function experiments by injecting Xenopus laevis embryos with a splice blocking antisense morpholino oligonucleotide. Morphant embryos underwent gastrulation and neurulation normally, however between stages 30-40 of development, a significant number of phenotypically normal appearing morphants died. At stages 44/45, MCTP2 morphants showed progressive edema with no evidence of endocardial cushion formation at any level of the developing outflow tract suggesting a possible defect in epithelial-mesenchymal transformation and confirming a role for MCTP2 in outflow tract development. These results identify MCTP2 as a novel genetic cause of coarctation of the aorta and related cardiac malformations.

Lung disease severity phenotype in Cystic Fibrosis modifier gene studies: benefits of population based samples.

C. Taylor[1], R. Dorfman[1], L. J. Strug[1], W. Li[1], A. Sandford[2], P. D. Paré[2], J. Zielenski[1], P. Durie[1], M. Corey[1] 1) Sick Kids Research Institute, Toronto, Canada; 2) James Hogg Centre, UBC, Vancouver, Canada.

Mutations in Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) gene cause CF but do not predict lung disease severity, the main cause of morbidity and mortality. The CF Modifier Study studies modifier genes for CF lung disease in a population based sample. Successes identifying modifier genes have been accompanied by conflicting results across study groups, hampering progress in the field. Two explanations are varying ascertainment criteria and the use of different derived phenotypes. Forced Expiratory Volume in 1 second (FEV1) predicts survival in CF and is accepted, clinically, as the best lung phenotype, generally reported as percent of predicted lung function based on age, gender and height (fev%pred). However, because of mortality selection in patients beyond early adulthood, fev%pred is a poor indicator of relative disease severity in older patients. Kulich et al., instead, used a CF specific percentile score (fevcf%; Am J Respir Crit Care Med 2004; 172:885-891) for patients under 40 years of age, which classifies severity relative to other CF patients of the same age but not across ages. Here we define a lung function phenotype for genetic analysis that can include all CF patients across age ranges and ascertainment schemes, and we compare heritability between this phenotype, fev%pred and fevcf%. We used three year longitudinal data from the CF Modifier Study, which consists of 60% of the Canadian CF population. Cohort survival estimates from the same national population were used to create a normalized survival adjusted lung phenotype (fevz). We calculated the Intraclass Correlation Coefficient (ICC) for 87 sibling pairs to get an estimate of heritability. Interestingly, the ICC for fev%pred (0.266) was similar to that for fevcf% (0.267), while the ICC was higher using fevz (0.411). Fevz is a more heritable phenotype for lung disease severity in this population. Association studies with fevz and reported modifiers will help to determine the utility of fevz for genetic analysis.

Preimplantation Genetic Diagnosis, Reprogenetics, and Policy Making: The Missing Participants in the Debate.

C. Bouffard[1], B. M. Knoppers[2] 1) Genetics Service, Faculty of Medicine and Health Sciences, Université de Sherbrooke (Quebec, Canada); 2) Canada Research Chair in Law and Medicine, Faculty of Law, Université de Montréal (Quebec, Canada).

Although preimplantation genetic diagnosis (PGD) is the first reprogenetic technique to be offered in a clinical setting, its precursor role for reprogenetics, genetics, regenerative medicine, and other fields is currently underestimated. Meanwhile, the highly colored language that pervades the debate around PGD is receiving insufficient critique. And yet this discourse exerts a determining influence on the development of genetics and reproductive health policies, as well as on the international legal and ethical measures now being devised to govern genomics, procreatics, the research on embryonic stem cells, and so on. In this context, our research attempts to highlight the need to consider a segment of the population often forgotten or ignored by policymakers and bioethics experts, the patients who live with severe genetic disorders. Methods: Ethnographic research in the 3 centres accredited for PGD in France: 990 hours of participant observation at PGD clinics and laboratories 79 semi-structured interviews (40 patients and 39 researchers, physicians, and health professionals). Analysis of legal and ethical literature on PGD. Results: The rhetoric employed in current policy debates, which center on concerns about eugenics and discrimination, disregards technical and clinical realities and patients experience. Furthermore, the often invoked notion of the perfect child bears little relation to parents desire to have a child free of the disease they themselves carry. Finally, PGD must be differentiated from in vitro fertilization. Conclusion: The need for an evidence-based discussion is urgent, but the debate should be transparent and include patients and their families. This inclusion could contribute to the development of a realistic and workable normative structure. It is urgently necessary to develop and sustain ethical norms that take into account patients particular context and needs, within a realistic analysis of the risks and benefits for the future child, the parents, and society.

Allele specific expression implicates *MMAB* as the most likely functional gene at the chromosome 12 locus associated with plasma HDL-cholesterol (HDL-C) level. *M. P. Fogarty[1], L. J. Scott[2], R. Xiao[2], K. L. Mohlke[1], FUSION study investigators* 1) Dept Genetics, U. North Carolina, Chapel Hill, NC; 2) Dept of Biostatistics, U. Michigan, Ann Arbor, MI.

Recent genome wide association studies (GWAS) have identified numerous complex trait susceptibility loci; however, the identity of the underlying susceptibility gene(s) and functional variant(s) often remains elusive. Our recent GWAS identified a novel locus on chromosome 12 strongly associated with plasma HDL-C levels ($p=3.4 \times 10^{-8}$; Willer et al, Nat Genet, 40;161). This locus spans at least 4 genes, including 2 strong biological candidates, and contains 54 strongly associated SNPs. We aim to identify the susceptibility gene and ultimately the underlying functional SNP(s). A functional SNP at this locus might play a regulatory role and could act in *cis* to affect gene expression, mRNA processing and stability, or translation. To detect the presence of *cis*-acting regulatory SNPs, we measured allelic expression of five genes in human hepatocytes (n=40 samples). Individuals heterozygous for regulatory variants affecting gene expression or mRNA levels should display allelic expression imbalance (AEI). Using 2-3 transcribed SNPs per gene as markers of AEI, allele-specific expression was measured in the cDNA of heterozygous samples by real-time PCR. We also quantified gene expression in each sample. Significant AEI was observed for 2 SNPs in *MMAB* ($p < 1.1 \times 10^{-8}$). Based on the pattern of linkage disequilibrium, these data suggest that the allele associated with higher HDL-C level is correlated with lower *MMAB* expression. Additionally, preliminary data quantifying gene expression in all samples is consistent with this direction of effect. In contrast, no AEI was observed in 4 other genes tested suggesting that *MMAB* is the most likely susceptibility gene at this locus. These results demonstrate that measuring AEI by real-time PCR has good potential to help identify functional genes in large association regions. We are working to identify the SNP most likely responsible for the AEI in *MMAB* using *in vitro* approaches to test for mRNA stability, transcriptional activity and protein-DNA interactions.

Identifying transcriptional targets of Dlx5 during early development of the mouse inner ear. *SA. Sajan[1], M. Warchol[2], M. Lovett[1]* 1) Division of Human Genetics and Dept of Genetics, Washington Univ School of Medicine; 2) Dept of Otolaryngology.

Development of the endolymphatic duct as well as the anterior and posterior semi-circular canals is compromised in mice lacking the gene *Dlx5*, a member of the Distal-less family of homeobox transcription factors. Its expression begins in the early otic vesicle, and the mutant phenotype becomes visually discernible at around embryonic (E) day 10. Because transcriptional targets of this gene in the developing inner ear are unknown, we sought to identify these targets by expression profiling otic vesicles microdissected from wild-type and *Dlx5*-null mouse embryos at stages E10 and E10.5 on Affymetrix arrays. We identified 293 genes differentially expressed by 1.5-fold or more between the two genotypes in one or both stages. Promoter analysis of the differentially expressed genes revealed 73 with at least one known Dlx5 binding site, of which 18 changed expression only in E10 or in both stages suggesting an earlier interaction with Dlx5. Of these 73 genes, expression patterns of six (*Isl1*, *Apcdd1*, *Pax8*, *Bmp4*, *Bmper*, and *Lrrtm1*) are known to overlap with that of Dlx5 in the developing otic vesicle whereas 19 (including *Otx2*, *Col1a1*, and *Lrrtm1*) have human orthologs whose promoters also contain at least one Dlx5 binding site. We then searched the promoters for any 12bp motifs shared by two or more genes to discover novel Dlx5 binding sites. We found 710 unique motifs of which 33 were also present in promoters of human orthologs, 15 that possessed homeodomain response elements required for binding to homeodomain-containing factors, and another 15 motifs that were found in promoters of genes that also contained known Dlx5 binding sites. Only one gene - Lrrtm1, whose expression is localized in the endolymphatic duct - satisfied all these three criteria, thereby making it a prime downstream candidate of Dlx5 in the otic vesicle. We are currently testing for a direct interaction of Dlx5 with these motifs within the genome by expressing it in an otic vesicle-derived cell line, carrying out chromatin immunoprecipitation using a Dlx5 antibody, and DNA sequencing the immunoprecipitated DNA.

Comprehensive copy number variant screen in hereditary peripheral neuropathies. *J. Huang[1], J. Price[1], G. Montenegro[1], G. Wang[1], X. Wu[2], J. Vance[1], M. Shy[2], S. Züchner[1]* 1) Miami Institute for Human Genomics, University of Miami, Miami, FL; 2) Department of Neurology, School of Medicine, Wayne State University, Detroit, MI.

Hereditary peripheral neuropathies present a group of clinically and genetically heterogeneous entities. All known forms, including the various forms of Charcot-Marie-Tooth disease (CMT) are characterized as Mendelian traits and over 30 genes have been identified thus far. It is well known that copy number variants (CNV) are involved in many diseases, including CMT type 1A. We speculate that hereditary peripheral neuropathy patients without missense mutations might instead carry rare CNVs in known genes, causing the disease phenotype. In this study, we investigated CNVs in 37 genomic regions harboring known genes for hereditary peripheral neuropathies (including the 17p12 duplication region) with NimbleGen 4-plex 385K CGH arrays in a set of 96 patients excluded for missense mutations in the majority of these genes. We identified two genomic regions with frequent CNVs (>20%): 1p35.1 (chr1:33,055,551-33,056,479, 5UTR region of YARS (DI-CMTC), 21%) and 8p23.3 (chr8:1,822,940-1,826,272, intronic region of ARHGEF10, 26%). Though frequent, these CNVs have not been reported previously. Because hereditary peripheral neuropathies are Mendelian diseases, common CNVs are unlikely to be causative for the disease phenotype. However, we also identified 91 regions with rare copy number changes (only gained or lost in a single sample), 18.7% of which covered exonic regions, affecting 11 genes for hereditary peripheral neuropathies. In summary, we performed the first high-density CNV study of hereditary peripheral neuropathy genes in 96 index patients. We have identified genomic regions that are frequently altered in our patient group, as well as rare changes that only occurred in a single patient. The significance of these aberrations is being further investigated.

Runs of Homozygosity Suggest a Role for Rare, High-Risk, Recessive Alleles in Bipolar Disorder. *F. J. McMahon, C. J. M. Steele, N. Akula for the BiGS Consortium* MAP Genetics, NIH/NIMH, Bethesda, MD.

Bipolar disorder is a common mental illness characterized by high heritability and non-mendelian inheritance. Previous studies have suggested the involvement of multiple genes, but so far only common, low-risk alleles have been identified. Empirical and theoretical analyses suggest that rare, high-risk alleles may also play a role. We investigated this hypothesis by searching for extended runs of homozygosity (ROH) among 1030 cases with bipolar I disorder and 1021 healthy controls, all of European origin, who were collected by the NIMH Genetics Initiative and genotyped with the Affymetrix 6.0 SNP array under the auspices of the Genetic Association Information Network (GAIN). Data were cleaned and filtered by a consortium data management committee and obtained by application to dbGAP. Analyses were carried out using Plink 1.01. Results were parsed by use of a PERL script (available upon request). A total of 725,282 markers passed all quality filters. There was no evidence of inbreeding in cases (median Wrights F = -0.0006271) or controls (median Wrights F= -0.0001372). We defined ROH as contiguous regions of homozygosity involving at least 10 adjacent SNPs. A total of 1376 ROH meeting these criteria were detected. ROH were significantly more common in cases than controls ($p < 0.0001$). 62 distinct ROH occurred at least 3 times more often in cases; only one ROH occurred at least 3 times more often in controls. ROH that were more common in cases averaged 102 kb and involved a mean of 28 SNPs. The largest ROH, seen in 6 cases and 1 control, spanned over 200 SNPs in a ~700 kb region on 5p13 that contains the annotated genes FLJ23577, IL7R, and CAPSL, and part of the coding region of UGT3A2, a glycosyltransferase. Other ROHs spanned KCNQ5, TACR1, DPP10, SDCCAG10, ZNF365 and CTNNA3, all of which have been previously implicated in genetic association studies of bipolar disorder. Preliminary analyses suggest that the majority of these ROH are not due to deletion polymorphisms. We conclude that ROH are more common in bipolar disorder than in healthy controls. This finding may reflect a contribution of rare, high-risk recessive alleles to this polygenic disorder.

Profile of Genetic and Metabolic Disorders in Puerto Rican Population. *S. Carlo[1,2], N. Arciniegas[4], A. Quintero[2], N. Ramirez[5], J. Flynn[5], M. Torres[6], A. S. Cornier[1,3]* 1) Dept. of Molecular Medicine, La Concepcion Hospital, San Germán, PR; 2) Dept. Biochem, Ponce Sch Med, Ponce, PR; 3) Dept. of Internal Medicine, Univ. of PR School of Medicine, Rio Piedras, PR; 4) Dept. of Pediatrics, La Concepcion Hospital, San Germán, PR; 5) Dept. of Orthopaedic, La Concepcion Hospital, San Germán, PR; 6) Epidemiology Center, Puerto Rico Dept. of Health, San Juan, PR.

Puerto Rico is an island located in the Caribbean with a population of approximately 4 million habitants.High incidence rates for disorders such as oculocutaneous albinism, Hermansky-Pudlack syndrome, Spondylothoracic Dysostosis (Jarcho-Levin syndrome) and Bardet-Biedl syndrome. However, there is no data regarding prevalence of genetic and metabolic disorders in Puerto Rico except, PKU, galactosemia, congenital hypothyroidism, sickle cell, congetial adrenal hyperplasia that are included in the newborn screening program. We reviewed 5,750 medical records of genetic clinics at the Pediatric Centers of Puerto Rico. The data was tabulated and analyzed in order to perform a statistical analysis so the prevalence and epidemiological profile of genetic and metabolic patients in Puerto Rico could be established. The groups were analyzed independently using the previous assigned number for the diagnoses, age, sex, reason for referral, municipality and management. Primary diagnoses were organized in general categories revealing the following results. Metabolic Disorders with 22.7%, Genetic disorders 29.9%; Congenital malformations 11.1%; Developmental Disease 18.3%; Behavioral Disorder 11.5%; and others 76 6.4%.The frequency of 45 specific diagnosis was also calculated and determined for different regions of Puerto Rico.The results of this research may prove to be useful for the determination of health care public policies, additions to the newborn screening program, assignment of resources in Puerto Rico. These data will serve as guide to health care services in states with a large amount of Puerto Rican population (NY, NJ, IL, CT, FL and TX) in the mainland US and may prove useful as a reference to compare with other Hispanics population in the mainland United States.

Molecular and Developmental Insights into Craniofacial Abnormalities in Tricho-Rhino-Phalangeal Syndrome (TRPS). *D. Napierala[1], K. Choudhry[2], E. Munivez[1], B. Lee[1,3]* 1) Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept Pediatric Endocrinology, Baylor College of Medicine, Houston, TX; 3) Howard Hughes Medical Institute.

Tricho-rhino-phalangeal syndrome (TRPS) is a dominantly inherited craniofacial and skeletal dysplasia caused by mutations involving the *TRPS1* gene. TRPS patients present with sparse hair and skeletal abnormalities reflecting disturbed endochondral bone formation. Moreover, TRPS patients have distinctive craniofacial features, some possibly attributable to defects of soft tissue, but the bulbous nose and micrognathia point to skeletal abnormalities. The *TRPS1* gene encodes for a zinc-finger transcriptial repressor TRPS1 that belongs to the GATA family of transcription factors. To understand the molecular mechanism of the TRPS craniofacial abnormalities we study *Trps1* mutant mice with an in frame deletion of the DNA binding domain of Trps1 (*Trps1GT/+* mice). Heterozygous mutations of the *Trps1* gene in mice phenocopy characteristic TRPS features. The heterozygous *Trps1GT/+* mice develop postnatally a mild craniofacial phenotype, while the homozygous *Trps1GT/GT* mice present with more severe craniofacial abnormalities including the cleft palate. Analyses of Trps1 expression during craniofacial development demonstrated that Trps1 is specifically expressed in perichondrium of all primordia of endochondral bones, cartilage of nasal capsule, tracheal cartilage and palatal shelves of maxilla. Moreover, high Trps1 expression was observed in primordia of all types of hair follicles, dental mesenchyme, developing ear and eye lids. Our analyses of the Trps1 function in cartilage demonstrated that Trps1 regulates chondrocyte proliferation and development. Moreover, Trps1 physically interacts with Runx2 and represses Runx2 during endochondral bone formation. Interestingly, we observed increased Indian hedgehog (Ihh) expression and signaling in Trps1 mutant mice. Therefore, Trps1 may regulate craniofacial development through interaction with hedgehog signaling pathway.

Animal models for functional evaluation of genes in autism spectrum disorders. *J. Buxbaum, N. Dorr, G. Elder, A. McInnes, M. Gama Sosa, T. Sakurai* Psychiatry, Mount Sinai Sch Medicine, New York, NY.

Autism is a genetic disorder of complex etiology. Autism can result from inherited and de novo chromosomal abnormalities and single gene mutations. These forms of autism, associated as they are with a single locus, are very amenable to modeling in mice. Our laboratory has developed a moderately high throughput behavioral screen to search for deficits in mice that might relate to key aspects of the autism phenotype. The screen includes an observational component, evaluation of spontaneous and elicited behaviors, and evaluation of complex behaviors including social interactions, learning, and memory. In parallel, we have generated 8 distinct murine models that have relevance to autism. The models target genes likely involved in social communication, social behavior, synaptic function, etc., and include knockouts and/or transgenics of AGC1, FOXP2, OXTR, AVPR1A, and GTF genes. We have applied our behavioral assays to these animal models, while also carrying out neuropathological analyses as well. In multiple models we see evidence for abnormalities in Purkinje cells. We also see deficits in social communication and social memory in two distinct models. We will describe the specific steps in the behavioral screen using results from these autism models.

Genetic testing of GAA: a prompt and reliable laboratory diagnosis of Pompe disease. *B. Tinkle[1], S. Peters[2], K. Zhang[1], N. Leslie[1]* 1) Div Human Genetics, Cincinnati Children's Hosp, Cincinnati, OH; 2) University of Cincinnati School of Medicine, Cincinnati, OH.

Pompe disease is due to the deficiency of acid -glucosidase resulting in glycogen accumulation in lysosomes. Diagnosis is suspected clinically; hypertrophic cardiomyopathy in the infantile form or muscluar weakness in the late-onset form. In affected infants, early recognition and initiation of ERT is paramount. Confirmation of Pompe can be done by histological demonstration of glycogen storage, enzyme deficiency, and/or GAA sequence analysis. Although enzyme testing is the gold standard, some difficulties exist. The enzyme is heat labile and can be artificially low on dried blood spots. WBCs contain maltase glucoamylase which can cause false negative results. The more sensitive and specific assay is enzyme analysis on fibroblasts but this can take several weeks. However, DNA analysis is very sensitive and can be done relatively quickly (McCready et al., 2007). DNA analysis has the additional benefit of being used predictively in prenatal testing as well as carrier testing. We developed a comprehensive DNA sequence analysis complemented by PCR fragment analysis of the common exon 18 deletion. 65 samples with features of Pompe and either an enzymatic or histological diagnosis were analyzed. Of the 65, 129 alleles were identified (99.2% sensitivity). Combining the data from McReady et al., (2007), 170 pathogenic alleles were identified among 172 alleles with an overall sensitivity of 98.8%. In addition, two patients were genotyped as normal that had reduced enzyme from dried blood spots. Dried blood spots and DNA sequencing offer quick and convenient confirmatory testing of Pompe disease. Dried blood spots may be heat and humidity sensitive and a control enzyme should be measured along with the GAA activity (The Pompe Disease Diagnostic Working Group, 2008). Further, enzyme activity in the late-onset form can be near-normal or normal in any of the enzyme assays. As neither test is infallible, both tests have advantages and are very sensitive for the infantile form but both likely have more, albeit minor, limitations in confirming the late-onset form.

Inter-individual variation in retrotransposition-competent human LINE-1 content. *C. R. Beck[1], P. Collier[2], C. Macfarlane[2], M. Malig[3], J. M. Kidd[3], E. E. Eichler[3], R. M. Badge[2], J. V. Moran[1]* 1) Departments of Human Genetics and Internal Medicine, University of Michigan Medical School, Ann Arbor MI; 2) Department of Genetics, University of Leicester, Leicester, UK; 3) Department of Genome Sciences and Howard Hughes Medical Institute, University of Washington, Seattle, WA.

L1 retrotransposition events continue to impact human DNA. The average human genome contains ~80-100 full-length, retrotransposition-competent L1s (RC-L1s); however, relatively few highly active or hot L1s appear to account for the bulk of human L1 retrotransposition activity. The currently active family of human L1s, the Ta-subfamily, arose ~4 MYA. These elements contain diagnostic sequence variants that allow their discrimination from older L1s that have accumulated during human evolution. Many hot L1s are present at low allele frequencies, suggesting that they may be under-represented in the human genome reference (HGR) sequence. Here, we combined genomic, genetic, and molecular biology approaches to uncover novel RC-L1s. First, we employed a fosmid-based end sequencing approach to identify insertion polymorphisms in the genomes of six individuals of unknown, Chinese, Japanese, European, and Yoruban (2 individuals) descent. Next, we used a PCR/Southern blot strategy to screen candidate fosmids for full-length, Ta-subfamily L1s, and designed genotyping assays to determine their allele frequencies. Finally, we used a cultured cell assay to determine if the candidate L1s were active in vitro. We identified 62 full-length L1s that are absent from a database of known L1 polymorphisms, and have assayed 46 of these for retrotransposition. Remarkably, 26 elements (~57%) were highly active, hot L1s. Preliminary analyses indicate that 5 of these hot L1s are absent from a CEPH genotyping panel consisting of 129 unrelated individuals, and may represent recent and/or population restricted RC-L1s. Thus, we have developed a powerful system to identify hot L1s from individual human genomes of diverse geographic origin. The data suggest that hot L1s are under-represented in the HGR, are far more prevalent than previously appreciated, and that their mobility continues to contribute to inter-individual genetic variation.

Mapping genetic susceptibility loci of hypocholesterolemic autism using nonparametric multipoint linkage analyses. *E. Tierney[1], Y. Kim[2], K. Weissbecker-Remer[3], F. D. Porter[4], J. E. Bailey-Wilson[2]* 1) Kennedy Krieger Institute, Baltimore, MD; 2) National Human Genome Research Institute, NIH, Baltimore, MD; 3) Tulane University, New Orleans, LA; 4) National Institute of Child Health and Human Development, NIH, Bethesda, MD.

Different loci have been identified as potential susceptibility genes for autism spectrum disorder (ASD) in previous genome-wide screens of multiplex families. To search for genes related to ASD, linkage analyses and association studies have been performed. Based on the previous finding that some individuals who had 1 or more family members with ASD were found to have low cholesterol levels, we hypothesized that either autism or other ASD subjects with hypocholesterolemia may have different genetic susceptibility loci. We obtained microsatellite genotype data for 390 loci on families with at least 2 children with ASD and hypocholesterolemia who donated blood to the Autism Genetic Resource Exchange. To analyze hypocholesterolemic probands, we defined 2 family groups: 1) cholesterol levels greater than 2 SD (standard deviation) below the mean (47 families; below-2SD), and 2) less than 100 mg/dl (28 families; below-100). In each group we analyzed different subsets depending on disease diagnosis: 1) both sibs had autism or 2) one or more sib had Not Quite Autism or Broad Spectrum using nonparametric multipoint linkage method. Additional analyses were performed on groups of male-only sibs and female-containing sibships in each subset. In the below-2SD autism families, D10S1412 at 10p14 shows nominal significance (P value of NPL score 0.005, Kong & Cox LOD=2.02); this is near a site for DiGeorge syndrome/velocardiofacial syndrome, a disorder associated with ASD, and a site of terminal deletion associated with ASD. Female containing sib pairs in below-100 autism families had nominally significant linkage at markers D5S822 (p value= 0.005, Kong & Cox LOD=1.37) and D5S1969 (p value= 0.002, Kong & Cox LOD=1.5) at 5q11.1-11.2. We cannot conclude that these loci have suggestive linkage evidence for sib pair analysis. However, they suggest that further analyses with more samples of hypocholesterolemic ASD families are needed.

Genetic variants on INSIG2 and PPARG and their associations with obesity related traits in an isolated population from Croatia. *G. Sun[1], H. Cheng[1], H. Xi[1], S. R. Indugula[1], P. Pal[1], J. Mallik[1], G. Zhang[1], R. Chakraborty[1], P. Rudan[2], R. Deka[1]* 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Institute for Anthropological Research, Zagreb, Croatia.

In an ongoing study on genetics of Metabolic Syndrome (MS) in an isolated population, we tested for association of tagging SNPs in two genes, INSIG2 and PPARG, with 28 obesity related anthropometric and biochemical traits. The study population, from an island of the eastern Adriatic coast of Croatia, has a high prevalence of MS. Since their migration to their current locale from the mainland Croatia in the 15th century, this population of Slavic origin has remained relatively isolated. Sequence variants in INSIG2 and PPARG are associated with obesity and type 2 diabetes. Forty one tagging SNPs (12 on INSIG2 and 29 on PPARG) were chosen (r2 >0.8, MAF 0.05) using the Caucasian HapMap database. Genotyping was performed on DNA from 870 subjects of age >18 years. We used ANOVA to test for differences between genotype groups. There was no significant association of PPARG variants with any of the traits. However, three variants on INSIG2 (rs1352083, rs13393332, rs2042492) were significantly associated (p = 0.0004-0.0005) with the tricep skinfold measures. Although we did not find association with other anthropometric measurements and biochemical traits, these results indicate that genetic variation on INSIG2 influences obesity related phenotypes. Supported by grant R01DK069845.

Improved Microarray-Based Genomic Selection (MGS) of Targeted Human Diploid and Haploid X-Chromosome Sequences for Next Generation Sequencing. *D. Okou[1], K. Meltz-Steinberg[1,2], A. Locke[1,3], P. Atri[1], V. Patel[1], M. Zwick[1,2,3]* 1) Dept Human Genetics, Emory Univ Sch Medicine, Atlanta, GA; 2) Graduate Program in Population Biology, Ecology and Evolution, Emory Univ, Atlanta, GA; 3) Graduate Program in Genetics and Molecular Biology, Emory Univ, Atlanta, GA.

Microarray-based Genomic Selection (MGS) can enrich targeted genomic regions for subsequent resequencing. Here we address two significant questions regarding the robustness of MGS: 1) the ability to accurately identify genotypes in diploid genomic regions and 2) the extent of coverage for large targeted regions. The Illumina Genome Analyzer (IGA) was used as platform for resequencing. To test the former, MGS arrays were used to enrich 300kb of coding and noncoding sequences from 1.7MB region on the human X chromosome in 10 female HapMap samples. Our improved protocol yielded ~2500-fold with 80X average sequence coverage in a single lane of IGA sequencing. In order to compare our MGS/IGA calls with HapMap calls, we focused our attention on ~344 SNPs genotyped in the HapMap (3190 genotypes total). Our average genotype-calling rate at all sites (97.8%) compared well with HapMap (98.7%). At homozygous genotypes, MGS/IGA called 98.4% of sites (HapMap 98.8%), whereas at heterozygous genotypes we called 84.2% of sites (96.6%). Our call rate at heterozygous sites significantly exceeds that previously reported (30%). When both technologies make a call at a given variable site, assuming that the HapMap data contains no errors, we observe an overall agreement of 96.3%. At homozygous sites, the MGS/IGA accuracy (96.7%) is nearly equivalent to that of HapMap (99.7%), while at heterozygous sites, the MGS/IGA accuracy is lower (84.8%) than that of HapMap (98.7%). To test the latter, an initial custom-designed MGS arrays (385k oligos) were used to enrich for 7066 exons (~2.4MB) on the human X-chromosome in 10 male HapMap samples. Data from a single lane of IGA sequencing yielded ~180-fold enrichment with 7.5 X average coverage in ten experiments. Our data suggest increased probe density will be required to obtain high fold enrichment and sequence coverage for large regions.

Identification of Diabetic Retinopathy Genes through a Genome-Wide Association Study among Mexican-Americans from Starr County, Texas. *Y. P. Fu[1], D. M. Hallman[1], V. H. Gonzalez[2], B. E. K. Klein[3], R. Klein[3], M. G. Hayes[4], N. J. Cox[4,5], G. I. Bell[4,5], C. L. Hanis[1]* 1) Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, Texas; 2) Valley Retina Institute, McAllen, Texas; 3) Department of Ophthalmology and Visual Sciences, Madison Medical School, The University of Wisconsin, Madison, Wisconsin; 4) Department of Medicine, University of Chicago, Chicago, Illinois; 5) Department of Human Genetics, University of Chicago, Chicago, Illinois.

To understand genetic susceptibility for diabetic retinopathy, a genome wide association study was conducted using the Affymetrix GeneChip Human Mapping 100K Set in a sample of 284 Mexican-Americans with type 2 diabetes from Starr County, Texas. All subjects had detailed ophthalmologic examinations including stereoscopic fundus photography and standardized retinopathy grading. A series of single and multi-marker association tests were performed to identify underlying genetic susceptibility for diabetic retinopathy. In initial single marker analysis, we found 10 loci associated with diabetic retinopathy with p-values less than 10^-4. Interestingly, 3 of these top 10 signals all mapped to STAC (src homology 3 and cysteine rich domain) located on chromosome 3. Furthermore, sliding-window haplotype analyses showed several regions with consistent significance in windows ranging from 2 to 8 SNPs. In particular, haplotypes containing SNPs residing in the intron region of TECTB (tectorin beta) on chromosome 7 reached statistical significance after Bonferroni correction. None of the SNPs with suggestive evidence in our single marker and haplotype analyses were in traditional candidate genes for diabetes or its complications. We are now conducting imputation analysis to expand coverage across the genome, and are turning to various multi-marker/gene/pathway analytical approaches to more fully extract the genetic risk and underlying biology of diabetic retinopathy.

Array-CGH analysis in a cohort of 112 Italian patients with MCA/MR. *E. Katzaki, FT. Papa, MA. Mencarelli, K. Sampieri, V. Uliana, M. Pollazzon, A. Marozza, I. Longo, F. Ariani, I. Meloni, F. Mari, A. Renieri* Medical Genetics, University of Siena, Siena, SI, Italy.

We have investigated 112 patients with mild to severe mental retardation associated to facial dysmorphisms and/or congenital anomalies. All patients but one (47,XXX) had a normal karyotype and have been evaluated by clinical geneticists (AR and FM) who excluded a recognizable syndrome on a clinical ground. Using either 44K or 105K oligo Array-CGH private imbalances were detected in 35 out of 112 patients. In 17 cases (15%) a private rearrangement was inherited from one healthy parent (Mencarelli et al Eur J Med Genet in press). In 18 cases (16%) the rearrangement was de novo: 5 were novel deletions, 2 were complex dup/del rearrangements and 11 were known syndromes in atypical cases. The last group included three cases of 22q11 deletions, the shortest 4p- and 6q- known in the literature, and two cases of Potocki-Lupski. Two complex rearrangements were found in two peculiar patients. One patient with bifid thumb, hypertonia, tricuspid atresia, aggressive behavior and normal karyotype, had a 9 Mb interstitial deletion on 3q including TP63 and a 4Mb duplication of chr 21. The other patient with microcephaly, iris coloboma and hypoplastic toes had a 4.5 Mb terminal 9pdel and a 3 Mb terminal 17pdup, reciprocal of Miller-Dieker, due to an unbalance of a balanced translocation present in the mother. The 5 novel de novo deletions ranged between 2.6 and 13.9Mb and they overlapped with polymorphic regions for an extent of 5-75% (Pescucci et al Eur J Med Genet 2007, Mencarelli et al Am J Med Genet 2007 and Papa et al. Am J Med Genet, 2008). Only two (6q24.3-q25.1 and 7q36.1-q36.2) are flanked by LCRs (Caselli et al, Eur J Med Genet, 2007 and Caselli et al Am J Med Genet, 2008). An accurate search of the literature allowed to identify patients with overlapping deletions. Comparative analysis of the phenotype of these patients with our patients suggested that a specific phenotype of these syndromes may be defined. These characteristics should be taken into account in order to identify additional patients.

***MTHFR* polymorphisms and genome-wide DNA methylation.** *CW. Hanna, MS. Peñaherrera, MS. Kobor, WP. Robinson* Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada.

The folate pathway provides a link between the environment and epigenetics, with dietary folic acid being metabolized into methionine that can then be used by methyltransferases to methylate DNA. A low folate diet and folate pathway polymorphisms can result in elevated homocysteine and decreased methionine levels. Both have been previously reported to be associated with altered DNA methylation. In addition, genetic variants in the folate pathway have been linked to hypertension, preeclampsia, Down syndrome, birth defects, and recurrent miscarriage in some populations. These effects could be due to hyperhomocysteinemia itself or the potential effects on DNA methylation. To identify DNA methylation changes associated with functional polymorphisms in the folate pathway we extracted DNA from whole blood from females of reproductive age. Genotypes for the -C677T and -A1298C polymorphisms in methylenetetrahydrofolate reductase (*MTHFR*) were determined using pyrosequencing on the Biotage PyroMark MD^{TM}. Global methylation was measured using pyrosequencing of a consensus LINE-1 element sequence (N=84) and by the Illumina Goldengate^{TM} Methylation Bead Array (N=35), which assesses the methylation level at 1505 CpG sites at over 800 genes. Global methylation did not differ by *MTHFR* genotype based on LINE-1 methylation or average methylation measured by Illumina Array. Nonetheless, some regions of the genome may be more susceptible to altered methylation in individuals homozygous for polymorphisms encoding a thermolabile MTHFR. Seven CpG sites were significantly associated with the *MTHFR* -677TT genotype ($p<0.01$), while twenty CpG sites were significantly associated with the *MTHFR* -1298CC genotype ($p<0.01$). Several interesting candidate genes are being followed up further by a targeted approach in a larger sample population. While we did not observe global alterations in methylation associated with susceptible genotypes, variation in dietary folate intake may have prevented genotype-associated changes from being apparent in our sample population.

Method for quality control and validation of multiplex ligation-dependant probe amplification (MLPA) assays.

G. Pont-Kingdon[1], L. S. Chou[1], C. Vaughn[1], T. Lewis[1], F. Gedge[1], E. Lyon[1,2] 1) ARUP Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 2) Pathology Department , University of Utah, Salt lake City, UT.

Deletions and duplications of single or multiple exons in specific genes are associated with human diseases. These types of mutations are detected in multiple laboratories by MLPA, which has the advantages of a resolution at the exonic level and a high multiplexing capability. MLPA uses a series of exon-specific probes that hybridize to their template prior to PCR amplification. Kits containing a mixture of exon-specific probes targeted to the gene of interest and control probes that hybridize to other genomic areas are commercially available (MCR-Holland, Amsterdam). Only validation results from positive samples can truly confirm that the probes listed in the kits correspond to the targeted exons, as negative (WT) samples contain all the genome and hybridize equally to any human DNA probes. Characterized positive samples can be extremely rare and difficult to obtain for validation purposes. Additionally, deletion of multiple exons in a sample will not interrogate each probe individually. We have designed an approach using master mixes of exon-specific PCR products to unequivocally verify each probe. As an example of the method, data will be presented using MLPA testing for a series of genes for which positive samples were difficult to obtain: COL4A5 (Alport syndrome), MSH6 and PMS2 (Lynch syndrome), FVIII (hemophilia A) or as a method for QA/QC of MLPA for CFTR (cystic fibrosis) and ENG and ACVRL1 (hereditary hemorrhagic telangiectasia). Data indicates that this easy and rapid approach can be used for analytical validation of the probes and for routine QA/QC of MLPA kits in absence of positive samples.

Fast and Robust Association Tests for Untyped SNPs in Case-Control Studies. *M. P. Epstein[1], A. S. Allen[2], S. Griffiths[3], F. Dudbridge[3], G. A. Satten[4]* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC; 3) MRC Biostatistics Unit, Cambridge, UK; 4) Centers for Disease Control and Prevention, Atlanta, GA.

Genomewide association studies of complex diseases typically genotype and analyze a set of tagSNPs that effectively capture genetic variation across the genome. Nevertheless, many such studies have substantial interest in testing SNPs that are not genotyped formally in the test sample. Such analyses of untyped SNPs can assist in signal localization and permit cross-platform comparison of results from different studies. While such untyped analyses might initially appear intractable, a study can extrapolate information on an untyped SNP in a sample using the observed tagSNP data coupled with external haplotype-based information on all SNPs (both typed and untyped) from an appropriate reference catalogue of human genetic variation (such as one of the samples from the International HapMap Project). Using this logic, we propose a novel statistical approach for testing untyped SNPs in case-control genomewide association studies. We base our approach on an efficient-score function derived from a prospective likelihood of data, which facilitates easy modeling and testing of untyped SNPs and covariates. In addition, we show both theoretically and empirically that our approach is robust to an inappropriate choice of reference sample for inference of untyped SNPs and, further, does not require adjusting for the additional variability in estimating haplotypes from genotype data. As a result, our efficient-score test is computationally much faster than existing approaches for untyped analysis and has a closed form even for stratified data that allows for easy programming in existing software packages. Regarding this former strength of our method, we can analyze ~1.6 million untyped SNPs in a case-control dataset of 1000 subjects in ~90 minutes on a single Windows processor. At the same time, we show using simulated data that our approach has near-equivalent performance compared to the popular hidden-Markov methods of untyped analysis.

Higher than Expected Frequency of a Third Mutant Allele in a Multiethnic Population Affected with Bardet-Biedl Sydrome. *G. Billingsley[1], J. Bin[1], E. Héon[1, 2]* 1) Dept Genetics & Genome Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Dept of Ophthalmology and Vision Sciences, The Hospital for Sick Children, University of Toronto.

Bardet-Biedl syndrome (BBS: OMIM 209900) is an autosomal recessive, genetically heterogeneous disorder characterized by the primary features of progressive retinal dystrophy, obesity, polydactyly, renal malformations, cognitive impairment and genital abnormalities. Its incidence is approximately 1 in 150,000 individuals in European populations, while the carrier frequency is estimated to be 1 in 50 (Laurier et al. Eur J Hum Genet (2006) 14, 1195). To date 12 BBS genes have been identified. Mutational analysis of the 12 BBS genes was performed on a BBS patient cohort (77 cases and 62 index cases) of mixed ethnicity. Family segregation and control screening (n=150) confirmed the pathogenicity of novel sequence changes. Together, the 12 BBS genes accounted for 68.5% of putative pathogenic changes in our index cases. BBS1 and BBS10 were major contributors to BBS in our patient cohort, each accounting for 20% of the mutational load. BBS6 and BBS12 each accounted for 6.5% of the total mutational load. In individuals with two bona fide mutations in a single BBS gene, we observed a much higher frequency of a third mutant allele than the predicted 2% carrier rate (23.3% of all cases and 19.3% of index cases). However, this observed frequency may actually be an underestimate of the carrier frequency in our cohort, since not all genes have been analyzed in all patients. In conclusion, our results show that BBS1 and BBS10 play a major role in our patient cohort. The observed enrichment of carriers of a third mutant allele supports the genetic complexity of BBS. It is suspected this third allele may have an effect on the clinical manifestation of the disease.

Up to 48-Months on Treatment: Open-Label Phase I/II Long-Term Study of Enzyme Replacement Therapy (ERT) with velaglucerase alfa in Patients with Type 1 Gaucher Disease. *A. Zimran[1], G. Altarescu[1], M. Phillips[1], K. Bhirangi[2], R. Mensah[2], D. Elstein[1]* 1) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Shire Human Genetic Therapies, Inc., Cambridge, MA, USA.

AIM: To evaluate the long-term safety and clinical activity of velaglucerase alfa, Gene-Activated human glucocerebrosidase, an investigational ERT for patients with type 1 Gaucher disease. BACKGROUND: velaglucerase alfa is produced in a human cell line and has an identical amino acid sequence to the naturally occurring human enzyme. METHODS: Ten of 11 patients who completed the Phase I/II study enrolled in the long-term extension study. One patient since discontinued treatment for reasons unrelated to velaglucerase alfa. At or after Month 12, all patients qualified (based on meeting at least 2 out of the 4 Therapeutic Goals for ERT in Type 1 Gaucher disease) to begin a step-wise dose reduction from 60U/kg to 45U/kg (13 weeks) and then to 30U/kg. Additionally, home therapy was made available to patients in the extension study. RESULTS: Up to Month 42 on treatment: Most AEs were mild to moderate in severity and include arthralgia, back pain, headache, abdominal pain upper, and pharyngolaynal pain. Notably, no patient has developed antibodies to velaglucerase alfa. Statistically significant mean and mean percent increases in hemoglobin concentration from baseline to Month 42 (2.18g/dL and 19.0%, respectively; p=0.004) and in platelet count (82.1 x 103/mm3 and 149.8%, respectively; p=0.004) were observed. Additionally, statistically significant mean percent decreases from baseline for spleen and liver volume were observed after 33 months of treatment, which indicated further improvement in organ volumes with long-term treatment of velaglucerase alfa (72.3% and 29.6%, p=0.008 and p=0.004, respectively). At Month 30, marked decreases were observed in the mean percent change from baseline in the biomarkers chitotriosidase (83.5%) and CCL18 (57.2%). Up to 48 month data will be presented at the meeting. CONCLUSION: velaglucerase alfa has continued to be generally well tolerated and demonstrated clinical activity in disease parameters in these adult patients with type 1 Gaucher disease.

A case of diphallia and anal atresia. *J. Samanich[1], C. Long[2], S. Nemerofsky[2]* 1) Center for Congenital Disorders, Children's Hospital at Montefiore, Bronx, NY; 2) Section of Neonatology, Children's Hospital at Montefiore, Bronx, NY.

Diphallia, or duplication of the phallus, is an extremely rare disorder, classified into categories of true diphallia (two corpora cavernosa) and bifid phallus (single corpora cavernosa). Several other anomalies have been reported in conjunction with diphallia, including imperforate anus, cryptorchidism, perineal mass, renal anomalies, rectal anomalies, duplicated bowel and duplicated bladder. Case Report: ML was a full term infant delivered after an uneventful pregnancy to a 22-year-old G3P2002 African-American mother and 37-year-old Jamaican father. There was no known family history of birth defects. At delivery, anomalous genitalia and an imperforate anus were noted. Physical examination revealed length 50.5 cm (50%), weight 3550 g (50%) and HC 32.5 cm (5-10%). He had a split metopic suture, a slightly depressed nasal bridge and a left preauricular tag, but generally non-dysmorphic facies. There was a duplicated phallus with two scrotums. The ventral scrotum contained 2 testes and the dorsal scrotum was empty. There was a well-defined gluteal crease, imperforate anus and a 2-vessel cord. Cystourethrogram revealed that the ventral urethra drained to the bladder and the dorsal urethra was atretic. Also noted was a duplicated rectum with the more anterior rectum connected to the bladder by a rectovesical fistula. The bladder was normal. Ultrasound showed normal kidneys, adrenals, spleen and sacrum. A large left hepatic lobe was noted, but otherwise normal liver. MRI of the brain was unremarkable. Echocardiogram revealed significant right ventricular hypertrophy of unclear etiology, with no structural defects. During surgery, he was found to have a high anorectal malformation and sigmoid colostomy was performed. Chromosomal analysis showed 46, XY. MRI of the pelvis to determine if he has true diphallia or a bifid phallus is scheduled. This is a unique case of a duplicated phallus, duplicated rectum, and an imperforate anus without clear genetic or environmental etiology.

Caring for families at risk for sudden death (SD): The organization and early outcomes of a multidisciplinary (M/D) cardiogenetics clinic. *K. O. Pope, E. D. Paljevic, C. A. Walsh, T. McDonald, R. W. Marion* The Montefiore-Einstein Center for CardioGenetics, Bronx, NY.

Background: Family members of SD victims are left with questions and lingering fear that others could have a similar fate. Ten percent of SIDS (Sudden Infant Death Syndrome) and 33% of SUDS (Sudden Unexplained Death Syndrome) result from mutations in cardiac ion channel genes, and the genetic contribution to SD is greater when familial hypertrophic cardiomyopathy (FHC) is also considered. Newly available genetic testing for these conditions makes collaboration between geneticists and cardiologists essential to address all aspects of care. We describe a M/D clinic, the Einstein-Montefiore Center for CardioGenetics. **Patients**: NY metro area families are referred by self, physician, or through a unique partnership with the NYC Office of the Chief Medical Examiner. **Methods**: The clinic includes a nurse practitioner (the clinic coordinator), geneticist & genetic counselor, pediatric & adult cardiologist, and social worker with grief management expertise, and occurs monthly. Cardiac screening and diagnostic tests are performed. The social worker meets each family, assesses needs, and provides support. Clinical geneticists recommend and facilitate appropriate genetic testing. For previously undescribed mutations, *in vitro* phenotyping of the resulting protein is performed to assess pathogenicity. **Results**: During the clinics first 6 months, 15 families have been seen with the following conditions: SIDS, SUDS, near miss SUDS, prolonged QTc, Andersen-Tawil syndrome, arrhythmogenic right ventricular dysplasia, and FHC. Interviews post-visit indicate overall patient satisfaction. **Discussion**: Pitfalls encountered to date include difficulty sending genetic testing on the proband and the identification in one family of a potentially deleterious variant in *SCN5A*. Counseling for these families is complex and challenging. **Conclusion**: Caring for families who have experienced the impact of sudden death requires collaboration among multiple professionals. We present a schema of a M/D cardiogenetics clinic, and report our initial experience.

Genome wide association signals of rare SNP variants are significantly associated with linkage evidence in rheumatoid arthritis. *X. Ke[1], S. Eyre[1], R. Lawrence[2], J. Bowes[1], A. Barton[1], W. Thomson[1], . WTCCC[3], J. Worthington[1], E. Zeggini[2]* 1) ARC Epidemiology Unit, Univ Manchester, UK; 2) The Wellcome Trust Centre for Human Genetics, Univ Oxford, UK; 3) The Wellcome Trust Case Control Consortium, UK.

Multiple genome-wide linkage scans have been carried out for rheumatoid arthritis (RA). Linkage peaks are likely to be caused by rare variants with high penetrance. Using data from the WTCCC study, the largest genome-wide association scan for RA to date, we investigated the overlap between linkage and rare variant association signals across the genome. We included 11 regions with replicating evidence for linkage ($p<0.05$) in independent studies. These linkage regions were delineated by the most significantly associated microsatellites plus 10Mb on each side. The WTCCC Affy500k scan contained 40,482 SNPs with minor allele frequency <5% in 1,860 RA cases and 2,938 controls. We defined 22,344 gene regions across the autosomal genome as intervals 50kb either side of the transcriptional start and end sites. 18,246 of these contained at least one rare variant. Genotypes of all rare variants within a gene were collapsed into a single locus and a global p value was calculated per gene region. We examined the extent of overlap between linkage evidence and rare variant association signals using logistic regression. There was significant association between the -log p values of rare variants in genes and linkage evidence in the genome ($p<0.0001$). The fucokinase gene (FUK), with 4 rare variants, is one example. It is located under a linkage peak on chromosome 16q22.1. A total of 29 of the 1,860 RA cases and 7 of the 2,938 controls carried the rare variant alleles (p value of Fishers exact test = 2.6x10-7). The enzyme involves in the utilization of free L-fucose, which may be important in mediating a number of cell-cell interactions such as blood group antigen recognition, inflammation and metastatis. Therefore, FUK may be an interesting candidate for RA susceptibility. This is the first study to examine the overlap between genome-wide rare variant association signals and replicating linkage peaks for a complex common disease.

Transglutaminase-1 gene mutations in Autosomal Recessive Congenital Ichthyosis: An Update and a Report of 24 Novel Mutations. *M. Herman[1], S. Farasat[1], M. H. Wei[1, 2], O. Toure[1], S. Bale[3], J. Toro[1]* 1) Genetic Epidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD 20892; 2) Basic Research Program, SAIC-Frederick Inc., Frederick, MD 21702, USA; 3) GeneDx, Inc, Gaithersburg, MD 20877, USA.

Autosomal recessive congenital ichthyosis (ARCI) is a cornification disorder. Mutations in the transglutaminase-1 (TGM1) gene cause ARCI in 55% of affected patients. We characterized the TGM1 mutations reported to date including 24 novel mutations in 26 patients (48 mutated alleles). Of the twenty-four novel mutations 16 were missense (T21A, V209F, R225P, E285K, F293V, I304F, R323W, W342R, V359M, L366P, H405N, M421V, F435V, A560G, R689C, R689H), two frameshift (c.802delG, c.1223_27delACACA), two nonsense (R54X, Q124X), and four putative splice site mutations (c.1-1G>C, c.984+1G>A, c.1159+1G>T, c.2226-2A>G). Missense mutations were the most common and 69% (11/16) occurred within the catalytic core domain. Of the twenty coding novel mutations, five mutations (25%) affected four different arginine codons. Including this study, a total of 117 different mutations have been reported in 282 individuals. Seventy-three (62%) of the observed mutations were missense, twenty (17%) nonsense, nine (8%) deletion, eight (7%) splice site and seven (6%) insertion. Thirty-seven of the mutations (32%) are expected to lead to truncated proteins. All translated exons (2-15) displayed at least one mutation. Exon three was the most mutated, accounting for 14% (16/117) of all mutations. Of the 817 amino acids in TGase-1, 54 (6.6%) are arginines of which (91%) of their codons begin with a CpG dinucleotide. Twenty-nine percent (34/117) of all mutations and 38% (28/73) of missense mutations occurred in arginine residues in TGase-1. Forty-eight percent (35/73) of missense mutations were within CpG dinucleotides and 74% (26/35) of these mutations were C-> T or G->A transitions. The high frequency of mutated arginine codons in TGM1 may be due to the deamination of 5-CpG dinucleotides. In conclusion, this study expands the TGM1 mutation spectrum and represents the largest report of TGM1 mutations.

Divergent genotype is associated with type 2 diabetes in the Mongolian population. *Z. Odgerel[1], H. S. Lee[1], E. Narnygerel[2], N. Sambuughin[3], S. Ganbold[4], K. Altaisaikhan[2], L. G. Goldfarb[1]* 1) Clinical Neurogenetics Unit, NINDS/NIH, Bethesda, MD; 2) Diabetes Center, School of Medicine, Health Services University of Mongolia, Ulaanbaatar, Mongolia; 3) Department of Anesthesiology, Uniformed Services University of the Health Sciences, Bethesda, MD; 4) National Center of Forensic Sciences, Ulaanbaatar, Mongolia.

We conducted an association study to determine whether gene variants commonly found to be associated with type 2 diabetes (T2D) in large mixed populations or homogeneous populations living in various geographic regions are shared. For this purpose, we selected the Mongolian population of North-Eastern Asia that had experienced limited genetic admixture and environmental variability over about 1000 years. T2D morbidity in this population grew dramatically in recent years: a survey conducted by the WHO has established the prevalence of T2D at 3.2% and impaired glucose tolerance at 9.2%. Most significantly, there has been a 5-time increase in T2D prevalence within the past decade. In 80% of T2D patients the disease is poorly controlled, and the frequency of complications such as neuropathy was at 56.4%, retinopathy at 37.8%, and nephropathy at 65.6%. We examined the frequency of the T2D risk alleles at 11 polymorphic sites of 6 diabetogenic genes, PPARG, SLC30A8, TCF7L2, UCP2, KCNJ11, and ABCC8 in 211 patients diagnosed with type 2 diabetes and 196 non-diabetic Mongolian nationals from the city of Ulaanbaatar, Mongolia. Significant association was established with rs1799857 in the ABCC8 gene (OR = 1.52; P = 5.5x10-3) and rs660339 at the UCP2 gene (OR = 1.35; P = 2.5x10-2), while the variations in other genes failed to replicate associations repeatedly demonstrated in European large scale collaborative studies. These results, if confirmed on a larger sample size and in other populations with rapidly increasing T2D incidence, point to the existence of population-specific set of genes associated with the risk of T2D and the possibility that therapeutic regimens established in one population may not be as effective in other populations carrying a different T2D risk genotype.

Association of Interferon Regulatory Factor 5 (IRF5) polymorphisms with Systemic Sclerosis (SSc). *P. Gourh, S. Assassi, G. Paz, Y. Salehi, S. K. Agarwal, F. K. Tan, M. D. Mayes, F. C. Arnett* Division of Rheumatology, Department of Internal Medicine, University of Texas-Medical School, Houston, TX.

Background: Type-I interferon (IFN) signature has been shown to be the hallmark peripheral blood gene expression pattern in lupus (SLE). More recent studies have also noted a similar type-I IFN signature in systemic sclerosis (SSc). The transcription factor interferon regulatory factor 5 (IRF5) is a component of this IFN-gene expression signature and regulates the expression of other genes involved in immune responses. The purpose of this work was to investigate the possible association between IRF5 polymorphisms with SSc. **Methods:** We performed SNP genotyping for 3 SNPs on IRF5 gene using the Taqman Assay in 1,391 Caucasian, African-American, and Hispanic SSc patients along with 1,027 race-matched controls. All SSc patients fulfilled ACR criteria or had at least 3 of the 5 CREST features. Chi-square and logistic regression analyses were used for statistical comparisons. Illumina Human-REF8 arrays were used for peripheral blood gene expression analysis. **Results:** After HWE verification and correcting for multiple testing, two SNPs showed significant association with white SSc patients. The TT genotype for the SNP rs2004640 had a frequency of 34.5% in white SSc patients as compared to 27.1% in white controls which was statistically significant. Logistic regression analysis (*Additive model*) controlling for gender and race showed that the TT genotype was an independent risk factor for SSc {p=0.0004;OR=1.56 & 95% CI:1.3-2.0}, including anti-topoisomerase-I antibody positive SSc and SSc with fibrosing alveolitis. IRF5 was the most highly differentially expressed gene based on the rs2004640 SNP genotypes in peripheral blood arrays of SSc patients (p=1.39×10-5). **Conclusion:** These data suggest an important role of this IRF5 polymorphism in susceptibility to SSc. The TT genotype causes a splice variant containing exon IB whereas the GG genotype contains exon IA and exon IC. This IRF5 polymorphism leading to this isoform, upon stimulation, may facilitate expression of genes encoding type-I IFNs and other proinflammatory cytokines, thus increasing the risk for development of SSc.

Genome-wide linkage analysis for congenital heart defect risk reveals modifier loci of cardiac transcription factor Nkx2-5. *J. Winston, J. Erlich, C. Green, P. Jay* Dept Pediatrics, Washington Univ, St Louis, MO.

There is currently no logical explanation for the variance in congenital heart defects observed in human babies. Animal model and family studies have revealed that cardiac transcription factor NKX2-5 is a core regulator in heart morphogenesis. While cardiac development has been systematically characterized, it is unclear how NKX2-5 and other major genes fit into pathways that lead to naturally occurring heart defects. Heterozygous mutations in NKX2-5 increase risk for a broad spectrum of heart defects including atrial and ventricular septal defects (ASDs and VSDs) and aortic coarctation in both humans and mice. In this study Nkx2-5+/- haploinsufficient mice provide a model of heart defect risk variance to identify genes and their interactions that affect mouse cardiac developmental pathways. F1 hybrid progeny of Nkx2-5+/- C57Bl/6 mice crossed to FVB/N or A/J strains result in a nil or rare incidence of defects indicating that genomic homozygosity affects risk. Defects are recovered in F2 progeny of inter- and parental backcross backgrounds further validating the presence of alternative genomic risk loci. To identify QTL which modify the affect of Nkx2-5+/-, neonatal hearts of 2,100 F2 Nkx2-5+/- mice were dissected and serially sectioned to diagnose defects. A total of 320 heart defects have been identified with the vast majority being VSDs and ASDs. Genome wide linkage analysis for VSD susceptibility loci revealed a significant main effect locus on chromosome 6 (LOD = 3.1) in the initial F2 scan. Outcrossing Nkx2-5+/- mice to alternative strain, A/J, resulted in different defect yields. Through combined cross analysis, susceptibility loci specific to C57Bl/6 mice were found to be significant on chromosomes 4,10 and 11 (LOD= 3.6, 4.7 and 3.3). In addition, novel epistatic interactions were identified between loci on chromosomes 3 and 13. Genes within 25cM of these loci were prioritized based on gene expression and ontology data. The results in this study demonstrate that mechanistic insight can be gained through the description of small effect genes responsible for incomplete penetrance and pleiotropy commonly observed in complex disease.

A novel, autosomal dominant, Pseudoxanthoma Elasticum-like phenotype in a five-generation family. *M. L. P. Robert[1], O. M. Vanakker[2], L. Costrop[2], A. de Paepe[2], L. Schurgers[3], R. Florijn[4], F. M. Pope[5], M. James[6], S. Tomkins[6], E. Young[7], S. Ellard[7], P. D. Turnpenny[1]* 1) Clinical Genetics, Royal Devon & Exeter NHS Trust, Exeter; 2) Center for Medical Genetics, Ghent University, Ghent; 3) VitaK & CARIM, University of Maastricht, Maastricht; 4) The Netherlands Ophthalmic Research Institute, Amsterdam; 5) Northwick Park Health Institute, London; 6) South Western Regional Genetics Service, Bristol; 7) Molecular Genetics, Royal Devon & Exeter Hospital, Exeter.

Pseudoxanthoma elasticum (PXE) is an autosomal recessive (AR) progressive disorder of elastic fibres characterised by dermal, ocular and vascular lesions, due to mutations in ABCC6, an ATP-binding cassette transporter, in ~80% of cases. Autosomal dominant (AD) inheritance is very rare and usually due to pseudodominance (Plomp et al. 2004). We studied 17 individuals from a 5-generation family with PXE-like skin manifestations. Many subjects also suffer premature claudication pain and ischaemic heart disease but they do not have typical PXE ophthalmic signs. Electron microscopy analysis of skin was normal except in one patient who had fragmentation and clumping of elastic fibres with no evidence of calcification. Sequencing of ABCC6 was negative and linkage to this locus excluded. Vanakker et al (2007) reported GGCX mutations in 3 families with an AR PXE-like phenotype and vitamin K-dependent coagulopathy. Our family has no history of abnormal bleeding, clotting assays were normal in one affected individual, and sequencing of GGCX and VKORC1 was normal. Immunohistochemistry of lesional skin tissue showed disturbance in the gamma-carboxylation of vitamin K-dependent mineralization inhibitors, particularly matrix gla protein (MGP). This suggests involvement of a related pathway as in the PXE-like phenotype of Vanakker et al (2007). Genome-wide linkage results, and candidate gene sequencing, are awaited. This 5-generation family with a PXE-like phenotype demonstrates unequivocal AD inheritance. We believe this is a previously unreported clinical and genetic entity, the pathogenesis of which may provide new information on the molecular pathways involved in PXE and related disorders.

Overexpression of Targeting Protein for Xklp2 Affects Mitotic Kinase Aurora A Stability and Cell Cycle Progress in Melanoma Cells. *B. Li[1,2], M. Dalla Palma[1], Y. Wang[1], G. Xu[1], K. Smalley[2], M. Herlyn[2], K. Nathanson[1]* 1) Department of Medicine and Department of Pathology, University of Pennsylvania School of Medicine, philadelphia, PA; 2) The Wistar Institute,Philadelphia,PA.

Amplification and overexpression genes have been demonstrated to be involved in the development and progression of cancer. Array based comparative genomic hybridization analysis of melanoma cell lines and tumors has identified targeting Protein for Xklp2 (TPX2) as the most commonly amplified gene on 20q11.21, a region of frequent amplification in melanoma. Gene expression profiling studies also have confirmed that TPX2 is overexpressed, suggesting a previously unknown role in the development of melanoma. TPX2 is mainly expressed in G2/M, as a microtubule-associated protein participating in mitosis apparatus-bipolar spindle assembly and regulation of centrosome replication. TPX2 also activates and targets the mitotic kinase Aurora A to spindle pole. Whereas the physiological functions of TPX2 are well understood, consequences of aberrant TPX2 expression in tumor cells remain elusive. We have used shRNA to knockdown TPX2 to define its associated phenotype. With 80% knockdown of TPX2 in 293T cells, we found dramatic downregulation of Aurora A. We also have studied knockdown in melanoma cell lines overexpressing TPX2. Cell cycle profile analysis has been performed on TPX2shRNA virus-transduced melanoma cells. Preliminary data suggest that TPX2 shRNA depletion delays melanoma cell cycling due to marked G2/M arrest. IHC of TPX2 in melanomas suggests that expression increases with progression from in situ to metastatic disease. Taken together, these data suggest that TPX2 overexpression could promote cell cycle progression via aberrantly regulating mitotic apparatus assembly and Aurora A kinase activity and is important for tumor progression.

A Genetic Model for IRF5, Autoantibodies, and Interferon Alpha in the Pathogenesis of Systemic Lupus Erythematosus. *T. B. Niewold[1], J. A. Kelly[2], S. N. Kariuki[1], K. Thomas[2], D. Walker[2], S. Kampf[2], J. T. Merrill[2,3], M. E. Alarcón-Riquelme[4], J. A. James[2,3], T. J. Vyse[5], R. P. Kimberly[6], J. C. Edberg[6], P. M. Gaffney[2], K. L. Moser[2], M. K. Crow[7], J. B. Harley[2,3,8]* 1) Section of Rheumatology, University of Chicago, Chicago, IL; 2) Oklahoma Medical Research Foundation, Oklahoma City, OK; 3) Department of Medicine, University of Oklahoma, Oklahoma City, OK; 4) University of Uppsala, Uppsala, Sweden; 5) Imperial College, London, UK; 6) University of Alabama at Birmingham, Birmingham, AL; 7) Mary Kirkland Center for Lupus Research, Hospital for Special Surgery, New York, NY; 8) US Department of Veterans Affairs Medical Center, Oklahoma City, OK.

Objective: Interferon alpha (IFN-) has been implicated as a heritable risk factor for systemic lupus erythematosus (SLE). Variants of interferon regulatory factor 5 (IRF5) have been associated with SLE susceptibility, and we have recently shown that IRF5 risk variants are associated with increased IFN- only in a subset of patients defined by SLE-specific autoantibodies. **Methods:** We analyzed IRF5 genotype data from 1034 SLE patients and 989 controls of European ancestry, as well as 456 SLE patients and 679 controls of African American ancestry. Serum IFN- activity was measured using a reporter cell assay. **Results:** SLE-risk variants of IRF5 were associated with the SLE-specific autoantibodies anti-dsDNA (rs2004640) and anti-Ro (rs10488631) in European ancestry SLE patients. IRF5 haplotypes showed strong association with SLE only in 393 European patients with either anti-dsDNA or anti-Ro antibodies ($p=7.9x10^{-16}$), compared to 641 patients lacking anti-Ro and anti-dsDNA ($p=0.0019$). In African American SLE patients, association of IRF5 with SLE was only seen in the subgroup of patients with both anti-dsDNA and anti-Ro antibodies. In both ancestral backgrounds, IRF5 risk variants were associated with increased serum IFN- only in those patients with anti-dsDNA or anti-Ro antibodies. **Conclusions:** These data suggest an intriguing model of SLE pathogenesis, in which common IRF5 risk variants cooperate with rare SLE-specific autoantibodies to result in dysregulation of IFN- production and subsequent risk of disease.

Multiple Associations for Independent Single Markers within the HLA Region Confer Susceptibility to Psoriasis.

J. Raelson[1], L. Bennour[2], V. PInchuk[2], M.-T. Cheng[2], O. Gingras[2], P. Croteau[1], B. Stojkovic[2], A. Belouchi[1], S. Debrus[1], J.-F. Levesques[2] 1) Dept Genetics R&D, Genizon Biosciences, St Laurent, PQ, Canada; 2) Dept of Information Technology and Software Development, Genizon Biosciences, St Laurent, PQ, Canada.

A locus located in the MHC-HLA region of 6p21 at or near HLA-C has long been identified as being strongly associated with psoriasis. We have systematically examined single marker association and two marker haplotype association for all pairs of markers across the HLA region using a sample of 326 female and 310 male psoriasis patients and matching controls genotyped for 1,912 markers across 7.371 Mb. In addition to the well replicated association near HLA-C, we have detected multiple associations for both adjacent and widely separated interacting markers resulting in 5-10 fold increases in -log p-values for various 2-marker haplotypes compared to the maximum -log p-value for associations of either of the single markers alone. Highly significant associations for specific combinations of alleles for non adjacent markers that are in linkage equilibrium suggest complex patterns of HLA region gene interaction leading to susceptibility to psoriasis.

Goltz syndrome and X monosomy mosaicism: case report and literature review. *T. A. Zanolla[1,2], D. Polito[1], L. Kulikovski[2], L. V. Pereira[3], M. C. S. P. Cernach[1,2], A. B. A. Perez[1,2]* 1) UNIMES, Santos, São Paulo, Brazil; 2) Centro de Genética Médica, UNIFESP, São Paulo, São Paulo, Brazil; 3) IB-USP, São Paulo, São Paulo, Brazil.

Goltz syndrome is a disorder characterized by involvement of the skin, skeletal, eyes and face. It is a X-linked dominant disorder. Females are heterozygous or mosaic for mutations in PORCN(Xp11.23). Live-born affected males are mosaic for mutations in that gene. It is presumed that non-mosaic hemizygous are not viable. Available data suggest that neither the mutation nor level of mutated X-chromosome inactivated correlates with severity of the phenotype. All females with deletions in PORCN have skewed X-chromosome inactivation, whereas most females with point mutations have random X-chromosome inactivation (Grzeschik et al., 2007; Wang et al., 2007). We describe a 22 month-old female born from a non consanguineous young couple. Delivery was term by normal childbirth. Birth weight was 2,315 g (50th centile), height 46 cm (5th centile) and OFC 32 cm (5th centile). At 22 months she presents asymmetric facies, low set ears, convergent strabismus, up-slanting fissures, narrow nasal bridge, broad nasal tip, notched nasal alae, pointed chin, bilateral cleft lip and palate, hypoplasia of teeth,sparse and brittle hair with areas of alopecia, skin atrophy, dystrophic nails, ectrodactyly and syndactyly of hands and syndactyly between 3 and 4 toes of left foot, clitoral hypoplasia and minor labial hypoplasia. There is no clinical signs of Turner syndrome. G-banding karyotype from lymphocytes cells was 46,XX(35%)/45,X (65%. There is no case reported relating the association of Goltz syndrome and monosomy X mosaicism. We expect a mild phenotype as observed in liveborn males. All males reported to date are mosaic for mutations in PORCN and are generally more mildly affected than females, but there is no typical phenotype. The evaluation of which chromosome harbor the mutation and of the pattern of X inactivation may clarify embryonic period of protein expression.

Prenatal microarray analysis in an apparently balanced de novo translocation: a counseling dilemma. *V. Jobanputra[1], A. Shanmugham[1], S. Brown[2], A. Sobrino[1], O. Nahum[1], B. Levy[1], D. Warburton[1]* 1) Columbia University Medical Center, New York, NY; 2) University of Vermont, Burlington, VT.

We saw a 38 year old women, G4P1, in our Genetics Clinic to discuss fetal chromosome results showing an apparently balanced de novo translocation 46,XY,t(2;13)(q37;q32). The patient had an amniocentesis due to her maternal age and a two vessel-cord on level II sonogram. Parental chromosome studies were normal. The family elected to have microarray analysis on the fetal material, with the understanding that it might or might not be helpful. SNP oligonucleotide microarray analysis (SOMA) revealed a 384kb duplication at the 2q37.3 breakpoint and a 564 kb at the 13q32.3 breakpoint. While deletions of the 2q37 region have been reported in patients with the Albright Hereditary Osteodystrophy - like phenotype, a phenotype associated with the duplication of this region has not been described. The duplicated region on chromosome 13q contains the ZIC2 gene. Haploinsufficiency of ZIC2 is likely to cause holoprosencephaly and the brain malformations seen in distal 13q deletion patients. Studies in vitro have suggested that overexpression of ZIC2 may also lead to brain malformations in the mouse. No human data on overexpression exist. To confirm the duplications, FISH was performed using a genomic DNA probe that included the ZIC2 gene as well as two additional BACs localizing to the proximal and distal ends of the duplicated 2q37 region. The ZIC2 probe hybridized to both the derivative chromosomes, confirming the duplication, but the signal pattern on the der(2) was at the terminal region. This hybridization pattern suggests an inversion on 13q with the inverted segment containing ZIC2 on the der(2q). Both copies of the proximal BAC on 2q hybridized to the der(13) and the distal BAC was found on both derivative chromosomes. This suggests that an inversion and duplication also occurred on 2q. The microarray results were conveyed to the patient, together with the news that it was still not possible to predict the pregnancy outcome. A fetal MRI of the brain was normal. The patient has elected to continue the pregnancy and is now at 38 weeks. Sonograms have reported normal fetal anatomy.

RAPID TARGETED SEQUENCING OF MULTIPLE HUMAN MITOCHONDRIAL GENOMES. *G. Ehret[1], M. Sosa[1], L. Li[2], P. Bouffard[2], K. Fredrikson[3], T. Harkins[3], A. Chakravarti[1]* 1) Center for Complex Disease Genomics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD, USA; 2) 454 Life Sciences, 1 Commercial Street, Branford, CT, USA; 3) Roche Diagnostics Corporation, Indianapolis, IN, USA.

Defects in mitochondrial biology are known to contribute to the pathology of many complex diseases. An excess of maternal inheritance has been observed for some complex diseases while for others the age-dependence of the phenotype is thought to involve degradation of mitochondrial function. Consequently, accurate and rapid sequencing of mitochondrial genomes is important so that its sequence alteration can be correlated with disease. Our protocol for mitochondrial genome sequencing is based on two steps. First, specific access to the mitochondrial genome is obtained by amplification of three overlapping fragments by long range PCR. Second, accuracy in sequence is obtained by sequencing the pooled fragments using the emulsion PCR based Roche/454 FLX sequencer. This process provides simplicity in handling and high coverage. The sequencing depth not only permits de novo assembly of the mitochondrial genome and reliable identification of mitochondrial sequence variants, but also determination of heteroplasmy at high accuracy. We have successfully completed sequencing of 50 mitochondrial genomes from the Yoruba (YRI) and CEPH (CEU) HapMap samples at different coverage depths (47 samples at ~200x coverage, 3 samples at 1,000x coverage). Across the mitochondrial genome, we observe a minimum coverage of ~400 and ~80 fold (for the ~1,000x and 200x coverage, respectively). The mitochondrial genomes were assembled de novo using a random subset of the total data (~20x coverage). Our amplification and purification strategy for mitochondrial DNA is specific since <1% of the sequence is of non-mitochondrial origin. Gel purification of the mitochondrial DNA amplicons did not improve sequence specificity. We observe an overrepresentation of amplicon blunt ends among the sequence reads. Sequence features of these genomes, as also compared to conventionally obtained sequence, will be presented.

Interleukin-1 Receptor Antagonist Gene Polymorphism in Egyptian Patients with Knee Osteoarthritis. *E. A. Toreih[1], F. M. Badr[1], M. H. Ghattas[2]* 1) Human Genetics & Cell Biology, Faculty of Mrdicine/Suez Canal University, Ismailia, Ismailia, Egypt; 2) Department of Medical Biochemistry, Faculty of Medicine, Suez Canal University, Ismailia, Egypt.

The pro-inflammatory cytokine, interleukin-1 (IL-1), has been implicated in the pathogenesis of several arthritic diseases. One of its natural inhibitors, IL-1 receptor antagonist (IL-1Ra), is a potent anti-inflammatory agent. The aim of the present study was to determine the influence of a polymorphism within intron 2 of the IL-1 receptor antagonist gene (IL-1RN) on the susceptibility to or severity of knee osteoarthritis (OA) among Egyptian patients. We genotyped 38 patients with primary knee OA and 38 healthy controls for IL-1RN variable number of tandem repeat (VNTR) polymorphism (for six different alleles), using polymerase chain reaction-based method. The heterozygote form A1/A*2 was the most predominant genotype among patients with knee OA compared with the controls (60.5% vs 31.5%, p= 0.012). The frequency and carriage rate of A2 allele was significantly higher in OA patients compared with the controls (frequency 38.2% vs 17.1%; carriage rate 68.4% vs 34.2%). Alleles A0, A4 and A5 were absent in the current study population. Frequency and carriage rate of A2 allele were associated with the severity of joint pain (p=0.016), but had no association with other clinical or radiological parameters of the disease. Our results suggest that IL-1RN gene polymorphism is associated with the occurrence of knee osteoarthritis. Whether the IL-1RN polymorphism makes a direct functional contribution to the pathogenesis of the disease or is acting as a marker for a linked gene needs to be investigated.

Bivariate genome-wide linkage scan for Traits BMD & AAM: Effect of Menopause on Linkage Signals. *Z. X. ZHANG[1], S. F. Lei[2], F. Y. Deng[2], F. Zhang[1], Y. J. Liu[2], R. R. Recker[3], H. W. Deng[1, 2, 3, 4]* 1) School of Life Science and Technology, Xi'an Jiaotong University, China; 2) Departments of Orthopedic Surgery and Basic Medical Science, School of Medicine, University of Missouri-Kansas City, USA; 3) School of Medicine, Creighton University, USA; 4) College of Life Sciences, Hunan Normal University, China.

Osteoporosis is an age-related systemic skeletal disease, characterized by low bone mineral density (BMD). Low BMD is closely associated with later age at menarche (AAM). Our previous bivariate genome-wide linkage analyses (GWLAs) between BMD and AAM were performed in 2522 Caucasian female subjects of European origin, including both pre- and post- menopausal females. However, the menopause causes a dramatic bone loss in postmenopausal females. This may introduce some confusing effect on the bivariate GWLA for BMD & AAM. To address the menopause effect on the estimation of genetic effects shared by BMD & AAM, we performed further bivariate GWLAs separately in two subgroups: 1462 pre- and 1122 post-menopausal Caucasian females. The phenotypes of BMD were measured by Hologic Dual-energy X-ray (DXA) scanners (Hologic Inc., Bedford, MA, USA). Adopting genome-wide thresholds corrected for multiple testing, we found 6, 2, and 2 significant genomic regions shared by spine BMD & AAM, hip BMD & AAM and UD BMD & AAM, respectively in pre-menopausal group, but we did not found any significant or suggestive linkage signals in post-menopausal group. The linkage signals are much stronger in pre-menopausal group than in other groups: post- menopausal females and total females. For example, the linkage LOD for hip BMD & AAM is as high as 5.1 in pre-menopausal females, but only 0.07 and 0.31 in post-menopausal females and total females, respectively. The results suggest that the estimation of shared genetic factors between BMD & AAM may be introduced some noise signals when including postmenopausal female, and more targeting genomic regions can be found if the female subjects were classified properly according to their menopausal status.

MEDICAL SEQUENCING OF 11 HYPERTENSION GENES IN THE EXTREMES OF THE BLOOD PRESSURE DISTRIBUTION*. *K. H. Nguyen, G. B. Ehret, A. Chakravarti* Center for Complex Disease Genomics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD, USA.

The genetic pathophysiology of essential hypertension (EH), despite its significant genetic component, still remains unknown. Although many linkage and association studies are underway, we wished to directly assess the contribution of DNA sequence variation at specific genes to EH. We examined 560 individuals randomly sampled from the ~15% extremes of the systolic blood pressure (SBP) distribution in GenNet, equally divided into African & European American (AA & EA), male & female samples. We sequenced 10 monogenic hypertension syndrome genes (CYP11B1, CYP17A1, HSD11B2, NR3C1, NR3C2, SCNN1A, SCNN1B, SCNN1G, WNK1, and WNK4) and angiotensin (AGT). For each, we sequenced all exons, 2kb up- & down-stream of the first & last exon, and all conserved intronic, 5& 3 elements beyond the 2kb boundary using bidirectional dideoxy Sanger sequencing. Sequencing quality was high with an average variant call rate of 93% and a replicate consistency of 99.8%. For each individual, we generated 152kb of sequence or ~85Mb in total yielding 2,691 variants (2,529 SNPs & 162 indels): ~1350 variants were unique to AA, ~610 to EA and ~730 were common. We observed a ratio of 4 novel:known (dbSNP, r128) substitutions and 14 for indels, higher than in previous studies. The overall distribution of sequence changes varies across genes but shows no pattern in the top and bottom 15%tiles. Individual genes do show differences with non-synonymous coding sequence changes that we are correlating with predicted functional effects (using the computer programs SIFT and PolyPhen). Interestingly, substitutions are enriched for WNK1 and AGT in the lower 15%tile and indels are concentrated largely in WNK1 (29% of total) and NR3C2 (45% of total). These types of sequence patterns are being assessed with respect to the measured BP values. This study demonstrates the value of direct DNA sequence data in studying complex traits and diseases. *Resequencing services: the J. Craig Venter Inst. and the Univ. of Washington, Dept of Genome Sciences, under U.S. Fed Gov contract #N01-HV-48196 and N01-HV-48194 from the NHLBI.

Hybrid Capture and Deep Resequencing of Stromally Contaminated Lung Adenocarcenoma. *K. Cibulskis[1], C. Sougnez[1], J. Maguire[1], S. Fisher[1], L. Ambrogio[1], M. Meyerson[2], E. Lander[1], S. Gabriel[1]* 1) Broad Institute of MIT and Harvard, Cambridge, MA; 2) Dana Farber Cancer Institute, Boston, MA.

Targeted resequencing of exons using capillary sequencing has successfully been used to find somatic alterations in cancer DNA, leading to the discovery of genes significantly associated with cancer. However, stromal contamination of tumor DNA makes the discovery of mutations even more difficult, and could lead to an underestimation of mutation frequency. One such large-scale capillary sequencing project is the Tumor Sequencing Project (TSP), which sequenced 602 genes across 188 lung adenocarcinoma samples. In the TSP, the least pure 30% of samples sequenced contained only 8% of the total mutations. We sought to determine the utility of deep sequencing, provided by next generation sequencing technologies, in discovering additional mutations in samples ranging in purity from ~ 30% to 90% by pathology review.

To explore this, we have performed deep sequencing (to an average 100-fold coverage) using the Illumina GAII platform on 24 tumor/normal pairs which have previously been sequenced via capillary sequencing. We targeted 75 genes previously found to be significantly mutated in this tumor type. Instead of PCR, a solution-based capture technique was used for target enrichment. We discuss the specificity and sensitivity of this approach, as compared to the current gold standard of PCR amplification and capillary sequencing, and the impact of deep sequencing on the overall frequency of mutation within these genes.

Single-molecule analysis of DNA methylation in induced pluripotent stem cells. *J. Deng[1], B. Xie[2], E. Leproust[3], D. Egli[4], N. Maherali[5], I. H. Park[6], K. Eggan[4], K. Hochedlinger[5], G. Daley[6], Y. Gao[2], K. Zhang[1]* 1) Dept. of Bioengineering, UCSD, La Jolla, CA; 2) Virginia Commonwealth Univ, Richmond, VA; 3) Agilent Technologies Inc, Santa Clara, CA; 4) Harvard Univ, Cambridge, MA; 5) Mass. General Hospital, Boston, MA; 6) Children's Hospital, Boston, MA.

DNA methylation is one of the primary epigenetic regulatory mechanisms involved in normal developmental processes and many human diseases including cancers. Rapid advances in DNA sequencing have catalyzed the development of new methods for characterizing DNA methylation in an unprecedented scale and resolution. Here we present a targeted bisulfite sequencing method, called cpgMIP, for digital quantitation of DNA methylation at the single-nucleotide resolution. In this method we synthesized libraries of long oligonucleotides on programmable microarrays, and enzymatically converted them into Molecular Inversion Probes (MIPs) targeting CpG islands (CGIs) in the human genome. CGIs were specifically captured from the bisulfite converted genomic DNA, and sequenced with next-generation DNA sequencers. cpgMIP dramatically reduces the size of sequencing targets and results in a >100x improvement in efficiency compared with whole genome bisulfite sequencing. We used cpgMIP to characterize the patterns of DNA methylation in the reprogramming of human fibroblasts into pluripotent cells. A total of 30,000 probes were synthesized for capturing 83% of non-repetitive CGIs in human chromosome 12 and 20, both were enriched for genes differentially expressed between fibroblasts and pluripotent cells. A capturing specificity of 100% was achieved with these probes. We characterized the methylation patterns in three pairs of fibroblasts and induced pluripotent stem cells reprogrammed with different sets of transcription factors, as well as a fourth pair of fibroblasts and pluripotent cell lines generated by somatic cell fusion. Functional CpG sites were identified through comparison with gene expression profiles. In summary, cpgMIP is a highly efficient method for accurate and large-scale characterization of DNA methylation. This method will help achieving a deeper understanding of DNA methylation in transcriptional regulation.

Updating the diagnostic decision tree for recessive hereditary sensory and autonomic neuropathies (HSAN). *C. Oddoux[1], H. Ostrer[1], F. Axelrod[2]* 1) Div Human Genetics, NYU Langone Medical Center, New York, NY; 2) Dysautonomia Diagnosis and Treatment Center, NYU Langone Medical Center, New York, NY.

Background: Recessive HSANs are a rare group of hereditary disorders characterized by dysfunction of the sensory and autonomic nervous systems. Classification of various subtypes remains incomplete and is continuing to evolve in part due to variable presentation, overlap of phenotypes, and the lack of consistently used objective measures of autonomic and sensory function. HSAN type 3 (familial dysautonomia) is the most common of the group, followed by HSAN type 4 (congenital insensitivity to pain), HSAN type 2 (HSN2), and HSAN type 5. Mutations in several genes have been found to be responsible for some of these phenotypes.

Methods: Clinical evaluation of sensory and autonomic function was performed on a large series of HSAN patients and correlated with mutation and sequence information in the IKAP, NTRK1, HSN2 and NGFbeta genes. Clinical assessments included response to intradermal histamine, pain, temperature, taste, positional sensation, corneal, gag and deep tendon reflexes, postural hypotension, erythmatous blotching, presence of fungiform papillae, gastrointestinal motility, tearing, anhydrosis and Charcot joints. These were further correlated to a meta-analysis of published studies of similar patients and these genes and to genomic information about the genes available in public genome databases. The data were used to derive a clinical evaluation decision tree to assist with classification of patients and to inform subsequent treatment, genetic testing, and counseling.

Conclusions: The results suggest that it is possible to use systematic non-invasive clinical evaluations to determine which patients have a high likelihood of having mutations in the IKAP, NTRK1, and HSN2 genes, thereby enabling efficient diagnosis, initiation of treatment and delineation of patients most likely to benefit from genetic testing for enhanced family planning. The results also reveal a large group of patients that do not fall into any of these categories suggesting that mutations in other genes, or *de novo* events may be responsible for their phenotypes.

Molecular cytogenetic and microarray characterization of a de novo der(Y)t(X;Y)(q27.1;q12) in a male with mental retardation, hypotonia, intractable seizure disorder and dysmorphic features. *A. Iglesias[1], M. Macera[2], P. Cotter[3], F. Cohen[2], J. Breshin[2], A. Babu[2]* 1) Dept Pediatrics, Div Genetics, Beth Israel Medical Ctr, New York, NY; 2) Dept Medicine, Div Molecular Medicine and Genetics, Wyckoff Heights Medical Ctr, Brooklyn, NY; 3) CMDX Laboratory, Irvine, CA.

The patient is a 12 year-old boy with seizure disorder, hypotonia and mental retardation. A brain MRI during infancy showed thinning of the corpus callosum. He was born full-term via c-section. Hypotonia, poor suck, vomiting and poor weight gain were noticed after birth. Gastroesophageal reflux was diagnosed. Floppiness and developmental delay were present early on. Seizures developed at 16 months. On exam, he was poorly reactive and non-interactive. A wide nasal bridge, full lips, short philtrum, macroglossia, high palate and abnormal ears were noted. Scoliosis and generalized joint contractures were present bilaterally. He has tapering fingers. Axial hypotonia and distal spasticity were present. Mydriasis and slow pupillary responses and soles hyperemia were observed bilaterally. Cytogenetic analysis revealed a 46,X,der(Y)t(X;Y)(q27;q12) karyotype in peripheral blood cells. Microarray-CGH showed a gain in copy number in the distal regions of Xq, (Xq27.2Xqter) encompassing 15.3Mb. Additional microarray studies at a separate facility, confirmed the duplication with an approximate size of 13.7 Mb from Xq27.2qter. Gene analysis of the MECP2 and LICAM1 genes also confirmed the duplication. When wcp X was applied, signal was visible at the distal q arm of the der (Y), corresponding to the translocation. The signal observed on the der(Y) appeared to be greater than the corresponding duplicated Xq27.2qter and is being investigated. The probands father had a normal 46,XY karyotype, establishing the de novo origin of this derivative chromosome, with the duplication and translocation most likely occurring during meiosis II. Duplications of the distal Xq encompassing the MECP2 with an average size of 2Mb have been recently reported with a related phenotype. To our knowledge, the size of this rearrangement is much larger than the previous cases and might help to elucidate our knowledge of these conditions.

Molecular cloning of LOC348751 and its association with T2D in Pima Indians. *T. Guo, Y. Dong, J. Dooley, R. Hanson, K. Sayuko, C. Bogardus, L. Baier* PECRB, NIDDK/NIH, Phoenix, AZ.

A genome-wide association study using the Affymetrix 100K chip was done in Pima Indians to identify susceptibility genes for type 2 diabetes mellitus (T2D). SNPs were initially genotyped in 895 case/control subjects for early-onset T2D, among which 482 were discordant siblings. SNPs nominally associated with T2D under both a general and within family analysis were prioritized for follow-up studies. One prioritized SNP, rs10497841, was followed-up by genotyping in a population-based sample of 3501 full-heritage Pima Indians (1561 with T2D), where its association with T2D was confirmed ($p=0.004$ and 0.04 for general and within family, respectively, adjusted for age, sex, and birth-year). In addition, among 372 subjects who had undergone metabolic testing for predictors of T2D when they were non-diabetic, the risk allele for T2D was associated with reduced insulin-mediated glucose uptake (ie- insulin resistance) during a hyperinsulinemic, euglycemic clamp (adjusted $p=0.008$). The risk allele for T2D and insulin resistance (C) is common in Pima Indians (frequency= 0.85), but is less common in other ethnic groups (frequency in Caucasians and Africans= 0.34 and 0.12 respectively). Further fine mapping using 31 SNPs in this region suggested that the associated variant is within a 300 kb haplotype block that includes 3 reference genes, (FLJ38973, C2orf60 and C2orf47) and a non full-length transcript LOC348751. Among these genes, only LOC348751 had a predicted conserved functional domain that could potentially be involved in a metabolism. This partial transcript was highly expressed in human insulin action tissues such as skeletal muscle and liver. We used RACE to identify the 5 and 3 ends of this transcript and detected 2 transcripts, both predicted to have a formiminotransferase N-terminal conserved domain (FTCD-N). A homologous gene FTCD encodes formiminotransferase-cyclodeaminase which serves to channel one-carbon units from formiminoglutamate to the folate pool. We propose that LOC348751 may potentially confer risk of T2D and insulin resistance via its action in a folate metabolic pathway.

Mutation in ITPR1 underlies an ataxic movement disorder in both mice and humans (SCA15). *J. van de Leemput[1,2], J. Chandran[3], M. A. Knight[4], L. A. Holtzclaw[5], M. R. Cookson[1], H. Houlden[2], J. Hardy[6], E. M. C. Fisher[2], J. T. Russell[5], H. Cai[1], A. B. Singleton[1]* 1) NIH/NIA, USA; 2) UCL/IoN, UK; 3) University of Edinburgh, UK; 4) NIH/NHGRI, USA; 5) NIH/NICHD, USA; 6) UCL/Reta Lila Weston Institute, UK.

A severe autosomal recessive movement disorder was observed in mice used within our laboratory. Disease-onset is around P14, characterized by ataxic movement, loss of balance, truncal torsions and tonic/ tonic-clonic seizures. The disorder is progressive and lifespan is 3-4 weeks. Interestingly, heterozygotes do not display any of the disease-related features. Through linkage and sequence analysis the disorder was shown to be caused by a homozygous in-frame 18bp deletion in the gene Itpr1, encoding inositol 1,4,5-triphosphate receptor type 1. Itpr118 leads to a decrease in the normally high level of ITPR1 expression in cerebellar Purkinje cells, as demonstrated by immunohistochemistry and western blot analysis. In addition, a gene expression study in cerebellar tissue of Itpr1 mice was carried out to study the molecular mechanism that regulates calcium balance in the absence of ITPR1. Spinocerebellar ataxia 15 (SCA15), a human late-onset autosomal dominant disorder, maps to the genomic region containing ITPR1; however, no causal mutations had been identified. Sequence analysis of the coding exons of ITPR1 and high density genome-wide SNP genotyping were performed concurrently to test the hypothesis that mutation at ITPR1 may be the cause of SCA15. Sequence analysis failed to show any alterations segregating with disease. However, genome wide SNP genotyping metrics showed heterozygous deletion of the 5 part of the ITPR1 gene, encompassing exons 1-10, 1-40 or 1-44 in three studied families, to underlie SCA15. Moreover, western blot analysis showed a decrease in ITPR1 protein levels in EBV immortalized lymphoblasts of affected, but not unaffected, members of the original SCA15 family. In addition, classical sequencing techniques were applied to a large cohort of SCA families to identify distinct ITPR1 mutations, and assess gene dosage of ITPR1 in order to estimate disease prevalence.

ClinSeq: A pilot for the development of high-throughput genomic sequencing as a tool for translational genomics. *L. Biesecker[1,2], F. Facio[1], J. Teer[1], R. Cannon[3], T. Finkel[3], A. Remaley[4], G. Bouffard[2], J. Mullikin[1,2], J. Shendure[5], E. Green[1,2], NISC Comparative Sequencing Group* 1) NHGRI, NIH, Bethesda, MD; 2) NISC, Rockville, MD; 3) NHLBI, NIH, Bethesda, MD; 4) NIH Clinical Center, Bethesda, MD; 5) Univ Washington, Seattle.

ClinSeq is a pilot to develop methods and approaches for whole-genome sequencing to be used in clinical research. We will study data generation, archiving, access and sharing, sequence variant detection, determination of pathogenicity, returning results to the subjects, and informed consent. The study will initially sequence about 400 genes relevant to atherosclerotic heart disease in 1,000 patients. When advances permit, the study will be expanded to the entire exome or genome. At submission, we have recruited more than 400 subjects and have generated more than 930,000 capillary sequencing reads of ~3,500 genomic target sequences, ~275 Mbp of bidirectional genomic sequence. The accuracy of the sequencing was measured using 9 HapMap DNA samples, showing a 4% discordance rate and 90% sensitivity over a sample set of 1,256 HapMap SNPs that overlap the ClinSeq gene list. An additional 1,138 novel variants, relative to dbSNP, were detected across 201 subjects. We detected pathogenic variants in known disease genes, including LDLR, APOB1, and others. Several of these were validated in a CLIA lab and returned to the subjects, with genetic and medical counseling. We are also developing molecular inversion probe capture target selection with solid phase sequencing. When compared to the PCR/capillary sequence data, for a variant called in any patient (~3,100-3,700 positions) genotypes were called at 42% of these positions, and 98% of the time, the calls agreed. These preliminary results demonstrate that high throughput sequencing can be applied to clinical research, that scientifically and clinically useful data can be derived from such a study, that the return of appropriate results is practical and ethically appropriate, and that it is feasible to consent clinical research subjects to a whole-genome sequencing study. The clinical research opportunities made possible by high-throughput clinical genomics will be discussed.

MOHR SYNDROME: CASE REPORT AND CLINICAL DISTINCTION BETWEEN ORO-FACIAL-DIGITAL SYNDROMES TYPE I AND II. *P. Nicola, G. Machado, Z. Lumack, J. Sanches, D. Brunoni, A. Perez* Dept Morphology, Univ Federal de Sao Paulo, Sao Paulo, Brazil.

The Oral-Facial-Digital Syndrome type II (OFD II) is an inherited condition phenotypically characterized by ocular hypertelorism, low nasal bridge, high-arched palate, lobulated tongue, syndactyly, brachydactyly and polydactyly. It was first described by Otto L. Mohr in 1941. Many types of Oral-Facial-Digital Syndromes were reported and the last one was OFD type XIII. All of them present oral, face and digits malformations. The OFD II presents conductive hearing loss and autosomal recessive inheritance. We reported a boy, the third child of non-consanguineous couple, that was born at full term, by cesarean delivery, birth weight was 3115g (p25), length 47cm (p3), and OFC 34cm (-1dp). Multiple congenital anomalies were noted including a non-communication hydrocephaly, right parietal brain cyst, hypertelorism, strabismus, low nasal bridge, triangulate mouth, hypertrophied oral frenula, cutaneous syndactyly between 3/4/5 fingers and also between 1/2 of right hand and partial duplication of right hallux. At the age of 1.7 years, the child presented weight 9450g (p<3), height 77cm (P3), OFC 44,5cm (p<3), microcephaly, delay of neurologic development and the bone age. This case report represents an OFD II due to clinical, radiological manifestation and also the central nervous system anomalies. As we have already reported the parents are non consanguineous. We classified this case on OFD type II syndrome based on phenotype, but there are clinical signs of the two principal forms of OFD syndromes, type I and II. There are few published cases of Mohr syndrome and we think that this case contributes to delineation of the syndrome. The correct definition of this heterogeneous group of syndrome is important also due to different pattern of inheritance.

Epigenetic silencing of LINE-1 retrotransposition events in human embryonic carcinoma cell lines. *J. L. Garcia-Perez[1], M. Morell[2], D. A. Kulpa[3], C. C. Carter[4], K. L. Collins[3,4], K. S. O'Shea[2], J. V. Moran[1,3,4]* 1) Human Genetics; 2) Cell and Developmental Biology; 3) Internal Medicine; 4) Cellular and Molecular Biology Program, University of Michigan Medical School, Ann Arbor MI.

Long INterspersed Element-1 (LINE-1 or L1) is an abundant retrotransposon that comprises ~17% of human DNA. The average human is estimated to contain ~80-100 active L1s, and L1 mobility (retrotransposition) continues to impact the genome in a myriad of ways. Despite these facts, how L1 retrotransposition is regulated remains unclear. Here, we have used engineered L1s equipped with an enhanced green fluorescent protein (EGFP) retrotransposition indicator cassette to assess L1 mobility in cultured embryonic carcinoma (EC) cell lines that naturally express both L1 RNA and the L1-encoded proteins. Our data demonstrate that certain EC cell lines (PA-1, 2102Ep, and 833KE cells) support L1 mobility, but that the resultant retrotransposition events undergo efficient epigenetic silencing either during or shortly after their integration. Remarkably, treatment of PA-1 cells containing silenced L1 insertions for 16 hours with the histone deacetylase inhibitors (IHDAC) trichostatin A, sodium butyrate, or valproic acid reverses epigenetic silencing, resulting in an approximate 20-fold increase in the number of cells expressing the retrotransposed EGFP indicator cassette. A similar trend in data also was obtained from experiments conducted with natural and synthetic mouse L1s and a zebrafish LINE-2 element. In contrast, control experiments demonstrated that an EGFP expression cassette delivered by either a Moloney murine leukemia virus vector or HIV is not efficiently silenced in PA-1 cells. Our data further suggest that L1 epigenetic silencing is tightly associated with the undifferentiated status of EC cells. In sum, we have shown that retrotransposition events derived from a cohort of non-LTR retrotransposons are efficiently silenced in various EC cell lines by a mechanism that likely involves the post-translational modification of histones. We speculate that the epigenetic silencing of de novo L1 insertions could represent a mechanism employed by the host to regulate retrotransposition.

FOLLOW-UP OF A MAJOR LINKAGE PEAK ON CHR 1 REVEALS MULTIPLE QTLS ASSOCIATED WITH ESSENTIAL HYPERTENSION: GENNET STUDY. *A. A. O'Connor[1], G. B. Ehret[1], A. Weder[2], R. Cooper[3], A. Chakravarti[1]* 1) Center for Complex Disease Genomics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD, USA; 2) Division of Cardiovascular Medicine, Department of Internal Medicine, University of Michigan Medical School, Ann Arbor, MI, USA; 3) Department of Preventive Medicine and Epidemiology, Loyola University Stritch School of Medicine, Maywood, IL, USA.

Essential hypertension is a principal cardiovascular risk factor with a significant genetic component. In contrast to other complex genetic traits, recently published genome-wide association studies have, however, failed to identify significant and replicable genetic findings for essential hypertension. We have previously published a large genome-wide linkage scan in Americans of African and European descent using data from the GenNet network of the NHLBI-supported Family Blood Pressure Program. The most significant linkage peak was on chromosome 1q, spanning a region of 100cM. In this study, we have genotyped 1,569 marker SNPs under the linkage-peak in 2,379 individuals in order to identify genetic variants that may be associated with blood pressure (BP). Our analysis, using two different family-based association tests, identifies a significant number of variants associated with BP. Using diastolic blood pressure as a quantitative phenotype, we identify three variants, located in or near the GPA33, CD247, and F5 genes, yielding significant p-values after Bonferroni correction (nominal p = 2x10-5). Using systolic blood pressure, variants in GPA33, CD247 and REN (nominal p = 8.3x10-6) are significant. In summary, we show that a consequential follow-up of a linkage signal can help to discover variants with small genetic effects that will be missed by genome-wide association studies. This collection of SNPs will serve as a priority list for future investigations of BP variants on the human chromosome 1.

Combined molecular and clinical analysis in Fanconi Anemia patients: A powerful approach to patient assessment. *M. A. Johnson[1], N. N. Moghrabi[1], X. Zhu[1], M. J. Al-Dhalimy[1], S. B. Olson[1], M. Grompe[1], B. P. Alter[2], C. S. Richards[1]* 1) Dept Molec & Med Gen, MP350, Oregon Health & Sci Univ, Portland, OR; 2) National Cancer Institute, Rockville, MD.

Fanconi anemia (FA) is a rare (<1:100,000 live births) genetically heterogeneous chromosomal breakage disorder exhibiting either autosomal recessive or (very rarely) X-linked mode of inheritance. FA is characterized by specific birth defects, progressive bone marrow failure, and specific malignancies (myeloid leukemia and epithelial tumors) associated with genomic instability. Diagnoses of FA patients are routinely confirmed by the presence of chromosomal breakage and radial formation in lymphocytes or fibroblasts due to increased sensitivity to DNA cross-linking agents such as diepoxybutane (DEB) and mitomycin C (MMC). These cells are further characterized by complementation group analysis using retroviral transfection and rescue of cross-link sensitivity. Mutations in complementation group A gene (*FANCA*), account for approximately 65% of all FA cases, with mutations in *FANCC, FANCG, FANCE*, and *FANCF* contributing an additional 25%. In this study we demonstrate the clinical utility of our laboratory-developed comprehensive molecular FA analysis. We used this molecular analysis, to validate complementation group assignment for *FANCA, FANCC, FANCG*, *FANCE* and *FANCF*, and identified and characterized FA mutations. We used a clinical information survey tool to capture clinical patient data. Combining these data with our patient mutation information enabled a systematic approach to elucidation of genotype-phenotype correlations. Additionally, in our cohort of 48 confirmed FA patients we have identified 27 novel putative pathogenic mutations, all of which will be deposited in a public data base. These results validate the clinical utility of FA complementation group assignments, detail our FA genotype-phenotype study, and document the discovery of novel FA mutations.

Limb/pelvis-hypoplasia/aplasia syndrome (#276820): Report of a Brazilian patient and discussion of the differential diagnoses. *Z. D. N. M. Lumack[1], A. B. A. Perez[1], T. A. Zanolla[1], M. F. F. Soares[2], M. C. S. P. Cernach[1]* 1) Centro de Genética Médica (CGM), Universidade Federal de São Paulo (UNIFESP), São Paulo, Brasil; 2) Departamento de Radiologia e Diagnóstico por Imagem, Universidade Federal de São Paulo (UNIFESP), São Paulo, Brasil.

The limb/pelvis-hypoplasia/aplasia syndrome (LPHAS) - described by Al-Alwadi in 1985 - is a rare condition, that seriously affects the limbs and pelvic bones with autosomal recessive inheritance. We describe a newborn, first daughter of nonconsanguineous young couple, without teratogenic exposures during the uneventful pregnancy. Born mature, weight: 2535g (10th centile), length: 30cm (<3rd centile), head circumference: 32,5cm (<3rd centile). Physical examination: brachycephaly, telecanthus, microtia, depressed nasal root and broad tip, midfacial capillary hemangioma, posterior cleft palate and bifid uvula. Genitalia: Hypoplastic labia, anterior displacement of the anus. Limbs: contractures at the elbows and knees, mesomelic shortening. Hands: brachydactyly. Feet: total syndactyly of the first and second toes with medial deviation and nail hypoplasia. C-banded karyotype: 46,XX, without premature centromere separation. Abdominal ultrasound: pyelectasis; paranasal sinus computerized tomography: left choanal atresia. Skeletal radiographs: hypoplastic ulnae, hypoplastic radius on the right and absent radius on the left. Bilateral tibiae and fibulae agenesis, short femur on the right and short and bowed femur on the left. Sacrum hypoplasia, coccyx and iliac agenesis. She underwent a laparotomic exploration due to a peritonitis, developed septicemia and died with three months. No additional malformation was noted at autopsy. Multiple congenital anomalies involving the skeleton comprise a phenotypically and genetically heterogenous group of conditions that in some instances bring prompt difficulties toward the differencial diagnosis. In 2006, Woods et al considered the WNT7A gene, in 3p25.1, a candidate for causative mutations in the family described by them. Further evaluation is needed to determine to what extent this gene could be involved in the aetiology of LPHAS.

Gene variants associated with coronary artery disease presenting as sudden death. *K. L. Hamilton[1], E. Rampersaud[1], D. Gamal el-Iman[2], R. Faugue[2], E. K. Mont[4], N. Yeboah[1], R. J. Myerburg[2], E. Martin[1], N. H. Bishopric[2,3]* 1) Miami Institute for Human Genomics, University of Miami Miller School of Medicine; 2) Department of Medicine, University of Miami Miller School of Medicine; 3) Molecular and Cellular Pharmacology, University of Miami Miller School of Medicine; 4) Miami-Dade County Medical Examiner Department, Miami, FL.

Sudden cardiac death (SCD) is a complex trait with multiple environmental and genetic factors. Cardiac ion channel mutations have been reported in association with 1/3 of cases of autopsy-negative SCD in young persons; however the contribution of genetic factors to SCD in the setting of common acquired cardiovascular disorders including acute cardiovascular syndrome (ACS) is unknown. We hypothesized that common polymorphic variants in these same genes may be associated with the occurrence of SCD as the initial presentation of ACS. 131 cases of SCD with critical coronary narrowing and/or fresh thrombus, but no evidence of previous myocardial scarring, were identified retrospectively in white SCD cases collected from the Miami-Dade coroners office. 662 German white subjects from the KORA population served as controls. 1,536 SNPs were genotyped using a GoldenGate genotyping assay. Quality control (QC) measures included elimination of SNPs and samples with low call rates (<99%), and checks for Hardy-Weinberg disequilibrium and population stratification. Association with SCD was tested using age and sex-adjusted logistic regression analysis. Cases were younger than controls (52 vs. 61 yrs) and were mainly male (93%). No population substructure was detected in these samples. 1,403 SNPs passed our QC checks. 181 SNPs were associated with SCD ($p<0.05$). The most highly associated were several correlated SNPs in ANK2 on chromosome 4 ($p<0.001$), KCNQ1 on chromosome 11 ($p<0.001$), and KCNE1 on chromosome 21 ($p<0.001$). In a cohort of white patients with SCD as the initial presentation of ACS, our high-density candidate gene analysis preliminarily identified association with SNPs in several genes regulating I_{Ks}. Variability in I_{Ks} function may be a major modulator of susceptibility to cardiac arrest as the initial presentation of ACS.

Identifying copy number variations: A comparison of array platforms (Nimblegen vs Agilent), quantitative PCR and SNP using the Parkin gene in Parkinsons Disease. *K. Raiford[1], J. Deng[2], Y. Li[3], L. Nathanson[1], D. Casadeseus[1], S. Zuchner[1], J. Vance[1]* 1) Institute for Human Genomics, University of Miami, Miami, FL; 2) Department of Neurobiology, School of Medicine, Duke University, Durham, NC; 3) Department of Medicine, Duke University, Durham, NC.

The role of genomic copy number variation (CNV) in disease susceptibility is the focus of many recent studies of complex disorders. Multiple CNVs have been described in the parkin gene (PARK2). These are postulated to contribute to loss of function and subsequent Parkinsons disease. A number of methods have been developed to screen for CNVs in DNA, including quantitative PCR (qPCR), loss of heterozygosity (LOH), and array-based assays (high-density SNP, specific comparative genomic hybridization (CGH) arrays), each with different advantages and disadvantages. Further complicating the analysis of CNV is the existence of different statistical algorithms for calling variants. We initially screened 789 PD patient and 174 control individuals using qPCR then followed potential CNVs with two high density array platforms: Agilent 8-plex 15K CGH array, and NimbleGen 4-plex 385K CGH array. When available, affected family members were also evaluated to test for segregation of the CNV. Multiple putative CNV were identified with each of the assays but results were not always concordant across algorithms. To explore this we compared the efficiency of CNV detection, the sensitivity, and the overall reproducibility of these three methods. We also compared the properties of different analysis algorithms implemented in array analysis software CGH Analytics and Nexus. This study provides important, practical guidelines for molecular assays and statistical detection of CNV.

Diagnosis of biotinidase deficiency by full gene sequencing of the BTD gene. *M. Procter[1], C. Glezos[1], P. Dobrowolski[1], M. Pasquali[1,2], R. Mao[1,2]* 1) ARUP Institute for Clinical and Experimental Pathology and ARUP Laboratories; 2) Department of Pathology, University of Utah, Salt Lake City, UT.

Biotinidase deficiency (BTD) is an autosomal recessive disorder in which the body cannot process or recycle the vitamin biotin. Over 100 mutations have been identified in the BTD gene that causes biotinidase deficiency. One of every 60,000 newborns is affected with complete or partial BTD. Left untreated, complete BTD causes seizures, hypotonia, developmental delay, rashes, alopecia, hearing loss, or ataxia. Untreated partial BTD, causes any of these symptoms but they may be mild or only exhibited when the individual is stressed or suffering from illness. Current diagnosis of BTD depends on clinical presentations and biotinidase enzyme activity. We developed a sequencing analysis to detect the mutations in the coding region and exon/intron boundaries of the BTD gene. DNA was extracted from 42 serum samples from individuals previously shown to have low biotinidase enzyme activity levels, and 9 whole blood samples from normal individuals. PCR of the BTD gene coding region was done followed by bidirectional DNA sequencing. Data analysis was performed using Mutation Surveyor software. Seventeen of 51 samples failed to amplify in one or more amplicon. Of the remaining 34, 12 samples contained 2 known mutations, 2 samples contained 1 known plus 1 unknown mutation, 1 contained a novel point mutation and a novel 1 bp deletion, while 19 samples contained no mutation. Five new mutations were detected in these samples. In all, 25 of 34 results (74%) correlated with the genotype expected based on enzyme activity. The other 9 samples may have had low enzyme activity levels caused by improper sample handling. Sequencing of the coding regions and intronic boundaries of the BTD gene can be used as a 2nd tier test after an abnormal newborn screen to detect known variations and help define previously unknown BTD variations. A larger sample population using paired controls is needed to verify proper sample handling conditions. A combination of genotype and enzyme activity using paired controls will provide an accurate diagnosis of biotinidase deficiency.

Discordant expression of *PANK2* and *miR-103-2*: a microRNA within its pantothenate kinase-associated neurodegeneration gene host. *B. Polster, M. Yoon, S. Westaway, S. Hayflick* Molecular and Medical Genetics, Oregon Health and Science University, Portland, OR.

Pantothenate kinase-associated neurodegeneration (PKAN) is an autosomal recessive neurodegenerative disorder with dystonia, pigmentary retinopathy, and iron accumulation in brain. The causative gene, *PANK2,* is a member of a family of homologous genes encoding pantothenate kinase. Interestingly, these genes host a family of microRNAs within their introns 5. *PANK1* contains *miR-107*, while *PANK2* and *PANK3* contain *miR-103-2* and *miR-103-1*, respectively. The mature microRNA sequences of *miR-103-1* and *miR-103-2* are identical, while mature *miR-107* differs by a single nucleotide, suggesting shared mRNA targets. The location of *miR-103/107* within the *PANK* genes has high evolutionary conservation. However, the significance of *miR-103/107* preservation within pantothenate kinase transcripts remains unclear.

We hypothesized that *miR-103-2* and *PANK2* would have identical expression patterns and overlapping function, which might give insight into PKAN pathogenesis. Surprisingly, we have demonstrated that *miR-103/107* expression does not correlate with each host pantothenate kinase gene's expression in various mouse tissues using qRT-PCR. In addition, expression of *miR-103-2* precursor and mature *miR-103* is discordant, as demonstrated by northern blot analysis. This difference may be due to post-transcriptional regulation of the microRNA, resulting in distinct *miR-103-2* and *PANK2* expression patterns despite their genomic colocalization. These findings shed light on intronic microRNA processing and highlight the complexity of *PANK2* structure and its potential role in PKAN pathogenesis.

Imputation of allele frequencies at untyped SNPs from summary (or pooled) genotype data. *X. Wen*[1], *M. Stephens*[1,2] 1) Department of Statistics, Univerisity of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL.

Recent studies have shown that accurate genotype imputation can greatly increase the power of detecting genetic variation in genome-wide association study. However, most existing imputation methods require individual-level genotype data. In practice, for meta-analysis in genome-wide association studies, there are situations that only summary-level statistics are available; Also, as an alternative to high-throughput genotyping technology, DNA pooling is considered to be more economic and efficient, but provide only summary-level data and not individual genotype data. In these cases, it is desirable to have an imputation method utilizing only summary-level information. Here, we introduce a new statistical method that can efficiently infer the frequency of untyped SNPs using only population panel data (e.g. Hapmap data) and allele frequencies from typed SNPs in the study sample. This approach is a natural extension of Hidden Markov Models (HMM) from Li and Stephens (2003) and Scheet and Stephens (2005), both of which have been successfully employed for genotyped imputation for individual-level data. We also explicilty consider the uncertainties of observed allele frequencies, which is an attractive feature for dealing with data from DNA pooling experiment. The result from real data simulation study and real data application shows that the proposed method yields accurate imputation result and reduces error rates of allele frequency estimates.

Identification of POLG2 mutations in the patients with mitochondrial disorders. *FY. Li, LY. Tang, S. Zhang, ES. Schmitt, LJ. Wong* Molecular and Human Genetics, Balor College of Medicine, Houston, TX.

DNA polymerase gamma is the only DNA polymerase in mammalian mitochondria. It plays a critical role in the biogenesis of mtDNA. The holoenzyme of DNA polymerase gamma consists of one 140-kD catalytic subunit, POLG, and two 55-kD accessory subunits, POLG2. Mutations in the POLG gene have been associated with a broad spectrum of heterogeneous disorders including PEO, Alpers syndrome, MNGIE, SANDO, parkinsonism and premature menopause. To date, over 100 mutations in the POLG gene have been recorded while there is only 1 heterozygous missense mutation in the POLG2 gene reported in 1 PEO patient. We sequenced the entire coding exons of the POLG2 gene in 150 samples, which were negative for POLG mutations (113) or had only one POLG mutation identified (37). This study identified 5 heterozygous missense variants and 1 frame-shift mutation (p.D386E, p.L153V, p.S423Y, p.P205R, p.R369G and c.1423_1424delTT (p.L475DfsX2)) in 7 patients. All missense variants change evolutionarily conserved amino acids. The SIFT and PolyPhen algorithms predict three variants (p.S423Y, p.P205R and p.R369G) to be deleterious and two variants (p.D386E and p.L153V) to be benign. Patients with the POLG2 mutations/variants were all negative for POLG mutations, suggesting that a synergistic effect of di-genic heterozygous mutations is probably not the mechanism of the disease in these patients. Only one patient had clinical symptoms consistent with autosomal dominant (ad) PEO. These patients with POLG2 mutations/variants presented with multisystemic symptoms involving in at least 2 systems (CNS, neuromuscular, visceral or other systems). CNS symptoms such as hypotonia, development delay, seizures or abnormal MRI (6/7), and the visceral symptoms such as gastrointestinal reflux, delayed gastric emptying, constipation or hepatic failure are prominent (7/7). Two patients (2/7) presented with severe multisystemic clinical symptoms at 2 years of age without PEO, a clinical course very different from the adPEO. Longley et al (2006) identified only 1 heterozygous POLG2 mutation by screening 101 patients with PEO. Thus, PEO may not be the major clinical symptom associated with POLG2 mutations.

Comparison of clinical features between *SIL1* mutation -positive and -negative patients in Marinesco-Sjögren syndrome. *A. K. Anttonen[1], I. Mahjneh[2], A. E. Lehesjoki[1]* 1) Folkhälsan Institute of Genetics, Department of Medical Genetics, and Neuroscience Center, University of Helsinki, Helsinki, Finland; 2) Department of Neurology, Pietarsaari Hospital, Pietarsaari, and Department of Neurology, University of Oulu, Oulu, Finland.

Marinesco-Sjögren syndrome (MSS, MIM 248800) is an autosomal recessive disorder affecting various tissues and organs. The main clinical findings are cerebellar ataxia with cerebellar atrophy, early-onset cataracts, psychomotor delay, progressive muscular weakness, and muscle atrophy. In addition, hypergonadotropic hypogonadism, skeletal abnormalities, short stature, strabismus, hypotonia, dysarthria, and nystagmus are frequent findings. Recently, mutations in the *SIL1* gene, which encodes an endoplasmic reticulum resident cochaperone, were identified as a major cause of MSS. However, some patients with typical MSS do not have identifiable mutations in *SIL1*, implying genetic heterogeneity. We have previously excluded functional candidate genes *HSPA5*, *HYOU1*, and *AARS* as genes underlying MSS. Here, we report the results of an ongoing mutation analysis in yet another candidate gene, *CTDP1*, which has been implicated in the congenital cataracts facial dysmorphism neuropathy (CCFDN) syndrome resembling MSS. Moreover, we review the clinical features of the patients with and without *SIL1* mutations in more detail. Our preliminary data imply that patients with *SIL1* mutations form a uniform group whereas *SIL1* mutation-negative patients have more heterogeneous clinical features.

The Integration Of Transcriptional Profiling And Functional Genetics Reveals RBM24 To Be A Novel Candidate For Cardiac Defects. *R. Miller[1], A. Bertoli-Avella[3], B. de Graaf[3], M. Wessels[3], J. Gearhart[4], D. McGaughey[1,4], A. McCallion[1,2]* 1) McKusick-Nathans Inst Gen Med, Johns Hopkins Univ, Baltimore, MD; 2) Department of Molecular and Comparative Pathobiology, Johns Hopkins Univ, Baltimore, MD; 3) Departrments of Clinical Genetics, Erasmus Medical Centre, 3016 AH Rotterdam, The Netherlands; 4) Institute for Cell Engineering, Johns Hopkins Univ, Baltimore, MD.

Cardiogenesis is the result of a complex and coordinated series of events. Perturbations of these processes can lead to congenital heart defects, the most prevalent of all birth defects (7/1000 live births). To better understand cardiac development, we determined the transcriptional profile of mouse embryonic stem cells (mESCs) as they differentiate along a cardiac lineage. By comparing the profile of differentiating cardiomyocytes (DCMs) with time-matched non-DCMs and undifferentiated mESCs we have identified genes whose expression is enriched in DCMs. We have determined the temporal/spatial expression of 31/133 (23%) novel candidates identified in this screen by RNA in situ hybridization at key points during cardiogenesis (E7.5, E8.5, E9.5). All candidates evaluated were expressed in key cardiac structures, with 9/31 detected as early as the formation of the cardiac crescent. One gene identified in this study, Rbm24, was selected for functional evaluation in zebrafish. The zebrafish homolog, zgc:136803 (rbm24, 92.6% identity by AA comparison) recapitulates the cardiac and somitic expression observed in mouse. Injection with translation blocking morpholinos against rbm24 resulted in cardiac looping defects and cardiac edema as well as defects in somite formation. Co-injection of the full-length transcript with the morpholino resulted in phenotype rescue of 62%of injected embryos. Importantly, the human ortholog (RBM24) lies on chromosome 6p22.3, within an interval linked to the segregation of congenital cardiac abnormalities (6p24.3-21.2) in a three-generation European family (nine affecteds). We will discuss this work, our ongoing mutation detection efforts at this locus, and associated functional evaluation of RBM24 coding and non-coding sequences.

A GWAS study of 17,500 individuals and replication in a further 19,000 individuals reveals new loci associated with plasma lipoprotein levels in humans. *D. M. Waterworth[1], S. Debenham[2,3], K. Song[1], E. Wheeler[9], N. Lim[1], J. H. Zhao[3], X. Yuan[1], T. Johnson[4], J. Chambers[8], P. Vollenweider[5], J. Kooner[8], K. Papadakis[6], D. Strachan[6], M. Boehnke[7], P. Deloukas[9], G. Waeber[5], L. Cardon[1], N. Wareham[3], V. E. Mooser[1], M. Sandhu[2,3], GEMS and Sardinia Investigators*

Plasma levels of lipoproteins are important risk factors for cardiovascular disease. In order to find novel loci associated with circulating HDL-C, LDL-C and triglyceride levels, we conducted a meta-analysis of GWAS summary data from up to eight studies, comprising around 17,500 individuals and approximately 2.2 million genotyped and imputed SNPs. Using a screening threshold of $p< 1 \times 10^{-5}$, we identified 11, 14 and 16 putative novel loci associated with HDL-C, LDL-C and triglycerides, respectively. Of the novel loci detected, a locus on chromosome 9 reached genome-wide statistical association, specifically for LDL-C ($p = 1.2 \times 10^{-10}$). Replication analysis of these loci in 19,000 individuals is now underway. So far, we have found evidence for replication of a novel locus on chromosome 11 that is associated with both HDL-C and triglycerides ($p = 1.5 \times 10^{-9}$ and 2.8×10^{-8} in the combined analysis) and another locus on chromosome 9 ($p = 2.2 \times 10^{-8}$) for HDL-C. We are also examining associations between these novel genetic variants and risk of coronary artery disease (CAD) in a consortium of case-control studies linking the risk factor trait with its clinical phenotype.

Interacting variants in the nicotinic receptor subunit genes influence nicotine dependence risk. *N. L. Saccone[1], S. F. Saccone[2], A. L. Hinrichs[2], J. A. Stitzel[3], W. Duan[1], M. L. Pergadia[2], A. Agrawal[2], N. Breslau[4], R. A. Grucza[2], D. Hatsukami[5], E. O. Johnson[6], P. A. F. Madden[2], G. E. Swan[7], J. C. Wang[2], A. M. Goate[1,2], J. P. Rice[1,2], L. J. Bierut[2]* 1) Dept of Genetics, Division of Human Genetics, Washington University School of Medicine, St Louis, MO; 2) Dept of Psychiatry, Washington University School of Medicine, St. Louis, MO; 3) Dept of Integrative Physiology, Institute for Behavioral Genetics, University of Colorado, Boulder, CO; 4) Dept of Epidemiology, Michigan State University, East Lansing, MI; 5) Dept of Psychiatry, University of Minnesota, Minneapolis, MN; 6) Research Triangle Institute International, Research Triangle Park, NC; 7) Center for Health Sciences, Stanford Research Institute International, Menlo Park, CA.

Recent research has underscored the importance of specific cholinergic nicotinic receptor subunit (*CHRN*) genes in risk for nicotine dependence, smoking, and lung cancer. Our study has surveyed genetic variation across the complete family of 16 *CHRN* genes, which encode the nicotinic acetylcholine receptor (nAChR) subunits, in the NICSNP consortium sample of 1050 nicotine dependent cases and 879 non-dependent controls. These subjects of European descent were recruited from the United States and Australia and assessed using Fagerström criteria. Our previously reported association between nicotine dependence and rs16969968, a non-synonymous SNP in *CHRNA5*, has since been replicated in multiple independent samples via analyses of the same SNP or strong linkage disequilibrium proxies. To further investigate the role of this confirmed locus together with other members of this important gene family, we genotyped additional SNPs in the *CHRN* genes and tested biologically motivated interaction hypotheses. Certain nAChR subunits are known to combine in receptors with the alpha5 subunit, and SNPs across these *CHRN* genes were tested for statistical interactions. Results demonstrate that the non-synonymous SNP rs16969968 in *CHRNA5* interacts with multiple SNPs in *CHRNA4* to further influence risk for nicotine dependence. These findings may inform future efforts to improve smoking cessation treatment.

Three dimensional evaluation of facial structures in autism spectrum disorders. *K. Angkustsiri[1,2], K. Camilleri[2], C. Nordahl[2], C. Li[3], T. Simon[2], R. Hansen[1,2], D. Amaral[2], S. Boyadjiev Boyd[2,4]* 1) Dept Pediatrics, Section of Developmental-Behavioral Pediatrics, University of California, Davis, Sacramento, CA; 2) Medical Investigation of Neurodevelopmental Desorders (M.I.N.D.) Institute, Sacramento, CA; 3) Dept Biostatistics, UC Davis, Sacramento, CA; 4) Dept Pediatrics, Section of Genetics, University of California, Davis, Sacramento, CA.

Background: There is clinical heterogeneity among the autism spectrum disorders (ASD). Identification of a physical phenotype is difficult due to the subjective nature of conventional dysmorphology assessments. We apply indirect anthropometry using 3dMD technology to objectively compare facial features between children with ASD and typical (TYP) development and investigate the association with total cerebral volume (TCV). Methods: As part of a longitudinal study on biomedical and behavioral phenotyping of ASD, 3D images and MRI scans were obtained on 17 Caucasian male (12 ASD, 5 TYP) participants between the ages or 36-47 months. Twelve facial landmarks were placed on the 3D images, generating 14 measurements and 3 indices, which were compared between the groups using two-sided Wilcoxon-Mann-Whitney tests. Spearmans rank-order correlation was used to investigate the association between TCV and each of the 14 measurements and 3 indices. Results: Preliminary analyses revealed no statistically significant differences in any of the measurements or indices between groups. There was an inverse relationship between nasal width and TCV, coefficient=-0.58, 95% CI (-1;0.15). Conclusions: Although our sample size is small, the suggested inverse relationship between nasal width and TCV may be a useful biomarker for children with abnormal cerebral volumes for whom brain imaging should be pursued. We will continue to obtain 3D and MRI data on additional participants and will pursue further analysis, including measures of disproportion using a craniofacial variability index (CVI) and symmetry.

Altered Expression of microRNAs in Post-mortem Brain Samples from Individuals with Major Psychosis. *M. P. Moreau[1], S. E. Bruse[2], R. David-Rus[1], S. Buyske[3,1], L. M. Brzustowicz[1]* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Mirus Bio Corp, Madison, WI; 3) Dept Statistics, Rutgers Univ, Piscataway, NJ.

Schizophrenia is a debilitating psychiatric disorder characterized by severely disturbed thought, perception, emotion, and behavior. The association of psychotic features with severe mood disorders, combined with recent genetic insights, suggests that schizophrenia and bipolar disorder are etiologically related. The discovery of small, functional non-coding RNAs has unveiled a layer of gene expression regulation that was completely unknown only a decade ago. MicroRNAs comprise a growing class of endogenous molecules that regulate gene expression post-transcriptionally. Enrichment of predicted miRNA target sites within brain-expressed mRNAs, as well as emerging functional evidence, suggest that miRNAs serve important neurobiological roles. We have performed comprehensive expression analysis of 435 miRNAs and 18 small nucleolar RNAs using TaqMan real-time PCR methodology. Expression signatures were obtained from post-mortem brain samples originating from matched sets of individuals with schizophrenia, individuals with bipolar disorder, and psychiatrically healthy controls (n = 35 each group). Sample covariates pertaining to demographic variables, sample handling, and substance exposure history were assessed using Bayesian model averaging (BMA). BMA revealed that sample storage time and antipsychotic treatment history were most likely to influence miRNA expression signatures. After standardizing miRNA expression values with respect to all sample covariates, 30 miRNAs were found to be significantly under-expressed in individuals with bipolar disorder relative to controls at a false discovery rate less than 10%. While these same miRNAs displayed a trend towards under-expression in individuals with schizophrenia, only one was found to be significantly misexpressed.

Worldwide variation in the serotonin transporter gene SLC6A4. *J. D. Murdoch, W. C. Speed, N. Mukherjee, K. K. Kidd* Department of Genetics, Yale University School of Medicine.

The serotonin transporter gene SLC6A4 displays significant genetic diversity within and between human populations; much of the literature has focused on variation within the promoter VNTR (or HTTLPR) and the intron 2 VNTR. Both have been implicated in a variety of neuropsychiatric conditions and behaviors, though results are often inconsistent among studies. The common promoter VNTR alleles are often described as 16-repeat long and 14-repeat short alleles. However, this ignores additional variation in number of repeat units and repeat unit structure; variation of both types has been described previously. Through resequencing to date of over 100 individuals from our global population samples, we replicated previously described variation and identified several novel rare alleles, confirming that actual allele types are far more numerous than reflected in much of the clinical literature. Most of these alleles are at very low frequency, but display distinct geographic distributions; e.g. a particular 20-repeat allele was observed only in East Asian and Pacific Island populations. Trends in allele frequencies across the globe showed the 16-repeat class to be the most frequent size class in Africa and somewhat less frequent in Europe, while the 14-repeat class is the most frequent in East Asia and the Americas. Resequencing of individuals from several other primate species showed that the 16-repeat human class of alleles is more homologous to the gorilla 16-repeat allele than to any other non-human primate allele. In contrast, resequencing of the intron 2 VNTR in individuals from around the world so far shows no novel repeat number variants or structural variants, and the 12-repeat allele was the most frequent allele worldwide. However, as with the promoter VNTR, rarer alleles did show discrete geographic distributions, e.g. the 9-repeat allele was observed only in European populations. Our findings demonstrate that precise allele characterization and awareness of potential population stratification are needed when performing association studies on either VNTR in SLC6A4, and warrant further investigation into the evolutionary histories of the VNTRs.

Variants in four genomic regions are associated with Aspergers Disorder. *D. Salyakina[1], DQ. Ma[1], J. Jaworski[1], I. Konidari[1], S. Slifer[1], R. Henson[1], D. Martinez[1], H. H. Wright[2], R. K. Abramson[2], J. R. Gilbert[1], J. L. Haines[3], M. A. Pericak-Vance[1], M. L. Cuccaro[1]* 1) MIHG, University of Miami, Miller School of Medicine, Miami, FL; 2) School of Medicine, University of South Carolina, Columbia, SC; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Background: We present the first genome-wide scan for a homogeneous subset of autism spectrum disorder (ASD) families defined by individuals who meet research diagnostic criteria for Aspergers Disorder (AS). AS is distinguished from other ASDs by the absence of delays in language and cognitive development. **Method:** Association testing was performed in 103 families genotyped on Illumina 1M beadchip. 804349 SNPs passed quality control (genotyping rate > 0.99, MAF > 0.05, HWE (p-value) > 10^{-5}). **Results:** We identified associations between AS and loci on chromosome (chr) 2p21. Thirty-one of sixty (> 50%) tested SNPs in this region (~150 kb) show $p < 0.05$ to $2.67*10^{-5}$, and lie within the SOCS5 gene that has not been previously tied to ASD. SOCS5 belongs to the suppressor of cytokine signaling (SOCS) family, also known as STAT-induced STAT inhibitor (SSI) protein family. Similar over-representation of significant p-values suggests loci on 20q13.22 (56227710-56385825 bp) and 22q13.33 (48955865-48995704 bp). On chr 20, 45 of 60 SNPs have p-values in the range 0.05 - $8.23*10^{-6}$ and on chr 22, 10 of 18 SNPs show p-values in the range 0.05 - $4.17*10^{-5}$. Candidate genes include PPP4R1L, RAB22A (20q13.22); and PANX2, TRABD and SELO (22q13.33). Chr 3q26.1 also contains a small cluster of SNPs with $p < 10^{-4}$ that lie within a hypothetical gene. **Conclusions:** Our study highlights 4 candidate regions for AS on chr 2, 3, 20 and 22. Although none of these results meets genome-wide significance criteria, this unique set of regions suggests that it is important to collect the full spectrum of ASD to define homogeneous subsets of families. This approach ultimately increases power to detect genetic effects in complex diseases such as autism.

Genetic Variation in an Individual Human Exome. *P. C. Ng, S. Levy, J. Huang, T. B. Stockwell, B. P. Walenz, K. Li, N. Axelrod, D. A. Busam, R. L. Strausberg, J. C. Venter* Genomic Medicine, J Craig Venter Inst, Rockville, MD.

Characterizing the functional variation in an individual is an important step towards the era of personalized medicine. In 2007, we published the genome sequence of J. Craig Venter. Here, we analyze the genetic variation of J. Craig Venters exome, focusing on variation in the coding portion of genes which is thought to contribute significantly to a persons physical make-up. We survey ~12,500 nonsilent coding variants and by applying multiple bioinformatic approaches, we reduce the number of potential phenotypic variants by ~90%. The majority of coding variants in this individual are common and appear to be functionally neutral. Our results also indicate that some variants can be used to improve the current NCBI human reference genome. Our analysis provides a snapshot of the current state of personalized genomics. As sequencing of individual genomes becomes more prevalent, the bioinformatic approaches we present in this study can be used as a paradigm to pursue the study of protein-coding variants for the genomes of many individuals.

Genome-wide profiling for determination of microRNAs involved in brain-related endophenotypes. *M. Carless[1], T. Dyer[1], J. Curran[1], R. Duggirala[1], D. Glahn[2], J. Blangero[1]* 1) Dept Genetics, SFBR, San Antonio, TX; 2) University of Texas Health Science Center at San Antonio, San Antonio, TX.

The genetic determinants of complex brain-related disorders, including schizophrenia, mood disorders, autism and dementia are currently poorly understood and as such, treatment of these debilitating illnesses remains inadequate. Much of the genetic complexity associated with psychiatric disease is related to the phenotypic variation accompanying diagnosis. By focusing on neuroanatomic and neurocognitive endophenotypes as optimal indices of disease risk rather than discrete disease status, the power of a study to identify novel genes can be dramatically increased. We are currently performing genome-wide microRNA expression profiling in a population of 1,000 Mexican Americans across approximately 40 families using the Illumina MicroRNA Expression Profiling Assay. We have extensive brain-related phenotypic data for this population and preliminary analyses have identified a number of microRNA associations with various phenotypes. Of 520 microRNAs that were significantly detected, 304 were identified as heritable using an FDR of 0.05, with a mean heritability of 0.585. We identified 10 microRNA transcripts that exhibited significant associations with total brain white matter volume at an FDR of 0.05. The most strongly correlated of these, *miR-545* ($p = 0.0001$), was also correlated with total brain volume ($p = 0.0018$), gray matter volume ($p = 0.0025$) and a measure of episodic memory ($p = 0.003$). A number of other microRNAs were also found to be strongly correlated with the Eysenck Personality Questionnaire (*miR-100*), working memory (*miR-100*, *miR-30a-3p*), various measures of IQ (*miR-135b*) and the Beck Depression Inventory (*miR-181b*). Interestingly, *miR-181b* has also been implicated in schizophrenia by a small association study. These results, although preliminary, provide strong evidence that microRNA expression levels are associated with a wide variety of neuroanatomic and neurocognitive phenotypes and are therefore likely to be involved in various psychiatric disorders.

Gene Expression Profiling in Aging and Exceptional Longevity. *G. Atzmon[1], T. Budagov[1], R. F. Thompson[1], N. Barzilai[1], A. R. Shuldiner[2]* 1) Dept Med, AECOM, Bronx, NY; 2) Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine.

The aging phenotype is due to the complex interaction of genetic and environmental factors. Changes in gene expression may be one of the central mechanisms by which aging predisposes to many age-related diseases, and may therefore play a role in lifespan and incidence of age-related degenerative diseases. We systematically assessed changes in gene expression with age by studying global patterns in lymphoblastoid cell lines from 12 male subjects of Ashkenazi Jewish descent (5 probands (i.e. centenarians), and 7 young unrelated controls). We measured gene expression levels with the Affymetrix GeneChip Exon array, representing more than 1.4 million sites across the human genome. Approximately 10% of the analyzed probes demonstrated significant differences between centenarians and controls, 61 of which passed the multiple comparison adjustment (accounting for false positive error). Centenarians exhibited lower expression in 45% of these significant loci compared to the control group. As expected, the number of genes whose expression was altered with age varied according to the length of the individual chromosomes. However, the highest ratio (number of total altered probes/number of total genes per chromosome) of significant altered gene expression was observed on chromosome 2 (average of 2 probes per gene) with more than 30 analyzed probes for the Titin gene (a key component in striated muscles). All 30 (distinct probes representing most of the gene) Titin probes demonstrated significant over expression in centenarians. This is especially interesting as nfi-1 mutant worms that are short lived demonstrate a decrease in Titin gene expression. In summary, our preliminary studies suggest differences in expression of a large number of genes in lymphoblastoid cell lines from centenarians compared to controls. Additional studies of expression patterns may elucidate novel genes and pathways involved in cellular and organismal aging.

Linkage mapping of CVD risk traits in the isolated Norfolk Island population. *C. Bellis[1,2], H. Cox[2], T. D. Dyer[1], K. N. Begley[3], S. Quinlan[2], R. A. Lea[2,4], S. Heath[5], J. Blangero[1], L. R. Griffiths[2]* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Genomics Research Centre, Griffith Institute for Health and Medical Research, Griffith University, Gold Coast, Australia; 3) Division of Information Services, Griffith University, Gold Coast, Australia; 4) Institute of Environmental Science and Research Ltd, School of Biological Sciences, Victoria University of Wellington, New Zealand; 5) Centre National de Génotypage, 2 Rue Gaston Cremieux, Evry, France.

To understand the underlying genetic architecture of cardiovascular disease (CVD) risk traits, we undertook a genome-wide linkage scan to identify CVD quantitative trait loci (QTLs) in 600 individuals from the Norfolk Island population. The central aim of this research focused on the utilization of a genetically and geographically isolated population of individuals from Norfolk Island for the purposes of variance component linkage analysis to identify QTL involved in CVD risk traits. Substantial evidence supports the involvement of traits such as systolic and diastolic blood pressures (SBP and DBP), high-density lipoprotein-cholesterol (HDL-C), low-density lipoprotein-cholesterol (LDL-C), body mass index (BMI) and triglycerides (TG) as important risk factors for CVD pathogenesis. In addition to the environmental influences of poor diet, reduced physical activity, increasing age, cigarette smoking and alcohol consumption, many studies have illustrated a strong involvement of genetic components in the CVD phenotype through family and twin studies. We undertook a genome scan using 400 markers spaced approximately 10cM in 600 individuals from Norfolk Island. Genotype data was analyzed using the variance components methods of SOLAR. Our results gave a peak LOD score of 2.01 localizing to chromosome 1p36 for systolic blood pressure and replicated some previously implicated loci for other CVD relevant QTL.

Powerful Association Tests for Genome-Wide Association Studies Using Admixed Populations. *C. Li[1], X. Zhu[2], M. Li[3]* 1) Ctr Human Genetics Research, Dept of Biostatistics, Vanderbilt Univ, Nashville, TN; 2) Dept of Epidemiology and Biostatistics, Case Western Reserve Univ, Cleveland, OH; 3) Dept of Biostatistics and Epidemiology, Univ of Pennsylvania, Philadelphia, PA.

In a population that was recently admixed among different ancestral populations, LD may extend over very long distances. Admixture mapping exploits this unique genetic structure to localize genes that underlie ethnic variation in diseases or traits of interest. However, the regions identified by admixture mapping can often be more than several mega-bases. With the availability of dense markers in genome-wide association (GWA) studies, it is urgent to develop association tests for admixed populations that improve both resolution and power over existing approaches. We developed two novel association tests that simultaneously analyze ancestral states and marker genotypes. The first test is designed for analysis of unrelated cases and controls in GWA studies, and the second test is a case-only test for fine mapping regions identified through traditional admixture mapping. These tests can be extended to joint analysis of multiple markers. Both tests focus on the correlation between ancestry state and genotype score. By bringing these two pieces of information together, our tests offer higher resolution and power than the traditional admixture mapping methods. For example, suppose a disease variant follows a multiplicative model with genotypic relative risk 2.0, and its frequencies are 0.05 and 0.30 in two ancestral populations which were admixed at proportions 80% and 20%, respectively. In this scenario, Montana and Pritchard (2004, AJHG) reported 1,483 cases are needed for admixture mapping to achieve 80% power at genome wide significance level = 0.05. Assuming 5000 SNPs are genotyped in the identified region, with full ancestry information, our method has >99% power to further identify disease-associated SNPs, even at a very stringent significance level of = 0.05/5000.

Effects of glucocerebrosidase (GBA) mutations on proteolytic pathways: The role of autophagy-lysosome and ubiquitin-proteosome systems in GBA-associated parkinsonism. *O. Goker-Alpan, T. Samaddar, BK. Stubblefield, E. Sidransky* MGB/NHGRI, NIH, Bethesda, MD.

Parkinson disease (PD) and other related disorders are caused by deposition of aggregated proteins and/or the failure to clear aggregates leading to neuronal degeneration. The ubiquitin-proteosome system (UPS) and autophagy-lysosome pathway (ALP) are two pathways that remove abnormal proteins. Mutations in genes causing rare familial PD cases implicate UPS dysfunction. Autophagy is the major pathway for the degradation of aggregated proteins, and -synuclein was shown to be cleared by ALP. However, there is not yet a specific gene linking PD to ALP. Recent studies indicate an association between glucocerebrosidase (GC), the lysosomal enzyme deficient in Gaucher disease, and PD and dementia with LBs (DLB). To examine in vivo effects of mutant GC on the pathways implicated in -synuclein clearance, brain samples from subjects with PD or DLB were examined. In samples from subjects with GBA mutations, immunofluorescence studies demonstrated that GC was present in most -synuclein-positive inclusions. In some LBs, GC was present at the core, where aggregates destined for UPS removal often localize. Only 40-60 % of GC-positive LBs were ubiquinated, although all displayed antigenicity against lysosome markers. The effect of glucocerebrosidase on two preoteolytic pathways was examined in a cell-model system over-expressing hA53T-synuclein and wild-type or mutant GBA. UPS function was explored using the small degron CL-1, which demonstrated no influence of either wild-type or mutant GBA on proteosome. The evaluation of ALP function by different methods including following the levels and distribution of the autophagic marker LC3, suggested defective autophagy in cell lines transfected with mutant GBA. GBA mutations may contribute to neurodegeneration by interfering with lysosomal clearance of -synuclein, and lead to PD/DLB pathology.

Synergistic effects of methotrexate (MTX) exposure and MYC inhibition (MYCI) on the growth of Burkitt lymphoma. *L. J. Krueger[1, 2], N. H. Rong[1], L. Tao[1, 2], M. S. Leonard[1, 2], S. P. Dunn[3]* 1) Nemours Biomedical Research, A I DuPont Hosp Children, Wilmington, DE 19803; 2) Department of Biology, University of Delaware, Newark, DE 19716; 3) Department of Surgery, A I DuPont Hosp Children, Wilmington, DE 19803.

In 1982, MYC was initially recognized as a key transforming oncogene and now is found in a wide variety of human tumors including BL, breast, prostate and cervical carcinomas, glioblastomas and osteosarcomas. MYC is a conserved nuclear protein that controls cell growth and differentiation. MYC levels are transiently elevated at the transition from G1 to S in normal lymphocytes, but then rapidly decline. Our previous results on the dysregulation of the non-coding miRNAs in Burkitt lymphoma showed that miRNAs let-7a, let-7b and mir-98 were involved in the dysregulation of MYC. We showed that MYC and let-7a formed an autoregulatory loop. In that study, we proposed that miRNAS may serve in therapeutic applications for Burkitt lymphoma and other human tumors overexpressing MYC (Sampson et al. Cancer Res. 2007). Here, we used compound 10058-F4 which belongs to a class of small molecular inhibitors that function by disrupting MYC-MAX heterodimers in characterizing MYC-MAX dysregulation in the presence of MTX. In Wilson, an EBV- and MYC highly overexpressing BL, effective concentrations of MTX were broad (ranging from 0.1-1.0X10-4 M). The responses were both time- and dose-dependent. Because MTX is specific for the G2 phase of the cell cycle, we anticipated a synergistic response with MYC inhibition. Wilson showed a significant synergism reducing the effective dose of 10058-F4 over 100-fold (0.7 uM). The effects showed decreases in cell number below the initial plating concentration, $p<0.001$. Effects of MYCI were subsequently analyzed by real time gene expression studies for MYC and MYC-regulated genes as well as by western blotting. While 3 other BL lines were responsive to each of the agents, a distinct synergy was not found. This underscores the heterogeneity of BL. In summary, we show the utility of synergy with chemotherapeutic agents and MYC-silencing for increasing inhibition and reducing overall toxicities.

Schizophrenia candidate gene selection and gene networks. *Z. Zhao[1,2], J. Sun[1], B. T. Webb[1], A. H. Fanous[1,3], K. S. Kendler[1]* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth Univ, Richmond, VA; 2) Center for the Study of Biological Complexity,Virginia Commonwealth Univ, Richmond, VA; 3) Dept Psychiatry, Georgetown Univ Medical Center, Washington, DC.

Schizophrenia is a complex and debilitating psychiatric disorder with a lifetime prevalence of ~1. The past decade has witnessed hundreds of reports declaring or refuting claims that candidate genes chosen for their location under linkage peaks or because of their known physiological or pharmacological properties associated with schizophrenia. Identification of potential schizophrenia susceptibility genes is expected to accelerate because of many genome-wide association studies (GWAS) of large samples. It now remains a great challenge for an investigator to decide how to select the data from various sources and weigh and rank the information so that the best candidates can be selected for further investigation (e.g. replication). In this study, we collected and complied the mostly available schizophrenia-associated data including several sets of genome-wide linkage scans, more than 2000 association studies, gene expression data, and extensive literature search, and then selected candidate genes and prioritized them for schizophrenia using a model based data integration (MBDI) procedure. Our evaluation using GWAS results, published expert reviews, and meta-analysis results suggested its utility in follow-up association studies and in further bioinformatics analysis. We next selected 161 top-ranking genes for network analysis. We found that 1) contrary to cancer genes, schizophrenia associated genes tend to be nonessential and do not serve as the network super-hubs; and 2) schizophrenia associated genes have an intermediate level of connectivity in the network (medium-hub). Subnetwork analysis also revealed many important features on their gene regulation and protein interactions. In summary, this study represents the first systematic gene ranking and network analysis for schizophrenia and provides many insights on how schizophrenia susceptibility genes interact with each other and with some environmental factors.

Haplotypes in the surfactant protein-B and interleukin-1 genes are associated with need for mechanical ventilation in children with community acquired pneumonia. *M. K. Dahmer, M. Baldwin, N. Halligan, C. Wang, M. W. Quasney* Children's Research Institute and Department of Pediatrics, Medical College of Wisconsin, Milwaukee, WI.

Community acquired pneumonia is one of the most common infections of childhood and accounts for a significant number of admissions to pediatric intensive care units. Previously we have demonstrated that a particular single nucleotide polymorphism (SNP) in the surfactant protein-B gene (SFTPB) is associated with the need for mechanical ventilation (MV) in adults with community acquired pneumonia. In this study we examined whether specific SFTPB or interleukin-1 (IL1B) haplotypes were associated with the need for MV in Caucasian children with pneumonia. Children with pneumonia (n= 177) were genotyped at 4 SNPs in the SFTPB gene (rs2118177, rs1130866, rs2077079, rs3024791) and 5 SNPs in IL1B gene (rs1071676, rs1143634, rs1143633, rs3136558, rs1143629). SNP genotypes did not deviate significantly from Hardy Weinberg equilibrium. Haplotypes were generated using Phase 2.1. The need for MV in children with pneumonia was associated with a single SFTPB haplotype, ACAG (p=0.0095, Fisher exact test), with 23% of children with this haplotype requiring MV. A single IL1B haplotype trended toward significance, CTGCT (p=0.048), with 21% of children with this haplotype requiring MV. When both the SFTPB and IL1B at risk haplotypes were considered together 35% of children with both haplotypes required MV, 18% of children with only the SFTPB at risk haplotype required MV, 11% of the children with only the IL1B at risk haplotype required MV and only 6% of children with neither required MV (p= 0.0009, Cochran Armitage trend test). These results suggest genetic variation in both the SFTPB and IL1B gene may influence the severity of illness in children with pneumonia. Furthermore, consideration of both SFTPB and IL1B haplotypes may be more informative than either alone.

Gene expression profile of surgical specimens obtained from patients with familial and sporadic forms of mesial temporal lobe epilepsy. *C. V. Maurer-Morelli[1], C. S. Rocha[1], R. R. Domingues[1], H. Tedeschi[2], E. De Oliveira[2], F. Cendes[2], I. Lopes-Cendes[1]* 1) Dept Medical Genetics, Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, SP, BRAZIL; 2) Dept Neurology, Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, SP, BRAZIL.

Rationale: Mesial temporal lobe epilepsy (MTLE) is the most common and severe form of focal epilepsy and it is frequently associated with the pathological finding of hippocampal sclerosis (HS). Patients with MTLE and HS who are pharmacoresistant may undergo unilateral surgical excision of hippocampal formation as an alternative for seizure control. To address questions related to the pathophysiology of HS in the context of MTLE, we aimed to determined gene expression profiles in hippocampal tissue from patients with pharmacoresistant MTLE who underwent surgical treatment. In addition, we want to compare gene expression patterns in familial and sporadic forms of MTLE. Methods: Eight surgical specimens were obtained from patients with MTLE (n=4 familial MTLE and n=4 sporadic MTLE), as well as control tissues (n=3) from autopsy. This study was performed using the Human Genome U133 Plus 2.0 array (Affymetrix). We used 5 g of total RNA in the One-Cycle Target Labeling protocol (Affymetrix). Data was acquired by GeneChip Scanner 3000 (Affymetrix) and analyzed using MAS5 expression measure (Affymetrix). Data analysis was performed using Bioconductor packages (Affy, Limma and Multtest) and Wilcox-Mann-Whitney test was used for statistical analysis. Results: We found 300 genes which were differentially expressed in samples from patients with MTLE as compared to controls (up and down regulated). In addition, we identified a significantly different gene expression profile in samples from patients with familial and sporadic MTLE. Conclusions: This is the first study using microarray in MTLE with HS to explore the differential gene expression between familial and sporadic forms of MTLE. Our results clearly show that, although similar in the clinical, imaging and neuropathologic features, the familial and sporadic forms of MTLE have distinct molecular signatures. Supported by FAPESP and CNPq.

Meta-analyses of genome-wide association studies for 2-hour Glucose and Insulin levels during an Oral Glucose Tolerance Test. *R. Saxena[1,2], M. F. Hivert[2], V. Mayor[3], R. M. Watanabe[4] for MAGIC* 1) Broad, Cambridge, MA; 2) MGH, Boston, MA; 3) CHUV, Lausanne, Switzerland; 4) USC, Los Angeles, CA.

Two-hour post-load glucose measured during the oral glucose tolerance test (OGTT) defines glucose tolerance and correlates with cardiovascular risk, whereas OGTT two-hour insulin may predict type 2 diabetes. Both measures may also reflect insulin resistance. Defining genetic factors influencing these diabetes-related quantitative traits might lead to better understanding of diabetes pathophysiology and cardiovascular complications. We combined results across four genome-wide association studies (GWAS) for 2-hour glucose and three GWAS for 2-hour insulin through a collaborative effort, MAGIC (Meta-Analyses of Glucose and Insulin-related traits Consortium). Component studies included CoLaus, DGI, the Framingham Heart Study (FHS) and FUSION for 2-hour glucose and DGI, FHS and FUSION for 2-hour insulin. Genotypes were generated using the Affymetrix 500k SNP Array (+MIPS 50K chip for FHS) or the Illumina HapMap 317k Array and imputed for ~2.1 million additional HapMap SNPs. An additive genetic model with study-specific covariates was used to test for genetic association. GWAS results across 6,171 individuals for 2-hour glucose and 4,532 individuals for 2-hour insulin were combined by a z-score-based fixed-effects meta-analysis. No association signal achieved genome-wide significance, however a small excess of signals was observed for both phenotypes. Strongest associations for 2-hour glucose include variants in an unannotated region of chr 18q (meta-analysis P=9.2x10^{-7}), at *MAML3*, an activator of NOTCH receptors (P=3.3x10^{-6}), near the EGF-like-domain 11 gene (*EGFL11*;P=4.3x10^{-6}), and near angiotensin II type 1 receptor (*AGTR*; P=4.8x10^{-6}). The strongest associations for 2-hour insulin were at SNPs near the *CREB3L2* transcription factor (P=1.9x10^{-6}), neurotrophic factor *GDNF* (P=3.2x10^{-6}), serine-threonine kinase *PCTK3* (P=5.4x10^{-6}) and the metalloprotease *ADAMTS5* (meta P=5.5x10^{-6}). In conclusion, we identified several promising candidate loci, and ongoing replication in additional samples will establish whether these variants represent novel genes for 2-hour glucose or 2-hour insulin.

Using Genome-wide SNPs to characterize admixture in African Americans and an African Caribbean population. *T. Murray[1], W. H. L. Kao[1], T. Beaty[1], R. Mathias[2], N. Rafaels[1], M. Faruque[3], H. Watson[1], I. Ruczinski[1], G. Dunston[3], K. C. Barnes[1]* 1) Johns Hopkins Bloomberg School of Public Health, Baltimore , MD; 2) National Human Genome Research Institute, Baltimore, MD; 3) National Human Genome Center at Howard University, Washington, DC.

Admixture is a potential source of confounding in genetic association studies, consequently, detecting admixture and estimating its impact is important. Populations of African descent in the U.S. and the Caribbean share similar historical backgrounds but the distributions of African admixture might differ.We selected 416 genome-wide ancestry informative markers (AIMs) to estimate and compare admixture proportions in 906 African Americans (AAs) and 298 Barbadians (ACs) using STRUCTURE. AAs on average were 72.5% African, 19.6% European and 8% Asian. ACs were 77.4% African, 15.9% European and 6.7% Asian. A Wilcoxon rank sum test of differences in distribution of African ancestry between AAs and ACs yielded p-value <10-19. A principal components analysis based on AIMs yielded one significant eigenvector that explained 48.1% of the variation. An ANOVA test of differences along the first eigenvector between the AAs and ACs yielded a p-value of 2.35x10-16. Estimated Fst between these two populations was 0.006 (SE=0.003), indicating that although Barbadians are on average more African than African Americans, the genetic distance is very small. To compare ancestry estimation between random SNPs and AIMs, we estimated admixture in AAs using 996 uncorrelated SNPs randomly sampled from the genome-wide panel of 622,264 autosomal SNPs. A random subset of 50 markers yielded estimated African, European and Asian ancestries of 63.7%, 21.0% and 15.3%, respectively. For a random subset of 400 SNPs these proportions were 74%, 18.2% and 7.8%, and for the full set of 996, they were 77.2%, 18.1% and 4.6%.Correlations in African admixture estimated by random SNPs and the 416 AIMs were 44% for 50 SNPS, 80.5% for 400 SNPs, and 89.9% for 996 SNPs. These results suggest random markers can detect population substructure in African Americans especially when large numbers of random SNPs are used.

The distribution of positive selection on coding and noncoding sequences across the human genome. *G. A. Wray*[1,2], *C. C. Babbitt*[1], *O. Fedrigo*[1,2], *R. Haygood*[2] 1) Institute for Genome Science & Policy, Duke University, Durham, NC; 2) Dept. of Biology, Duke University, Durham, NC.

The relative contribution of mutations in coding and noncoding regions of the genome to adaptive evolution remain unclear. Several recent studies have surveyed the human genome for evidence of positive selection since the *Pan-Homo* common ancestor. Collectively, these studies constitute a trove of information about adaptation during human origins. We conducted a formal meta-analysis to search for correlations across these studies, focusing on functional categories and tissues of expression. Correlations between categories reveal informative patterns of congruence and heterogeneity between coding and noncoding partitions. We find consistent support across studies for extensive adaptation in several functional categories, including T-cell-mediated immunity, anteroposterior patterning, and the insulin/IGF pathway-protein kinase B signaling cascade. We also find strong contrasts between studies that examined coding and noncoding sequences in terms of enrichment for functional categories and tissues of expression. In particular, it appears that adaptation in developmental processes has occurred largely through noncoding changes, whereas in the immune system this has occurred mainly through coding changes. In addition, signals of positive selection for genes expressed in the CNS are predominately noncoding, in the immune system coding, and in testis both. These results highlight strongly contrasting patterns in the genomic distribution of positive selection among coding and noncoding regions during human evolution.

The genetics concept inventory (GenCI): Identifying and addressing student misconceptions. *S. L. Elrod[1], B. P. D. Bartel[1], J. C. Walz[1], K. M. Polacek[1,2]* 1) Biological Sciences/CESaME, California Polytechnic State University, San Luis Obispo, CA; 2) Fielding Graduate University, Santa Barbara, CA.

College students often graduate with the same scientific misconceptions they had when entering high school; e.g., they believe that air has no weight and thus the carbon dioxide in it cannot contribute to the weight of a plant. The identification of misconceptions is an important step in creating effective learning experiences. A genetics concept inventory (GenCI) has been developed to identify and address current student misconceptions in genetics. Concept inventories are research-based assessment instruments designed to reveal student misconceptions. The GenCI has been given to nearly 400 introductory and upper division genetics students at a large public university in pre- and post-test formats. Our results reveal that students: 1) have a superficial understanding of sister and homologous chromosomes, gene function, and the ubiquity of genetic information in different cell types within a single organism; 2) understand the general nature of alleles, but cannot place this understanding in the context of other concepts such as ploidy; and, 3) can readily identify the products of transcription but are less clear regarding the products of translation. Additionally, our results suggest there are at least two kinds of misconceptions among students: naïve conceptions and alternative conceptions. Naïve conceptions may originate from the use of genetic terms that also have common meanings (e.g., sister, daughter), historical terminology that may over-generalize (e.g., chromosome), or figures in textbooks (e.g., chromosomes represented as X-shaped structures); these should be easily rectified with appropriate instruction. Alternative conceptions are mental models that are not aligned with current scientific evidence, are highly resistant to instruction and can interfere with subsequent learning. Concept inventory and student interview data will be presented, along with suggested instructional interventions and next steps in the development the GenCI. The use of the GenCI is predicted to foster improved instructional approaches and student learning.

Positional cloning of a gene for 46,XY DSD implicates a gene in a common signal transduction pathway in human testis determination. *H. Ostrer[1], S. Shajahan[1], C. LeCaignec[2], S. White[3], A. Friedman[1], J. Willan[4], G. Camerino[5], A. Crosby[6], A. Greenfield[4], A. Sinclair[3], A. Pearlman[1]* 1) New York Univ, USA; 2) CHU Nantes, France; 3) Univ Melbourne, Australia; 4) MRC Mammalian Genetics Unit, UK; 5) Universita di Pavia, Italy; 6) Saint Georges Hosp Med Sch, UK.

Previously, we used linkage analysis to map a gene for familial 46,XY disorder of sex development (46,XY DSD) to the long arm of chromosome 5. Subsequently, we applied the chromosome 5 marker linkage analysis to a second family. The combined, multipoint parametric LOD scores from these two pedigrees (6) favors the existence of a sex-determining locus, which, when mutated, results in 46,XY DSD. When this information was applied to the candidate genes in the critical region on chromosome 5, 11 demonstrated expression above background in developing mouse E10.5 and E11.5 Sertoli cells with none showing greater than 2-fold increases or decreases in expression. For two of these genes, encoding a DNA-binding protein and a signal transduction molecule, respectively, we confirmed the cordal expression in mouse embryonic gonads by in situ hybridization. By DNA sequence analysis, both had genetic variants that were in-phase with inheritance of the phenotype and were not described in the SNPdb database; however, in the upstream region of one gene, an AG transition was observed on 16% of control chromosomes, making it an unlikely cause of the DSD phenotype. A variant in the polypyrimidine track of the splice donor site of exon 2 (IVS2-8TA) of the second gene was not present on control chromosomes. As judged by qPCR and cDNA cloning, this variant disrupted the efficiency of splicing from this site, creating a novel in-frame splice donor at the site of the mutation that resulted in the addition of 2 amino acid residues (IQ). Subsequently, mutations in this gene were demonstrated in the second family (G616R) as well as in a sporadic case (L189P) of 46,XY DSD. A mouse knockout model for this gene demonstrated no bias in the sex ratios of the mice nor diminution of fertility in male mice. Thus, mutations in this gene appear to result in 46,XY,DSD on the basis of gain-of-function, rather than loss-of function, mutations.

High density SNP association analysis of potential HDL candidate genes reveals molecular architecture and functionally relevant domains: focus on CETP. *I. M. Stylianou[1], A. Edmondson[1], M. Li[2], S. L. DerOhannessian[1], A. Khera[1], M. L. Wolfe[1], B. J. Keating[1], M. P. Reilly[1], D. J. Rader[1]* 1) ITMAT, University of Pennsylvania, School of Medicine, Philadelphia, PA; 2) Department of Biostatistics & Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA.

Several genes are known to be associated with variation in human HDL-C levels, though in many cases the molecular architecture of these associations is not known. Basic research and mouse genetics have identified a large number of new genes that plausibly affect HDL metabolism but have not been associated with HDL-C levels in humans. GWAS has proven a powerful means to identify novel genes linked to complex phenotypes such as HDL-C. However, many genes are poorly represented on current arrays and correcting for a large number of tests can lead to rejecting marginally significant genes that are still important. We used a custom candidate gene array using tag-SNPs to extensively cover a large number of known and possible HDL candidate genes to interrogate a population of cases with extreme high HDL-C (>95th percentile; n=665) compared with low HDL-C (<25th percentile; n=703). The most significantly associated SNPs were in CETP ($p<1x10\ 14$). The array contains 100 CETP SNPs and the data reveals detailed association and linkage disequilibrium (LD) in three discrete blocks. Our data indicates that the association of CETP SNPs to HDL is dependent upon which of the three LD blocks the SNP is in, hence the LD blocks have distinct properties regarding HDL regulation. In addition, the proximal LD block, which contains the most significant SNPs, is composed of two distinct LD sub-blocks which is apparent in the candidate gene array data (but not the HAPMAP). A better definition of the genetic architecture of CETP and its relationship to HDL-C will help resolve the relationship between CETP, HDL, and CAD. High-density candidate gene arrays will permit detailed interrogation and reveal insights of candidate genes that extend findings from genome-wide association studies.

Identifying novel genes in brachydactyly type A-1. *L. Racacho[1,2], A. Byrnes[1,2], S. A. Nikkel[3], J. MacKenzie[4], D. E. Bulman[1,2]* 1) Regenerative Medicine, Ottawa Health Research Institute, Ottawa, ON, Canada; 2) Biochemistry, Microbiology and Immunology, University of Ottawa, ON, Canada; 3) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 4) Department of Medical Genetics, Kingston General Hospital, Queens University, Kingston, ON, Canada.

Brachydactyly type A-1 (BDA1) is a congenital disorder that affects normal bone development and patterning. Affected individuals have short fingers, broad hands and are generally short in stature. We have previously reported linkage to chromosome 5p in a large family resulting in the assignment of BDA1B as a new locus; OMIM #607004. We further refined the locus to an approximately 3 Mb genomic region. We have also shown that missense mutations in the Indian hedgehog gene (IHH) are known to cause BDA1 in approximately 50% of our families. Currently, all of the BDA1 mutations have been clustered within the IHH N-terminal fragment. Taken together, this data supports a crucial role of IHH in normal bone development and the existence of another locus for BDA1. We hypothesize that the causative genes involved in BDA1 pathogenesis are involved in the IHH signaling pathway and as such, represents novel members of the pathway. Our main objective is to identify these causative genes and to characterize their involvement with the IHH pathway in bone development.

Obstetric and Gynecologic Issues in Patients with Hermansky-Pudlak Syndrome. *M. A. Merideth[1,2], A. M. Garcia[1], J. Salas[1], K. O'Brien[1,2], T. C. Markello[1], W. A. Gahl[1,2]* 1) NHGRI, NIH, Bethesda, MD; 2) Intramural Office of Rare Diseases, NIH, Bethesda, MD.

Hermansky-Pudlak syndrome (HPS) is a panethnic autosomal recessive disorder characterized by oculocutaneous albinism, a bleeding disorder, and, in some patients, granulomatous colitis and/or a fatal pulmonary fibrosis. There are 8 known subtypes of HPS caused by mutations in 8 separate genes involved with intracellular vesicle formation and trafficking. The bleeding disorder in HPS is due to platelet storage pool deficiency. Women with HPS often have problems with heavy menstrual periods and excess bleeding during deliveries, yet very little information has been published on the obstetric and gynecologic issues in HPS. To pursue this, we surveyed 45 patients under an NIH IRB-approved protocol. The patients ranged in age from 13-65 y with a median of 33 y, and were diagnosed with HPS at a median age of 22 y. Forty-one of the 45 patients (91%) report a history of heavy menstrual periods. Thirty-one patients were treated with oral contraceptive pills to manage heavy menses, and 21 of 31 reported improvement. Three of 4 patients had improvement of heavy menses after insertion of a Mirena progesterone IUD. Four patients underwent hysterectomy for heavy menses at a median age of 33.5 y. Twenty-one patients have been pregnant with a median of 2 pregnancies (range 1-5). Only four of 21 patients had problems with bleeding during pregnancy. Bleeding problems were reported in 9 deliveries, requiring platelets, blood transfusion or ddAVP in 4. Prophylactic platelet transfusion or ddAVP was given prior to 12 deliveries, with no subsequent bleeding problems reported. Postpartum hemorrhage occurred in 13 deliveries: treatment by surgery, transfusion of platelets or medication was required in 10. Obstetrician/Gynecologists have an opportunity to assist in the diagnosis of HPS patients, particularly since a majority of patients surveyed were diagnosed many years after the onset of menses. The history of a menstrual bleeding disorder, combined with some degree of hypopigmentation, should prompt investigation into the diagnosis of HPS.

Human Variation Panels in the NIGMS Human Genetic Cell Repository: Availability of genotyping data and preliminary analysis. *D. L. Coppock[1], A. Hebert[2], N. Gerry[1], P. Bender[1], J. Leonard[1]* 1) Coriell Cell Repositories, Coriell Inst Medical Research, Camden, NJ; 2) Boston University, Boston, MA.

The NIGMS Human Genetic Cell Repository has made available four panels of 100 samples from Caucasians, African-Americans, Han People of Los Angeles and the Mexican American Community of Los Angeles, CA. These panels have been available for several years and have been distributed widely to the research community. The ethnicity and familial relationships were self reported. The samples were either unaffected samples from the NIGMS Repository or were collected specifically for these panels (Mexican and Chinese samples from Los Angeles). The 400 samples have been genotyped on the Affymetrix Genome-Wide SNP Array 6.0 and the genotype data are available for downloading from Coriell at http://ccr.coriell.org/Sections/Collections/NIGMS/GenotypeCopyData.aspx?PgId=564&coll=GM. An analysis of the samples by panel using Helix Tree showed the Chinese, Caucasian and African-American samples clustered with little overlap, but some of the Mexican samples overlapped the African American samples. An analysis of the amplified or deleted autosomal regions greater than 500 kb for the 400 samples showed there were 289 copy number variations in 66 autosomal regions. These large copy number variants were found in 210 of the 400 samples and were relatively evenly distributed in the four populations. These regions were found in all autosomes except chromosome 18. The most common variants, occurring at least 10 times, were at chr15q11.2, 8p23.1, 2p11.1-2p11.2, 10q11.22, 14q11-14q12, and 1q21.1. A more detailed analysis of smaller copy number variants in the Human Variation Panels will be shown.

An ENU Screen for Mutations that Disrupt Brain Cortical Development in the Mouse. *R. W. Stottmann[1], J. L. Moran[1], D. Cunningham[2], M. A. Kennedy[2], G. E. Herman[2], D. R. Beier[1]* 1) Brigham and Women's Hospital/Harvard Medical School, Boston, MA; 2) Dept Pediatrics, Nationwide Children's Hosp, Columbus, OH.

The forebrain is the largest portion of the human brain and is responsible for many higher order cognitive functions including reasoning and memory. Remarkably, a large portion of the genetic regulation of forebrain development remains unknown. We have completed an ENU mutagenesis screen in the mouse to identify more of the genes required for forebrain development. We use a traditional breeding strategy to obtain autosomal recessive mutations and observe for phenotypes at E18.5. This stage of development, just before birth, allows the embryo to survive with relatively severe defects in organogenesis which would be lethal in a newborn animal. Affected progeny are used directly for genetic mapping utilizing a 768-marker SNP panel that allows a rapid genome-wide analysis. With this strategy, we are able to localize the mutation to a single linkage group by genotyping 8-10 affected mice. The screen presented here has three components: a traditional phenotypic screen complemented by histological analysis, use of a reporter allele to highlight distinct brain structures, and use of a sensitizing allele to increase the incidence of defects in neural developmental *(Lis1/Pafah1b1)*. In this screen we identified thirteen mutations of interest, eight of which affect CNS development. All of these are mapping as monogenic, recessive traits and we have cloned four mutations and identified the gene mutated in a fifth using whole genome polymorphism analyses, microsatellite mapping and microarray analysis. The most remarkable phenotype uncovered to date shows severe cortical agenesis as well as defects in the appendicular skeleton (smaller long bones). This mutation reveals a requirement for embryonic cholesterol metabolism in brain development and possibly in Sonic hedgehog signaling. Other mutations show significant changes in brain morphology. Some phenotypes are present in grossly normal brains with defects only detectable upon histological analysis or by reporter gene staining. These results demonstrate how ENU mutagenesis can be utilized to query specific developmental processes.

Causal penetrance: definition and relevance to 2-locus heterogeneity. *A. M. Madsen[1], S. E. Hodge[2,3]* 1) Epidemiology; 2) Biostatistics, MSPH, Columbia U; 3) NYSPI, New York, NY.

Background: We introduce the concept of causal penetrance (CausPen) = P[D caused by genotype (gt)|gt] in contrast to the usual statistical penetrance (StatPen) = P[D|gt]. CausPen, akin to attributable risk, pertains to the proportion of disease preventable by eliminating the causal effects of the detrimental variant. This measure may be valuable for risk prediction, data simulations, etc. A model used to predict the risk of disease among carriers of two susceptibility genes that independently affect disease risk is Rischs (1990) two-locus heterogeneity formula: $w_{ij}=x_i+y_j-x_iy_j$ (Eq. 1); w_{ij}=penetrance of genotype G_iH_j; x_i and y_j=penetrance summands for genotypes G_i and H_j, respectively. Objectives: To compare the calculated w_{ij} with the true CausPen of G_iH_j for two different estimates of x_i and y_j: the single-locus StatPen and our estimate of CausPen, the risk difference (RD): RD=P[D|gt]-P[D|no gt]. Methods: We define a causal model of complex genetic disease by combining a sufficient component cause (SCC) model of genetic heterogeneity, Greenlands response types, and a counterfactual definition of causation. Our SCC model assumes no epistasis, no imprinting, and independence between genes and environment. We assign different sets of prevalences of the component causes in the SCC model. For each set, we calculate w_{ij} using StatPen and RD to estimate x_i and y_j. We compare these w_{ij} with the true CausPen of G_iH_j. Results: (1)When the single-locus genotypes are neither necessary nor sufficient, w_{ij} does not equal, and usually overestimates the probability that the two-locus genotype will cause disease using StatPen or RD. The overestimation is proportional to the prevalence of causes of disease in the population that do not include locus G or H. (2)Using RD substantially reduces this overestimation. E.g., when the causal G and H genotypes occur with p=0.1, an additional cause of disease occurs with p=0.1, and the true CausPen= 0.84, the StatPen w_{ij}= 0.96 and the RD w_{ij}=0.85. Conclusion: When the CausPen of two loci is of interest, e.g. in some risk and simulation settings, the RD should be used to estimate the penetrance summands of Eq. 1.

A whole-genome association study of severe malaria. *K. S. Small, MalariaGEN Consortium* Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, United Kingdom.

Malaria kills approximately a million children each year, but a much larger number survive despite repeated infections, and it is poorly understood why some children and not others die of malaria. The MalariaGEN Consortium (partner institutions listed at www.malariagen.net)was established to carry out multicentre studies investigating the genetic basis of resistance to malaria. Here we present the results of two whole-genome association studies of severe malaria; a case-control study of 2,500 children in The Gambia, West Africa, and a family-based association study of 1,500 affected-offspring family trios from The Gambia, Ghana and Malawi.

The Effects of Polymorphisms on CPS1 Activity. *S. Reiss[1], L. Hall[2], A. Putnam[1], G. Cunningham[1], M. Summar, M.D.[1]* 1) Pediatrics, Vanderbilt University, Nashville, TN; 2) Medicine, Vanderbilt Universitiy, Nashville, TN.

The urea cycle is the only metabolic process capable of eliminating the bodys accumulation of ammonia by converting ammonia into its easily excreted form of urea. Carbamyl phosphate synthetase 1 (CPS1) is the primary rate limiting enzyme catalyzing the first committed step of the urea cycle by converting ammonia and bicarbonate into carbamyl phosphate in the presence of ATP and N-acetyl glutamate synthetase (NAGS). Variations in this highly conserved enzyme could have significant clinical effects. We have found that one particular change in the CPSI gene, a threonine to asparagine missense change at amino acid 1405, T1405N (het. .44) is strongly associated with in vivo variations in urea cycle intermediates and the ability to produce nitric oxide. We have incorporated both versions of the T1405N polymorphism and both versions of the T344A (het .45) change subsequently. We performed human cell culture expression of the recombinant versions of this enzyme. We detected a significant difference in the activity levels for the 2 versions of T1405N but not for T344A. We also found that co-factor levels of N-acetylglutamate have an effect on the difference in activity between these two versions of T1405N (the change is in the cofactor binding domain). These findings may provide a biochemical rationale for the clinical associations seen with this polymorphism. We wish to demonstrate the effects on CPS1s activity through comparison of the incorporated polymorphisms.

Accommodating uncertainty in SNP calling in population genetic inference from deep resequencing data. *A. G. Clark[1], K. E. Lohmueller[1], X. Liu[2], T. J. Rea[3], A. R. Templeton[4], J. S. Pankow[5], T. Maxwell[2], E. Boerwinkle[2], D. M. Muzny[6], D. A. Wheeler[6], O. Hall[6], L. Bull[6], R. A. Gibbs[6], C. F. Sing[3]* 1) Dept Molec Biol & Genetics, Cornell Univ, Ithaca, NY; 2) Univ of Texas Health Science Center at Houston; 3) Dept Human Genetics, Univ Michigan; 4) Dept Biology, Washington Univ; 5) Univ. Minnesota; 6) Human Genome Sequencing Center, Baylor College Medicine.

While deep resequencing data provides the opportunity to capture rare variants that would be missed by standard genotyping arrays, it gives rise to challenging problems in population genetic inference in the face of uncertainties in the data. Here we performed PCR-resequencing of the HHEX (7.7 kb) and KCNJ11 (5.4 kb) genes in a sample of 1786 individuals as part of a project to identify variants that are associated with inflated disease risk. Inference of association with rare variants and population genetic analysis of recent demographic history both rely heavily on the rarest segregating alleles, precisely those that are likely to suffer the highest miscalling rate. We identified 85 segregating sites with high confidence in KCNJ11 and 148 segregating sites in HHEX (using Sanger sequencing and SNPdetector), and performed analysis by multiple imputation over the cloud of potential SNPs assessed from the base quality scores. The approach generates 1000 data sets, each representing a sampling of the base calls weighted by their phred quality scores. All population genetic parameters are estimated for each such data set, producing distributions of the parameters that reflect the sequencing uncertainty. Counter to the intuition that synonymous and neutral sites might be saturated with a sample of this size, the observed count of segregating sites, their site frequency spectrum, and the pattern of linkage disequilibrium are consistent with standard models of human demography. The variation is sharply at odds with models that assume equal mutability of all sites and homogeneous recombination. Assessment of association with disease in such deep sequence data will be best done if these inhomogeneities can be accommodated in the model.

Polymorphisms in the Genes of key HPA Axis Molecules are Examined for Association to Cushing's Syndrome.
J. T. Papademetriou, A. Horvath, L. Herishanu, S. Verma, E. Bimpaki, S. Boikos, C. Stratakis Section on Endocrinology and Genetics, National Institutes of Health, Bethesda, MD.

The purpose of this study was to examine whether polymorphic variants of key genes of the hypothalamic-pituitary-adrenal (HPA) axis influence the recovery time of patients following surgical cure of Cushings Syndrome (CS). Patient genotypes were accumulated for twelve polymorphisms: including nine single nucleotide polymorphisms (SNPs) on the corticotropin releasing hormone receptor 1 (CRHR1) gene , one on the pro-opiomelanocortin (POMC) gene, and two SNPs on the glucocorticoid receptor (GC) gene. Clinical data indicative of disease severity (pre-operative Urine Free Cortisol levels (UFC), pre-operative Midnight Cortisol levels (MC)), and return to normal HPA axis functionality following Transphenoidal Surgery (TSS)(post-operative cortisol levels 12 months after TSS (C12post)) were collected and assessed for genotypic differences at each polymorphic locus. Four new polymorphisms were discovered and included in our analysis. One of them (CC/CT), located approximately 4,428bp after the splice site of intron 4 of the CRHR1 gene, was associated significantly with pre-operative MC levels: CC patients had MC levels of 28.4 +/- 14.0 pg/mL, whereas CT patients were 6.75 +/- 4.6 pg/mL (p=0.03998). TT patients were not observed in our cohort. All other polymorphisms did not produce significant differences between genotypic groups. We conclude that severity of CS is significantly affected by the genotype of patients at this CC/CT site. Therefore, this polymorphism may be useful as a diagnostic tool, and its role in CS warrants further investigation. All other polymorphisms studied did not show statistically significant genotypic differences in UFC, MC, or C12post.

Chromosomal identification of multiple HER-2/neu loci in an ovarian cyst. *M. Macera[1], W. Thelmo[2], A. Abdu[2], P. Chandra[3], F. Hristescu[1], A. Babu[1]* 1) Dept of Medicine, Div of Molecular Medicine & Genetics; 2) Dept of Pathology; 3) Dept of Medicine, Wyckoff Heights Medical Ctr, Brooklyn, NY.

A 71 year old female was admitted due to increasing abdominal girth for the last 2 months. Upon examination, no vaginal bleeding was observed. She had no previous operations or disease. A huge ovarian cystic mass filling up the pelvis and involving the omentum, weighing 2150 gms, was surgically removed. The uterus, right ovary and fallopian tube were negative for tumor. Cytogenetic analysis of the cyst, growing aggressively in culture, revealed only abnormal cells with a karyotype of: 56~58,X,-X,+ del(1p32), +2, +der(3)t(3;?)(q11:?), +6, +7, +8, +10, +10, i(13q), t(13;?)(p11;?), der(17), +20, +20, i(21q), -22, +2-4mar. FISH analysis revealed 2 copies of CCND1 and three copies of BCL6, with a signal on the der(3). On the der(17), two signals for D17Z1 were detected towards the distal ends, four HER-2/neu sites were identified along the length of the chromosome. The entire chromosome was positive for wcp 17 except for a small segment, which has not been identified. The der(17) can be described as: pterq11.1q25.3::q25.3q11.2::q11.2q25.3::q25.3q11.1:: ?, or der(17)dic(17)inv dup(q11.2q25.3)dup(q11.2q11.2)t(17:?)(q11.1:?) .ish(wcp17+, cep17x2, HER-2x4). Amplification of HER-2/neu, also found in ovarian cancer, is determined by a ratio of the number of copies of HER-2/neu to 17 centromers. Although HER-2/neu is over represented with additional copies in this case, imniohistochemistry staining on the histological section was negative. Some interphase nucli, with 3 centromere, showed more than 15 HER-2/neu copies. None of these were seen at mitosis. These cells appear to represent a second clone that was not observed in mitosis. Further investigation is underway. This study presents a novel cytogenetic mechanism contributing to multiple copies/amplification of HER-2/neu loci.

Analyses of gene and protein variations of Retinoic Acid Induced 1 (*RAI1*) in Smith-Magenis Syndrome. *T. Vilboux[1], A. C. M. Smith[3], A. Garcia[1], C. Ciccone[1], J. Blancato[2], W. Introne[3], W. A. Gahl[1,3], M. Huizing[1]* 1) NHGRI/MGB, NIH, Bethesda, MD; 2) Georgetown Univ, Washington, DC; 3) Office of Rare Diseases, OD, NIH, Bethesda, MD.

Smith-Magenis syndrome (SMS) is a complex developmental disorder involving variable symptoms such as mental retardation, craniofacial dysmorphia, height-growth delay, infantile hypotonia, brachydactyly, attention deficit, decreased sensitivity to pain, self-injury, maladaptive behaviors and sleep disturbance. Disrupted sleep patterns and behavioral problems characteristic of SMS could be related to an inverted diurnal rhythm of melatonin release. The prevalence of SMS is estimated to be 1/25000 but it is likely underdiagnosed. The syndrome is ascribed to a 2-9Mb interstitial deletion on chromosome 17p11.2. A small number of SMS patients lack any deletion, but carry dominant mutations in *RAI1* (*Retinoic Acid Induced 1*), which resides in the common deletion area. Individuals with mutated *RAI1* have many of the major features of SMS. *RAI1* function is unknown. It is highly conserved through mammalian evolution and appears to be a transcriptional regulator, likely involved in neuronal development. We analyzed *RAI1* and its involvement with the clinical features of SMS. We studied 10 patients with the SMS phenotype but without a common deletion, confirmed by FISH and copy number qPCR. We confirmed presence of two copies of *RAI1* in these patients and sequenced RAI1 exons and intronic boundaries for mutations. Multiple variants were found, including known SNPs, but also 3 unreported variants, 2 are amino-acid changing. We are analyzing the patients RNA, isolated from skin fibroblasts and/or lymphoblast cell lines, for variations in *RAI1* transcription or splicing. Next, we will determine RAI1 protein expression through Western blotting to detect variations in translation. Identifying new mutations and understanding how they affect *RAI1* can help to define the precise cellular function of this protein. Determining how a single mutation in *RAI1* can result in the varied clinical features of this disorder may also assist in understanding the pathways involved in craniofacial development, sleep and behavior.

Rank correlations among results of intra-familial tests of association for quantitative traits with low heritabilities. *H. Sung[1], J. E. Herrera-Galeano[1,2], A. J. M. Sorant[1], R. A. Mathias[1], A. F. Wilson[1]* 1) Genometric section, IDRB, NHGRI, NIH, Baltimore, MD; 2) Dept. of Medicine, Johns Hopkins Medical Institution, Baltimore, MD.

Several different methods are now available for testing for associations between quantitative traits and SNPs in family data. These methods use different kinds of information and have different strengths and weaknesses with respect to their statistical properties. In a study of platelet aggregation, Herrera-Galeano et al. [ASHG, 2007] used several different association methods and found little correlation between results. Computer simulation was used to investigate the lack of agreement among methods. Genetic Analysis Simulation Program (G.A.S.P. v3.3) was used to generate 10,000 samples, each with 200 nuclear families with sibship size three. A quantitative trait was simulated based on a single biallelic locus with equally frequent alleles. The underlying genetic model was additive and heritabilities considered included 0, 0.001, 0.005, 0.01, 0.05 and 0.1. The data availability was modeled as complete or 50% missing. Five tests of association were performed: ASSOC (SAGE), FBAT, GEE (SAS GENMOD), ROMP (Regression on Mid-Parent) and ROOP (Regression on One Parent). Pair-wise Pearson correlations of resulting p-values and pair-wise Spearman correlation using ranks of p-values were calculated. In general, pair-wise Spearman rank correlations have higher correlation than Pearson correlation. For example, with complete data and heritability equal to 0.01, Pearson correlation was as low as 0.03 (FBAT and GEE) but Spearman rank correlations were generally over 0.5. However, in general, different association tests did not agree well even in rank, except for ASSOC and GEE.

Medical and Social Obstacles to the Optimal Intake and Care of Patients with Neurofibromatosis Type 1. *C. M. Legendre, R. Drouin, C. Bouffard* Service of Genetics, Department of Pediatrics, Faculty of Medicine and Health Sciences, Université de Sherbrooke, Sherbrooke (Quebec) Canada.

With a prevalence of 1/3000 and an autosomal dominant mode of transmission in 50% of cases, neurofibromatosis type 1 (NF1) is one of the most common genetic diseases worldwide. Paradoxically and for undetermined reasons, it is still largely unknown to both the general public and health professionals. Thus despite its major impact on physical and psychological health and the importance of early diagnosis, NF1 is rarely diagnosed prior to the onset of complications or before affected individuals have had children. It would therefore appear important to better understand the factors that stand in the way of the optimal intake and care of NF1 patients. Methods: Analysis of the literature on the medical, psychological, ethical, and social aspects of neurofibromatosis; informal interviews: Association de la NF du Québec and NF Canada. Results: Late diagnosis of NF1 is often due to unawareness of the disease, which is indeed still confused with Proteus syndrome. Even when it is diagnosed, the consequences of the disease are often minimized. Thus patients are not consistently referred to a genetics service. When genetic counselling is offered, it is poorly adjusted to differences in age. In addition, the psychosocial consequences of adolescence and the onset of physical deformities, the impact of cultural representations on NF, and the absence of intergenerational dialogue are all, despite their significance, neglected by social scientists; and few studies have taken an interest in questions of reproduction and genetic counselling. Conclusion: This ignorance has serious repercussions on patients intake and care, quality of life, and reproductive decisions, and in particular on the development and physical, intellectual, and psychological health of children with NF1.

Genome-wide association study of plasma polyunsaturated fatty acids in the InCHIANTI study. *T. Tanaka[1,2], J. Shen[3], G. Abecasis[4], A. Kisialiou[2], J. M. Ordovas[3], D. Arnett[5], M. Y. Tsai[6], A. Singleton[7], S. Bandinelli[2], A. Cherubini[8], J. Guralnik[1], L. Ferrucci[1,2]* 1) Clinical Research Branch, NIA, Baltimore, MD, USA; 2) Geriatric Rehabilitation Unit-ASF, Florence, Italy; 3) Laboratory of Nutritional Genomics, USDA-HNRCA at Tufts University, Boston, MA, USA; 4) CSG Dpt. of Biostatistics, University of Michigan, Ann Arbor, MI; 5) SPH,Clinical Nutrition Research Center, University of Alabama at Birmingham, AL,USA; 6) Laboratory of Medicine and Pathology, University of Minnesota, MN,USA; 7) Laboratory of Neurogenetics-NIA,MD, USA; 8) University of Perugia, Dept. of Clinical and Experimental Medicine, Italy.

Polyunsaturated fatty acids (PUFA) have multiple physiological roles from substrates for energy production, inflammation modulators, and cell membrane components. High PUFA intake has beneficial effects on cardiovascular morbidity and mortality. To identify genetic contributors to plasma PUFA concentrations, we conducted a genome-wide association study on plasma levels of six omega-3 and omega-6 fatty acids in 1075 subjects of the InCHIANTI study. The first locus with the greatest significance was observed in a region of chromosome 11 with three fatty acid desaturases (FADS). The most significant SNP was rs174537 near FADS1 for arachidonic acid (AA; P=5.95x10-46). Homozygotes for the minor allele had 2.3%; lower AA compared to the homozygotes for the major allele and rs174537 accounted for 18.6%; of the additive variance in AA concentrations. Genome-wide significance was observed for this SNP for eicosadenoic acid (P=6.78 x 10-9) and eicosapentanoic acid (P=1.07 x 10-14). Subject carrying the allele associated with higher AA, EDA, and EPA also had higher LDL cholesterol and total cholesterol levels. The second most significant locus mapped to chromosome 6 encoding an elongase of very long fatty acids 2 (ELOVL2) was associated with eicosapentanoic acid (rs953413; P=1.1 x 10-6). These findings were replicated with an independent sample of 1076 subjects in the GOLDN study where fatty acids were quantified in erythrocyte membrane. Our findings may provide insight into the role of genetics on serum levels of fatty acids.

Modelling mutation and random variation in SNP data as a per-site uncertainty rate. *L. Moutsianas, G. McVean*
Statistics, University of Oxford, Oxford, United Kingdom.

Useful statistical models for capturing genetic variation should explain as much of the observed variability as possible, while retaining their computational tractability. Most widely used models today focus on effects of meiotic crossover and point mutations on genomic data. Many of these use a constant, site-independent mutation rate across extended genetic regions.

Given the confirmed variability of mutation effects across the human genome,we consider a site-dependent mutation rate as a more realistic representation of this biological process. Hence, we introduce a per-site uncertainty rate, not just to replace the site-independent mutation rate, but as an explanatory factor for possible genotyping errors or any other, not explicitly considered, source of genetic or random variation. Based on the imperfect mosaic idea, we have built a Hidden Markov Model which explicitly accounts for crossover and mutation effects. We then employ an Expectation - Maximization algorithm to estimate the per-site uncertainty rates which better explain the observed variation in the sampled data.

Results on data simulated from the coalescent show that our algorithm successfully identifies sites with artificially introduced variation, and assigns high uncertainty rates to them. Results on real data from the HapMap project show a slight improvement in allelic predictions, compared to these obtained using a uniform mutation rate, as well as a more marked one in calibration, especially for the sites with increased uncertainty rates.

Our method can be used to weight marker information from sources of variable quality. Moreover, it should be easily modifiable for use with different types of samples, such as whole sequence data. In addition, it can be extended so as to incorporate other sources of genetic variation, at the expense of increased computational complexity.

Expanded Catalog of eQTLs for Lymphoblastoid Cell Lines. *L. Liang[1], N. Morar[2], M. Moffatt[2], G. M. Lathrop[3], G. R. Abecasis[1], W. O. C. Cookson[2]* 1) Center for Statistical Genetics, Department of Biostatistics, School of public Health, Ann Arbor, Michigan 48109-2029, USA; 2) National Heart and Lung Institute, Imperial College London, London SW3 6LY, UK; 3) Centre National de Genotypage, 91057 Evry Cedex, France.

Gene expression levels can be an important step between DNA variation and phenotypic manifestations. Our initial map of global gene expression based on ~400K SNPs and ~50K transcripts in ~400 sib pairs using Affymetrix arrays helped interpret the results of GWAS for asthma, Crohns disease and Type 1 diabetes, among other traits. Here, we describe an expanded catalogue of expression QTLs (eQTLs), generated by examining (a) additional 550 sib pairs, (b) examining imputed HapMap SNPs and genotyped SNPs, (c) measuring gene expression with Illumina BeadChips. In agreement with our previous results, transcript levels for genes involved in immune response, signal transduction and cell adhesion are highly heritable. We identify significantly associated SNPs for 1,867 genes accounting for 3.5-62.6% of the variance in transcript levels. Analysis of imputed SNPs increases the number of genes mapped in *Cis* by 12.0% to 1,458. To validate the accuracy of imputed genotypes, we compared association results for imputed and genotyped SNPs at 58,268 SNPs (correlation between imputed and true LOD scores was 0.952). Surprisingly, only 17.7% of genes identified using Illumina arrays at $p<10^{-7}$ also show significant association in the Affymetrix data at a similar significance level. The overlap increases to 29.3% when we used a threshold of $p<0.001$ for the Affymetrix data. This expanded eQTL catalog emphasizes the importance of developing even more robust platforms for measuring gene expression and the utility of large datasets. In a preliminary scan of significant eQTL associations that are associated with hit-SNPs from published GWAS (www.genome.gov/gwastudies/), we find ~20 hits from the Affymetrix data and ~35 hits from the Illumina data. There is significant added value from including the Illumina platform and the two platforms provide complimentary information. Both the Illumina and imputation results will be available to the public.

Extending the spectrum of Ellis van Creveld syndrome: a large family with a mild mutation in the EVC gene. *H. Ulucan[1,2], D. Gül[3], J. C. Sapp[1], J. Cockerham[4], J. J. Johnston[1], L. G. Biesecker[1]* 1) Natl Human Genome Res Inst, NIH, Bethesda, MD, USA; 2) Adnan Menderes University Medical Faculty, Department of Medical Genetics, Aydin, Turkey; 3) Gulhane Military Medical Academy, Department of Medical Genetics, Ankara, Turkey; 4) Childrens National Medical Center, Department of Cardiology, Washington, DC, USA.

Ellis-van Creveld (EvC) syndrome is characterized by short limbs, short ribs, postaxial polydactyly, dysplastic nails and teeth and is inherited in an autosomal recessive pattern. We report a family with complex septal cardiac defects, rhizomelic limb shortening, and polydactyly, without the typical lip, dental, and nail abnormalities of EvC. The phenotype was inherited in an autosomal recessive pattern, with one instance of pseudodominant inheritance. Because of the phenotypic overlap with EvC, microsatellite markers were used to test for linkage to the EVC/EVC2 locus. The results did not exclude linkage, so samples were sequenced for mutations. We identified a c.1868TC mutation in EVC, which predicts p.L623P, and was homozygous in affected individuals. We conclude that this EVC mutation is hypomorphic and that such mutations can cause a phenotype of cardiac and limb defects that is less severe than typical EvC. EVC mutation analysis should be considered in patients with cardiac and limb malformations, even if they do not manifest typical EvC syndrome.

Accounting for Disease Model Uncertainty in Mapping Heterogeneous Traits - A Bayesian Model Averaging Approach. *S. Biswas* Department of Biostatistics, School of Public Health, University of North Texas Health Science Center, Fort Worth, TX.

Locus heterogeneity is a ubiquitous feature of complex genetic traits. It refers to the situations when a disease can be caused in different individuals by different genes and/or environmental factors. Recently, a Bayesian approach has been proposed to account for variable rates of heterogeneity across families in a parametric linkage analysis setup (Biswas and Lin, 2006; Journal of the American Statistical Association). As is the case with any parametric approach, its application requires specification of disease model (disease allele frequency and penetrances), which limits its practical utility. To address this limitation, we propose a Bayesian Model Averaging (BMA) approach. We implement BMA in the Bayesian framework proposed by Biswas and Lin (2006) by considering a finite number of disease models and treating model as an unknown parameter with a finite number of categories. In practice, for all our applications we use simple single-locus disease models such as dominant, recessive, and intermediate as various categories for disease model. We first conduct a simulation study wherein true disease models are single-locus models generated under heterogeneity. We show using various simulation scenarios that BMA approach retains at least 80% of the power that is obtained by analyzing under the true disease model. Next we investigate the properties of BMA when the true model is extremely complex consisting of multiple interacting loci. For this, we analyze all 100 replicates of Genetic Analysis Workshop 13 simulated data that were generated to mimic the real data from Framingham Heart Study. Similar results were obtained. This shows that the proposed BMA approach utilizing simple single-locus models for analysis and averaging is effective for mapping heterogeneous traits.

Intracerebroventricular delivery of copper for the treatment of a murine model of Menkes disease. *A. Donsante*[1], *L. Brinster*[2], *S. Lal*[3], *J. A. Centeno*[3], *S. Kaler*[1] 1) UPG, NICHD; 2) DVR, NIH, Bethesda, MD; 3) DPT, AFIP, Washington, DC.

Menkes disease (MD) is a genetic copper deficiency that strikes male infants early in life, resulting in neurodegeneration, seizures, loss of early neurodevelopmental milestones, and premature death. Biochemically, MD is characterized by low concentrations of copper in blood and brain, reflecting impaired transport across the gastrointestinal epithelium and the blood-brain barrier, respectively, due to mutations in an evolutionarily conserved copper transporter, ATP7A. Current treatment is limited to daily subcutaneous copper injections for the first three years of life and is especially effective in patients with mutant alleles that possess some copper transport capacity (N Engl J Med 2008 358:605-614). For patients with complete loss of function mutations, e.g., large deletions, alternative treatment approaches are needed to optimize neurodevelopmental outcomes. We examined the efficacy of direct central nervous system treatment in a murine model of classical Menkes disease, atp7amo-br, caused by a six base deletion in atp7a. We developed a genotyping assay that identified mutant pups at birth prior to clinical manifestions and administered one-time, bilateral intracerebroventricular (ICV) injections of copper chloride (50 ng total) on or before 3 days of age. The dose was extrapolated from the maximum tolerated dose we determined previously in adult rats (Molec Genet Metab 2007 91:30-36). Treatment increased the amount of copper in the brains of mutant mice from 1600 parts per billion (ppb) to 4200 ppb (untreated normal male littermates: 9100 ppb). Neuronal histopathology between treated and untreated mutant pups was comparable, although treatment extended the lifespan of mutant males by 7% [13.3 days untreated (n=9) vs. 14.3 days treated (n=13); p0.05]. These data indicate that ICV adminstration of copper results in distribution of copper throughout the atp7amo-br brain and increases total brain copper levels. While dose refinement may be needed to optimize outcomes, ICV copper administration ultimately may be a useful approach for rescue of the atp7amo-br mouse, and ultimately for treating classical Menkes patients with severe mutations.

Germline mutation of *SMARCB1* is associated with both syndromic and non-syndromic atypical teratoid rhabdoid tumors (ATRT). *F. Bernier[1], O. Caluseriu[1], E. Payne[2], L. Lafay-Cousin[2,3], D. Strother[2,3], M. Somerville[4], B. McInnes[1]* 1) Department of Medical Genetics, Calgary, AB, Canada; 2) Deparment of Pediatrics, Calgary, AB, Canada; 3) Department of Oncology, Calgary, AB, Canada; 4) Department of Medical Genetics, Edmonton, AB, Calgary.

Atypical teratoid rhabdoid tumors (ATRT) represent 1-2% of pediatric brain tumors. Germline mutation of *SMARCB1/INI1*, a tumor suppressor, results in early predisposition to ATRT as well as multiple schwannomatosis. We present two new patients with ATRTs with different clinical presentations and mutational mechanisms. Patient 1 is male first seen at 11 months of age for dysmorphic features including plagiocephaly, subtle hemifacial microsomia, a hypoplastic right ear, bilateral preauricular skin tags and a left eye epibulbar dermoid cyst and on the basis of these features was diagnosed with Goldenhar syndrome. At 12.5 months of age he presented with neurological deficits due to a large intraaxial mass in the left frontal lobe. Pathology identified a possible glioblastoma multiforme but rhabdoid features and negative immunohistochemical staining for INI1 confirmed a diagnosis of ATRT. FISH in both tumor tissue and cultured skin fibroblast showed a hemizygous deletion of the BCR locus and MLPA confirmed the presence of a constitutional deletion spanning the INI1 locus between markers LZTR1 and SNRPD3 (minimum size of 2.37Mb, maximum of 3.6Mb). Patient 2 is a non-dysmporphic male who presented at 14 months of age with increased head circumference, irritability, and focal neurological signs. A CT scan revealed a mass extending from the 3rd ventricle into the lateral ventricles and hydrocephalus. Tumor pathology and INI1 immunohistochemistry were again consistent with an ARTR. Sequence analysis of SMARCB1 identified a mutation (c.805delC) in exon 7. These patients highlight the need to perform careful clinical and molecular investigations of patients with ATRTs in order to identify the molecular mechanism. In addition this is the second case of a patient with Goldenhar syndrome and microdeletion in the 22q11 region further supporting that this genomic region is a candidate region for Goldenhar syndrome.

Whole genome scan of salt-sensitivity and response to diuretic treatment in essential hypertension. *C. Barlassina[1], C. Cosentino[1], L. Citterio[3], C. Lanzani[3], L. Zagato[3], N. Casamassima[3], M. Simonini[3], E. Salvi[1], F. Torri[1], S. Lupoli[4], P. Manunta[3], G. Bianchi[3], L. Milanesi[5], F. Macciardi[1], D. Cusi[1,2]* 1) Sci & Biomedical Technol, Milan Univ, Milan, Milan, Italy; 2) Division of Nephrology, San Carlo Borromeo Hospital, Milan; 3) Nephrology, Dialysis and Hypertension, Vita-Salute San Raffaele University, Milan; 4) INSPE San Raffaele Scientific Institute Milan; 5) ITB. CNR, Milan.

Introduction: Hypertension is caused by a primary increase of kidney Na reabsorption in at least a subgroup of essential hypertensive patients (EH), also if the underlying genetics is far from being clarified. We addressed this issue with a GWA study in two experimental settings: 1) acute Na-sensitivity test and 2) chronic diuretic treatment. Methods: Illumina HumanHap 300-Duo BeadChips. Plink used for quality control of genotype data, single marker quantitative association and permutations. 1) 326 EH infused with 2L saline i.v. in 2 hrs, after 2 weeks of controlled Na intake (150 mMol/24h), BP recorded over the infusion and recovery (2 more hrs). Phenotype: the difference between mean BP at baseline and after 2 hrs of recovery. 2) 177 EH treated with 25 mg Hydrochlorothiazide UID as monotherapy for 2 months. BP measured throughout the treatment period. Phenotype: the difference between basal mean BP and mean BP after 2 months treatment. Results: 1) 98.3% of SNPs passed QC (mean individual call rate 98.4%). Significant association (p=8x10^-5) was found for SNP rs12064256 in NECAP2 a gene involved in the endocytosis process and expressed in the kidney. It is intriguing to remark that cells expressing the alpha-adducin 460Trp allele display reduced Na/K pump endocytosis as a major pathogenetic event of Na-sensitivity. 2) 99.4% of SNPs passed QC (mean individual call rate 98.8%). Significant association (p=4x10^-5) was found for SNPs rs1531916 in SLC12A1 the kidney specific bumetanide sensitive Na-K-Cl cotransport (2 more SNPs significant within the same gene at p 10^-5). These findings suggest that SLC12A1 may harbor a mutation involved in Na/volume-dependent hypertension.

The power of a multivariate trait-specific test for linkage in complex disorders with multiple quantitative traits.
S. Han, J. Chang Statistics, Yale University., New Haven, CT.

This paper compares a multivariate trait-specific test to a univariate and a more traditional multivariate joint null hypothesis test for detecting linkage for complex disorders with multiple quantitative traits. Multivariate joint null hypothesis tests, which test the effect of a main gene on multiple traits simultaneously, have been found to be more powerful than univariate tests by several studies so far. However,some recent papers have also reported decreased significance using this test, when including a large number traits (3) in multivariate models. A multivariate trait-specific test, proposed by Marlow et al., drops a single variance parameter to test the marginal effect of a main gene on a given trait, in the presence of other traits in a multivariate model. Although this test has been successfully applied to data by several other papers, no systematic evaluation of this test has yet been performed. We first establish the asymptotic null distribution of the multivariate trait-specific test, which needed to be clarified in view of the nonstandard boundary conditions inherent in variance components testing in this multivariate model. We show that the asymptotic null distribution is a chi-square with one degree of freedom regardless of the number of traits in the model. Then we investigate the power of this test, comparing it to both univariate and multivariate joint null hypothesis tests. To characterize the power of all of tests being compared, we show how to evaluate their noncentrality parameters. We find that the noncentrality parameter of the multivariate trait-specific test for a given trait is a function of the genetic effects on the other traits in the model as well as the genetic effects on the given trait and correlations among these effects. Increasing the number of traits in the model having small genetic effect sizes substantially lowered the power of the multivariate joint null hypothesis test due to the sharp increase of its critical values, while the multivariate trait-specific test, with critical values remaining constant over the increase of the number of traits, was less vulnerable to losing its power.

Weaver syndrome (WSS): NSD1 sequence variations, phenotypic spectrum, and natural history, in five new patients. *M. Giovannucci Uzielli, M. Ottaviani, S. Guarducci, E. Lapi, G. Scarselli, L. Giunti* Dept. of Paediatrics, Genetics and Molecular Medicine, University of Florence, 13 Via Luca Giordano, 50132 Florence, Italy.

In 1974, Weaver et al. described two unrelated children with accelerated growth, advanced bone age and a characteristic facial appearance. The disorder subsequently became known as the Weaver-Smith syndrome (WSS): it is characterized by the same clinical features as Sotos syndrome (SS) and other overgrowth disorders (pre-natal and post-natal overgrowth during childhood, development delay, and advanced bone age), but has its own distinctive facial gestalt, and other peculiar features. The range of clinical features associated with WSS is broad and the phenotype is especially characteristic at the facial, fingers, and knee levels. More than 100 distinct intragenic mutations in NSD1 have been identified. NSD1 gene microdeletions or intragenic mutations are present in 60-80% of SS, whereas intragenic mutations are associated with less than one on three WSS subjects. All our patients show broad forehead, round face in infancy, hypertelorism, prominent and large philtrum, micrognathia, with everted lower lip, rounded cheeks, large ears, large hands with deep-set nails and camptodactyly, progressively overriding toes. Flexion at knee level, and limitation of elbow joints extension, are obvious since the infancy. Progressive scoliosis is a constant feature. Variable delays in cognitive, language, and motor development are also observed in all our patients, at any age. No biochemical or endocrinological markers, no cytogenetic abnormalities have been documented in any of the five subjects. We identified 12 new different NSD1 sequence variations in our five, new non-related patients with typical WSS clinical phenotype. Molecular analysis in parents of patients is in progress, in order to better define the nature of the NSD1 sequence alterations.

A Rare Familial Duplication of Xp22.31 that Adds to Characterization of Phenotype-Genotype Correlations of the Short Arm of the X Chromosome. *N. Shur[1, 2], M. Vecchiotti[1, 2], K. Reddy[3], S. Gunn[3], D. Abuelo[1,2]* 1) Hasbro Children's Hospital, Lifespan, Providence, RI; 2) Warren Alpert Medical School of Brown University, Providence, RI; 3) Combimatrix Molecular Diagnostics, Irvine, CA.

Background: Duplications on the short arm of the X chromosome have been rarely reported in males with variable mental retardation (MR) and dysmorphism. Female duplication carriers have been described as normal. Clinical characterization and stratification of affected males, based on aCGH, has initiated the process of phenotype-genotype mapping of the Xp arm. We report a novel familial Xp22.31 duplication, which is likely a reciprocal duplication to the STS deletion, frequently involved in the XX sex reversal exchange between the X and Y chromosomes. Since the duplication is in a highly recombinant region, it may be more common than previously suspected. Case report: Our patient was referred at the age of 3 ½ years because of dysplastic pinnae and behavioral problems, which were increasingly noted during his second year. On physical examination, his head circumference was 52.5 cm (25-50%); weight was 39.5 lbs (less than 3rd percentile); and height 36 cm (< 3rd %). He had short stature, a prominent forehead, simple ears, and hypernasal speech. Velopharyngeal insufficiency was confirmed by videofluoroscopy. A developmental evaluation demonstrated difficulties in fine motor skills and sensory processing. A genetic etiology was suspected: oligoarray on the 44k platform revealed a gain of ~1.5Mb. The genes included in the duplication were VCX3A, HDHD1A, STS, VCX and PNPLA4. The mother was found to be a carrier of the same duplication. Discussion: Previously, cases of males with Xp duplications who had abnormalities were found to be in association with known MR genes on Xp. The genes duplicated in our case (VCX3A, HDHD1A, STS, VCX and PNPLA4) have not been well-characterized, aside from an association of VCX3A with X-linked MR in just one study. We report a novel familial Xp duplication in a patient with sensory processing issues, behavioral problems, and dysmorphic features. Thus, our case offers further insight into the role of various genes on the short arm of the X chromosome.

Modeling ancestry in structured populations using spectral analysis. *K. Roeder, A. Lee, D. Luca* Dept Statistics, Carnegie Mellon Univ, Pittsburgh, PA.

Data for genome-wide association studies are being collected for a myriad of phenotypes. Many of these studies do not include control samples selected to reflect ancestry similar to the case samples. Large "control databases" are becoming available to be utilized as a common resource. How to couple case and control databases effectively is a pressing question. Dissecting ancestry based on principal component analysis (PCA) is the traditional approach to summarizing patterns of ancestry, but a number of problems can arise. PCA is quite sensitive to outliers and fails to detect the key axes of variation when spurious data are present. Moreover, if the sample is ascertained from individuals of disparate ancestries, PCA detects the major axes of variation, but often fails to detect subtle ancestry, such as gradients, present within clusters. As an alternative to PCA, spectral analysis can overcome many of these obstacles. We develop a statistical method to find the axes of genetic ancestry that is not sensitive to outliers and that also discovers major and subtle substructure. We apply these methods to several GWA studies to illustrate the approach in practice.

Characteristics of the Affymetrix 500K GeneChip in African Americans. *L. K. Vaughan[1], A. Patik[1], K. Zhang[1], H. K. Tiwari[1], U. Broeckel[2], D. K. Arnett[3]* 1) Dept Biostatistics, Univ Alabama at Birmingham, Birmingham, AL; 2) Medical College of Wisconsin, Milwaukee, WI; 3) Department of Epidemiology, University of Alabama at Birmingham, Birmingham, AL.

Recent advances in genotyping have opened the door for large scale genome-wide association (GWA) studies to become a powerful tool in the attempt to elucidate the genetic factors underlying complex diseases. Current genotyping platforms have provided valuable information on the genetic architecture of the HapMap populations and their coverage, or ability to capture genetic variation, has been well studied. However, there is little information on the performance of the current genotyping platforms in non-HapMap populations such as African Americans (AA). In such populations coverage cannot be directly estimated. Instead other characteristics such as allele frequencies, linkage disequilibrium, transferability and haplotype structure can be used to evaluate the performance of these platforms in populations other than those represented in the HapMap. We provide a comparison of these characteristics of the Affymetrix 500K GeneChip in the Yoruban (YRI) HapMap individuals with those from an AA population. Although, tagSNPs chosen from the YRI sample are highly portable to the AA population with an average of 93% of the variation in the AA sample captured using YRI tagSNPs, the AA and YRI populations are notably different in terms of the number of mono-allelic markers (0.64% vs 6.62%) and mean r^2 (0.2389 for AA and 0.2528 for the YRI (P 0.0001)). Haplotype analysis also illustrated marked differences between the populations with approximately 60,000 haplotype blocks identified in AA and 50,000 in YRI, with a mean number of SNPs of 6.998 and 8.312 respectively (significantly different at P 0.0001). The average length of the haplotype blocks was also different, with AA haplotypes being shorter (36.2 vs. 44.3 kb) than YRI. Based on our analysis, we expect that the 500K GeneChip will perform as well, if not better, in African Americans when compared to the Yoruban HapMap individuals. This difference may be due in part to the higher coverage for the European component of AA ancestry.

Adsorption of proteins analysis on chemical modified alginate-based capsules for cellular gene therapy. *F. Shen[1], R. Cornelius[1], M. Mazumder[2], J. Brash[1], H. Stover[2], M. Potter[1]* 1) Pathology & Molecular Medicine, McMaster University, Hamilton; 2) Chemistry, McMaster University, Hamilton.

Calcium alginate hydrogel beads layered with poly-L-lysine (PLL) and alginate (APA capsules) for immunoisolation of genetic cells secreting therapeutic proteins have been applied in the treatment of mouse models of disorders such as dwarfism, lysosomal storage diseases, and hemophilia. However, the reliance on calcium cross-linking for capsule stability limits their application for long-term human use. Therefore, incorporation of a covalently cross-linked network in alginate-based capsules was developed. We used a polyanion (designated A70) in the capsules, either as part of the core alginate bead (designated composite capsule) or as part of the coating process (designated layer-by-layer capsule), to react with the polycaton layer (PLL or C70) to form a covalent polymer network. Changes in the chemical composition of capsules were assessed for their effect on biocompatibility, an important component of which is binding of possible immunogenic or pro-inflammatory proteins. The adsorption of proteins from human plasma to the capsule was analyzed using SDS-PAGE and immunoblotting techniques. In this study, four kinds of capsules were investigated: A) APA capsules; B) high PLL APA capsules; C) layer-by-layer capsules; and D) composite capsules. Capsules were incubated in human plasma, and then rinsed 16 times with normal saline before treatment with sodium dodecyl sulfate solution to extract the bound proteins. SDS-PAGE and immunoblotting for 21 different proteins showed that the major species adsorbing to all the capsules were albumin, transferrin, IgG , prothrombin, C3, and vitronectin. However, capsules B and D had higher protein bound. The ratio of total protein bound A:B:C:D was 2:3:2:10. These results suggest that increasing PLL content of the capsules leads to a quantitative increase in bound protein. This model of protein adsorption will be a useful in vitro screening test to identify potentially problematic protein interactions before in vivo studies are conducted.

Prospective evaluation of kidney function in Autosomal Recessive Polycystic Kidney Disease/Congenital Hepatic Fibrosis (ARPKD/CHF). *M. Gunay-Aygun[1,2], L. Lukose[1], K. Drayanani[3], J. Graf[3], J. Bryant[1], A. Garcia[1], D. Adams[1], E. Johnson[1], L. Guay-Woodford[4], P. Choyke[5], W. A. Gahl[1,2]* 1) Section on Human Biochemical Genetics, Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Intramural Program of the Office of Rare Diseases, DHHS, Washington, DC; 3) NIH Clinical Center, Bethesda, MD; 4) University of Alabama, Birmingham, Al; 5) Molecular Imaging Program, NCI, Bethesda, MD.

The effectiveness of targeted therapies (vasopressin 2 receptor inhibitors, somatostatin analogs, mTOR (mammalian Target Of Rapamycin) inhibitors, src-inhibitors) in preventing progression of kidney and/or liver disease in animal models of PKD/CHF highlights the importance of identifying disease-specific outcome parameters. In ADPKD, kidney volume is useful as an outcome parameter as it correlates negatively with glomerular function. Such data are not available for ARPKD/CHF, which differs from ADPKD with regard to its age of onset, and the nature of the kidney and liver disease. Between November 2003 and August 2008, we prospectively evaluated 85 probable ARPKD/CHF patients at the NIH Clinical Center (ClinicalTrials.gov, number, NCT00068224). We analyzed the cross sectional and longitudinal data of the 65 patients with at least one mutation in PKHD1, some followed for up to 5 years. Kidney volume in ARPKD/CHF was increased at birth; however, the rate of increase was much slower than for ADPKD. The weighted mean rate of decline in creatinine clearance was 4.0 ml/min/1.73m2 per year; in contrast to ADPKD, this decline rate did not increase with age or kidney volume. Glomerular dysfunction and the urinary concentration defect were significantly worse in patients with both medullary and cortical involvement compared to those with cystic changes limited to the renal medulla. Serum vasopressin was elevated despite dilute urine suggesting resistance to vasopressin. Longer follow up of more ARPKD/CHF patients, along with safety and efficacy data from the ongoing treatment trials on adults with PKD, should enable us to design future therapeutic trials for ARPKD.

Paternal uniparental disomy for the X chromosome causing homozygosity for a large *FMR1* premutation in a female with recurrent miscarriages. *K. J. Friedman[1], E. M. Williams[2], B. L. Williford[4], K. G. Schoch[2], L. L. Oliviero[3], J. H. Tepperberg[4], P. R. Papenhausen[4]* 1) Mol Genetics/CMBP, LabCorp, RTP, NC; 2) Genetic Services/CMBP, LabCorp, RTP, NC; 3) NJ Perinatal Assoc, St Barnabas Med Ctr, Livingston, NJ; 4) Cytogenetics/CMBP, LabCorp, RTP, NC.

Fragile X gene (*FMR1*) premutations are implicated in female reproductive deficits. A 27 year old female with recurrent miscarriages was evaluated for both cytogenetic and *FMR1* abnormalities. A single FMR1 premutation allele of 127 CGG repeats was detected by both PCR and Southern blot. Turner syndrome was ruled out by a normal karyotype as well as the absence of compatible clinical findings. An assessment of consanguinity was addressed by family studies. The patients father is mosaic for premutation alleles of 105 and 136 repeats, while her mother carries two normal range alleles of 20 and 39 repeats. The patients healthy brother received 39 repeats, while a younger sister with a "strange affect" is a premutation carrier, with alleles of 20 and 115 CGG repeats. All have normal karyotypes. The possibility of a small *FMR1* gene deletion on a maternally derived X was evaluated with a comparative genomic hybridization (CGH) array which interrogates 607 submicroscopic loci, including one locus within the Fragile X gene. No deletion was detected. In the absence of consanguinity or detectable chromosomal abnormalities, uniparental disomy studies were performed. Six microsatellite markers on the X were studied. Two markers (DXS559 at location Xq12, and DXS1062 at Xq26) confirmed the absence of a maternal X contribution. A second whole genome copy number cytogenetic array analysis targeting 262,000 single nucleotide polymorphism (SNP) sites (Affymetrix; array also measures DNA dosage at each locus) was performed. The patient had normal dosage at each locus, with complete homozygosity at all loci evaluated, in contrast to the 38% heterozygosity that is typically seen. These data taken together suggest her X chromosomes are paternal duplicates. This paternal uniparental isodisomy for the X likely resulted from paternal meiosis II non-disjunction error (duplicate X) in conjunction with maternal X chromosome loss.

Accurate and Flexible Power Calculations on the Spot for any study design. *H. Tiwari[1], T. Birkner[1], A. Moondan[2], S. Zhang[3], G. Page[1], D. Allison[1,4]* 1) Department of Biostatistics, Section on Statistical Genetics, Univ Alabama at Birmingham, Birmingham, AL; 2) Indian Institute of Technology, New Delhi, India; 3) Department of Statistics, Texas A&M University, Kingsville, TX; 4) Clinical Nutrition Research Center, Univ Alabama at Birmingham, Birmingham, AL.

Often we need to calculate power to demonstrate feasibility of any genetic study for a proposal to NIH or other government agency. Also, power is an essential tool to show superiority of a particular test statistic used in a method over other available methods. There are many tools available to calculate power based on closed formulae following asymptotic theory where the null distribution follows known distribution and the inverse of the distribution can be easily derived. However, in some situations it may not be feasible to derive a closed formula due to the distribution of test statistic follows either a mixture of distribution or unknown distribution and in these situations inverse of the density function may not be possible. In these situations investigator need to perform simulations specific to the study with given parameters such as sample size, mode of inheritance, allele frequency of the disease and marker, etc. In general, most of the investigators depend on collaborators with expertise in statistical genetics either from their own institute or assistance from collaborators from other institutes to perform the simulations to estimate power. In addition, the simulations could be computationally extensive as well as time consuming and could take several weeks to months depending on the nature of the study and may not be available before the proposal deadline. In this manuscript, we provide a simple method to estimate power based on asymptotic theory using other available studies similar to the study of interest to the investigator.

Utilization of high resolution genome-wide oligonucleotide microarrays to detect copy number variations. *M. Nimmakayalu[1], H. Major[1], Q. Qining[1], R. Van Rhedeen[1], D. Hulseberg[1], V. C. Sheffield[1], P. L. Nagy[2,3], S. R. Patil[1]* 1) Dept. Pediatrics, Div. Medical Genetics,; 2) Dept.Pathology; 3) Dept. Biochemistry Univ. Iowa Hospitals & Clinics, Iowa City, IA.

We validated the 385,000 feature comparative genomic hybridization (CGH) oligonucleotide array from Nimblegen-Roche on patients referred for genetic disorders. The array has oligonucleotides representing genes and intragenic regions with an average spacing of 6000bp. The validation studies identified all known macro and micro deletions/duplications and also found 3 novel changes not previously detected with routine karyotyping. These changes were subsequently confirmed by alternative methods. Since the introduction of this platform, we have tested in excess of 124 cases. We found genomic copy number variations (CNVs) not previously described in the normal population in approximately 20% of the cases. Of these, less than half represented changes characteristic of known clinical syndromes while the rest consisted of CNVs not previously described. The smallest deletion detected was 100kb where as the smallest duplication seen was 400kb. Further testing of these cases with the 2.1 million feature array will allow us to precisely identify breakpoints and to design PCR primers to test the parents material for the corresponding changes as well as predisposing inversions. We will present the de novo CNVs found and propose that they represent rare disease associated variants.

Novel MTM1 mutation in a child with myotubular myopathy: Clinical observations with survival to 24 months.

S. Demsey[1], R. Hassan[1,2] 1) Dept of Genetics, Kaiser Permanente Medical Ctr, Bellflower, CA; 2) Dept of Genetics, Kaiser Permanente Medical Ctr, Downey, Ca.

Myotubular myopathy is a heterogeneous disorder characterized by hypotonia, muscle weakness and respiratory distress. The clinical spectrum ranges from a severe neonatal presentation with early death to a mild phenotype with survival up to many decades of life. We report a male infant born at 30 weeks gestation via Caesarean section secondary to premature rupture of membranes, breech presentation, oligohydraminos and a non-reassuring fetal heart rate to a 30 year old primigravida. At birth, the child weighed 1420 grams, did not spontaneously breathe and was intubated and ventilator dependent for first 78 days of life. Extensive metabolic workup, karyotype, DNA methylation testing for Prader-Willi and SMA1 mutation testing was normal. Ultrastructural analysis of skeletal muscle biopsy at 6 months of age revealed a centronuclear myopathy, consistent with myotubular myopathy.

Sequence analysis of MTM1 revealed a transition in exon 13 (c.1388 TC) resulting in substitution of tryptophan for a conserved leucine residue at position 463 (p. L463W). The mother was found to be a carrier of this same previously unreported mutation.

The child is currently 2 years old and has tracheostomy and gastrostomy tubes in place. He has been affected by recurrent pneumonia, is non-ambulatory, nonverbal and requires intermittent ventilator use. His trunk, head, gross and fine motor skills have improved over the course of the last year and he now sits unsupported, has some scooting ability and uses 25 hand signs for communication. The clinical picture of this child with a novel mutation adds to the genotype/phenotype correlation in this disease.

Genome-wide association meta-analysis of 32,000 individuals and replication in 58,000 individuals identifies novel genetic variants associated with body mass index. *C. J. Willer[1], E. K. Speliotes[2], R. J. F. Loos[3], S. Li[3], I. M. Heid[4], C. M. Lindgren[5], GIANT Consortium* 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Medical Research Council Epidemiology Unit, Institute of Metabolic Science, Cambridge, UK; 4) German Research Center for Environmental Health, Neuherberg, Germany; 5) Wellcome Trust Centre for Human Genetics, Univ Oxford, Oxford, UK.

Obesity is a major and growing public health problem worldwide, resulting in increased morbidity, mortality, and severe economic burdens on health care systems and for individuals. To date, only two common variants (in FTO and near MC4R) have been shown convincingly to impact body mass at the population level. We first conducted a meta-analysis of association results between body mass index (BMI) and ~2.4 million imputed or genotyped SNPs from 13 genome-wide association studies including 32,615 individuals from Germany (KORA), Sweden and Finland (DGI, FUSION), the USA (PLCO, NHS), the UK (WTCCC-T2D, WTCCC-HT, WTCCC-CAD, BC58, NBS and GEM-EPIC), Switzerland (CoLaus), and Italy (SardiNIA). We then attempted replication of 39 promising signals in European-ancestry samples from 14 independent studies (N58,000). Meta-analysis of all GWA and follow-up association results strongly confirms association of FTO ($p = 1 \times 10^{-42}$) and MC4R ($p = 8 \times 10^{-19}$) and identifies six novel loci strongly associated with BMI ($p<10^{-7}$). Non-synonymous SNPs or copy number variants suggest the identity of likely causal genes in several loci, and many of these likely causal genes are highly-expressed in the central nervous system (CNS), including the homologue of a gene implicated in obesity in mice (SH2B1, $p=2\times10^{-10}$, N=83,020), a neuronal growth regulator (NEGR1, $p=6\times10^{-8}$, N=83,660), and a mitochondrial carrier protein (MTCH2, $p=3\times10^{-8}$, N =71,277). Furthermore, it is known that alterations of expression of MC4R and SH2B1 are associated with eating-related phenotypes and that expression of FTO is regulated by feeding and fasting. These results suggest that, as in rare monogenic forms of obesity, the CNS plays a key role in regulation of body mass and common forms of human obesity.

Genome-wide association study of blood pressure in African Americans and Nigerians. *B. Tayo[1], G. Lettre[2,3], S. Kang[4], H. Lyon[2], A. Luke[1], A. Adeyemo[5], C. Rotimi[5], J. Hirschhorn[2,3], X. Zhu[4], R. Cooper[1]* 1) Prev Medicine & Epidemiology, Loyola Univ, Chicago, Maywood, IL; 2) Childrens Hospital Boston, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) Case Western Reserve University, Cleveland, OH; 5) NIH Intramural Center for Genomics and Health Disparities, Bethesda, MD.

Hypertension shares similar heritability with many other traits related to cardiovascular risk, however identifying the genetic variants involved in the etiology of high blood pressure has been difficult. To identify genetic variants influencing high blood pressure among individuals of African origin, we conducted genome-wide association study of systolic and diastolic blood pressure in two separate samples of 735 African Americans and 900 Nigerians without history of use of high blood pressure medication at the time of study recruitment. Association analyses were performed without and with adjustment for sex, age and BMI in both samples, and included 857,989 and 792,581 SNPs genotyped on Affymetrix Genome-Wide SNP array 6.0 in the African-American and Nigerian samples, respectively. Some of the significant (P<1.0E-5) BP-associated variants in these Afro-origin populations are located on known genes such as SLC12A8 and TRERF1 while others are found in regions not yet annotated. Our results present evidence of significant association of BP with a number of genetic variants in regions across the human genome.

Mutations in *TMPRSS6* Cause Iron-Refractory, Iron Deficiency Anemia. *K. E. Finberg[1], M. M. Heeney[2], D. R. Campagna[3], M. D. Fleming[3], N. C. Andrews[4]* 1) Dept Pathology, Duke Univ Med Ctr, Durham, NC; 2) Div Hematology/Oncology, Children's Hosp Boston, Boston, MA; 3) Dept Pathology, Children's Hosp Boston, Boston, MA; 4) Depts Pediatrics and Pharmacology & Cancer Biology, Duke Univ Med Ctr, Durham, NC.

We and others have ascertained kindreds in which multiple individuals exhibit iron deficiency anemia unresponsive to oral iron therapy but partially responsive to intravenous iron, a phenotype we term Iron-Refractory, Iron Deficiency Anemia (IRIDA). Using a positional candidate approach, we have found that IRIDA is caused by mutations in *TMPRSS6*, located at 22q12.3, which encodes a type II transmembrane serine protease primarily expressed by the liver. Sequence analysis of *TMPRSS6* coding regions and intron/exon boundaries revealed frameshift, nonsense, splice junction, and non-conservative missense mutations in 5 multiplex IRIDA kindreds and 2 sporadic IRIDA cases; the disease-associated variants were absent in public SNP databases and in 100 control chromosomes. In 3 of these 5 multiplex kindreds, we identified biallelic mutations; however, in affected individuals from the 2 other kindreds (which were compatible with linkage to 22q12.3), a single heterozygous mutation was identified. In these 2 kindreds, *TMPRSS6* 5 and 3 UTR sequences and *TMPRSS6* exon copy number, as assessed by multiplex ligation-dependent probe amplification, were normal, suggesting that the parental chromosome 22 on which a *TMPRSS6* mutation was not detected harbors a genetic alteration outside of the *TMPRSS6* coding and UTR regions that results in impaired TMPRSS6 function. Urinary levels of hepcidin, a peptide hormone produced by the liver that downregulates intestinal iron absorption and macrophage iron release, were inappropriately elevated in 5 IRIDA cases from 3 kindreds examined, suggesting that TMPRSS6 normally functions to downregulate hepcidin expression. In summary, our results reveal a novel regulatory role for TMPRSS6 in systemic iron homeostasis in humans. Clinical testing for *TMPRSS6* mutations may be complicated by the existence of genetic alterations outside of the coding and 5 and 3 UTR regions in some IRIDA cases.

Association and homozygosity mapping for loci contributing to type 2 diabetes on the Pacific island of Kosrae. *J. B. Maller[1,2,3], J. K. Lowe[1,2,4], B. M. Neale[1,2,5], J. Salit[4], J. L. Breslow[4], M. Stoffel[4], M. J. Daly[1,2,6], D. M. Altshuler[1,2,6], J. M. Friedman[4,7]* 1) Broad Institute of Harvard & MIT, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Department of Statistics, University of Oxford, Oxford, United Kingdom; 4) Rockefeller University, New York, NY; 5) Kings College, London, UK; 6) Harvard Medical School, Boston, MA; 7) Howard Hughes Medical Institute.

We performed association and homozygosity mapping in an inbred population from Kosrae, Federated States of Micronesia, to identify risk loci for type 2 diabetes. As observed in other population isolates (eg, Pima Indians), native Kosraens exhibit markedly increased prevalences of type 2 diabetes and obesity as compared to Caucasians. Approximately 33% of Kosraen adults age 40-60 are diabetic, compared to ~10% of US adults of similar age. The type 2 diabetes and obesity epidemics on Kosrae are thought to result from rapid adoption of a Western lifestyle, and suggest an enrichment of genetic susceptibility factors in this population. The Kosrean population shows reduced genetic diversity from a strong founder effect, geographic isolation and severe population bottlenecks. Consequently, we hypothesize the existence of comparatively few genetic variants of larger effect underlying disease in this cohort as compared to Caucasian populations. Approximately 75% of Kosraen adults were ascertained over population-based screens in 1994 and 2001. A total of 2906 individuals were successfully genotyped with the Affymetrix 500k platform, of whom 2842 individuals can be joined in a single extended pedigree. We developed analytic methods for identification of common variants via genome-wide association analyses, and rare variants via homozygosity mapping in this highly related cohort. We compare our findings to true associated variants identified in Caucasian populations. Our results suggest that common variants of small effect underlie type 2 diabetes on Kosrae.

Reciprocal Co-regulation of *EGR2* and *MECP2* is Disrupted in Rett Syndrome and Autism. *S. E. Swanberg, R. P. Nagarajan, D. H. Yasui, S. Peddada, J. M. LaSalle* Medical Microbiology and Immunology, University of California Davis, Davis, CA.

Mutations in *MECP2* encoding methyl CpG-binding protein (MeCP2) cause the neurodevelopmental disorder Rett syndrome (RTT) and MeCP2 rxpression defects are frequent in autism brain. MeCP2 is a neuronal epigenetic factor important in modulating gene expression, including expression of the activity-dependent genes *Bdnf* and *JUNB*. Another activity-dependent gene, Early Growth Response Gene 2 (*EGR2*), which plays a role in both early hindbrain development and mature neuronal functioning, has putative binding sites in the 5' regulatory regions of a number of neurologically relevant genes including *MECP2*. Conversely, MeCP2 family members, MBD1, MBD2 and MBD4 bind a methylated CpG island with enhancer-like properties, located in *EGR2* intron 1. This study was designed to test the hypothesis that *MECP2* and *EGR2* regulate each other's expression during neuronal maturation in postnatal brain development. Downregulation of *EGR2* and *MECP2* in cultured human neuroblastoma cells by RNA interference reciprocally reduced expression of both genes and their protein products. Chromatin immunoprecipitation analysis showed Egr2 binding to the *MECP2* promoter and MeCP2 binding to the enhancer region in *EGR2* intron 1. Consistent with a role for MeCP2 in enhancing *EGR2*, *Mecp2*-deficient mouse cortex samples showed sinificantly reduced Egr2. Furthermore, RTT and autism postmortem cortex samples showed significant reduction of EGR2 compared to controls, supporting the involvement of an MeCP2-EGR2 co-regulated pathway. Taken together, these data suggest dysregulation of the reciprocally-regulated factors MeCP2 and EGR2 in RTT and autism.

A Searchable Database of Genetic Evidence for Psychiatric Disorders. *T. Konneker[1], T. Barnes[1], H. Furberg[1], M. Losh[2], C. M. Bulik[3], P. F. Sullivan[1,3]* 1) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Department of Psychiatry, University of North Carolina at Chapel Hill, NC.

Background. We have developed a new bioinformatics tool called SLEP (Sullivan Lab Evidence Project). SLEP was created to contextualize the relevant findings from the many psychiatric genetic studies. SLEP is a searchable archive of findings from psychiatric genetics that is freely available on the web for non-commercial use (http://slep.unc.edu). Methods. More than 150 papers have been identified for SLEP through overlapping Pubmed searches and citations. All studies with a genome-wide focus and clear phenotypic definitions were included. These studies included genomewide linkage, genomewide association, and microarray studies. Two raters reviewed each paper and recorded significant findings (GWL LOD 1.5, GWA p-value <0.05, MA p-value <0.05). Results. Via a simple interface, users can retrieve findings from GWL, GWA, and MA for ADHD, autism, bipolar disorder, eating disorders, major depression, nicotine dependence, and schizophrenia. Users can search for findings by gene name, genetic markers, and chromosome region. Results are displayed in summary form and include relevant study information and links to PubMed and the UCSC Genome Browser. SLEP includes a database of genetic signposts (i.e., physical genomic features, confirmed associations from complex human diseases, genes with evidence of imprinting, selection, or monallelic expression, SNPs associated with gene expression differences in human cortex, and copy number variants and inversions from the Database of Genomic Variants. The SLEP database will be updated quarterly. Conclusions. Given that limited power has been a concern for most psychiatric genetic studies, SLEP will likely turn up false positives. With that in mind, SLEP should be treated as a tool for searching and integrating findings from psychiatric genetics research. It will be useful for researchers looking to place new empirical findings in the context of prior studies.

Genome-wide association study of amyotrophic lateral sclerosis identifies multiple loci. *B. J. Traynor[1,14], A. Chio[2], J. C. Schymick[1,15], G. Restagno[3], S. Lai[1], G. Mora[8], L. Ferrucci[4], F. Macciardi[5], S. J. Chanock[6], C. Gieger[7], H. E. Wichmann[7], J. Connor[10], T. Dunkley[12], D. A. Stephan[12], M. Sendtner[11], M. Beck[11], L. Bruijn[13], J. Rothstein[14], A. Singleton[1], J. Hardy[1,9]* 1) Laboratory of Neurogenetics, NIA, NIH; 2) Department of Neuroscience, University of Turin; 3) Molecular Genetics Unit, Department of Clinical Pathology, A.S.O. O.I.R.M.-S.Anna, Turin; 4) Longitudinal Studies Section, NIA, NIH; 5) Department of Science and Biomedical Technology, University of Milan; 6) Division of Cancer Epidemiology and Genetics, NCI, NIH; 7) Institute of Epidemiology, Neuherberg/Munich, Germany; 8) Salvatore Maugeri Foundation, Lissone, Italy; 9) Institute of Neurology, Queen Square, London, UK; 10) Department of Neurosurgery, Penn State College of Medicine; 11) Institute of Clinical Neurobiology, University of Wuerzburg, Germany; 12) Neurogenomics Division, TGEN, Phoenix, AZ; 13) The ALS Association, Palm Harbor, FL; 14) Department of Neurology, Johns Hopkins University, Baltimore; 15) Department of Physiology, Anatomy and Genetics, University of Oxford, UK.

BACKGROUND: We sought to identify genetic variants associated with an increased or decreased risk for developing ALS in a cohort of sporadic cases. **METHODS:** We undertook a two-stage GWAS: we followed our initial GWAS of 545,066 SNPs in 553 individuals with ALS and 2,338 controls of European descent by testing 7,600 SNPs in three independent cohorts consisting of 2,160 cases and 3,008 controls. **FINDINGS:** We identified four highly significant loci on chromosomes 3, 7 (two loci) and 11, three of which exceeded Bonferroni correction for multiple testing (P value between 1.17x10-5 and 3.55x10-6). The locus on chromosome 3p13 includes RYBP, a member of the apoptosis pathway. Loci on chromosome 7 include SUNC1, a nuclear envelope protein; and CNTNAP2, which regulates clustering of voltage-gated potassium channels at juxtaparanodal regions of myelinated axons. The fourth locus is located near CD82. **INTERPRETATION:** Our findings suggest that multiple loci with moderate effects are associated with susceptibility to sporadic ALS.

Characterization of common human copy number variants with oligonucleotide arrays. *A. Ben-Dor, P. Anderson, N. Sampas, A. Tsalenko, S. Giles, P. Tsang, A. DeWitte, D. Bailey, Z. Yakhini, S. Laderman, L. Bruhn* Agilent Technologies, Santa Clara, CA.

Technological improvements for efficient genotyping of CNVs over a broad dynamic range of copy number are important for genetic studies of normal and disease-related human variation. We are developing microarray-based methods and data analysis tools to identify CNV regions and distinguish their copy number states. We employ two complementary statistical methods to determine the copy number state of a particular CNV. The first approach is based upon direct correlation of CNV copy number to its signal intensity level. The second approach aims at identifying distinct clusters of copy number states across the cohort for each individual CNV region. In order to examine the systems capability for discriminating copy number states, we used an oligonucleotide array set comprised of two 244K feature arrays enriched for coverage of 19,400 previously identified CNV, in-del and segmental duplication regions. We employed a non-enzymatic labeling protocol that is amenable to high-throughput applications, to measure 27 HapMap samples in two-color hybridizations with a common reference sample (NA15510). We detected an average of 841 CNVs per sample as compared to an average of 6 calls in 3 self-self experiments. Of 1326 CNV regions called in two or more individuals, 817 (60%) have consistent breakpoints (+/- 1 probe). The remaining CNV regions have boundaries that vary between individuals, in some cases reflecting what appear to be complex structures as observed in previous studies. Based on the robust separation of signal intensity levels, we call distinct copy number states for 0, 1, and 2 copies. On average, approximately 5% of the CNVs detected are homozygous deletions, 25% have 1 copy, 25% have 2 copies, and 45% have 3 copies or more. Employing a cohort based approach, we identify many regions with clear separations of the samples into distinct copy states including some with 4 or more copy number states. We are exploring the appropriate interpretation of the signal and ratiometric measurements in these regions as a foundation for more broadly ascertaining copy number states of CNVs.

The A-844G Polymorphism in the PAI-1 gene is associated with susceptibility in systemic lupus erythematosus. *J. R. Padilla-Gutiérrez[1,2], C. A. Palafox-Sánchez[1], N. M. Torres-Carrillo[1], Y. Valle[1,2], G. Orozco-Barocio[3], I. García-De la Torre[3], N. Torres-Carrillo[1], M. Vázquez Del Mercado[1], J. F. Muñoz-Valle[1]* 1) IIRSME, C.U.C.S, UdeG; 2) Posdoctoral Fellow in Biomedical Sciences (Immunology), UdeG; 3) HGO, SSJ.

Introduction. Systemic lupus erythematosus (SLE) is a systemic autoimmune disease characterized by the presence of autoantibodies against nuclear autoantigens as well as cytoplasmic and circulating proteins. The thrombotic phenomena in SLE is associated in a 10-20%. Recent studies indicate that endothelial cells play an important role in fibrinolysis by secreting both tissue-plasminogen activator (t-PA) and plasminogen activator inhibitor-1 (PAI-1), which regulates the activity of t-PA. In fact, it is known that the expression of the PAI-1 is modulated by proteins such as cytokines. Several studies have suggested that in patients with systemic diseases, the fibrinolysis may be decreased, due mainly to an excess of PAI-1. Methods. We enrolled 71 SLE patients classified according to ACR criteria and 71 healthy subjects (HS). The A-844G PAI-1 polymorphism was identified by PCR-RFLP. The DNA fragments were observed on a 2% agarose gel staining with ethidium bromide. The statistical analysis was performed using MedCalc Statistical Software. Results. The allele A of PAI-1 polymorphism (A-844G) showed a significant difference in SLE patients (41%) compare with HS (27%) [p= 0.01; OR=1.8, 95%, CI=1.1-3.0]. In addition, the A-844G PAI-1 polymorphism was associated with increased risk for SLE in a dominant model (OR= 2.2, 95% CI=1.14-4.44). Conclusions. The A allele of the A-844G PAI-1 polymorphism might be an additional risk factor for the development of SLE in Mexican population.

Microarray- DNA Sequence Capture of the Human Exome in a Family Identifies Spontaneous Mutations in the Human Germline. *M. N. Bainbridge[1,2], T. J. Albert[3], D. M. Muzny[1], L. Nazareth[1], C. M. Middle[3], T. A. Richmond[3], M. J. Rodesch[3], M. Egholm[4], R. A. Gibbs[1]* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Program for Structural and Computational Biology and Molecular Biophysics, Baylor College of Medicine, Houston, TX; 3) NimbleGen Systems Inc., Madison, WI; 4) 454 Life Sciences Corp., Branford, CT.

Spontaneous mutations in the human germline are of central importance in genetics and evolution. Their rate of occurrence has been estimated by indirect methods to be 100-200/genome/generation, or ~5 amino acid changing mutations. We used DNA capture and sequencing (via Roche/NimbleGen/454 Life Sciences technology) of the entire exon set (exome) of a family to discover new mutations. We found 7 occurrences among ~7.5 million scanned bases and calculated these correspond to an exonic spontaneous mutation rate of 33-45/generation-exome, a higher value than previously thought. As expected, approximately 40% of the new mutations are transitions in CpG residues. In addition, the other single base mutations within exons do not occur randomly, but appear to preferentially occur at sites already known to be polymorphic. While additional families (meiosis) should be studied, these findings already support finite-site models for human mutation and have implications for human evolution.

Allele and genotype sharing in large databases: reconciliation of observed and expected statistics. *R. Chakraborty, J. Ge, H. S. Lee* Center for Genome Information, Univ Cincinnati, Cincinnati, OH.

Using a variety of panels of genetic markers, several large databases in various contexts have been created and curetted for different purposes. Population- or family-based multilocus genotype profiles of cases and control subjects involving genome-wide panel of genetic markers are commonly used for mapping genes for disease traits as well as phenotypes that are influenced by genetic factors. In DNA forensics, large databases of multilocus DNA profiles involving unlinked genetic markers are used for solving crimes where perpetrators are not initially identified by common criminal investigative tools. Allele and genotype sharing distribution between individuals in such databases have recently come under discussion in the context of validity of population genetic assumptions in estimating rarity of any specific multilocus profile. This research starts with a brief overview of this subject. Under the assumption of independent segregation of markers encompassed in the multilocus genotype profiles, algorithms are provided to compute the expected distributions of allele and genotype sharing in such databases, even with complexities of having relatives within such databases and existence of population substructure within the sample. It is shown that for testing the assumptions of independence of alleles within and across loci, reconciliation of the observed and expected distribution of allele and genotype sharing is possible only with complete details known for each individual in the database, including not only their individual multilocus profiles, but also their substructure affiliation and pairwise relatedness with others at individual level. Further, we show that the expected distributions are not necessarily the same using the locus average values as opposed to genotype-specific composition of the database. Finally, we argue that simulation or large-sample approximations do not always provide an accurate approach of reconciliation of observations and expectations based on population genetic models, particularly when the number of markers is large, or majority of them contain large numbers of segregating alleles.

Robin sequence, short and bowed long bones and multiple fractures - A new skeletal dysplasia? *N. Martin[1], J. Kingdom[2], C. Grasemann[3], E. Sochett[3], S. Unger[4], D. Chitayat[1,5]* 1) Prenatal Diagnosis, Mount Sinai Hospital, Toronto, ON, Canada; 2) Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, ON, Canada; 3) Dept. of Endocrinology, Hospital for Sick Children, Toronto, ON, Canada; 4) Institute of Human Genetics, University of Freiburg, Germany; 5) Clinical and Metabolic Genetics, University of Toronto and Hospital for Sick Children, Toronto, ON, Canada.

Prenatal finding of bowed limbs and post-natal fractures is most often seen in osteogenesis imperfecta. Our case demonstrated both of these features but is distinguished by exclusion of type I collagen defects and an unusual fracture pattern. The patient was born to a G2P1L1 mother. Both parents were healthy and non-consanguineous and their family history was non-contributory. Fetal ultrasound at 25 weeks gestation identified short limbs. Follow-up ultrasounds demonstrated bent femurs, apparently normal mineralization, and a narrow chest. Delivery was at 39 weeks gestation via C-section. The birth weight was 2.4 kg (10th percentile), length 45.5 cm (10-25 percentile) and OFC 33.2 cm (25-50 percentile). On physical examination, the child had a long trunk with short limbs (upper/lower segment ration = 2.03), prominent eyes with blue-grey sclera, low set, thin ears, micrognathia, and a narrow chest with pectus carinatum. Skeletal survey revealed hypomineralization of the skull, bell-shaped chest with gracile ribs and healed fractures. All long bones showed flaring and beaking of the metaphysis, patchy mineralization and cortical deformity. Multiple fractures involving the left clavicle, right ulna and tibia were noted. There was also shortening of the metacarpals. He has a duplex right kidney, bilateral hydroceles, and severe gastroesophageal reflux. Mutation analysis of the COL1A1 and COL1A2 genes showed no detectable mutaion. Collagen electrophoresis studies, and electrolytes, karyotype were normal. To the best of our knowledge this is a not yet reported non-lethal skeletal dysplasia associated with osteopenia, multiple fractures and facial dysmorphism.

Mutations in CYP7B1 are responsible for hereditary spastic paraplegia type 5. *C. Goizet[1,2], A. Boukhris[1], A. Durr[1], J. Truchetto[1], L. Guyant-Marechal[3], B. Fontaine[4], D. Grid[1], C. Depienne[1], S. Forlani[1], M. Tsaousidou[5], A. Crosby[5], A. Brice[1], G. Stevanin[1]* 1) INSERM / UPMC U679 - NEB, Paris, France; 2) Med.Genetics, Univ. Victor Segalen Bordeaux 2, CHU Pellegrin, Bordeaux, France; 3) Dept of Neurology, CHU Rouen, Rouen, France; 4) Federation of Neurology, GH Pitié-Salpêtrière, Paris, France; 5) Med. Genetics, St Georgess Univ., London, UK.

Thirty-eight different loci for hereditary spastic paraplegia (HSP) have been mapped, 20 in autosomal recessive spastic paraplegias (AR-HSP). AR-HSPs usually have clinically complex phenotypes but the SPG5, SPG24 and SPG28 loci are considered to be associated with pure orms of the disease. Very recently, five mutations in the CYP7B1 gene, encoding for a cytochrome P450 oxysterol 7- hydroxylase, have been demonstrated in SPG5 families. We analyzed CYP7B1 by direct sequencing in a series of 60 unrelated AR-HSP and 20 sporadic HSP patients, all manifesting a pure form of the disease. We identified 4 different mutations in 4 index cases with AR-HSP, including 3 missense and 1 nonsense mutations. No mutation was found in sporadic cases. The mutations segregated with the disease in all the families and were absent from 494 control chromosomes. We obtained clinical and paraclinical data in a total of 7 patients from these families. The frequency of SPG5 was 6.6% (n=4/60) in our series of AR-HSP families with pure form. We detected a cluster of missensse mutations in the exon 6 at the C-terminal end of the protein. Mean age at onset was 15.9 yrs 12.8 (4-47). Spasticity and functional handicap were noted moderate to severe in all cases (severe, n=5) after mean disease duration of 24.1 yrs 16.5. The recent identification of CYP7B1 as the SPG5 responsible gene highlight a novel molecular mechanism involved in the HSP determinism.

Tracing ancestral lineages, long-range LD, and homozygosity blocks in the genomes of the Qatari. *R. G. Crystal[1], T. P. O'Connor[1], N. R. Hackett[1], L. Chouchane[2], J. Salit[1], J. G. Mezey[3], A. R. Boyko[3], K. E. Lohmueller[4], A. G. Clark[4]*
1) Genetic Medicine, Weill Cornell Medical College, New York, NY; 2) Weill Cornell Medical College in Qatar; 3) Biol. Statistics and Comp. Biology, Cornell Univ, Ithaca, NY; 4) Molec. Biol. and Genetics, Cornell Univ, Ithaca, NY.

People of the Qatari peninsula represent a relatively recent founding by a small number of families from three tribes of the Saudi peninsula, Persia, and Oman. The combination of this founding effect and the customary first-cousin marriages among the ancestral Islamic populations could result in an interesting pattern of LD, shared identity blocks, and runs of homozygosity, all relevant to efforts to map genes associated with complex disorders. Here we obtained DNA samples from 120 self-reported Qatari nationals sampled from Doha, Qatar in the past 12 months, and performed hybridizations to Affymetrix Genome-wide Human SNP array 5.0 to obtain genotypes calls of nearly 500,000 SNPs in each individual. The overall levels of diversity in this sample is close to that of European populations, but the extent of linkage disequilibrium is more extensive, and runs of homozygosity in some individuals reflects impressive consanguinity. The among-individual sharing of long haplotypes is also exceptional in this population, with several multiple-Mbp identity blocks found in multiple individuals. Principal components analysis was performed along with samples from the global collection of the Glaxo-SmithKline PopRes dataset, revealing a cluster of genotypes between the northern African and eastern European samples. Simulations of a population in which one-half the population marries a first cousin generally reflect greater identity-by-descent sharing than was observed, but the discordance is small. Most of these conclusions are robust to the fact that the SNPs of the Affymetrix 500k chip were ascertained with bias toward SNPs common in Europeans. The data strongly support the notion that the Qatari population could provide a valuable resource for the mapping of genes associated with complex disorders, and that tests of pairwise interactions are particularly empowered by populations with elevated LD like the Qatari.

Genome-wide patterns of population structure and admixture in Africans and African Americans. *K. Bryc[1], M. Nelson[2], J. Oksenberg[3], S. Hauser[3], C. Bustamante[1,5], S. Tishkoff[4,5]* 1) Dept Biol Statistics/Comp Biol, Cornell Univ, Ithaca, NY; 2) GlaxoSmithKline, Research Triangle Park, NC; 3) Department of Neurology, University of California, San Francisco, CA, USA; 4) Departments of Genetics and Biology, University of Pennsylvania, Philadelphia, PA, USA; 5) These authors contributed equally to this work.

We present results from a study of high-density genome-wide patterns of variation in Africans, Europeans, and African Americans. Our data set consists of 203 individuals from 12 African populations concentrated in West Africa, 365 African Americans and 400 Europeans from 42 countries, genotyped using the Affymetrix GeneChip 500K Array Set. Arrays passing quality checks were analyzed using both FRAPPE and *smartpca*, a principal component analysis (PCA) method for genotype data. We find that population structure within the African populations coincides with geographic distance and barriers to gene flow, and that the sample clustering on PC1 and PC2 resembles a map of sample origins in Africa.

To facilitate admixture mapping within our African American individuals, we introduce a PCA-based approach for estimating local and genome-wide admixture proportions. Applying our method, we find evidence for admixture of Europeans with several (but not all) of the sampled African populations from West Africa. Furthermore, our results suggest that much admixture in African Americans derives from ancestral populations that are not represented in current studies of African diversity. Overall, we estimate that the median proportion of European admixture among African Americans is 18.5% (inter-quartile range 11.6% - 27.7%) in line with previous estimates. The estimated proportion of European ancestry varies by geographic origin of the African Americans sampled. Comparing the median values of European ancestry of regions in the United States, we find that the proportion of European ancestry is lowest in the South (16.6%) and highest in the West (20.7%) and Northeast (21.0%) regions. Funded by NIH grant 5R01GM083606-02 to CDB and SAT.

Clinical and Molecular-Cytogenetics Characterization of a man with a 14 ring chromosome: a 19-year follow-up.

V. F. A. MELONI[1], F. T. LIMA[1], R. M. MINILLO[1], R. S. GUILHERME[2], C. P. CORREIA[2], L. D. KULIKOWSKI[2], M. I. MELARAGNO[2], D. BRUNONI[2] 1) CENTRO DE GENÉTICA MÉDICA, UNIVERSIDADE FEDERAL DE SÃO PAULO, SÃO PAULO, SÃO PAULO, BRAZIL; 2) DISCIPLINA DE GENÉTICA, UNIVERSIDADE FEDERAL DE SÃO PAULO, SÃO PAULO,SÃO PAULO, BRAZIL.

The 14-human chromosome accounts for over 550 genes and over 30 diseases. Its ring aberration occurs more often in females and encompasses facial dysmorphic features, seizures, developmental delay, hypotonia, growth retardation, retinal pigmentation abnormalities and pulmonary infections. We describe a 22-year-old male who at birth presented bilateral cryptorchidism, sacrum dysgenesis, coccyx agenesis and talo-valgus deformity. At the first evaluation he was a 3-year-old boy with short stature, microcephaly, facial dysmorphisms and mild psychomotor delay. His first GTG-banded karyotype showed 46,XY,r(14)(p13q32) in 300 analyzed cells. Parents were cytogeneticaly normal. Nowadays he has mild mental retardation, short stature, microcephaly and slightly different facial dysmorphisms. He also has a hypopigmented area in posterior pole in both eyes. Cytogenetic reevaluation was done 19 years later and showed 5% of metaphases with aneuploid of chromosome 14 in 200 analyzed cells. FISH using Alpha Satellite probe specific for chromosome 14 was performed according to standard protocols on 100 interphase nuclei of the proband. In 90 cells (90%), the FISH showed a monocentric r(14) chromosome and 2 cells (2%), a dicentric ring containing duplicated short and long arm material of chromosome 14 was observed. Eight metaphases lacked any ring of chromosome 14. The ring chromosome found in this individual shows evidence of the characteristic instability associated with ring chromosomes, such as duplicated segments, double rings, and subsequent loss of the ring resulting in cells with monosomy 14. This abnormalities associated with the clinical follow-up help our understanding of the mechanisms underlying the genotype-phenotype correlation. The long follow-up allows a better knowledge of the natural history of the disorder helping the counseling and management of the patients. Financial support: CAPES, FAPESP.

Defining the etiology of pancreatic cancer: implications for targeted adjuvant therapy and genetic counseling. *S. Charles, S. Showalter, A. Witkiewwicz, J. Cozzitorto, J. Belin, P. Sauter, E. P. Kennedy, C. J. Yeo, J. R. Brody* Thomas Jefferson University Hospital, Philadelphia, PA.

Better comprehension of the molecular pathogenesis of pancreatic ductal adenocarcinoma (PDA) has led to the development of novel targeted treatments and, in some cases, more accurate genetic counseling for PDA susceptibility. We present two cases of PDA: Patient 1 presented with PDA at 71 years in the context of a frameshift mutation (2157delG) in BRCA2, suspected due to her personal and family history of breast cancer. As recent data have shown that PDAs with defects in the BRCA2/Fanconi Anemia pathway are hypersensitive to interstrand cross-linking agents, most notably platinum-based drugs, Patient 1 was treated with gemcitabine and cisplatin, in addition to capecitabine and radiation. She is currently disease free 18 months post distal pancreatectomy. Family members have undergone counseling and testing for the familial BRCA2 mutation, and screening recommendations tailored to their genetic status and family history have been made. Patient 2 presented with PDA at 50 years and had a family history notable for pancreas cancer in her father and paternal cousin, plus pancreatitis in two paternal cousins. Germline genetic studies for patient 2 were not informative, as she did not carry a BRCA1/2 Ashkenazi Jewish founder mutations (i.e., 187delAG and 5385insC in BRCA1 and 6174delT in BRCA2) and she did not carry the novel missense PRSS1 variant identified in a paternal cousin with pancreatitis (i.e., C185Y, a cysteine changed to a tyrosine within exon 4). No molecular targets were identified in DNA repair genes FANCA, FANCC, BRCA2, and BLM, which were analyzed from a non-xenografted PDA cell line. Patient 2 received neoadjuvant gemcitabine and erlotinib. She died 8 months after surgery. Family members have been counseled and offered surveillance under the assumption of familial pancreatic cancer, though etiology remains unclear. These cases highlight the challenge of efficiently selecting patients that will optimally benefit from targeted therapy, as well as the challenges of providing genetic counseling for familial pancreatic cancer when causative genes remain undefined.

Investigation of relationship between NDUFS1 gene with MS disease. *Z. Baratieh Najafabadi[1,2], M. H. Sanati[2], M. Houshmand[3], M. Rezaei-Tavirani[1]* 1) Cellular & Molecular Biology Depatment, Khatam University, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran; 3) Genetic section, Special Medical Center, Tehran, Iran.

Multiple sclerosis (MS) is the most common inflammatory demyelination disease of the central nervous system. Preferential maternal transmission in familial cases and the occasional association of MS and LHON, suggests on involvement of mitochondrion (mtDNA, electron transport chain enzymes) in the aetiology of MS. Besides, in recent study, researchers found a relationship between biochemical defect in complex I enzyme activity and pathogenesis of MS. Complex I is a largest complex of the mitochondrial respiratory chain that contains 43 subunits.36 subunits being encoded by nuclear and 7 subunits being encoded by mitochondrial DNA. As mutations in NDUFS1 gene were reported previously in patients afflicted by complex I deficiency and also biochemical defect in complex I enzyme was found in Iranian MS patients, we encouraged to study relationship between NDUFS1 gene with MS disease in Iranian MS patients. This gene is a nuclear gene encoding catalytic subunit of complex I enzyme. So we analyzed four exons of NDUFS1 gene (8, 9, 15 & 19) that some mutations are identified in patients with complex I deficiency. We amplified these exons by PCR and screened them for finding any variations by SSCP method. Suspicious samples for mutations were sequenced. Finally, in our samples, we couldn't find any variation in these regions of NDUFS1 gene. To identify the relation between NDUFS1 gene and complex I with MS disease, further analyzes should be done on other exons of this gene and also other genes of complex I subunits.

Effects of sequence variation on mtDNA deletion quantification: Ramifications for genetic testing in biomedical research. *S. I. Zhadanov[1,2], T. S. Vierbuchen[1], T. G. Schurr[1]* 1) Anthropology Dept, Univ Pennsylvania, PA; 2) Institute Cytology and Genetics SB RAS, Russia.

It has been proposed that a lifetime accumulation of mtDNA deletions in postmitotic tissues can be an important contributor to the progression of neurodegenerative or cardiovascular disorders and is likely to have a central role in the aging. To quantify the presence of mtDNA deletions at the cellular level in single cells and tissues, many detection methods currently employ Taqman/RT-PCR assays. However, this approach may be biased by the considerable individual- and population-specific genetic diversity of the mtDNA. We examined the effects of polymorphic mtDNA sequence variants (SNPs) in the primer and probe regions frequently used for this analysis. Using Taqman MGB probes, we determined the effects of sequence variation on the RT-PCR reactions. Using absolute quantification RT-PCR, we compared mtDNA derived from cultured cells that contained two SNPs in the primer and two SNPs in probe binding site. Our sample with four total SNPs showed a 16-fold copy number difference for our region of interest, thus, making it indistinguishable from a large scale deletion. We hypothesize that heteroplasmic SNPs in the primer and probe regions can significantly confound the results of these analyses, causing both overestimation and underestimation of the true deletion load. Our findings indicate that common population-specific SNPs reside in the primer and probe regions used for many mtDNA deletion assays, thereby confounding RT-PCR assessments of somatically derived mutation levels. For this reason, researchers should not rely solely on RT-PCR to diagnose mtDNA deletions in single cells or in homogenous tissue samples. Without confirmation from alternative methods, such as sequencing or Southern blotting, it may be difficult to ascertain the exact level of deleted mtDNA within the range of error caused by SNPs in the primer and probe regions. Thus, to appropriately screen tissue samples for mtDNA deletions (esp. at low levels) as biomarkers of oxidative stress or age-related pathologies, one must employ multiple approaches to offset the effects of this genetic heterogeneity.

Interrogation of Folate Pathway Genes and NSCLP. *R. R. Henry[1], J. B. Mulliken[2], S. Stal[3], A. Burt[4], S. H. Blanton[4], J. T. Hecht[1]* 1) University of Texas Medical School at Houston; 2) Children's Hospital, Boston, MA; 3) Texas Children's Hospital; 4) University of Miami Miller School of Medicine.

Nonsyndromic cleft lip with or without cleft palate (NSCLP) is a common birth malformation caused by genetic, environmental, and/or gene-environment interactions. Periconceptional supplementation of folic acid, a key component in DNA synthesis and cell division, has reduced the birth prevalence of neural tube defects and may similarly affect other complex birth defects such as NSCLP. Past studies have yielded conflicting results when evaluating two common polymorphisms, C677T (rs1801133) and A1298C (rs1801131), in the MTHFR (methylenetetrahydrofolate reductase) gene and their relation to NSCLP. In this study, we asked whether variation in other genes in the folate pathway were associated with NSCLP and if so, was there a detectable interaction between these genes. Fourteen folate metabolism related genes were interrogated using 94 SNPs (single nucleotide polymorphisms) in 325 parent-child trios and 120 multiplex NSCLP families. These families were either of nonHispanic white or Hispanic ethnicity. Evidence for association between NSCLP and SNPs in the BHMT2 (betaine-homocysteine methyltransferase 2), MTHFD1 (methylenetetrahydrofolate dehydrogenase 1), TYMS (thymidylate synthetase), and CBS (cystathionine-beta-synthase) genes was detected in the nonHispanic white samples, whereas evidence for association with SNPs in the TYMS, CBS, and MTR (methionine synthase) genes was detected in the Hispanic samples. Over-transmitted SNP haplotypes were identified in many of the genes in both population samples. Gene-gene interactions were also found in both groups. These data suggest that there is no direct association with the common SNPs of the MTHFR gene and NSCLP, but that the C677T polymorphism may interact with SNPs from other genes in the folate pathway to create a risk for NSCLP.

Pathogenesis and treatment of retinal degeneration in the rd16 mouse: a model for syndromic disorders caused by mutations in the centrosomal-ciliary protein CEP290/NPHP6. *R. A. Rachel[1], R. Kandpal[1], J. Nellissery[1], Z. Wu[2], C. Murga-Zamalloa[3], L. L. Bell[1], R. Farris[4], B. Chang[5], H. Khanna[3], P. Colosi[2], A. Swaroop[1]* 1) Neurobiology, Neurodegeneratlon & Repair Laboratory, National Eye Institute, Bethesda, MD; 2) Ocular Gene Therapy Laboratory, National Eye Institute, Bethesda, MD; 3) University of Michigan, Ann Arbor, MI; 4) Biological Imaging Core, National Eye Institute, Bethesda, MD; 5) Jackson Laboratories, Bar Harbor, ME.

Diverse mutations in CEP290 cause a spectrum of ciliopathies, including Joubert syndrome, Meckel-Gruber syndrome, Bardet-Biedl syndrome and Leber congenital amaurosis (LCA). We have shown that an in-frame deletion in the myosin-tail (myo-tail) domain of CEP290 in the retinal degeneration 16 (rd16) mouse and potential hypomorphic mutations in LCA patients result in a restricted phenotype with defects in retinal, olfactory, and possibly other sensory neurons. To dissect the function of CEP290 and pathogenesis of associated disease(s), we are taking several approaches. First, we have identified proteins that potentially interact with CEP290 by immunoprecipitation and mass spectroscopy, and by yeast two-hybrid analysis. Secondly, we are evaluating the time course and pathology related to retinal degeneration in rd16 retina. Thirdly, we are evaluating the ability of an AAV5-Cep290 gene transfer vector to complement the ciliopathy in postnatal rd16 mice. Collectively, these studies should assist in understanding the mechanism of restricted neurodegeneration phenotype in patients with CEP290 mutations.

Kelvin: A 2nd generation software package for computation of the PPL framework. *Y. Huang[1], A. Segre[2], J. O'Connell[3], W. Valentine-Cooper[1], S. Seok[1], V. Vieland[1,4]* 1) Battelle ctr for Mathematical Medicine, The Res Inst at Nationwide Children's Hospital, Columbus, OH; 2) Computer Science Dept, U. of Iowa, Iowa City, IA; 3) U. of Maryland, College Park, MD; 4) Pediatrics Dept, Ohio State University, Columbus, OH.

KELVIN is a comprehensive statistical genetic analysis software package developed under the PPL framework. At its core is a 2nd generation distributed multiprocessor linkage and linkage disequilibrium analysis program. It currently supports more than 20 different types of analyses, including combinations of marker-to-marker or trait-to-marker analysis, dichotomous trait, quantitative trait or QT threshold analysis, two point or multipoint analyses based on sex averaged or sex specific maps, linkage and trait-marker linkage disequilibrium, and gene x gene interaction models. Kelvin uses Bayesian sequential updating to accumulate evidence across multiple data sets. It is designed for ease of expansion to allow new features in order to quickly address new research questions. Its supported platform base has been widened to include Macintosh OSX and Windows XP/Vista in addition to LINUX. Its performance both in terms of execution time and memory utilization has been radically improved such that it is now capable of performing many analyses that were formerly too complex to be computationally tractable. A few of the techniques employed in KELVIN include polynomial representation of likelihoods for fast evaluation, and an innovative and very efficient numerical integration method. A new graphical interface has been incorporated for setting-up analysis parameters in a user-friendly fashion. The package also provides an easy-to-use graphing tool for displaying analysis results. A new feature added to KELVIN is the ability to analyze case-control analyses for use in genome wide association studies, with the ability to simultaneously analyze case-control and family data utilizing sequential updating to accumulate evidence across potentially heterogeneous data sets or subsets.

The need for microarray testing in patients with presumptive diagnoses of mitochondrial disease. *C. Phornphutkul[1,2], D. Mandelbaum[1,2], R. Burke[1,2], K. Reddy[3], P. Cotter[3], S. Gunn[3], N. Shur[1,2]* 1) Hasbro Children's Hospital, Providence, RI; 2) The Warren Alpert Medical School of Brown University, Providence, RI; 3) Combimatrix Molecular Diagnostics, Irvine, CA.

Introduction: In patients with psychomotor retardation, seizures, and hypotonia, mitochondrial diagnosis is often suspected. Muscle biopsy has an integral role in the evaluation, though limitations are well-documented. We describe a case that highlights the need to include microarray for patients in this category. Case report: The patient presented to metabolic clinic for the first time at 9 ½ years with a long-standing history of mental retardation, psychomotor delay, possible seizures, and presumed metabolic disease. Birth history included club-feet, and ventricular septal defect. Prior work-up showed normal high resolution karyotype and FISH for velocardiofacial and Smith-Magenis syndromes. Testing for Rett and Angelman syndrome were negative. Metabolic work up included normal very long chain fatty acids, phytanic acids, congenital disorders of glycosylation, amino acids, and urine organic acids. Lactate and pyruvate and mitochondrial DNA studies were normal. A muscle biopsy showed a mildly elevated butcitrate synthetase level and mitochondrial proliferation. The presumptive diagnosis of mitochondrial disease was given to the family. Physical examination at 9 1/2 years was significant for synophorys, a prominent forehead, and a low anterior hairline with simple ears. Muscle tone was diffusely decreased with abnormal gait. Due to history of congenital heart disease and mild facial dysmorphism, microarray testing was obtained. A 105K oligoarray platform showed a gain of ~5.9 Mb of DNA (152059382 -158018753 bp) on chromosome 1q21.2 containing ~137 genes. High density BAC aCGH confirmed the diagnosis. The genes in the region had no apparent direct mitochondrial function or interaction with the mitochondrial genome. Conclusion: Our case highlights the need for microarray testing in patients with psychomotor delay, seizure and hypotonia, especially prior to invasive testing.

Craniosynostosis: Clinical insights and identification of a potentially new locus. *D. M. McDonald-McGinn[1], C. Stolle[2], T. Shaikh[1], C. Haldeman-Englert[1], S. Bartlett[3], E. H. Zackai[1]* 1) Division of Human Genetics; 2) Department of Pathology and Laboratory Medicine; 3) Division of Plastic and Reconstructive Surgery, The Children's Hospital of Philadelphia, Philadelphia, PA.

Classic syndromic craniosynostosis such as is seen in Crouzon, Pfeiffer, Jackson-Weiss, Muenke, and Saethre-Chotzen syndrome has been associated with mutations in FGFR 1, 2, 3 and TWIST and with TWIST deletions. However, there are a number of patients with apparent syndromic craniosynostosis whose etiology has yet to be elucidated. Here we report on two patients with craniosynostosis due to TWIST mutations whose clinical findings are dramatically divergent from each other. In addition we have identified a patient with craniosynostosis due to an interstitial 4q deletion and, having reviewed the literature, propose this as a potentially new craniosynostosis locus. Patient 1, identified intrauterine with bicoronal and metopic suture fusion necessitating emergent decompression after birth, was found to have an in frame duplication of seven amino acids (Lys133Pro139) in the loop domain region of the TWIST gene. Patient 2, a 32-year-old PhD student with bicoronal synostosis, blepharophimosis, and small ears, was found to have a complete deletion of the TWIST gene by southern blot, later confirmed by FISH. Patient 3, a 4 year old with posterior sagittal, lambdoidal and bicoronal craniosynostosis, hypertelorism, and sensorineural hearing loss was found to have a 4q27-q31.22 deletion detected using array CGH. A similar patient with craniosynostosis and an interstitial deletion of this same area was reported previously by DeValle Torrado et al. (J Med Genet 19:477) in 1982. Thus, we will discuss the genotype phenotype correlations in Patients 1 & 2 and propose the 4q27-q31.22 deletion as a potentially new craniosynostosis locus. High density oligonucleotide microarray identifying genes in this area will be discussed with attention to possible candidate genes.

Web-based collection of gene sequence variants and their phenotypic consequences. *I. F. A. C. Fokkema, P. E. M. Taschner, G. J. B. Van Ommen, J. T. Den Dunnen* Human & Clinical Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands.

Soon it will be possible and affordable to sequence a human genome within a few weeks, making medical and clinical application of genome sequencing an attractive option. However, when we want to understand the consequences of all the variation we will find, we need to improve considerably the way we currently report and catalogue these variants and their consequences. One logical and diagnostically attractive option is to store this information on a gene-by-gene basis, i.e. in Locus-Specific DataBases (LSDBs). To facilitate fully web-based management of LSDBs we have developed the Leiden Open-source Variation Database software (LOVD, http://www.LOVD.nl). LOVD is a free, open-source, platform-independent tool to build, curate and share gene variant databases. After installation, simply from CD, a basic database is available following current recommendations of the Human Genome Variation Society. The database manager can add any data field desired, e.g. to capture disease-specific phenotype information, deciding per field the input accepted (free text, numeric, dropdown menu, etc.) and whether or not those data will be available for public display. LOVD supports several levels of data access (website visitor, submitter, curator, database manager), searching in (using Boolean operators) and across data columns, custom design of direct links (to internet, intranet or even local-PC files), data exchange with central repositories (incl. NCBI, UCSC), automatic mutation nomenclature error checking using Mutalyzer and data storage on variants in different genes found in one patient. LOVD allows searching of data in non-public records, returning the number of hits and the option to mail the curator or submitter asking for more information. With the support of the EU-funded Gen2Phen project, LOVD currently offers free support to establish and host gene variant databases. Currently, LOVD is used to curate >160 LSDBs world-wide, with the Leiden server hosting over 100 and data collected for ~48,000 variants from >27,000 patients contributed by >240 submitters, the largest series covering gene variants in relation to neuromuscular disorders.

A whole-genome association study of schizophrenia in 6,792 individuals. *S. Purcell[1,2], J. Stone[1,2], E. Scolnick[1,2], P. Sklar[1,2], International Schizophrenia Consortium* 1) CHGR, Massachusetts Gen Hosp, Boston, MA; 2) Stanley Center for Psychiatric Research, Broad Institute of Harvard and MIT.

The International Schizophrenia Consortium (ISC) was established to promote rapid progress towards the identification of genetic causes underlying schizophrenia. The ISC is comprised of investigators from the University of Aberdeen, Cardiff University, the University of Edinburgh, the Karolinska Institutet, Massachusetts General Hospital, the University of North Carolina-Chapel Hill, the Queensland Institute of Medical Research, the University of Southern California, the Stanley Center for Psychiatric Research at the Broad Institute of Harvard and MIT, Trinity College Dublin and University College London. To identify alleles that increase risk for schizophrenia, we completed a genome-wide association study using the Affymetrix Genome-Wide Human SNP 5.0 and 6.0 Arrays in 3,380 unrelated schizophrenic patients and 3,592 ancestrally matched controls. Our analysis of over 750,000 directly genotyped single nucleotide polymorphisms (SNPs), augmented by imputation of ungenotyped SNPs, revealed loci at 6q21 ($P = 2 \times 10\text{-}8$, rs2894254) and 1q21 ($P = 5\times10\text{-}8$, rs11165690) as significantly associated with schizophrenia. We have also completed a number of secondary analyses including tests of multilocus and pathway models and runs of homozygosity.

Triphalangeal thumbs in a patient with cat eye syndrome. *S. L. Dugan, L. Hudgins* Division of Medical Genetics, Stanford University School of Medicine, Stanford, CA.

Purpose: Cat eye syndrome is an uncommon form of aneuploidy consisting of a supernumerary isodicentric chromosome 22. Affected individuals present with multiple anomalies, including congenital heart disease, anorectal malformations, preauricular pits and tags, and ocular coloboma. We present a newborn with triphalangeal thumbs whose karyotype shows supernumerary isodicentric chromosome 22. This case expands the reported phenotypic range of cat eye syndrome and highlights its overlap with Townes-Brocks syndrome.

Methods: Chart review and a complete history and physical examination were performed on the patient. Karyotype was performed on peripheral blood. The patients father also underwent physical examination.

Results: The infant had downslanting palpebral fissures with telecanthus, bilateral radially deviated thumbs, bilateral preauricular pits and tags, and imperforate anus. Imaging studies revealed total anomalous pulmonary venous return, hydronephrosis, and triphalangeal thumbs. Karyotype was 47,XY,+idic(22)(q11.2) in all 20 cells examined. The patients cognitively normal father has a unilateral triphalangeal thumb and bilateral preauricular pits.

Conclusions: As triphalangeal thumb has not previously been described in an individual with cat eye syndrome, this case expands the reported phenotypic spectrum of the condition. The finding of triphalangeal thumbs in our patient calls further attention to the clinical overlap between cat eye syndrome and Townes-Brocks syndrome, an autosomal dominant condition resulting from alteration of the *SALL1* gene. Ongoing elucidation of the molecular mechanisms behind the Townes-Brocks phenotype and mapping of the cat eye syndrome critical region will suggest investigative pathways into the molecular mechanisms behind the cat eye syndrome phenotype.

Novel variants identified in methyl-CpG-binding protein genes. *H. N. Cukier[1], R. Rabionet[1], I. Konidari[1], M. Y. Rayner[1], M. L. Baltos[1], H. H. Wright[2], R. K. Abramson[2], M. L. Cuccaro[1], M. A. Pericak-Vance[1], J. R. Gilbert[1]* 1) Miami Institute of Human Genomics, University of Miami, Miami, FL; 2) University of South Carolina School of Medicine, Columbia, SC.

Misregulation of the *methyl-CpG-binding protein 2* (*MECP2*) gene causes a myriad of neurodevelopmental disorders characterized by social and intellectual impairmentsmost notably Rett syndrome and some cases of autism. We hypothesized that mutations in additional members of the methyl-CpG-binding family (*MBD1, MBD2, MBD3* and *MBD4*) may also be involved in autistic spectrum disorders (ASD). This is further supported by evidence that different MBD proteins are capable of binding the same promoter region, suggesting a functional interdependence. To date, only one study has evaluated the MBD genes of autistic patients and was limited to a Japanese population. A single variation of interest was identified, R269C in MBD1. In this study, 230 autistic individuals (198 Caucasians (CA) and 32 African-Americans (AA)) were evaluated for the coding regions of *MBD1-4* by denaturing high performance liquid chromatography and results were confirmed either by TaqMan or direct sequencing. We used both multiplex and singleton families and examined transmission and disease concordance. We identified 91 autistic individuals (71 CA and 20 AA) carrying genetic alterations at 50 unique loci. 19/50 were known single nucleotide polymorphisms (SNPs), while 31/50 were novel (6 insertion/deletions and 25 SNPs). While the majority of alterations were synonymous or noncoding SNPs, we identified 9 non-synonymous changes in MBD1, 3 and 4, the deletion of a single amino acid in MBD3, and a frameshift mutation in MBD4 that truncates almost half of the protein. We did not find the MBD1 R296C variant. Ten of the novel SNPs identified in the CA affecteds, 9 of which were inherited, were not found in 300 CA control alleles. Similar studies are ongoing in AA controls. The investigation of these rare variants indicates a potential role for the MBD genes in the molecular and genetic etiology of autism, thereby furthering our understanding of this complex disorder.

Identification of a novel *DSPP* mutation which shows that the Dentinogenesis Imperfecta vs. Dentin Dysplasia phenotypes are due to a linked genetic modifier and not the location of the mutation within exon 5. *D. A. McKnight[1], P. S. Hart[2], T. C. Hart[1], L. W. Fisher[1]* 1) CSDB, NIDCR/NIH, Bethesda, MD; 2) Office of the Director, NHGRI/NIH, Bethesda, MD.

Dentinogenesis Imperfecta types II and III (DGI) and Dentin Dysplasia type II (DD) are the major, nonsyndromic autosomal dominant diseases of dentin. DGI affects both the primary and permanent dentition while only the primary teeth are severely affected in DD. While both diseases have been linked to a single gene, dentin sialophosphoprotein (*DSPP*), the clinical diagnosis of each affected member of extended families remain the same. Recently, we described a new series of frameshift mutations in the 2 kb repetitive portion of DSPPs exon 5 that is predicted to change the long hydrophilic tandem repeat (~220 x SerSerAsp) into 100-600 amino acid hydrophobic domains rich in Ile, Val and Ala. This long stretch of hydrophobic residues will most likely cause the translated proteins to precipitate in the rER and therefore interfere with odontoblast processing of normal DSPP and/or other matrix proteins such as type I collagen. This hypothesis also explains the dominant phenotype in these disorders. Based on our results and those published simultaneously by another laboratory, all reported DD frameshifts were 5 to all DGI mutations. Here we describe a novel frameshift mutation (c.3139delC) from an extended DD family that is found within the proposed DGI-mutation domain. This newly identified mutation therefore indicates that the length of mutant hydrophobic protein itself does not determine the disease outcome of the DGI vs. DD phenotypes. Instead, we propose the strictly inherited phenotypes within affected families are the result of a yet-to-be-identified genetic modifier closely linked to the *DSPP* gene, perhaps within the promoter or mRNA-stabilizing domain within the 3 UTR. This research was supported [in part] by the Intramural Research Program of the NIH, NIDCR.

Prenatal diagnosis of chromosomal abnormalities by clinical array comparative genomic hybridization (aCGH).

I. Van den Veyver[1,2], S. Kang[2], C. Shaw[2], A. Pursley[2], P. Ward[2], S. Neill[2], W. Bi[2], A. Breman[2], P. Eng[2], C. Eng[2], L. White[2], J. Lupski[2], S. Cheung[2], A. Beaudet[2] 1) Dept of Ob-Gyn; 2) Dept of Molec Human Genetics, Baylor Coll Medicine, Houston, TX.

Experience with aCGH for prenatal diagnosis is still limited. We evaluated the performance of a targeted clinical aCGH test for prenatal diagnosis of unbalanced chromosomal abnormalities. Women who underwent amniocentesis or chorionic villus sampling (CVS) were offered aCGH as an adjunct test on a fee basis. Fetal DNA was analyzed on targeted BAC or oligonucleotide arrays, optimized for detection of genomic disorders with reduced detection of polymorphic copy number variants (CNV). All samples were also cultured for karyotype analysis or needed confirmatory studies. Parental samples were obtained concurrently to determine if detected CNVs were inherited. We analyzed 350 samples: 217 amniotic fluid (AF) (62%), 38 CVS (11%), 70 already established amniocyte cultures (21%), 23 chorionic villi cultures (6%), 1 cystic hygroma fluid and 1 fetal skin biopsy. Results were reported on DNA directly extracted from uncultured samples in 113/217 AF (52%), of which 56/113 (50%) required prior whole genome amplification (WGA), and in 32/38 (84%) CVS, of which 5/32 (16%) required prior WGA. No gain or loss was detected in 285/350 samples (81%). There were 65/350 CNVs, 41/350 (12%) of which were interpreted as likely benign, 20/350 (6%) of defined clinical significance and 4/350 (1%) of uncertain clinical significance, the most difficult of which was a de novo deletion 16p13.1 (PMID: 17480035). For 11/350 samples (~3.1% or 1/32), aCGH contributed important new information. For 4/350 (1 % or ~1/88), the abnormality would not have been detected without aCGH analysis. Array CGH also facilitated rapid identification of 5 of 10 supernumerary marker chromosomes found on the fetal karyotype. We conclude that aCGH is an important new diagnostic tool for prenatal diagnosis of submicroscopic and larger unbalanced genomic rearrangements and for identification of the genomic content of marker chromosomes. Although aCGH detected benign inherited variants in 12% of cases, these did not present major counseling difficulties.

Identification of modifier genes for cutaneous malignant melanoma (CMM) and dysplastic nevi (DN) in melanoma families with and without CDKN2A mutations. *R. Yang, R. Pfeiffer, M. Tucker, A. Goldstein, Core Genotyping Facility* DCEG/NCI/NIH/DHHS, Bethesda, MD.

The CDKN2A gene is the major high-risk melanoma susceptibility gene identified to date. The variable penetrance and clinical manifestations among mutation carriers suggest the existence of modifier genes or other risk factors. The presence of dysplastic nevi (DN) is also a strong risk factor for familial CMM and to date no candidate genes have been identified for DN. The goal of this study is to identify low-penetrant genes for CMM and DN in CMM/DN-prone families with and without CDKN2A mutations. We genotyped 537 individuals (107 CMM, 209 DN, 135 CDKN2A mutation carriers) from 28 CMM families (19 CDKN2A+, 9 CDKN2A-) for 1536 SNPs in 152 genes included in a custom designed Illumina panel, which includes genes involved in important pathways such as DNA repair, apoptosis, and immune responses. We used conditional logistic regression conditioning on families to detect SNPs that are associated with the risk of CMM and DN as separate outcomes. As expected, we found that some genes had differential effects for CMM or DN, whereas some were associated with both outcomes. Most notably, SNPs in BCL2 (OR_{het} = 0.4 [0.25, 0.65]; OR_{homo} = 0.27 [0.13, 0.54]; P_{trend} = 0.0003) and IL10RB (OR_{het} = 1.91 [1.22, 2.99]; OR_{homo} = 2.71 [1.28, 5.76]; P_{trend} < 0.0001) were only associated with the risk of CMM; whereas SNPs in TNFSF13B had stronger effects on DN (OR_{het} = 0.43 [0.26, 0.71]; OR_{homo} = 0.18 [0.02, 1.56]; P_{trend} = 0.0004). Genes such as TNFRSF8 and IL1R1 were associated with increased risk of both CMM and DN. Risk estimates were similar among CDKN2A carriers and non-carriers for most of these SNPs. We also used a random effect model (Pfeiffer R, Biometrika, 2001) to further account for residual familial correlations among family members and the effect estimates obtained from the random effect model were more significant compared to those from logistic regression analysis. In the future, we will examine specific gene and pathway effects and will also incorporate host and sun exposure variables in the model. In addition, we will validate these findings in larger, independent datasets.

Genetic variants at 17q21 locus contribute to early-onset asthma and interact with environmental tobacco smoke exposure in early-life. *E. Bouzigon[1], E. Corda[1], H. Aschard[1], MH. Dizier[2], N. Chateigner[1], I. Pin[3], F. Kauffmann[4], M. Lathrop[5], F. Demenais[1]* 1) U794, INSERM, CEPH, Paris, France; 2) U535, INSERM, Paris, France; 3) U823, INSERM, Grenoble, France; 4) U780, INSERM, Villejuif, France; 5) CNG, Institut de Génomique, CEA, Evry, France.

A genome-wide association (GWA) study identified genetic variants at chromosome 17q21 that modulate expression of *ORMDL3* and are associated with an increased risk of asthma. To elucidate further the relationship of this locus with disease, we investigated whether the effects of these variants differ according to age-of-onset of asthma and interact with environmental tobacco smoke (ETS) exposure in early-life. We tested 36 SNPs in 17q21 region in 1,511 subjects from 372 French EGEA families. Association analysis was carried out using a likelihood-based method implemented in LAMP program. We first replicated association of asthma with 11 SNPs (P<0.01) of which 3 obtained P<0.001. We then conducted ordered-subset regression analysis that led us to select onset at or before 4 years of age to classify patients into early-onset and late-onset asthma. Association with early-onset asthma was found to be highly significant ($P<10^{-5}$ for 4 SNPs), while no association was found with late-onset asthma (P0.002 against homogeneity). When examining ETS exposure in early-life, association with early-onset asthma was only significant in the exposed families ($P<5x10^{-5}$ for 6 SNPs). The early-onset asthma odds-ratios (ORs) were consistently increased by ETS exposure: OR=3.11 (95% confidence interval, 1.79 to 5.42, under the best fitting recesive model)for rs8069176, the most strongly associated SNP. Furthermore, we showed that a single haplotype block accounts for association with early-onset asthma, thus narrowing down the region of interest as compared to the initial GWA study. This study demonstrates that increased risk conferred by 17q21 SNPs is restricted to early-onset asthma and is further enhanced by ETS exposure in early-life. These results are an important contribution to the understanding of the mechanisms by which 17q21 genetic variants act and have important implication for improving prevention strategies against asthma.

Association Analysis of Serotonin and Dopamine Transporter Genes with Posttraumatic Stress Disorder (PTSD).

H. Munger[1,3], R. Morey[2,3], J. Rimmler[1,3], M. F. Dennis[2,3], K. Green[2,3], M. A. Hauser[1,3], S. Schmidt[1,3], J. C. Beckham[2,3] 1) Center for Human Genetics, Department of Medicine, Duke University Medical Center, Durham, NC; 2) Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC; 3) Mid-Atlantic Mental Illness Research, Education and Clinical Center (MIRECC), Durham VA Medical Center, Durham, NC.

The serotonin (SLC6A4) and dopamine (SLC6A3) transporter genes have previously been investigated as candidate genes for several psychiatric disorders, including PTSD. As part of the Mid-Atlantic MIRECC, we have psychiatrically evaluated over 900 individuals, most of whom are veterans returning from recent deployment to Iraq or Afghanistan. To date, 572 DNA samples have been genotyped for a total of 27 tagging SNPs in SLCA3 and SLCA4, and for two functional polymorphisms: the 5HTTLPR/rs25531 promoter variant in SLCA4 and the 3 VNTR in SLCA3. Caucasian subjects carrying either the low- or high-expressing genotypes at 5HTTLPR had an increased risk of lifetime PTSD, relative to individuals with normal SLCA4 expression levels: OR 2.34, 95% CI 0.99-5.53 for high expression; OR 2.42, 95% CI 1.09-5.37 for low expression (72 cases/78 controls). The effect size increased (to OR 2.83, 95% CI 1.15-7.0 for high expression) when we adjusted for level of lifetime trauma exposure. Genotypes at the intronic SNP rs420422 in SLC6A3 were associated with self-reported current PTSD in both Caucasians and African-Americans (uncorrected p=0.005), regardless of the extent of traumatic events. In addition, a significant association with any Axis 1 disorder was detected for the intronic SNP rs250682 in SLC6A3 in Caucasians (p=0.008) and for the intronic SNP rs9303628 in SLC6A4 in African-Americans (p=0.005). These results suggest that SLC6A4 and SLC6A3 genotypes are associated with PTSD specifically and psychiatric disorders more generally, and that these associations vary across ethnicities. Furthermore, they suggest that lifetime trauma exposure may modulate the 5HTTLPR association with PTSD.

Inherited and de novo copy number variation changes in neurodevelopmental disorders. *S. Villatoro[1], L. Armengol[1], I. Crespo[4], E. Gabau[2], L. Comadran[4], MD. Coll[3], M. Guitart[4], X. Estivill[1,5]* 1) Genes and Disease, Center for Genomic Regulation; 2) Servei de Pediatria, Corporació Sanitària Parc Taulí; 3) Departament de Biologia Cellular Universitat Autònoma de Barcelona; 4) Laboratori de Genètica, Corporació Sanitària Parc Taulí; 5) Pompeu Fabra University, Barcelona, Spain.

Angelman syndrome (AS) is a neurodevelopmental disorder with a recognizable molecular cause in about 85% of cases. Copy number variation (CNV) is an important source of genomic changes, and genes located therein are likely to exhibit altered expression patterns, therefore contributing to phenotypic changes. Twenty AS patients without the typical molecular alterations but with well-defined clinical features were analyzed by aCGH using the 244K Agilent platform. Altered regions that contained rare CNVs (1 finding in the literature) or not reported in the Database of Genomic Variants were selected for validation using custom Multiplex Ligation-dependent Probe Amplification (MLPA) assays (83 probes targeting 73 different regions). We assessed the CNV status in the 20 AS cases and in their parents, and also expanded the study to larger sets of samples of individuals suffering idiopathic mental retardation (n=296), autism (n=164) as well as to a control cohort of normal individuals (n=453). We identified 3 de novo deletions (1p36, 1q44 and ZNF528 gene), two maternally inherited duplications (Xp11.23 and Xq28), 19 inherited altered regions present in disease cases but not identified in our control population. We also identified 37 inherited genomic variants that are present in the general population. Three of those exhibit significant frequency differences between cases and controls ($P<0.05$; Fisher Test). Our results support the view that a considerable proportion of genomic regions showing variability in copy number could be involved in neurodevelopmental disorders. The absence of genomic abnormalities in controls of inherited genomic changes detected in cases, suggests that even if inherited, they could be responsible for some of the clinical features perhaps unmasking recessive mutations in specific genes involved in the phenotypes.

***IL18* and *IL2* polymorphism in Psoriasis susceptibility in the Irish population.** *A. Ryan[1], K. Al-Jubury[1], G. Turner[1], P. Gallagher[2], A. Irvine[1], O. Fitzgerald[2], B. Kirby[2], R. McManus[1]* 1) Department of Clinical Medicine, Institute of Molecular Medicine, Trinity College, Dublin, Ireland; 2) St Vincents University Hospital, University College, Dublin, Ireland.

Psoriasis is an inflammatory disease of the skin and joints with a prevalence of up to 2% in European populations. IL18 is a pro-inflammatory cytokine, which promotes Th1 T-cell development by inducing -interferon. Genetic variation in this gene has been implicated in the pathogenesis of several autoimmune conditions, including inflammatory bowel disease, type 1 diabetes, atopic eczema and asthma. There is some evidence that IL18 may play a role in psoriasis. rs6840968 is a single nucleotide polymorphism (SNP) within the *IL2/IL21* region of chromosome 4q27, which has recently been associated with Type I Diabetes, Rheumatoid Arthritis, Graves Disease and Celiac Disease. The functional relevance of the *IL2* and *IL21* genes in inflammatory and autoimmune conditions is highlighted by the role of these cytokines in T-cell activation and development. We have genotyped *IL18* rs187238 (*IL18-137*) and *IL2/IL21* rs6840968 in 231 ethnically uniform Irish patients with psoriasis and 871 Irish controls. Both SNPs conformed to Hardy Weinberg Equilibrium in both populations. Both loci showed evidence of association with psoriasis in this population (*IL18* rs187238, Odds Ratio 0.61 [0.44 - 0.86], ^{2} = 8.99, P = 0.0027; *IL2/IL21* rs6840978, Odds Ratio 0.67 [0.48 - 0.92], ^{2} = 6.41, P = 0.01134, for carrier status of the minor allele in both cases). This latter value for *IL2/IL21* rs6840978 is similar to a recent study of psoriasis susceptibility for the same SNP in UK and US populations (OR = 0.77 [0.62 - 0.95] and OR = 0.81 [0.68 - 0.96], respectively), for the same allele and direction, substantiating existing evidence that the *IL2/IL21* haplotype block represents a risk factor for the development of psoriasis.

An education strategy for addressing barriers to the entry of genomic medicine in community healthcare. *K. Powell[1], C. Christianson[1], S. Hahn[2], S. Blanton[2], M. Pericak-Vance[2], V. Henrich[1]* 1) Univ NC at Greensboro, NC; 2) Univ of Miami, FL.

The Genomedical Connection is a demonstration project to develop and test a model for the integration of genomic medicine into primary care. The project includes an education program that addresses a variety of barriers within three stakeholder populations: the community, the healthcare providers, and their patients. Barriers for each audience were identified through a front end needs assessment utilizing surveys and focus groups. Identified barriers for the community and patients included a lack of knowledge about genetic concepts, terms and information about the health of other family members, low literacy and low health literacy. Provider barriers identified include the lack of: knowledge about genetics, genetic testing and/or genetic counseling, confidence in handling patient concerns raised in a family history, time to collect, assess and address family history, supportive resources, and protocols for managing patient healthcare after initial risk assessment. All audiences were concerned about privacy and confidentiality. To address these barriers we developed a comprehensive education strategy with coordinated and complementary educational objectives for each audience. Educational materials and events were developed in collaboration with community-based health professional organizations, a community advisory board, and partner organizations. Community and patient education materials and presentations were developed at a 6th-8th grade level. To address a subset of the provider barriers, on-line education modules offering CME credit for family history and 3 pilot diseases (breast/ovarian cancer, colon cancer, and thrombophilia) were created to teach providers how to recognize patients who may be at risk based on family health history, to stratify them into risk categories, and to manage their care accordingly. Our research indicates that the successful integration of genomic medicine into the primary care setting will require that numerous barriers be addressed; targeted education is the first of a multifaceted effort to be implemented.

Direct access genetic tests advertised online. *A. Roche*[1,2], *D. Doyle*[1,2] 1) Washington State Department of Health, Kent, WA; 2) Genetic Services Policy Project, Seattle, WA.

The number of genetic tests offered directly to the public via the internet is growing, raising concerns as well as providing the potential for benefit. Using a list of 31 companies tracked by the Genetics and Public Policy Center, we reviewed websites advertising direct access genetic tests to characterize the types of tests offered, marketing approaches employed, the accuracy of information provided, and the extent of genetic counselor or other health care provider involvement in the testing process. We found wide variation in all of these areas. Tests offered include whole genome sequencing, single nucleotide polymorphism (SNP) genome profiles, SNP panels for complex disease risk or to create a personalized intervention product, and single-gene Mendelian disorders, with prices ranging from $75 to $350,000. Five companies provide access to a genetic counselor as part of the test purchase price, but the majority do not address genetic counseling at all. When provided with appropriate support, some online genetic tests may help improve consumer access. To protect consumers from harms that might arise in online genetic services markets, the Advisors to the Genetic Services Policy Project, a federally funded grant to assess genetic services delivery and translation of new research into practice, recommend several policy actions. The federal government may: a) consider regulating home brew tests, b) evaluate the need for broad regulations regarding direct access genetic tests, c) assure that the Federal Trade Commission, Food and Drug Administration, and state attorneys general carry out their mission of preventing harm and fraud, and d) consider licensing companies selling direct access genetic tests.

Natural history and phenotype of NF1-associated glomus tumors. *J. Sloan[1], A. Moshyedi[2], L. Yao[2], R. Lee[2], D. Stewart[1]* 1) NHGRI, Bethesda, MD; 2) NIH Clinical Center, Bethesda, MD.

Glomus tumors are benign tumors that arise from the glomus body, a thermoregulatory shunt in the fingertips. Multi-focal glomus tumors in patients with neurofibromatosis type 1 (NF1) have been reported suggesting a possible association. Seven adults with NF1 recruited for a natural history study reported classic glomus tumor symptoms, were evaluated by MRI and in 4 cases surgery was performed. Patient 1 was a 35-year-old female with a 5-year history of pain in 6 digits. MRI revealed lesions in 3/6 symptomatic digits. Two surgeries were performed over a 6-month period. Three lesions were histologically confirmed glomus tumors. The other 3 digits showed enlarged Pacinian corpuscles. Between the 1st and 2nd surgeries, a glomus tumor recurred in the left 4th digit. The pain returned and a 3rd explorative surgery was conducted in 3 fingers. No glomus tumors were identified. Six months after the 3rd surgery the pain returned. Patient 2 was a 50-year-old male with a 15-year history of pain and disuse of his left arm with symptoms consistent with complex regional pain syndrome (CRPS). In 3 fingers, glomus tumors were identified by MRI and removed. Six months later the pain returned and surgery confirmed recurrence in all 3 digits. Six months after the 2nd surgery the pain returned. Patient 3 was a 28-year-old female with a 4-year history of pain in 3 fingers. MRI identified a 3 mm lesion in the left 3rd digit only. Surgical exploration revealed a glomus tumor in this digit but none were identified in the other painful fingers. Eight months later pain in the left 3rd digit returned. Patient 4 was a 48 year-old female with pain in the left 3rd digit since childhood. A 3 mm lesion was identified on MRI, surgery was performed and revealed a glomus tumor. Six weeks postoperatively the pain resolved. Our experience supports an association between NF1 and glomus tumors. Glomus tumor symptoms were variable ranging from intermittent pain to CRPS. Two patients had recurrence of their glomus tumors in less than a year. Early intervention may be desirable to prevent the development of CRPS. Clinicians should routinely ask about fingertip pain in patients with NF1.

The rs1333049 SNP near CDKN2a/2b, associated with Myocardial Infarction, is associated with increased risk of Peripheral Artery Disease in older people. *C. Cluett[1], T. Tanaka[2], A. Kisialiou[3], J. Guralnik[4], L. Ferrucci[2], T. M. Frayling[5], A. Murray[1,5], D. Melzer[1,5]* 1) Epidemiology and Public Health, Peninsula Medical School, Exeter, Devon, United Kingdom; 2) Longitudinal Studies Section, Clinical Research Branch, Gerontology Research Center, National Institute on Aging, Baltimore, Maryland, United States of America; 3) Tuscany Regional Health Agency, I.O.T. and Department of Medical and Surgical Critical Care, University of Florence, Florence, Italy; 4) Department of Geriatric Medicine Laboratory of Epidemiology, Demography and Biometry, National Institute on Aging, Bethesda, Maryland, United States of America; 5) Genetics of Complex traits, Institute of Biomedical and Clinical Sciences, Peninsula College of Medicine and Dentistry, University of Exeter, UK.

Recent human genome wide association studies have found consistent associations between a common variant near the CDKN2a/2b loci on chromosome 9p21 and Myocardial Infarction (MI) /Coronary Artery Disease (CAD). Proximal to this polymorphism lie two cyclin dependent kinase inhibitor genes, CDKN2a and CDKN2b, which are are key regulators of the cell cycle. The variant has also been shown to be associated with abdominal aortic and intracranial aneurysms, independent of the validated effect on CAD. However, similar associations with peripheral artery disease (PAD) and cardiogenic stroke were not significant when subjects with known CAD were excluded. We aimed to estimate the association between this variant (tagged by rs1333049) and Ankle Brachial Index and PAD in elderly people. In 2630 elderly individuals (mean age 76.4 years) the C allele of rs1333049 was associated with lower mean ABI measures (-0.017 ABI units, 95% CI: -0.03--0.01, p=1.3x10-4) and an increased risk of PAD (OR: 1.29 95% CI: 1.06-1.56, p=0.012) after removal of baseline and incident MI cases in a 6 year period. This is the first report of a common variant associated with MI and aneurysms, being independently associated with ABI and PAD.

SUMF1-activated IDS activity retained after fusion with a brain-targeting ligand: application in encapsulated cellular therapy. *M. J. Schwindt, M. A. Potter* Medical Sciences, McMaster University, Hamilton, ON, Canada.

Mucopolysaccharidosis type II (MPS II), also known as Hunter syndrome, is a rare X-linked genetic disorder which is characterized by the deficiency of the lysosomal enzyme iduronate-2-sulfatase (IDS). This deficiency results in lysosomal storage of the glycosaminoglycans (GAGs) dermatan sulfate and heparan sulfate, which in severe forms of the disease includes accumulation in the CNS, leading to developmental regression and shortened lifespan. The recent development of enzyme replacement therapy has achieved success in improving the somatic conditions of MPS II, however little to no GAG clearance occurs in the brain as the blood-brain barrier (BBB) impedes vascular delivery of the enzyme. In this study, mouse embryonic fibroblasts (MEFs) and C2C12 murine myoblasts have been co-transfected with modified IDS and its activator, sulfatase-modifying factor 1 (SUMF1). IDS was fused to the receptor-binding domain of Apolipoprotein B (ApoB), which has been used as a ligand to transport therapeutic molecules across the BBB via low-density lipoprotein (LDL) receptors, and tagged with an AU1 epitope for tracking purposes. IDS modification, including c- and n-terminal AU1 tags, ApoB fusions, and a combination of both, does not diminish enzyme activity secreted from cells in vitro, although cell type had a large effect on secretion (C2C12s had 5-fold more secretion than MEFs). Furthermore, co-transfection with SUMF1 leads to a two-fold increase in secreted enzyme activity compared to cells transfected with IDS alone. Immunofluorescence and Western blots, performed on the various constructs utilizing AU1-targeted antibodies, confirms the identity and intracellular localization of the constructs. Correction of human MPS II fibroblasts has been achieved following 48 h incubations in various conditioned media and in co-culture with microencapsulated engineered cells; thus indicating that the modified IDS is taken up from the medium and targeted to lysosomes. Future in vivo work will evaluate the efficacy with which ApoB is able to transcytose the BBB and deliver therapeutic IDS to MPS II mice.

Clinical and functional studies in subjects carrying glucocerebrosidase (GBA) mutations. *J. Davis[1], K. Berman[2], G. Lopez[3], TL. Urban[1,4], E. Sidransky[1], O. Goker-Alpan[1]* 1) MGB/NHGRI/NIH, Bethesda, MD; 2) NIMH/NIH, Bethesda, MD; 3) NINDS/NIH, Bethesda, MD; 4) UPENN School of Nursing, PA.

Multiple studies indicate that GBA mutations are a risk factor for parkinsonism. A prospective study was designed and initiated to identify and objectively characterize the early parkinsonian manifestations and the rate of progression of symptoms in affected and at risk individuals carrying GBA mutations. All subjects undergo neurological, neurocognitive evaluations and olfactory testing. Presynaptic dopaminergic function and cerebral blood flow are assessed with F-18-L-DOPA and 15 O-H2O PET scans. Transcranial ultrasonography is explored as a noninvasive tool to evaluate hyperechogenicity of the substantia nigra. The subjects include patients with Gaucher disease and Gaucher carriers with parkinsonism, and/or with a family history of a first degree relative with parkinsonism. The genotypes identified are N370S, L444P, c.84dupG and recombinant alleles. Among 21 subjects recruited to the study, there are 10 patients with parkinsonism and two discordant sib-pairs with Gaucher disease where only one has parkinsonism. In subjects with parkinsonism(7M: 3F), the mean age of onset was 49 years, disease duration was 8 years, and UPDRS III score was 26. Six subjects were given the diagnosis of classic Parkinson disease (PD). Half of the patients reported cognitive changes later in their disease course. Three subjects were considered to have Lewy body dementia (LBD), and one parkinson plus syndrome. The most frequent non-motor finding was olfactory dysfunction. Thus, GBA mutations, in both homozygotes and heterozygotes, are associated with a spectrum of parkinsonian phenotypes ranging from classic PD, to a less common phenotype characteristic of LBD. The results of the clinical and functional imaging studies will enable us to estimate the frequency and earliest onset symptoms in at-risk subjects, better define the associated parkinsonian phenotype, follow the progression of manifestations and identify at-risk individuals. This study will also help us to identify whether specific abnormalities in L-Dopa metabolism occur in subjects with GBA mutations.

Barth syndrome caused by a novel deletion mutation in the TAZ gene in a Hispanic kindred. *Y. Fan[1], R. Chang[2], R. L. Forst[2], L. S. Pena[1], A. C. McCanta[3], M. Vatta[1], J. A. Towbin[1]* 1) John Welsh Cardiovascular Diagnostic Laboratory, Department of Pediatrics (Cardiology), Texas Children's Hospital, Baylor College of Medicine, Houston, TX; 2) Division of Metabolic Disorders, Childrens Hospital Orange County, Orange County, CA; 3) Pediatric Cardiology, The Children's Hospital Denver, Aurora, CO.

Barth syndrome is an X-linked recessive disorder characterized by dilated cardiomyopathy, variably expressed skeletal myopathy, short stature, neutropenia, abnormal mitochondria, and 3-methylglutaconic aciduria. The disorder is caused by mutations in the tafazzin (TAZ/G4.5) gene located on Xq28, as first described by Bione et. al. in 1996. Alternative splicing of the gene yields several different proteins, the functions of which remain largely uncharacterized. Sequencing of the TAZ gene is currently the most reliable diagnostic approach for Barth syndrome. We describe a Hispanic family in which the 3-year-old proband presented with cyclic neutropenia, gross motor regression, decreased stature, dilated cardiomyopathy, and 3-methylglutaconic aciduria. His mother had two siblings, at least one of whom was male, who died in infancy of unknown causes. She had no other siblings. A novel 10-bp deletion mutation (728_737del10) in exon 10 of the TAZ gene was identified in the proband through bi-directional sequencing. This deletion creates a premature stop 20 codons downstream. Family studies revealed that the probands mother carries the same deletion, however, his maternal grandmother does not. The identification of TAZ gene mutations is important for early diagnosis of atypical Barth syndrome and the provision of accurate genetic counseling and carrier testing for at-risk relatives.

Impact of *APOBEC3B* gene deletion on HIV-1 infection and disease progression. *P. An[1], J. Phair[2], G. D. Kirk[3], S. Donfield[4], S. Buchbinder[5], J. J. Goedert[6], C. A. Winkler[1]* 1) Lab Genomic Diversity, SAIC-Frederick Inc, National Cancer Institute-Frederick, Frederick, MD; 2) Northwestern University, Chicago, IL; 3) Department of Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; 4) Rho, Inc., Chapel Hill, NC; 5) San Francisco Department of Public Health, San Francisco, CA; 6) Epidemiology Branch, National Cancer Institute, Bethesda, MD.

The human APOBEC3 family proteins are cytidine deaminases that inhibit virus, replication by inducing G to A hypermutation in the minus DNA strand during reverse transcription.. APOBEC3B, one of seven members of APOBEC3 family, has been shown to weakly or strongly inhibit HIV-1 replication *in vitro*. Recently, a common 29.5-kb deletion that removes the APOBEC3B gene was identified. We examined the impact of the *APOBEC3B* gene deletion on HIV-1 infection and disease progression in five well-characterized U.S.-based HIV-1 natural cohorts consisting of more than 4000 HIV-1 infected and exposed but uninfected subjects. The gene deletion was more frequent in European Americans (7.5%) than African Americans (4%). The analysis was done by a logistic regression for the comparison of HIV-1 infected and uninfected groups and by Cox proportional hazards model for the rate of AIDS progression stratified by the deletion genotype. The hemizygous deletion had no effect on either infection or progression in both populations. However, the homozygous deletion was significantly associated with increased susceptibility to infection and accelerated rate of progression to AIDS in European Americans. It is possible that other APOBEC3 family proteins can compensate for loss of one copy but not two copies of *APOBEC3B*. This finding suggests a role of *APOBEC3B* gene in HIV-1 pathogenesis. [Funded by NCI contract NO1-CO-12400].

Genome-Wide Copy Number Analysis in a Cohort 525 Probands with Non-Syndromic Bilateral Sensorineural Hearing Loss Using a Novel Analysis Software (PECONPI). *D. Clark[1], M. Berman[1], L. Conlin[1], H. Rehm[2], M. Kaur[1], J. Glessner[1,3], H. Hakonarson[1,3], S. Grant[1,3], N. B. Spinner[1,4], I. D. Krantz[1]* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, PA; 2) Harvard/Boston Children's Hospital; 3) The Center for Applied Genomics, The Children's Hospital of Philadelphia, PA; 4) Division of Clinical Labs, Department of Pathology, The Children's Hospital of Philadelphia, PA.

SNP array platforms have been increasingly used to identify structural duplications and deletions (copy number variation or CNV) in patients with syndromic findings. Using these platforms for novel gene discovery in patients with single gene disorders has been hampered by the prevalence of small benign CNV in the genome. We have developed Perl Copy Numbers of Potential Interest (PECONPI), a program that ranks CNVs based on their pathogenic potential, scoring calls based on an adaptable set of parameters. Hearing loss is an ideal disorder to study using this approach as it is one of the most common hereditary human disorders, is highly heterogeneous, and most forms are believed to be caused by mutations in dominantly or recessively acting genes. Although there have been major breakthroughs in understanding the molecular basis of hearing loss, the causative genes in at least 60% of affected probands remain unidentified. We utilized the Illumina 550K SNP array to detect CNVs in 525 probands with non-syndromic sensorineural hearing loss (NSSNHL) and applied this novel software program to rank the CNV calls based on likely pathogenicity. By differentiating rare pathogenic CNVs from benign CNVs in this population, PECONPI was able to validate all known *GJB6* gene deletions in our cohort, identify novel deletion mechanisms in known hearing loss genes (e.g. *OTOF* and *USH2A*), and identify multiple novel candidate genes mapping to established and novel loci. PECONPI is a useful tool to identify new mechanisms and novel genes implicated in genetic hearing loss. It can be adapted for any population, and will prove useful for investigating disorders suspected to be caused by small genomic alterations, even those involving single genes.

Maternal-Grandpaternal Age Is a Potential Risk Factor for the Development of Autism Spectrum Disorder. *E. Faulks, O. Abdul-Rahman* Peds-Genetics, U of MS Med Center, MS.

Autism spectrum disorder and pervasive developmental disorders (ASD/PDD) usually present before the age of three years with impairments in communication and social interaction. Studies have provided strong evidence that ASD/PDD is a genetically heterogeneous entity. A few studies have found that increased paternal age is associated with a higher incidence of autism which provides evidence for new mutations as causative of ASD/PDD. A high predominance of males to females affected with autism has been well documented suggesting that mutations on the X chromosome may account for a number of affected individuals. Recent studies suggest that mutations on the maternal X chromosome may be causative based on data showing increased rates of psychiatric problems among mothers of children with autism, but not among fathers. Many mutations on the X chromosome arise during spermatogenesis due to the increased rates of DNA replication that occur in this process. The concept of new mutations occurring on the X chromosome during spermatogenesis in the maternal grandfather is known as the grandfather effect and accounts for several conditions such as Duchenne Muscular Dystrophy. We propose that increased maternal-grandpaternal age may be associated with an increased risk for autism in subsequent generations. We conducted anonymous surveys of families with children affected with autism to ascertain the ages of both sets of grandparents at the birth of each parent as well as geographical, employment, and military history. The paternal grandparents served as an internal control for the maternal grandparents. Of the 67 families successfully surveyed, we found that the average maternal grandfathers age was 2.5 years older than the paternal grandfather at the time of the parent's birth which was statistically significant. The data provides evidence for advanced maternal-grandpaternal age as a potential risk factor for the development of autism. Future studies should focus on the X chromosome and may also need to evaluate the environment of maternal grandparents for potential mutagens to explain the increased incidence of ASD/PDD seen in recent years.

An improved alpha-glucosidase enzyme for Pompe disease. *E. Kakkis[1], K. Antonsen[1], A. Cheng[1], T. Christianson[1], J. Femenia[1], B. Prince[1], M. Vellard[1], J. White[1], T. Zankel[2], V. Koppaka[1]* 1) BioMarin Pharmaceutical Inc. Novato, CA. 94949; 2) Raptor Pharmaceuticals Corp. Novato, CA. 94949.

Many Pompe patients with acid-alpha-glucosidase (GAA) deficiency have benefited from enzyme replacement therapy (ERT) using recombinant GAA (Myozyme, Genzyme Corp. Cambridge, MA) but a significant number do not achieve sufficient improvement. The efficacy of the GAA enzyme used may not be optimal due to low amounts of the high affinity N-linked oligosaccharide bis-mannose 6-phosphate mannose 7 (bisMan6P-Man7) needed for efficient uptake. Using a novel mutant CHO cell line, we have produced a highly phosphorylated GAA (BMN103) with fivefold higher bisMan6P-Man7 than Myozyme. The increased phosphorylation resulted in a 15-fold uptake efficiency improvement for BMN103 (Kuptake: 2 nM vs 30 nM for Myozyme) in Pompe fibroblasts that is comparable to other MPS enzymes used for ERT. Other GAA enzyme characteristics (Km, Vmax, Specific Activity, Sialic acid) were similar. When BMN103 was compared with Myozyme using 4 short IV infusions over 2 weeks in Pompe mice (3 month old; knockout, GAAtm1Rabn/J), BMN103 demonstrated 2-fold greater total enzyme activity compared to Myozyme in all tissues that were tested. BMN103 also reduced more of the accumulated glycogen in the target tissues both by total glycogen and by pathology. At a dose of 20 mg/kg, administration of BMN103 resulted in >85% reduction in glycogen in heart after only 2 weeks, while administration of Myozyme achieved only 50% reduction. At this dose, BMN103 achieved a ~50% glycogen reduction in diaphragm compared to only ~3% for Myozyme, a critical difference in a tissue required for respiratory function. In type-II skeletal muscle the 20 mg/kg dose of BMN103 showed ~ 25% clearance of glycogen while the same dose of Myozyme showed only <1% clearance. In a type-I skeletal muscle, 20 mg/kg BMN103 showed 30% glycogen clearance and the same dose of Myozyme only 13%. The enhanced phosphorylation and M6PR-mediated uptake, along with the dramatically improved clearance of glycogen from affected tissues, suggests that BMN103 may be a more effective GAA than Myozyme for treatment of Pompe Disease.

Genome-wide assessment of human-specific LINE-1 insertions. *A. D. Ewing[1], L. Zhang[1], V. G. Cheung[3], P. D. Sniegowski[2], H. H. Kazazian, Jr.[1]* 1) Genetics, University of Pennsylvania, Philadelphia, PA; 2) Biology, University of Pennsylvania, Philadelphia, PA; 3) Howard Hughes Medical Institute, Philadelphia, PA.

Human-specific LINE-1 elements (L1Hs) are the only active family of LINE-1 retrotransposons in the human genome. Throughout evolutionary history there has been a succession of L1 families which through their copy-and-paste replication mechanism are directly responsible for ~17% of genomic sequence. The active L1Hs family is still inserting new copies into the genome as evidenced by ~250 polymorphic insertion sites catalogued in several studies and at least 16 known cases of a de novo L1 insertion contributing to human diseases. These known polymorphic and private insertions are likely to represent only a small fraction of the total amount of genomic variation induced by L1 activity, much of which may be somatic. Results from mouse and rat models in our lab suggest that the majority of L1 retrotransposition events occur somatically and are therefore not transmissible to offspring. In order to confirm this phenomenon in humans, we analyze the genomic L1 content of monozygotic twins for differences. The presence of L1 insertions in one twin absent from the corresponding genomic location in the other twin is evidence of a somatic L1 retrotransposition event in the twin harboring the unique insertion. To address this possibility, we have developed an assay whereby the Human-specific LINE-1 content in the genome of a given individual can be assessed in a high-throughput manner, on a genome-wide scale. Following amplification of the 3 flanking sequences via a PCR-based approach, amplicon ends are sequenced on the Illumina Genome Analyzer platform yielding millions of reads per individual. Analysis of the sequencing results via our bioinformatics pipeline yields a number of interesting candidate somatic insertions for further validation. Furthermore, our results indicate that any given individual shares approximately 800 L1 insertion sites with the reference human genome and differs from this reference L1 content at ~200 loci. This technique allows us to study human L1 insertion sites on a genome-wide scale, enabling further studies of the impact of L1 activity on human disease.

The inadequacy of the Bonferroni correction in genome-wide association studies. *J. C. Wakefield* Statistics and Biostatistics, University of Washington, Seattle, WA.

The Bonferroni threshold is ubiquitous in genome-wide association studies, with the only source of contention being the number of tests that one must control for, accounting for the correlation between tests. A common target level is 5×10^{-8} (McCarthy et al, Nature Reviews Genetics, 9, 356-369), corresponding to 1 million tests and an level of 0.05. Using a Bayesian approach we show the prior over the collection of null hypotheses that corresponds to the Bonferroni correction, and argue that this prior is rarely realistic in a genome-wide setting. Even if one accepts that the control of the family-wise error rate is a reasonable criteria to adopt, a major problem with its use is the specification of a threshold for significance. In contrast to current practice, we show that the threshold should decrease with sample size, since a rule that is independent of sample size corresponds to a belief that the cost of type II errors decrease in importance as sample size increases, and in a manner which is implicit in the procedure, rather than being user-specified. We illustrate how power may be increased using a Bayesian approach and explicitly specifying both a prior on the effect size, and the costs of type I and type II errors. This approach revolves around the Bayes factor, which differs from the p-value by accounting for power. Hence a Bayesian threshold depends on sample size as well as the minor allele frequency. All derivations are based on an easily computable Bayes factor that requires only a confidence interval on the effect parameter for implementation (Wakefield, AJHG, 81, 208-227).

Effects of Genetic Background On ENS Development in the *Sox10^{Dom}* Model of Hirschsprung Disease. *L. C. Walters, V. A. Cantrell, E. M. Southard-Smith* Medicine and Cell & Developmental Biology, Vanderbilt University, Nashville, TN.

Abnormalities in development of enteric neural progenitors (ENPs) can lead to aganglionosis in a variable portion of the distal intestine, causing Hirschsprung disease (HSCR). Cumulative evidence suggests that variation in HSCR is due to gene interactions that modulate the ability of ENPs to populate the developing gut. *Sox10* is an essential gene for enteric ganglia development. *Sox10^{Dom}* mice on a mixed genetic background exhibit the variable aganglionosis seen in HSCR cases. We have established congenic lines of *Sox10^{Dom}* mice on distinct inbred genetic backgrounds, C57BL/6J (B6) and C3HeB/FeJ (C3Fe). These lines differ in penetrance and extent of aganglionosis. To define the impact of genetic background on processes during enteric nervous system ontogeny, we assayed these congenic lines for differences in migration, lineage potential, and proliferation of ENPs. Migration was evaluated by whole-mount immunohistochemistry. Both strains of *Sox10^{Dom}* mice displayed deficits in migration and decreased density of ENPs; however, the phenotype of B6.*Sox10^{Dom}* embryos was more pronounced. Differences in developmental potential were assayed by isolating enteric neural crest-derived stem cells (eNCSC) from *Sox10^{Dom}* congenic lines by flow cytometry for cell surface markers. eNCSC were cultured at clonal density, and immunohistochemistry was used to identify lineages within the resulting colonies. The number and type of colonies were quantified across multiple independent trials. We observed significant differences in lineage potential between the strains and genotypic classes. Proliferation was evaluated through immunohistochemistry of dissociated embryonic guts in culture. The significant differences between the *Sox10^{Dom}* congenic lines indicates that the deficiencies of ENP development leading to aganglionosis are not strictly due to migration defects. Our study of congenic lines contributes to understanding the effects of genetic background and mechanisms that impact variation in HSCR disease phenotype.

Prediction of regulatory elements in human histone deacetylases. *S. Khuri*[1,2], *Z. Jiang*[1] 1) Center for Computational Science, University of Miami, FL; 2) Dr John T Macdonald Fdtn Dept Human Genetics, Univ Miami Miller Sch Med, Miami, FL.

Human histone deacetylases (HDACs) remove acetyl groups from histone tails, thus repressing transcription. The 11 known human HDACs have an evolutionarily conserved catalytic domain, but differ in size, domain organization, and function. HDACs have some tissue and time specificities that have not been fully characterized. Recent evidence has shown that some HDACs may bind proteins other than histones. We used bioinformatics to gain a better understanding of how the HDACs themselves are regulated, and therefore of how they regulate gene expression in the human genome. We took the promoter region as the 2000bp flanking the transcriptional start site, and used several predictive methods to find possible active regulatory elements in these genes. We found that in HDACs 1, 3, 4, 5, 8, and 11, the highest density of predicted motifs was in the 500bp upstream of the TSS, whereas they were more widely spaced in other HDACs. We compared these against the promoter regions of HDAC homologs from different species using Footprint. The results show that the regulatory motifs are well conserved, and they clustered in a similar pattern on the promoter sequences of several mammals, indicating that the regulation of these genes is conserved across mammals. The motifs we found point to transcription factors that have some tissue and time preferences, which implies distinct expression patterns among the HDACs. In addition, we measured the accessibility of this 2000bp region using NXSensor (which predicts nucleosome exclusion sequences and thus accessibility of the transcriptional machinery to DNA). The accessibility scores correlated with the clustering pattern of the predicted motifs in several HDACs, further verifying that these motifs may well be active. In conclusion, we used motif prediction, footprint verification, and DNA accessibility mapping to identify putative active regulatory motifs in the promoter regions of human HDACs. These results can form the basis for laboratory experiments, and this integrated approach could be used for other protein families and metabolic pathways.

Genetic differentiation of genes involved in craniofacial anomalies between human populations. *R. Kimura, M. Osawa* Forensic Medicine, Tokai University School of Medicine, Kanagawa, Japan.

Modern humans show considerable intra- and inter-population variation in facial morphology. Although this common phenotypic variation is attributed to genetic factors, they have hardly been elucidated. In contrast, genes involved in craniofacial malformation have been clarified due to the recent advances in developmental biology and human genetics. Such genes might also be associated with the common variation. Furthermore, the inter-population variation can play a key role in effectively picking out the most likely candidate genes. If we hypothesize that phenotypic differentiation between populations has been accelerated by positive selection, causal genes are expected to show genetic differentiation. In this study, considering craniofacial anomalies (CFA)-related genes (201 genes) as candidates, we examined genetic differentiation between African (YRI), European American (CEU), and East Asian (CHB+JPT: EAS) populations using the HapMap Phase II data. As an indicator of genetic differentiation, maxFST, that is the maximum of single-locus FST values in a 100 kbp window, was used. As results, high differentiation was observed in windows including ADAMTS2, PAFAH1B1, SNRPN (YRI vs CEU and YRI vs EAS), GLI3 (YRI vs CEU and CEU vs EAS), EDAR (YRI vs EAS and CEU vs EAS), AGPS, PTHR1, COL5A1, GH1, TWIST1, ENAM (YRI vs CEU), MAP2K2, GJB6, COL11A1, ERCC2, and FOXL2 (YRI vs EAS), FBN1, FLNB, PTPN11, INSR, and LMNA (CEU vs EAS). Between YRI and CEU, maxFST values in windows including CFA-related genes were elevated compared with those in windows including other genes, implying that some CFA-related genes have been subjected to recent positive selection. Of course, future association studies are indispensable to identify genes associated with the common variation in facial morphology. Taken into account the statistical limitation of large scale association studies, observations in this study would greatly help us to accomplish our goal efficiently.

Genetic linkage of measures of hand joint structure and osteoarthritis to chromosomes 7p and 14q. *D. L. Duren[1], R. J. Sherwood[1], J. Blangero[2], J. Subedi[3], T. Dyer[2], B. Jha[4], J. L. VandeBerg[2], B. Towne[1], S. Williams-Blangero[2]* 1) Lifespan Hlth Res Ctr, Wright State Univ Boonshoft Sch Med, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Miami University, Oxford, OH; 4) Institute of Medicine, Tribhuvan University, Kathmandu, Nepal.

Osteoarthritis (OA) is a multi-factorial disease with a strong genetic component. The specific genetic underpinnings of OA, however, have yet to be identified. Because the OA phenotype is comprised of a set of multiple distinct sub-phenotypes (e.g., joint space narrowing and osteophyte formation), each may be under unique genetic influence. We present evidence for significant genetic effects on joint space and overall grades of OA in the hand joints of 304 subjects from a single, large extended family in Nepal. All 304 of these individuals have been genotyped for some 400 autosomal markers spaced approximately every 10 cM. A variance components-based linkage analysis method (SOLAR; Almasy and Blangero, 1998) was used to obtain multipoint LOD scores. Linkage analysis of these measures of joint health and structure revealed two significant LOD scores (> 3.0) for linkage to markers on chromosomes 7 and 14. One significant linkage for hand joint space grade (LOD = 3.08) was found on chromosome 7p between markers D7S507 and D7S493, which overlap regions 7p21.1 and 7p15.3. This region is very near those identified by other groups to be associated with hand OA phenotypes. The second linkage (LOD = 3.00) was for a global score of hand OA, and was found on chromosome 14q near marker D14S292, which corresponds to region 14q32.33. Candidate genes of interest in the significant linkage regions include SP8, Twist1, and AKT1. Twist1 is of notable interest in that it inhibits chondrocyte gene expression through the Wnt signaling pathway and is differentially expressed in bone tissue of patients with OA. The identification of linkage to these two regions harboring genes involved in cartilage and/or bone is both promising and exciting. Future work will seek to identify other specific genes that influence the health of the joint tissues of hands. Supported by NIH grants R01 AI37901, R01 AI44406, R01 HD40377.

Management trials of exfoliative cutaneous lupus erythematosus in German shorthaired pointers with cyclosporine, hydroxychloroquine and adalimumab. *E. A. Mauldin[1], D. O. Morris[2], M. L. Casal[2]* 1) Pathobiology, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA; 2) Clinical Studies, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA.

Cutaneous lupus erythematosus (CLE) is well-characterized in humans and is divided into three major categories: chronic CLE (includes localized and generalized discoid lupus), subacute LE and acute LE. We have developed a colony of German shorthaired pointer (GSP) dogs with exfoliative cutaneous lupus erythematosus (ECLE), which appears to be quite similar clinically and histologically to chronic CLE in humans. Pedigree analysis of dogs with ECLE is highly suggestive of an autosomal recessive trait. Six affected dogs were enrolled in the study (2 females and 4 males) ranging from 6 weeks to 2.3 years of age at study begin. Five affected GSPs received immunomodulatory drugs sequentially to alleviate clinical signs (lameness, erythema, scaling, erosions/ulcers). Five dogs received oral cyclosporine (2.5-10 mg/kg/q24h) for a minimum of 4.5 months and maximum of two years. In four dogs, the drug was combined with ketoconazole (5-7 mg/kg/q24h). Cyclosporine decreased joint pain and stiffness and provided temporary improvement of some skin lesions but did not halt disease progression. Three dogs received hydroxychloroquine 5 to 10mg/kg/q24h for six weeks, 7 months, and 9 months, respectively, with no side effects (weekly CBC/serum biochemistry screens, normal EKG). Hydroxychloroquine mildly ameliorated clinical signs in the two dogs on extended treatment and normalized globulin levels in all three dogs. Four dogs were euthanized between one and three years of age due to disease progression. The two remaining male dogs (donated at > 1yr age) received a commercial human monoclonal TNF- antagonist, adalimumab at 0.5 mg/kg q2wks sc for 12 weeks. Biweekly CBC/serum biochemistry screens were within normal limits. A temporary improvement was seen in both skin lesions and lameness. None of the drug therapies provided long-lasting improvement. However, dogs with this heritable form of what appears o be chronic CLE in humans provide a unique model to study disease progression and treatment trials.

The Frequency of a Polymorphism in the Glutamate Cysteine Ligase Gene Correlates With Malarial Prevalence in Populations of African Descent. *T. Le[1], G. Ayodo[2], J. Canter[3], D. Reich[2], M. Summar[3]* 1) Pediatric Critical Care Medicine, Vanderbilt Children's Hospital, Nashville, TN; 2) Department of Genetics, Harvard Medical School, Boston, MA; 3) Center for Human Genetic Research, Vanderbilt University Medical Center, Nashville, TN.

Background: Glutamate cysteine ligase (GCL) is the rate-limiting enzyme in the glutathione biosynthesis pathway, and genetic variation in this gene can affect the ability to produce glutathione and respond to oxidative injury. We previously identified a non-synonymous polymorphism (C1384T) present only in individuals of African descent and demonstrated that this polymorphism encodes an enzyme with no activity in vitro. Objective: To determine whether the 1384T polymorphism is correlated with development of severe malaria in populations of African descent. Methods: Using high-throughput genotyping, we have genotyped Kenyans from malaria-endemic and non-endemic regions as well as several African-descent populations. Results: In a malaria-endemic region of Kenya, the 1384T polymorphism is found in 7.8% of individuals. In contrast, within a non-endemic region of Kenya, the 1384T polymorphism is present in only 3.8% of the population ($p<0.05$). Similarly, individuals from a non-endemic region of Ghana have a 5% prevalence of this allele, whereas African-Americans from North Carolina exhibit 7.4% prevalence. Within the endemic regions we studied, we note that the 1384T allele is present in 6.3% of patients with severe malaria, whereas it is present in 9.0% of controls. Though not statistically significant, these results suggest the 1384T polymorphism is associated with less severe malarial disease. Conclusions: We have previously described a glutathione production pathway polymorphism common in individuals of African descent with little or no in vitro activity. Here, we demonstrate an increased frequency of the 1384T GCLC allele among malaria endemic populations as compared to populations from non-endemic areas. In addition, our results suggest that this polymorphism is associated with less severe disease.

Oliogenic analysis locates several triglyceride metabolism genes in the GOLDN study. *E. W. Daw[1], I. B. Borecki[1], A. VanBrunt[1], J. M. Ordovas[2], M. Y. Tsai[3], P. N. Hopkins[4], J. Hixson[5], M. A. Province[1], D. K. Arnett[6]* 1) Washington Univ, St Louis, MO; 2) Tufts Univ, Boston, MA; 3) Univ of Minnesota, Minneapolis, MN; 4) Univ of Utah, Salt Lake City, UT; 5) UT Health Science Center, Houston, TX; 6) Univ of Alabama, Birmingham, AL.

The GOLDN study examined the Genetics of lipid metabolism and response to treatment in 201 families, ranging in size from 53 to 3. 1027 subjects completed the Post-prandial Lipoprotein arm of the study: after fasting, subjects were asked to drink a fatty shake and Lipid levels were measured just prior to drinking the shake, at 3.5 hours, and at 6 hours after drinking the shake. We have examined the Triglyceride (TG) levels at each time point, as well as the slopes between time points and the area under the curve to search for genes contributing to TG Metabolism. Both raw TG values and log transformed TG values were examined. Microsatellite markers were typed in over 2000 family members, including a number of markers typed in additional family members in the predecessor study. Using all these markers improved meiotic inference. We conducted an oligogenic simultaneous segregation and linkage analysis with Monte Carlo Markov chain (MCMC) methods for each TG measurement, and identified several linked regions. The strongest signals were obtained on chrs 4, 11, and 17, with LOP values > 4 (Daw et al., Genet Epidemiol, 24, p181-90,2003). The chromosome 4 and 11 genes are linked to several TG measures, while the chromosome 17 gene is linked primarily to TG uptake. In the chr 4 and 11 regions, SNPs were typed in previously identified candidate genes. However, these genes were on the edge of the linked region, and MCMC combined segregation and linkage analysis did not find any of these SNPs to be strongly associated with the linkage peak. Thus, we conclude that there are genes other than the previously identified candidate genes involved in lipid metabolism in these regions. In addition, these results demonstrate the utility of MCMC oligogenic simultaneous segregation and linkage analysis combined with association testing of candidate genes for pharmecogenetic traits.

A High-Density Screen of 25 Genes Identifies Adiponectin as a Candidate Locus for Skeletal Muscle Fat Accumulation. *I. Miljkovic[1], L. M. Yerges[1], C. L. Gordon[2], B. H. Goodpaster[1], C. M. Kammerer[1], L. H. Kuller[1], C. H. Bunker[1], A. L. Patrick[3], V. W. Wheeler[3], J. M. Zmuda[1]* 1) University of Pittsburgh, Pittsburgh, PA, USA; 2) McMaster University, Hamilton, Ontario, Canada; 3) Tobago Health Studies Office, Scarborough, Tobago, West Indies.

Adipose tissue in skeletal muscle has recently been identified as an important fat depot that increases with aging, contributes to the development of diabetes, and is greater in individuals of African origin compared with Caucasians. However, despite the fact that it is a heritable trait, specific genetic factors contributing to skeletal muscle fat remain to be defined. The aim of this study was to examine the potential genetic contributions to peripheral quantitative computed tomography (pQCT) measured intermuscular adipose tissue (IMAT, expressed in mm^2) in 471 individuals aged 18 to 103 years belonging to 8 large Afro-Caribbean families (median family size 51 individuals; 3535 relative pairs). We systematically screened 768 tag and potentially functional single nucleotide polymorphisms (SNPs) in 25 genes, which have previously been associated with lipoprotein metabolism or were identified as potential candidate genes in animal studies. After adjusting for age, gender, height, total adiposity as measured by whole body dual-energy X-ray absorptiometry (DXA) percent total body fat, and muscle area, 7 genes showed nominal associations with IMAT ($P<0.05$). The most significant association was with an intronic tag SNP rs3821799 (MAF=43%) in adiponectin (ACDC), a gene whose protein product promotes fatty acid oxidation, increases insulin sensitivity and promotes glucose uptake in skeletal muscle. Individuals with two copies of the minor allele for rs3821799 had ~25% higher IMAT (additive $P=0.008$) compared to those with two major alleles (adjusted means SE: 209.227.5 versus 262.436.2 mm^2). This SNP accounted for ~1% of the total phenotypic variability in IMAT. These findings require confirmation, but suggest a novel association between common variants in adiponectin gene and the distribution of ectopic fat in skeletal muscle.

MPS BRAZIL-NETWORK: 4 YEARS IMPROVING DIAGNOSIS AND MANAGEMENT OF MUCOPOLYSACCHARIDOSES IN BRAZIL. *I. Schwartz, R. Giugliani, A. Federhen, L. Pinto, S. Leistner-Segal, U. Matte, M. Burin, J. Coelho, E. Valadares, A. Duarte, C. Steiner, C. Kim, A. Martins, D. Horovitz, M. Ribeiro, R. Boy, A. Acosta, J. Pina Neto, E. Ribeiro, L. Silva* Medical Genetics Service, Hospital Clinicas de Porto Alegre, Porto Alegre RS, Brazil.

Aim: To present the epidemiological data generated by MPS-BRAZIL NETWORK, a collaborative partnership among centers from different Brazilian regions aiming to improve the diagnosis and management of MPS diseases. Methods: The Medical Genetics Service of Hospital de Clínicas de Porto Alegre is the coordinating center, providing the information on the management of patients and making available the laboratorial tests necessary for their diagnosis. Results: 1)Since the MPS-BRAZIL NETWORK started operations in 2004 the rate of diagnosis of MPS performed by the coordinating center increased from 1.97 patients/mo to 6.6 patients/mo; 2)MPSII appears to be the most frequent type of MPS in Brazil; 3)MPSI is more common in the South and Southeast regions,while MPS VI seems to be less frequent in the South region; 4)MPSIII seems to be underdiagnosed in Brazil; 5)The higher prevalence of MPSVI in Northeast is probably explained by the combination of founder effect and endogamy; 6)Mean age at diagnosis was found to be high in all the types of MPS,especially in Northeast; 7)The rate of recurrence of MPS in the same family was found to be higher in Northeast. Conclusions: The MPS BRAZIL NETWORK is improving the diagnosis of MPS in Brazil.Economic and cultural aspects are still important contributors to the epidemiology,since it was found differences among Brazilian regions in relation to age at diagnosis,rate of consanguinity and rate of recurrence of MPS. Support: CNPq, BioMarin, Shire, Genzyme, LOREAL, Brazilian Academy of Sciences, UNESCO.

A targeted association study in Systemic Lupus Erythematosus (SLE) identifies novel risk alleles, and replicates known susceptibility alleles. *J. Lian[1], P. Goyette[1], R. Graham[2], J. Wither[3], P. R. Fortin[3], J. D. Rioux[1,2,4], GenES/CaNIOS Investigators* 1) Research Center, Montreal Heart Institute, Montreal, Quebec, Canada; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and the Massachusetts Institute of Technology, Cambridge, Massachusetts, USA; 3) Division of Rheumatology and Toronto Western Research Institute, University Health Network; University of Toronto, Toronto, Ontario, Canada; 4) Department of Medicine, University of Montreal, Montreal, Quebec, Canada.

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease associated with the abnormal production of autoantibodies directed mostly against nuclear antigens. Although the etiology of the disease is not fully known, it is believed that genetic, hormonal and environmental factors contribute to susceptibility. Epidemiological studies have revealed a significant genetic impact on the pathogenesis of SLE. Recent candidate-gene and genome-wide association studies (GWAS) have identified several susceptibility genes for SLE. The current study aims to replicate these previously reported risk alleles for SLE, as well as evaluate risk alleles recently identified in other complex immune disorders, including IRGM, IL23R, ATG16L1, IBD5, CARD15 and PTGER4 in Crohns disease (CD), TNFAIP3 in rheumatoid arthritis (RA), and IL2R, IL7R, PTPN2, CTLA4 and ERBB3 in Type 1 Diabetes (T1D). The study was performed using a cohort of 270 well-phenotyped Canadian SLE trios, mostly of European descent, collected through the GenES/CaNIOS Consortium. Our results replicate several previously reported associations and identify novel associations to SNPs in genes previously reported in RA and T1D. A stratification of the data for renal involvement suggests that some of these markers may be associated with specific SLE subphenotypes. The current study confirms the existence of multiple risk alleles for SLE, and suggests that some risk factors for SLE may be shared with other autoimmune disorders.

Evaluation of mechanically enhanced alginate-based capsule for cellular gene therapy. *M. Mazumder[1], F. Shen[2], N. Burke[1], H. Stöver[1], M. Potter[2]* 1) Chemistry, McMaster University, Hamilton, Ontario, Canada; 2) Pathology & Molecular Medicine, McMaster University, Hamilton, Ontario, Canada.

Microencapsulated cells engineered to secrete therapeutic proteins have been effectively applied in treating mouse models of several genetic disorders such as dwarfism, lysosomal storage diseases, and hemophilia. The most commonly used and studied capsules are alginate-Poly-L-lysine-alginate capsules (designated APA capsules), which have suitable biocompatibility and permeability for implantation. A concern with APA capsules is the loss of structural integrity during implantation due to loss of ionic ally bonded calcium, essential for stability of the alginate core. Our objective was to find a biocompatible covalently linked alternative to the APA capsule. In our study, poly(sodium methacrylate-co-2-(methacryloyloxy)ethyl acetoacetate) (designated A70), was introduced to the alginate core of the capsules (designated composite capsules). The A70 reacts with poly-L-lysine (PLL) to form a covalent interpenetrating polymer network, with the distribution of the covalent network depending on the A70/PLL ratio and the molecular weight of the polymers as demonstrated by confocal microscopy using FITC labelled A70 or PLL. In vitro tests of mechanical stability showed that 100% of the composite capsules were intact after shaking in dd-H2O for 3 hours, and ~40% of the capsules were intact after shaking in 0.003% EDTA for 15 minutes, while regular APA capsules totally collapse with both kinds of treatment. The cell viability of the capsules, as demonstrated by alamar blue staining, is decreased by 20% when A70 is included in the core. However, post-encapsulation the average cell number per composite capsule increased at the same rate as the cells in APA capsules. Permeability of the composite capsules was assessed by incubating the capsules with a series of different molecular weights of FITC-labelled dextrin under confocal microscopy. The cut-off size of the composite capsule was approximately 150kDa, similar to APA capsules. This preliminary data indicates that composite capsules are significantly stronger than APA capsules while maintaining suitable biocompatibility and permeability.

Candidate gene identification and analysis in Toriello-Carey Syndrome. *J. C. Yedowitz[1], D. H. Tegay[1, 2], H. V. Toriello[3], E. Hatchwell[2]* 1) Internal Medicine, New York College of Osteopathic Medicine at NYIT, Old Westbury, NY; 2) Stony Brook University Medical Center, Stony Brook, NY; 3) Spectrum Health, Grand Rapids, MI.

Toriello-Carey Syndrome (TCS; OMIM#217980) is a rare multiple congenital anomaly syndrome characterized by corpus callosum agenesis, cardiac defects, Robin sequence, developmental delay, hypotonia and dysmorphic facial features (including micrognathia, ear anomalies, telecanthus or hypertelorism, small nose and full cheeks). Although the phenotype is well established, the cause of TCS remains unknown.

Previously, using aCGH on 24 subjects diagnosed with Toriello-Carey syndrome, we reported the detection of 4 pathologic submicroscopic de-novo CNVs (one ~5Mb deletion at 6q14.2-15, one ~7Mb deletion at 1q41-42.3 and two ~5Mb deletions involving an overlapping region at 22q12), implicating 3 distinct loci in TCS pathogenesis. In addition a fourth locus was reported in a TCS subject with a balanced de novo translocation directly interrupting the SATB2 gene. We have focused our recent work on identifying candidate genes for TCS from within these regions using hierarchical clustering based on expression pattern similarity to SATB2.

For the identified candidate genes, including RFPL-1 (Ret-finger protein-like 1; OMIM#605968) at chromosome 22q12, having the greatest degree of expression homology to SATB2, we will present sequencing and deletion/duplication data obtained from our cohort of 24 TCS subjects.

Fine-Mapping of the Chromosome 10q.21 Linkage Region in Alzheimers Disease Cases and Controls. *D. Avramopoulos[1,2], K. H. Miller[3], M. Szymanski[2], R. Wang[2], S. S. Bassett[1], M. D. Fallin[3]* 1) Dept Psychiatry, Johns Hopkins Univ, Baltimore, MD; 2) McKusick Nathans Inst. of Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 3) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Many studies including our own have reported genome wide significant linkage for Alzheimers disease on chromosome 10. Our linkage results showed a strong parent of origin effect that was consistent in two independent data sets, where linkage was present in families with an affected mother. We have now fine mapped the region of interest on 349 cases (104 with an affected mother) and 289 controls by genotyping ~4,500 Single Nucleotide Polymorphisms (SNPs) across a 17.3 Mb interval. The SNPs were selected to provide a complete representation of all variation genotyped by the HapMap project with a pair wise SNP correlation of r-squared = 0.8 or better. We found no single common variant of an effect size sufficient to produce the linkage result. We identify 3 regions that show a high concentration of positive signals, two of which also show strong parent of origin effects consistent with the linkage results. One is a gene devoid region adjacent to the GDF10 gene and to an array of low copy repeats containing multiple genes, the second region includes the PRKG1 gene while the third includes the PCDH15 gene. Additionally a SNP close to the Acetylcholine transporter gene showed a strong signal in male carriers of the APOE e4 allele (p=10-5), an interesting result given the prior evidence for this gene. In conclusion, our dense fine mapping, in agreement with the results of recent less dense genome wide association studies, shows no single common variant responsible for the chromosome 10 linkage signal. Rather, our data point to a number of interesting sub-regions that might harbor multiple risk alleles contributing to the disease.

EphB2 sequence variation and prostate cancer risk in African American men. *W. Hernandez[1], C. Robbins[2], J. Carpten[2], R. A. Kittles[1]* 1) Dept of Medicine, University of Chicago, Chicago, IL; 2) Division of Integrated Cancer Genomics, Translational Genomics Research Institute, Phoenix, AZ.

The Eph receptors and the ephrin family of ligands are involved in many developmental functions including angiogenesis. The receptors are signaling molecules composed of an extracellular domain-motif typically found in adhesion molecules and a conserved tyrosine kinase domain in the cytoplasmic region which is flanked by a less conserved juxtamembrane region. Several variant forms of Eph receptors have been identified, including EphB2, which originate from alternative splicing and may have different functional properties. Deregulation of EphB2 has been implicated in the development and progression of several types of cancer, including prostate cancer (PCA). Here we performed re-sequencing of EphB2 and then a case-control association study on EphB2 polymorphisms to investigate their role in prostate cancer among African Americans. SNP discovery occurred in a set of 48 AA sporadic PCA cases. All coding exons of EphB2 were screened for sequence variants by DNA re-sequencing. In addition we supplemented discovered variants with random evenly spaced SNPs selected from the International HapMap Project to encompass the entire EphB2 transcription unit including introns and 5kb of upstream and downstream untranslated sequences. We genotyped 320 markers in 490 prostate cancer cases and 572 controls and identified common EphB2 SNPs significantly associated with prostate cancer. Empirical P-values that corrected for multiple testing were generated using the adaptive permutation approach. For several SNPs, rs4612601, rs12117711, rs2817897, and rs4600017, homozygotes for each minor allele had at least a two-fold increased risk of PCA ($P < 0.00001$). Haplotype analyses confirmed the single marker associations. Our data further demonstrates that variants of EphB2 are associated with prostate cancer risk in African American men.

Large-Scale Transcriptional Profiling and Genome-Wide Association of Intelligence in the Genetics of Brain Structure and Function Study. *J. Charlesworth[1], J. E. Curran[1], M. Carless[1], M. P. Johnson[1], H. H. H. Göring[1], T. D. Dyer[1], L. Almasy[1], P. T. Fox[2], R. Duggirala[1], E. K. Moses[1], D. C. Glahn[2], J. Blangero[1]* 1) SFBR, San Antonio, TX; 2) UT Health Science Center, San Antonio, TX.

The genetic architecture of general intelligence is complex, involving interactions between multiple genetic and environmental factors; however the specific genes involved are largely unknown. In this study, we employ an integrative genomic approach that utilizes large-scale transcriptional profiling and genome-wide association to identify novel genes influencing general intelligence. This study is being conducted on 1,000 individuals from 40 Mexican American families previously investigated as part of the San Antonio Family Heart Study. As collection is ongoing, the data provided here are from the first 453 individuals. Intelligence as measured by the WASI 2-subset IQ test showed a significant heritability of 0.865 ($p=2.8x10^{-20}$). We genotyped individuals using the Illumina HumanHap 550K beadchip and obtained genome-wide transcriptional profiles (Illumina Human 6v1) using RNA extracted from lymphocytes obtained approximately 15 years prior to IQ testing. We identified 633 transcripts whose expression was significantly correlated with IQ at a false discovery rate of 10%. Zinc ion binding is significantly enriched in this set (80 genes; $p=8.3\times10^{-7}$), with the three most significantly correlated genes (*ZNF618*, *ZBED3* and *WDFY3*) all related to zinc binding and a total of 31 zinc-finger proteins in the set. Given the prospective nature of the study design, these results suggest a striking role of transcriptional variation in cognitive function. Early results from the genome-wide association analysis of IQ reveal three suggestive regions of association, with multiple associated SNPs in each region. The first is at 18q22.3 near *CBLN2*, the second at 3p26.3 near *LRRN1* and the third at 6p24.1 near *HIVEP1* and *EDN1* (a region previously identified as harboring both an IQ-related QTL and a schizophrenia susceptibility locus). We hope that unraveling the genetic architecture of intelligence will offer insight into related conditions such as cognitive dysfunction, learning disabilities and degenerative disorders.

Intragenic deletion in FLNA causes periventricular nodular heterotopia. *I. Coupry[1], D. Lacombe[1,2], G. Sole[1], E. Guérineau[1], C. Rooryck-Thambo[1,2], S. Dubois[1], F. Martins[1], N. Phillip[3], L. Villard[4], B. Arveiler[1,2], C. Goizet[1,2]* 1) Lab of Hum Genet, Univ Victor Segalen, Bordeaux 2, Bordeaux, France; 2) Dep of Med Genet, Hôpital Pellegrin, Bordeaux; 3) Dep of Med Genet, Hôpital Timone-Enfants, Marseille; 4) INSERM U491, Marseille, France.

Filamin A, encoded by the FLNA gene located on chromosome Xq28, is a cytoskeletal protein that cross-links actin in a regulated fashion. Mutations in FLNA have been associated with bilateral periventricular nodular heterotopia (BPNH) and also with other various phenotypes including oto-palato-digital syndrome type 1 and 2 (OPD), Melnick-Needles syndrome (MNS) and frontometaphyseal dysplasia (FMD). We have analyzed the FLNA gene in 50 patients with characteristic signs of BPNH on brain MRI. Using DHPLC and sequencing, we identified a total of 18 different point mutations predominantly leading to a truncating protein. All mutations except one were novel. Alternatively, we developed gene dosage analysis using Quantitative Multiplex Fluorescent PCR (QMF-PCR). QMF-PCR was used for analyzing 10 patients negative for a FLNA point mutation. We identified an intragenic deletion suppressing exons 31-48 in one patient displaying BPNH associated with Ehlers-Danlos syndrome. Although the frequency of such gene dosage anomalies needs to be evaluated in a larger population, our preliminary data reveal that gene dosage analysis of FLNA should be considered in the molecular diagnosis strategy of BPNH.

Comparison between targeted and targeted plus whole genome aCGH platforms - A pilot study of 35 cases. *B. A. Brown-Kipphut, L. Li, N. Wang, M. A. Iqbal* Cytogenetics/Pathology, University of Rochester, Rochester, NY.

Objective: Compare and contrast the targeted array against the targeted plus whole genome array using BAC and Oligo aCGH platforms. Methods: 35 cases (12 normal) and (23 abnormal) were included in the study. Nine normal cases were determined by chromosome analysis in our laboratory and 3 had previous normal aCGH results at other institutions. Abnormal cases included: 1) 5 cases determined by chromosome analysis in our laboratory, 2) 11 cases using DNA from the Coriell Institute, and 3) 4 cases with previous abnormal aCGH results at other institutions. To examine clinical sensitivity and specificity of different BAC and Oligo aCGH chips, genomic DNA was processed and analyzed according to manufacturers guidelines using a) Perkin Elmer targeted constitutional chip (CC) v3.0 (30 cases) b) Perkin Elmer targeted plus whole genome v4.0 (5 cases) and c) custom Agilent 4x44 targeted plus whole genome oligo aCGH chip (4 cases). Fluorescent in situ hybridization (FISH) was used to confirm abnormal aCGH findings. Results: Twenty-nine out of 30 samples (15 normal and 15 abnormal) analyzed by targeted CC v3.0 confirmed previous results; however, one developmental delay case with a 2q23-2q31 duplication was missed. Four out of 5 abnormal samples including dup 2q analyzed by the targeted plus whole genome CC v4.0 were confirmed; however, one abnormal case with a marker chromosome was missed. Four samples previously identified as normal by CC v3.0 and a BAC emulated oligo aCGH chip (custom Agilent 4x44) from another institution were evaluated on a custom Agilent 4x44 targeted plus whole genome oligo aCGH chip. The analysis confirmed normal findings in 3 out of 4 cases. In one case with autism previously reported as normal by the BAC emulated oligo aCGH platform, a ~0.5Mb duplication, which included three genes (PRMD1, MLT4, and DAC2) at chromosome 6q27 subtelomere region, was identified. Conclusion: 1) Targeted plus whole genome oligo aCGH platforms are more sensitive in detecting copy number abnormalities. 2) aCGH analysis should always be used after routine chromosome analysis is performed.

Genome-wide Association Mapping in Multiplex Autism Families. *L. A. Weiss[1], D. E. Arking[2], T. Green[1], J. F. Gusella[1], S. L. Santangelo[1], R. E. Tanzi[1], P. Sklar[1], A. Chakravarti[2], M. J. Daly[1], Autism Consortium Gene-Finding Group & Autism Genome Project* 1) Ctr Human Genetic Research, Harvard-MGH/Broad, Boston, MA; 2) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Autism is a highly heritable developmental disorder, though to date, identifying specific genes has met with limited success. We therefore initiated the first genome-wide association mapping study using 500,000 SNP markers in multiplex autism families. (Linkage analysis is reported in an abstract by Arking et al.) Our primary datasets were ~800 AGRE families genotyped on Affymetrix 5.0 at the Broad Institute, and an NIMH autism sample (250 families independent from AGRE), genotyped on the Affymetrix 500K/5.0 at Johns Hopkins University. Combining these datasets using stringent QC measures yielded 864 complete families with 1,594 trios. Data analysis was performed using PLINK. Initial TDT analysis did not yield genome-wide significant association. However, we utilized additional SNP microarray follow-up data, as well as designing Sequenom assays in our top hits for genotyping by the Autism Genome Project. In the combined dataset, an array SNP on chromosome 5p15 shows genome-wide significant association with autism. We followed up these results by performing imputation analysis to capture additional variation, identifying signals of interest that were validated by Sequenom genotyping. We also looked at positional and functional candidate regions previously implicated for autism, such as genes for Mendelian disorders associated with autism, genes containing rare variants associated with autism, regions of copy number variants associated with autism, and candidate genes for association between common variation and autism. The only region meeting criteria for region-wide association is the Williams Syndrome region on chromosome 7. Our results suggest that individual common variants of major effect do not explain a large proportion of the heritability of autism, nor do previously studied candidate genes. We report here a novel association of genetic variation on 5p15 with autism. This signal falls between *SEMA5A* and *TAS2R1*.

Genetic History of human populations of East African inferred from mtDNA and Y chromosome analyses. *J. Hirbo[1], S. Omar[2], M. Ibrahim[3], S. Tishkoff[4]* 1) Dept. of Biology, University of Maryland, College Park, MD; 2) KEMRI, Centre for Biotechnology Research and Development, Nairobi, Kenya; 3) Dept. of Molecular Biology, Institute of Endemic Diseases, University of Khartoum, Khartoum, Sudan; 4) Department of Genetics and Biology, University of Pennsylvania, Philadelphia.

Evidence from genetic, paleobiological, and archaeological studies suggest that Africa, especially East Africa, is most likely to be the cradle of the modern human species. Despite this fact, very little is currently known about genetic diversity in African populations in general, and East African populations in particular. Genetic data demonstrate that the patterns of genetic variation in East African populations are complex. All four major language families spoken in Africa (Afro-Asiatic, Nilo-Saharan, Niger-Kordofanian, and Khoisan) are found in the region. As part of a large study of population genetic diversity of East and Northeast Africa, we examined Y chromosome genetic diversity (to ascertain paternal lineages) as well as mitochondrial genetic diversity (to ascertain maternal lineages) in 1200 - 1500 individuals from ~ 40 Tanzanian, Sudanese, and Kenyan populations. For the Y chromosome analysis, we genotyped 60 UEPs (analyzed in a hierarchical manner to construct haplotypes) in a total of ~1500 male individuals. In order to infer ages of lineages and migration patterns, we further genotyped the individuals for 16 Y chromosome microsatellites. For the mtDNA analysis, we sequenced the mitochondrial D-loop in a total of 1200 individuals from the same populations, and for 200 individuals, we did complete mitochondrial genome sequencing. We compare our results with published results of studies from other parts of Africa and the Middle East. Our results indicate that East African populations have some of the most ancestral Y chromosome and mtDNA lineages in Africa, suggesting that they may have been an ancient source of dispersion throughout Africa. Additionally, we find evidence for ancient geneflow between East Africa and the Middle East. We also ascertained the effect of the Bantu-expansion and signature of recent migration of Cushitic-speaking groups originating from Ethiopia on peopling of East Africa.

Termination of damaged protein repair defines the occurrence of symptoms in carriers of the m.3243A>G tRNA-Leu mutation. *H. Smeets[1], R. van Eijsden[1], L. Eijssen[1], P. Lindsey[1], C. van den Burg[1], L. de Wit[2], M. Rubio-Gozalbo[3], C. de Die[1], T. Ayoubi[1], W. Sluiter[2], I. de Coo[2]* 1) Dept Gen & Cell Biol, Univ Maastricht, Maastricht, Netherlands; 2) Department of Biochemistry, Mitochondrial Research Unit, Erasmus MC, Rotterdam - The Netherlands; 3) Department of Paediatrics and Laboratory Genetic Metabolic Diseases, Maastricht University Hospital, Maastricht - The Netherlands.

The m.3243A>G mutation in the mtDNA tRNALeu gene displays a heterogeneous phenotypic expression. It is the most frequent cause (80%) of the MELAS syndrome (Mitochondrial Myopathy, Encephalopathy, Lactic Acidosis and Stroke-like episodes), but it can also lead to type 2 diabetes, deafness, renal tubulopathy and/or cardiomyopathy. To identify pathogenic processes induced by this mutation, we compared global gene expression levels of muscle biopsies from affected and unaffected mutation carriers with controls. Gene expression changes were relatively subtle. In the a symptomatic group 200 transcripts were up- and 12 were down-regulated, whereas in the symptomatic group this was 15 and 52 respectively. In the a symptomatic group, oxidative phosphorylation (OXPHOS) complex I and IV genes were induced. Protein turnover and apoptosis were elevated, most likely due to the formation of dysfunctional and reactive oxygen species (ROS) damaged proteins. These processes returned to normal in symptomatic patients. Components of the complement system were up-regulated in both groups, which might indicate muscle regeneration. Most likely, protein damage and OXPHOS dysfunction stimulate repair (protein regeneration) and metabolic adaptation (OXPHOS). In a symptomatic individuals these processes suffice to prevent the occurrence of symptoms. However, in affected individuals the repair process terminates, presumably because of excessive damage, and switches to muscle regeneration, as indicated by a stronger complement activation. This switch leaves increasingly damaged tissue in place and muscle pathology becomes manifest. Therefore, the expression of complement components might be a marker for the severity and progression of MELAS clinical course.

Identification of an X-Linked locus associated with acute rejection in kidney transplant patients. *W. S. Oetting[1], S. Basu[2], M. J. Brott[1], K. R. Linnihan[1], A. J. Matas[3]* 1) College of Pharmacy, Univ Minnesota, Minneapolis, MN; 2) Div. of Biostatistics; 3) Dept. of Surgery.

DNA variants associated with solid organ transplant outcome were identified using a custom chip containing 3,590 single nucleotide polymorphisms (SNPs), many of which are thought to be functional variants within biologically relevant genes including genes in pathways associated with immunity, cell signaling, ADME, cell growth and proliferation. Additional haptag and admixture SNPs were included. Blood was obtained with informed consent and DNA isolated from 271 kidney allograft recipients, 136 of whom had acute rejection (AR) within 6 months of transplant, and 135 of whom did not have any detectable AR after at least 8 years post-transplant. All received Ab induction and CNI, with either MMF or sirolimus. An additional validation cohort was also analyzed, consisting of 99 males without rejection and 38 individuals with AR. SNPs for the test cohort were genotyped using the Affymetrix ParaAllele system for SNP detection and genotyping. Additional SNPs and DNA from the validation cohort was genotyped using TaqMan analysis. For statistical analysis, a chi-square test to assess the significance of association of each SNP with AR was used. Haplotype analysis was performed using the R package haplo.stats. By analyzing males only we associated two anonymous X- linked SNPs with AR (rs2189394, $p = 0.008$ and rs2211463, $p = 0.02$). These SNPs were not significant when analyzed in females alone showing that predisposing AR alleles at this locus are acting as X-linked recessive alleles. These markers are near the locus LOC646193, located at Xq13.3. We then analyzed additional SNPs flanking and within this locus. The most significant SNP was rs2301467 with a p value for the test cohort of 1.37×10^{-14}, a p value of 0.002 for the validation cohort and a combined p value of 7.87×10^{-12}. Using the most significant SNPs, there were two major haplotypes identified. The major haplotype gave an odds ratio of 1.8 for AR. Conversely, a second haplotype was protective of AR with an odds ratio of 0.00004. This provides evidence for an X-linked locus associated with AR in kidney allograft recipients.

Integration of structural variants and single nucleotide polymorphisms in linkage and association studies. *B. Kerner[1], P. Sanchez[1], G. K. Chen[2], J. DeYoung[1], M. Almonte[1], O.-W. Choi[1], N. B. Freimer[1]* 1) Department of Psychiatry, UCLA, Los Angeles, CA; 2) Department of Preventive Medicine, USC, Los Angeles, CA.

The telomeric region on Chromosome 8p is a genomic region known for a common inversion/deletion polymorphism. This region has also been claimed for linkage and association with psychotic bipolar disorder and schizophrenia. Inversions and deletions are difficult to detect. However, recent studies have indicated that these regions are characterized by unusually high linkage disequilibrium (LD) patterns among high-density SNPs in individuals who carry the inversion (Bansal V, 2007). This LD pattern can potentially influence the results of linkage and association studies. In our analysis, we applied the following three methods to help infer a polymorphic inversion at 8p23 in families from the NIMH-Bipolar Genetics Initiative, in which evidence of linkage has been found. 1. The pattern of Mendelian errors and failed SNPs during genotyping suggested genomic structure abnormalities in this region. 2. The computer software program GOLDEN HELIX was used to determine the linkage disequilibrium in this genomic region in our data and to explore copy number variations that often flank regions of inversions and deletions. The segmentation algorithm integrated in this software program allowed to determine the segments in each sample separately and to find the cut-points of each segment for each sample. 3. Based on the inferred locations of the flanking regions of the inversion, the posterior probability of carrying an inversion was calculated in each individual of a pedigree using the computer software program MENDEL. We then performed family based linkage and association analysis in these families with psychotic symptoms as phenotype. Taking the deletion/inversion polymorphism into account influenced our results of linkage and association with SNPs in this chromosomal region. Our approach and results demonstrate the importance of integrating information on structural variants with SNP data.

Filamin A Mutations Cause Tetralogy of Fallot (ToF) with Ascending Aortic Aneurysm. *N. D. Patel[1], D. H. Kim[1], M. E. Lindsay[1], T. M. Holm[1], A. John[2], J. Garbarini[2], E. Goldmuntz[2], H. C. Dietz[1]* 1) Institute of Genetic Medicine and HHMI, Johns Hopkins Univ, Baltimore, MD; 2) Children's Hosp Phila, Philadelphia, PA.

ToF is the most common form of complex congenital heart disease. Although surgery during infancy can be curative, a subset of individuals are at risk of developing progressive ascending aortic aneurysm (AAA) years after ideal surgical repair. While there are known etiologies for ToF, the genetic basis for ToF/AAA remains unknown. The absence of large families with this condition precludes positional strategies for gene identification. We have focused on rare patients with syndromic presentations of ToF/AAA. We identified a male patient with a maternal history of periventricular nodular heterotopia (PVNH), a condition caused by mutations in the FLNA gene on chromosome X that encodes the cytoskeletal protein filamin A. Prior reports suggest that male inheritance of a PVNH-associated FLNA allele results in fetal demise. Sequencing of all exons of FLNA revealed two missense substitutions that were hemizygous in the boy with ToF/AAA, heterozygous in his mother and aunt with PVNH, and absent in unaffected relatives and controls. Both mutations substitute evolutionarily conserved residues and one occurs within a domain that interacts with multiple TGF regulatory factors (R-Smads, caveolin and decorin), correlating well with prior data suggesting that multiple forms of aneurysm are caused by perturbation of TGF signaling. We next sequenced FLNA in 11 unrelated patients with nonsyndromic TOF/AAA who had previously been shown not to harbor deletion at 22q11. Two of 11 (18%) had the same missense mutation in the hinge region of the FLNA protein that disrupts a calpain cleavage site. This substitution was not found in >400 control X chromosomes. The conclusion that disruption of filamin A function causes TOF/AAA is furthered by the demonstration of truncus arteriosus (another conotruncal defect) in filamin A-null mice and by the rare occurrence of late-onset aortic dilatation in women with PVNH and related phenotypes. This genetic foundation will allow stratification of risk for AAA in patients with ToF and guide the discovery of molecular mechanisms and therapeutic strategies.

Next Steps in Managing Incidental Findings in Human Subjects Research: From Imaging to Genomics. *S. M. Wolf*[1, 2, 3], *J. K. Paradise*[1, 3] 1) University of Minnesota Law School; 2) University of Minnesota Medical School; 3) University of Minnesota Consortium on Law and Values in Health, Environment & the Life Sciences.

Incidental findings arising during the course of human subjects research are a profound but neglected problem and one of tremendous importance to researchers and Institutional Review Boards because of the potential clinical implications. An incidental finding (IF) is a finding concerning an individual research participant that has potential health or reproductive importance and is discovered in the course of conducting research but is beyond the aims of the study. IFs can range from trivial to life-threatening. Examples of IFs include an unexpected finding of misattributed parentage in genetic research on families and an unexpected allele or pattern of genes discovered during genomic microarray research. This NHGRI-funded project has focused on the ethical, legal, and scientific issues raised by IFs in human subjects research, using empirical research on how researchers and institutions currently address IFs in the both the genetics/genomics context and imaging context (neuroimaging and CT colonography) as a basis for normative recommendations. The multidisciplinary project group of 21 national experts published groundbreaking recommendations in June 2008 for managing IFs in genetics and genomic research in 36(2) Journal of Law, Medicine & Ethics 219-248 (2008), as part of a 17-article symposium. Ours are the first major consensus recommendations on how to handle IFs in human subjects research. This presentation will move beyond the consensus paper to address next steps to handle the growing problem of IFs and suggest how to implement project recommendations. The presentation will offer needed analysis on handling IFs in large genome-wide research protocols and archived datasets. We will address both ethics and law, including the scope of the Common Rule, potential for civil liability, and pragmatic problems such mechanisms to implement the IF recommendations at the level of institutions, IRBs, and researchers.

Collaborative genome-wide association analysis of 10,596 individuals supports a role for Ankyrin-G (*ANK3*) and the alpha-1C subunit of the L-type voltage-gated calcium channel (*CACNA1C*) in bipolar disorder. *P. Sklar[1, 3], M. Ferreira[1, 3], D. Ruderfer[1, 3], J. Smoller[1, 3], H. Gurlin[2], A. McQuillin[2], E. Scolnick[3], A. Corvin[4], D. Blackwood[5], M. O'Donovan[6], M. Owen[6], N. Craddock[6], S. Purcell[1, 3], WTCCC; STEP-BD* 1) Dept Psychiatry, Harvard Medical Sch, Boston, MA; 2) Molecular Psychiatry Laboratory, Department of Mental Health Sciences, Windeyer Institute of Medical Sciences, University College London, 46 Cleveland Street, London W1T 4JF; 3) Stanley Center for Psychiatric Research, Broad Institute of Harvard and MIT; 4) Trinity Centre for Health Sciences, St James's Hospital, Trinity College Dublin, Republic of Ireland; 5) Division of Psychiatry, University of Edinburgh, Royal Edinburgh Hospital, Edinburgh EH10 5HF, UK; 6) Department of Psychological Medicine, Henry Wellcome Building, School of Medicine, Cardiff University, Heath Park, Cardiff CF14 4XN, UK.

To identify susceptibility loci for bipolar disorder, we combined individual genotyping data from the Wellcome Trust Case Control Consortium (WTCCC), Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD), University College London (UCL), University of Edinburgh and Trinity College Dublin samples, resulting in 4,387 cases and 6,209 controls. Including imputed single nucleotide polymorphisms, we tested ~1.8 million variants and identified a region of strong association (rs10994336, $P = 9.1 \times 10^{-9}$) in the Ankyrin-G gene, *ANK3*. We also found further support for the previously reported alpha-1C subunit of the L-type voltage-gated calcium channel gene, *CACNA1C* (combined $P = 7.0 \times 10^{-8}$, rs1006737). Taken together, our results underscore the value of large, collaborative studies and suggest that ion channelopathies may be involved in the pathogenesis of this complex disorder.

-383 A/C Tumor Necrosis Factor Receptor 1 polymorphism and serum levels of TNFR I and TNFRII in rheumatoid arthritis. *Y. Valle[1,2], I. Ledesma-Lozano[1], N. M. Torres-Carrillo[1], N. Torres-Carrillo[1], J. R. Padilla-Gutiérrez[1,2], R. E. Navarro-Hernández[1], M. Vázquez-Del Mercado[1], E. Sánchez-Corona[1], J. Armendáriz-Borunda[3], J. F. Muñoz-Valle[1]* 1) IIRSME, C.U.C.S, UdeG; 2) Posdoctoral Fellow in Biomedical Sciences (Immunology), UdeG; 3) Instituto de Biología Molecular y Terapia Génica, C.U.C.S,UdeG.

Introduction . Tumor necrosis factor-alpha (TNFalpha) plays a central role in inflammation, and has been directly implicated in the pathogenesis of rheumatoid arthritis (RA). TNF mediates its pleiotropic activities via two cell surface receptors, p55TNFR (TNFRI) and p75TNFR (TNFRII); both are active in membrane-bound and soluble forms. Soluble receptors act as physiological attenuators of TNF alpha activity. Methods: We recruited 190 RA patients classified according to ACR criteria and 190 healthy subjects (HS). The -383 A/C TNFR1 polymorphism was identified by PCR-RFLP method. The sTNFRI and sTNFRII were measured using a ELISA kit. The clinical activity in RA patients was evaluated using the Disease Activity Score (DAS28). The statistical analysis was made using SPSS v 10.0 Software. Results. The -383 A/C TNFRI polymorphism not showed significant differences in both studied groups. However, in RA patients the AA genotype carriers had the higher DAS28 score (p=0.01). The serum levels of TNFRI and TNFRII were higher in RA patients than HS (p=0.04 and 0.001, respectively). In addition, serum sTNFRI levels correlated with sTNFRII (r=0.699, p=0.000), whereas the sTNFRII correlated with DAS28 (r=0.699, p=0.000), RF (r=0.505, p=0.004) and, ESR (r=0.323, p=0.042). Conclussion. The -383 A/C TNFRI polymorphism is not a susceptibility marker in RA. However, the A/A genotype is associated with a high DAS28 score. The increase of TNFRII serum levels reflect the clinical activity in RA patients because correlated with the DAS28 index, RF and ESR.

Replicated statistical associations between schizophrenia and intronic variations flank a novel cassette exon in the dopamine transporter gene. *M. E. Talkowski[1,5], L. McClain[1], M. Bamne[1], J. Wood[1], M. Chen[2], K. McCan[2], P. Papasaikas[2], G. Kirov[2], L. Georgieva[2], M. C. O'Donovan[3], M. Owen[3], D. Toncheva[4], D. Lewis[1], B. Devlin[1,5], A. J. Lopez[2], V. L. Nimgaonkar[1,5]* 1) Psychiatry, University of Pittsburgh; 2) Biological Sciences, Carnegie Mellon University; 3) Psychological Medicine, Cardiff University; 4) Medical Genetics, University Hospital Maichin Dom, Bulgaria; 5) Human Genetics, University of Pittsburgh.

The dopamine transporter (*SLC6A3*, DAT) is a critical gene involved in the re-uptake of dopamine from the synapse. We previously identified significant, replicable statistical associations and gene-gene interactions between intronic DAT variations and schizophrenia in two large Caucasian samples (Talkowski *et al.*, 2008). We describe a parallel, comprehensive effort to identify plausible common liability loci (minor allele > 5%) in these intronic regions (introns 3 and 4) along with a functional basis for the statistical results. We conducted in-house sequencing using CEPH individuals in conjunction with publicly available resources (HapMap and SeattleSNPs). We genotyped 88 tag SNPs chosen at a high correlation threshold ($r^2 < 0.95$ between loci) to represent most common variations in two independent samples (659 Bulgarian trios and 526 cases / 501 controls from the US). We detected seven significant associations ($p < 0.05$) and nine non-significant trends, 56.3% of which were localized to introns 3/4. These plausible risk loci included multiple SNPs not represented in our studies prior to this fine mapping effort. We found that several SNPs in complete LD with our strongest associations (including a novel deletion) flanked a potential cassette exon. Consistent with sequence predictions, a novel cassette exon within intron 3 of DAT was detected. The cassette exon truncates the DAT protein, is expressed in adult human brain, is conserved among primates, and was confirmed through in vitro studies (see Chen *et al*. abstract for details). Parallel statistical and functional studies are ongoing to further characterize the role of putative schizophrenia risk alleles on dopamine transporter function.

Semaphorins as Candidate Genes in Hirschsprung Disease. *S. Arnold[1], M. Guy[1], K. Kashuk[1], Y. Li[2], G. Abecasis[2], A. Chakravarti[1], International HSCR Consortium* 1) IGM, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Ctr for Stat Gen, Dept of Biostat, Sch of Pub Health, Univ of MI, Ann Arbor, MI.

Hirschsprung Disease (HSCR) is a complex disorder for which a growing number of candidate genes and chromosomal regions, identified via linkage and various mouse model studies, hypothetically modify the function of the major HSCR gene, the receptor tyrosine kinase *RET*. HSCR varies in the length of colon affected by aganglionosis, from the least severe and most common short segment disease (S-HSCR) to the least common and most severe form, total colonic agangionosis. In order to identify candidate genes that might contribute to the majority of HSCR cases, 220 S-HSCR trios were analyzed on the Affymetrix 500K SNP array platform. A significant cluster of SNPs was identified, via TDT analysis, in a region on Chr. 7 that fell downstream from *SEMA3D* and upstream from additional SEMA Family 3 members (3A, 3E, and 3C, in order of proximity). Imputation, which added ~2 x 10^6 SNPs to the analysis, strengthened the significance of this cluster and refined the location of its peak. The two pre-imputation SNPs with highest significance (SNP1, with p-value of 6.11 x 10^{-6} and SNP2, with p-value of 5.16 x 10^{-6}) were genotyped in an independent replication population of 430 HSCR trios that represented all segment lengths. Both SNPs maintained significance (p-values of 1.39 x 10^{-2} for SNP1 and 2.56 x 10^{-4} for SNP2) in the full replication population. When data obtained from the S-HSCR replication subset was combined with the original Affy data, SNP1 improved to a p-value of 1.57 x 10^{-7} while SNP2 improved to 4.26 x 10^{-6}. These SNPs displayed greater penetrance in males and for individuals homozygous for the transmitted allele, analogous to the *RET+3* enhancer variant. The four SEMA Family 3 members demonstrated very similar temporal and spatial patterns of expression throughout the gut and were coexpressed with *RET* in these tissues, supporting the possibility that one or all might modify *RET* function in the developing enteric nervous system. Consequently, sequencing of coding regions is now underway to determine whether one SEMA Family 3 member can be distinguished as the HSCR-associated gene.

Functional analysis of DUSP2 in Zebrafish in attempt to better understand the molecular mechanisms in Apert Syndrome. *E. Kague[1], S. Fisher[2], R. D. Fanganiello[1], M. R. Passos-Bueno[1]* 1) Dept Genetics & Evolutive Biol, Univ de Sao Paulo, Sao Paulo, Brazil; 2) Johns Hopkins University School of Medicine- Baltimore USA.

Apert syndrome is an autossomal dominant disorder characterized by craniossinostosis and malformations of limbs. It is caused by a limited number of mutations in FGFR2 gene. Two mutations were identified so far, Ser252Trp and Pro253Arg. Mutant mouse carrying the S252W mutation has, besides defect in closure of sutures, skeletal system abnormalities including increase cartilage of the basicranium, malformation of the palate and thickened nasal cartilage. In study, performed in Brazil, attempting to understand gene expression profile of periosteal cells from Apert patients, DUSP2 was found as upregulated in patients (Fanganiello et al., 2008), pointing this gene as a downstream target of FGF signal in the cell and also a target of study for the molecular mechanism involved in Apert syndrome. DUSP2 localizes to the nucleus and inactivates MAPK (JNK) by dephosphorylation. JNK is downstream of Dsh-mediated noncanonical Wnt pathway. To better understand the functionality of DUSP2, we overexpressed it in double transgenic Zebrafish embryos (carrying EGFP and mChrerry as cartilage and bone markers, respectively). It was possible to classify injected embryos in two groups. Group one embryos showed phenotype similar with Silberblick (wnt11/slb) mutants, with incomplete separation of the eyes, what could be explained by over inhibition of JNK by DUSP2. Class two embryos had no eyes commitment but just showed cartilage malformation including defects in Meckels cartilage, palatoquadrate, ceratohyal and ceratobranchials, representing its importance in bone formation. We carried out dusp2 in situ hybridization in zebrafish, and it showed a restricted expression, and quite similarity with fgfr2. At 90% epiboly dusp2 is expressed in paraxial mesoderm, at 8 somites in eyes field, forebrain and midbrain, at 24h and 48h in forebrain and midbrain. The results reinforce DUSP2 importance in bone formation, pointing it as a potential target in the molecular mechanism of Apert Syndrome and it also indicates participation of non-canonical wnt signaling, but further studies must be performed.

Genomic Landscape of Autism Spectrum Disorders. *M. Bucan[1, 2], K. Wang[2, 5], J. Glessner[5], M. Imielinski[5], D. Hadley[2, 3], J. Bradfield[5], C. Kim[5], L. Sonnenblick[7], N. Gidaya[2], V. Kustanovich[1], A. Singelton[6], C. Lajonchere[1], J. Kim[3], M. Li[4], R. Cantor[1,8], B. Abrahams[7], S. Grant[5], D. Geschwind[1, 7,8], H. Hakonarson[5]* 1) Autism Genetic Resource Exchange, Autism Speaks; 2) University of Pennsylvania, Department of Genetics; 3) University of Pennsylvania, Department of Biology; 4) University of Pennsylvania, Department of Biostatistics; 5) Center for Applied Genomics6, Division of Genetics7, The Children's Hospital of Philadelphia; 6) Porter Neuroscience Research Center, National Institute of Aging, National Institute of Health; 7) Department of Human Neurology, University of California Los Angeles; 8) Department of Human Genetics, University of California Los Angeles.

Genomic copy number variants (CNVs) are important to the etiology of complex diseases such as the autism spectrum disorders (ASDs). However, published work suggests that identified CNVs represent a relatively small number of disease-linked variants. We have undertaken a comprehensive CNV analysis to assess the contribution of CNVs in the ASDs. With the HumanHap550 BeadChip containing 561,466 SNPs, we genotyped 943 autism multiplex families (4,454 individuals) from the Autism Genetics Resource Exchange (AGRE) and 1,612 control subjects from two independent groups. Using the PennCNV algorithm, we detected ~164,000 CNVs and classified them as common or rare, and inherited or de novo. De novo CNV >200kb were identified in 3.0% of ASD subjects versus 2.4% of their unaffected siblings. Remarkably, rare CNVs surrounding or overlapping 37 membrane-spanning neuronal genes, including CDH18, CNTNAP2, NRXN1, NCAM2 and SLITRK1, were enriched in cases versus unaffected siblings and unrelated controls (P=1.9e-4). These data indicate that previous work captured only a small subset of CNVs likely to be important in disease pathogenesis. Our results also suggest that rare CNVs, both inherited and de novo, particularly in genes encoding neuronal membrane proteins, contribute to the pathogenesis of autism. The work described here will serve as an important foundation for the study of genomic aspects of diseases.

A Follow-Up of Enzyme Replacement Therapy in Two MPS VI Patients with Poorly Engrafted Bone Marrow Transplantation. *V. Valayannopoulos[1], M. Raff[2], S. Turbeville[3], H. Nicely[3]* 1) Metabolic Unit, Necker-Enfants Malades Hosp, Paris, France; 2) Children's Hospital and Regional Medical Center, Seattle, WA, USA; 3) BioMarin Pharmaceutical Inc., Novato, CA, USA.

Background & Purpose: Mucopolysaccharidosis VI (MPS VI) is a genetic lysosomal storage disorder classified by missing or defective enzyme *N*-acetylgalactosamine-4-sulfatase and accumulation of glycosaminoglycan (GAG) dermatan sulfate. In some cases, HLA-matched bone marrow transplantation (BMT) has been an appropriate treatment option. With approval of Naglazyme (galsulfase) in 2005 (US) and 2006 (EU), enzyme replacement therapy (ERT) became available to MPS VI patients including poorly-engrafted BMT patients, 2 of whom were followed using a BioMarin-designed questionnaire completed by 2 physician authors. **Method**: Weekly ERT infusions of Naglazyme at 1mg /kg over a minimum of 4 hrs were given to 2 rapidly progressing MPS VI patients with severe symptoms: Patient A (female; 4 y; U.S.) and Patient B (male; 18 y; France), respectively; both with increased urinary GAG levels, decreasing chimerism over time and disease progression on BMT, prior to ERT. Physicians recorded clinical changes post-ERT initiation on a questionnaire. **Results**: Patient A at 1 y 7 mo after first ERT showed improvements in visual acuity, cardiac function, endurance, general health; with a non-significant reduction in urinary GAGs from 99.7 g/mg creatinine pre-ERT to 86.0 g/mg creatinine at 3 mo on ERT; and improvement in subcortical and periventricular white matter. Infusion-associated reactions (IAR) included arthralgia, fever and headache, which were safely resolved and this patient continues to be treated with ERT. Patient B by 9 mo of ERT, showed improvements in dysmorphia, visual acuity, joint flexibility, ear, nose and throat dysfunctions; with reduced urinary GAGs from 51.8 g/mmol creatinine pre-ERT to 19 g/mmol creatinine at 9 mo on ERT; and no reported IARs. Unfortunately, Patient B died suddenly due to underlying cardiopathologies unrelated to ERT at 9 mo on drug. **Conclusion**: Administration of Naglazyme ERT after poorly engrafted BMT was well tolerated and provided some clinical benefit to 2 MPS VI patients.

Functional and predictive analysis of variants of the Wilson Disease Gene, *ATP7B*. *L. Luoma, T. M. M. Deeb, G. Macintyre, D. W. Cox* Department of Medical Genetics, University of Alberta, Edmonton, Canada T6G 2H7.

Wilson disease (WD), an autosomal recessive disorder with an incidence of approximately 1 in 30,000 worldwide, affects copper homeostasis. Copper is essential for structure and catalytic activity of many enzymes, however due to its reactivity can be toxic to cells at high concentrations. WD is characterized by excess copper in the liver, kidney and brain leading to hepatic, renal and/or neurological damage. Because of the wide range of manifestations, WD is challenging to diagnose, but treatable. Since discovery of the causative gene, *ATP7B*, a copper-transporting ATPase that has a critical role in copper homeostasis, WD can be diagnosed by mutation analysis. Mutation of *ATP7B* affects its ability to transfer copper to other proteins and prevents excretion of copper, resulting in copper overload and cell damage. *ATP7B* variants, both disease-causing and normal, occur throughout the gene, but are difficult to distinguish. An effective way to determine if a variant is disease-causing is to do functional analysis, using yeast and mammalian model systems. However, this testing is labor- and time-intensive and we have explored the value of predictive programs. Computer-based predictive programs such as SIFT (Sorting Intolerant from Tolerant), Align GVGD and PolyPhen may be helpful for determining whether a newly identified variant is deleterious, or functionally normal. We tested accuracy of predictive programs by comparison of predictions with functional analysis in yeast assays of the same variants. We investigated 31 variants identified in WD patients located in the ATP-loop and transmembrane (TM) regions of ATP7B. Of the three programs PolyPhen appears to be best at predicting disease variants. SIFT could be adjusted to be as accurate by modifying sequences used. Of 18 variants in the TM domains that were functionally tested in yeast, 15 were found to be deleterious. Predictions by PolyPhen and adjusted-SIFT were 83% accurate. Accuracy of predictions was found to be dependent on sequences used in the analysis. Use of both functional studies and predictive programs may lead to a better understanding of *ATP7B* and assist in reliable DNA diagnosis of WD.

The mutational spectrum of BCOR: Candidate gene analysis of patients with oculofaciocardiodental and Lenz microphthalmia syndromes, mental retardation and ocular anomalies, and cardiac laterality defects. *S. Whalen[1], E. Hilton[2], J. Johnston[3], N. Okamoto[4], Y. Hatsukawa[4], L. Biesecker[3], I. Giurgea[1], G. Black[2]* 1) INSERM 654, Department of Genetics & APHP, Hospital Henri Mondor, Creteil, France; 2) Academic Unit of Medical Genetics, St Mary's Hospital, Manchester, UK; 3) Genetic Disease Research Branch, National Human Genome Research Institute, NIH, Bethesda, MD, USA; 4) Maternal and Child Health, Osaka Medical Centre and Research Institute, Osaka, Japan.

OFCD and Lenz microphthalmia syndromes form part of a spectrum of X-linked microphthalmia disorders characterised by ocular defects, dental anomalies, cardiac defects, digital and skeletal anomalies and mental retardation. The two syndromes are allelic and caused by mutations in the BCL-6 corepressor (BCOR). To extend the series of phenotypes associated with pathogenic mutations in BCOR, we have sequenced the BCOR gene in patients with 1) OFCD syndrome 2) putative X-linked (Lenz) microphthalmia syndrome 3) isolated ocular defects and 4) laterality phenotypes. We present a new cohort of females with OFCD syndrome and null mutations in BCOR, supporting the hypothesis that BCOR is the sole molecular cause of this syndrome. The identification of a BCOR mutation in a female with ocular defects in the absence of a classic OFCD syndrome phenotype demonstrates the phenotypic variation observed in this syndrome and suggests that OFCD syndrome may be underdiagnosed. We have sequenced a cohort of males diagnosed with putative X-linked (Lenz) microphthalmia and found a mutation in a single case, suggesting that BCOR mutations are not a major cause of X-linked microphthalmia in males. The absence of BCOR mutations in a panel of patients with non-specific laterality defects suggests that mutations in this gene are not a major cause of isolated heart and laterality defects. Analysis of the phenotypes associated with OFCD and Lenz microphthalmia syndromes shows that in addition to the standard diagnostic criteria of congenital cataract, microphthalmia and radiculomegaly, patients should be examined for skeletal defects, particularly radioulnar synostosis and cardiac/laterality defects.

Chromosome abnormalities in spontaneous abortions: a cytogenetic study of 4068 cases. *L. Dong, W. Bai, R. Habibian, J. Wang, B. Huang, A. Hajianpour* Cytogenetics Lab, Genzyme Genetics, Monrovia, CA.

It is well known that about 10-15% of recognized pregnancies result in spontaneous abortion (SA) with chromosomal abnormalities being the most frequent cause of SA. Maternal age is an important factor and a leading contributor to chromosomal abnormalities in SA cases. We retrospectively reviewed the cytogenetic results from our laboratory for specimens of products of conception (POC) with the clinical indication of SA between 2005 to the present. A total of 5545 POC specimens were received for chromosome analysis. After careful examination, 4803 (86.6%) cases with recognized villi and/or fetal tissues were cultured for cytogenetic evaluation. We obtained cytogenetic results for 4068 (84.7%) cases, of which, the sex ratio (XY/XX) was 1.12. Chromosome abnormalities were observed in 2461 (60.1%) cases. The most frequent abnormalities detected were autosomal trisomies (1567/2461, 63.7%), followed by triploidy or near-triploidy (282 cases, 11.5%), 45,X (226 cases, 9.2%), unbalanced structural rearrangements (116 cases, 4.7%), double trisomies (78 cases, 3.2%), tetraploidy or near-tetraploidy (74 cases, 3.0%), balanced rearrangements (31 cases, 1.3%) and monosomy 21 (23 cases, 0.9%). Of note, monosomy 21 was the only autosomal monosomy we observed. Trisomy was identified for all autosomes except of chromosome 1. In 1567 trisomy cases, the most common trisomy was chromosome 16 (385 cases, 24.6%), followed by chromosomes 22 (268 cases, 17.1%), 15 (188 cases, 12.0%), 21 (136 cases, 8.7%), 13 (97 cases, 6.2%) and 18 (72 cases, 4.6%). The single most common anomaly identified in our study was trisomy 16 (385/2461, 15.6%). In cases with unbalanced structural rearrangements, 32 (27.6%) were due to Robertsonian translocations. We also evaluated the relationship between maternal age and chromosome abnormalities in SA. The median maternal age for the abnormal chromosome group (35.4 +/- 5.5 years) was higher than that for the normal chromosome group (32.9 +/- 6.1 years). The difference was statistically significant at $P < 0.0001$. In conclusion the cytogenetic results obtained in spontaneous abortions in our laboratory were similar to those reported in the literature.

Sequencing a female genome in an academic hospital - what did we learn? *Y. Ariyurek[1], M. Kriek[1], M. Van Galen[1], P. De Knijff[2], M. P. Villerius[1], M. H. Breuning[1], G. J. B. Van Ommen[1], J. T. Den Dunnen[1]* 1) LGTC-Human & Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) FLDO-Human & Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands.

Current developments in DNA sequencing technology go very fast. Although the industrial goal to sequence a human genome for € 1000 has not yet been achieved, it will be possible soon. For any academic hospital the possibility to sequence a complete genome in order to resolve a health problem that might have a genetic cause seems an attractive option. To experience what hurdles we will meet, technically, computationally and analytically, we sequenced the genome of a European female, a clinical geneticist. From this we learned that technologically, even in an academic hospital setting, it is already feasible. It only costs time (a few months) and money (50-100K Euro). Computationally it was at the limits of our possibilities; with data storage and data transfer negatively influencing the final full sequence assembly and interpretation. The analysis of the genome shows it is female, that we can follow its ancestry (mainly European, based on mitochondrial and genomic DNA), that we can predict some of her appearance (e.g. red hair, blue eyes), that it contains no major early-onset genetic disease mutations and that it carries varying risks for all kinds of other traits. As expected, the genome analysis was beyond our current capabilities. Partly this relates to the computational hurdles mentioned, but the key problem was the analysis of all the variants we found compared to the human genome reference sequence (> 1 million). There is currently no software to score these variants effectively and existing information on sequence variants is limited and scattered over many databases, websites and diverse publications. In fact this is the reason why sequencing a patient's genome, although technically possible, cannot be applied on a routine basis to answer health related issues. To resolve this problem we need to develop mechanisms to efficiently collect and share all sequence variants identified, with their phenotypic consequences, and to connect this information to the reference genome sequence.

Fibroblast Growth Factor Receptor Gene Polymorphisms: Association with Obstructive Sleep Apnea in Children. *M. Kalra[1], P. Pal[3], L. Dolan[2], J. Mallik[3], S. Guha[3], R. Deka[3], R. Chakraborty[3]* 1) Dept Pulmonary Medicine, Cincinnati Children's Hosp, Cincinnati, OH; 2) Dept Endocrinology, Cincinnati Children's Hosp, Cincinnati, OH; 3) Center for Genome Information, University of Cincinnati.

Obstructive sleep apnea (OSA), which affects 2%-5% children, is associated with neurocognitive deficits and cardiovascular and metabolic sequelae. Although genetic predisposition for OSA has been demonstrated, the exact genetic determinants are not yet known. With strong evidence for craniofacial characteristics as its risk factors, genes that are involved in craniofacial developments such as Fibroblast Growth Factor Receptor 2 (FGFR2) have been proposed as candidate genes for OSA. The objective of this study was to test the association of FGFR2 polymorphisms and OSA status. All Caucasian children diagnosed with OSA at Cincinnati Childrens Sleep Center between January and June 2006 were recruited as cases (n = 165) and ethnicity matched controls (n= 381) were selected from the population-based Princeton School District Study. Four SNPs (rs1649161, rs2981430, rs2981452, and rs2420946) that tag the FGFR2 gene were selected using SNPbrowser ver. 3.5 (ABI). Genotyping was performed using the SNPlex (ABI) high-throughput genotyping platform. OSA was defined as apnea hypopnea index >1 on polysomnogram; cases were compared to population-based controls. The mean age of the OSA cases was 11.5 years (S.D. 4.4), 58% were males, and mean BMI was 30.7 (S.D. 12.0). The mean age of the controls was 14.6 years (S.D. 2.1), 55 % were males, and mean BMI was 22.9 (S.D. 3.4). Structure analysis revealed absence of significant population stratification between cases and controls. Allele frequency differences between cases and controls were significant for 2 SNPs (rs2981452, $p< 0.01$; and rs2420946, $p< 0.01$). Multivariate logistic regression analysis with BMIz score as covariate revealed independent genotypic association at SNP rs2420946 with OSA status (OR 5.0, 95 %CI 2.0-10.0). This is the first report on association of FGFR2 polymorphisms with OSA in children, supporting the role of FGFR2 in the pathogenesis of pediatric OSA.

Leveraging regulatory features to prioritize SNP markers for follow-up studies. *M. A. Levenstien, R. J. Klein*
Cancer Biology and Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY.

Curation of the human genome has expanded to include regulatory features based on experimental evidence from genome-wide assays. This information represents a powerful resource for prioritizing regions of the genome outside of annotated coding regions as having functional importance. We target these regulatory features as a means to identify and prioritize groups of SNPs that are more likely to affect phenotypes in order to facilitate efficient SNP selection for follow-up studies to genome-wide tests of association where signals exist far from an annotated protein-coding region. Based on the annotations available in the Ensembl database, we categorize SNPs in the human genome into classes related to regulatory features, such as epigenetic modifications and factor binding sites. Using the distribution of derived allele frequencies (DAF) within each class, we assess the strength of natural selection for each class relative to the genome as a whole. We apply this DAF analysis to Perlegen resequenced SNPs genome-wide. Groups of regulatory elements annotated by Ensmbl as well as some individual elements, such as PolII binding sites, DNase I hypersensitivity sites, and several histone methylation sites, show negative selection in comparison to the genome as a whole. In fact, some histone modification sites show derived allele frequencies comparable with those of the coding regions. These DAF distribution comparisons highlight which functional classes are under negative selection, have functional importance, and contain SNPs which are strong candidates for follow-up studies.

Facioscapulohumeral muscular dystrophy: gene discovery by DNase-chip. *M. Ehrlich[1], X. Xu[1], K. Tsumagari[1], G. Crawford[2]* 1) Human Genetics, Tulane Med. Sch., New Orleans, LA; 2) Inst. for Genome Sciences & Policy, Duke Univ., Durham, NC.

Facioscapulohumeral muscular dystrophy (FSHD) patients have one short array (<11 units) of tandem 3.3-kb repeats (D4Z4) about 15-25 kb from the end of 4q (4q35.2). Nonpathogenic D4Z4 arrays contain 11-100 units. There are almost identical arrays near the end of 10q (10q26). Short 10q arrays are phenotypically neutral despite high 4q/10q homology 42 kb proximal to D4Z4 and in all distal sequences; similar size polymorphisms; and a common candidate FSHD gene, *DUX4*, in their 3.3-kb repeats. There should be a disease-related sequence in 4q35.2 that is responsible for the pathogenicity of short D4Z4 arrays only at 4q. No 4q35 sequence differentially expressed in FSHD *vs.* control muscle was seen in several microarray expression analyses. To discover undocumented 4q35.2 genes possibly related to FSHD, including noncoding RNA genes, we looked for DNaseI hypersensitive (DH) sites, a gene hallmark. By DNase-chip analysis with high-resolution tiling arrays, DH sites were examined in the terminal 4 Mb of 4q in three FSHD and three control myoblast cell populations. The proximal 1.5 Mb of 4q35.2 had a normal density of DH sites and suggested the presence of undocumented genes. In the most distal 2.5 Mb of 4q, only one DH peak was seen in all myoblast cell strains that was not attributable to short tandem repeats. It overlapped the 5 end of *FRG1*, a gene which did not show FSHD-specific expression. FSHD myoblasts preferentially displayed one DH site 272 kb proximal to 4q D4Z4. Nearby, we found a transcribed sequence with homology to a predicted noncoding RNA. The very low density of DH sites in the terminal 2.5 Mb of 4q is consistent with the very low percentage of sequences overlapping RefSeq genes or UCSC gene predictions. In contrast, there was a normal density of DH sites at the end of 10q.These results suggest that a unique sequence about 0.3 Mb proximal to D4Z4 might determine the FSHD linkage of short D4Z4 arrays to 4q, but not to 10q. Alternatively, our data support the hypothesis that the extreme paucity of genes at 4q35.2 contributes to the 4q-specific nature of the disease (Supported in part by NIH Grant NS048859 and FSH Society Grant FSHS-MGBF-013).

A Novel Mutation in the NTRK1 Gene Causes Congenital Insensitivity to Pain and Anhidrosis among Moroccan Jews. *T. Falik-Zaccai[1,2], C. Suriano[1], A. Zinger[3], N. Kfir[1], M. Weiler[1], C. Aslanidis[4], G. Schmitz[4], M. Khayat[1]* 1) Inst. Human Gen, Western Galilee Hosp, Nahariya, Israel; 2) Rappaport Faculty of Medicine, Technion, Haifa, Israel; 3) Genetics Institute, Barzilai Medical Center, Ashkelon, Israel; 4) Institute for Clinical Chemistry and Laboratory Medicine, University of Regensburg, Medical Faculty, Regensburg, Germany.

Congenital insensitivity to pain with anhidrosis (CIPA) or Hereditary sensory and autonomic neuropathy type IV (HSAN IV) is a rare, autosomal recessive (AR) neurologic disorder, characterized by absence of reaction to painful stimuli, mental retardation, self- mutilating behavior, anhidrosis, and recurrent episodes of hyperthermia. 48 mutations in the neurotrophic tyrosine kinase receptor 1 (NTRK1), a receptor phosphorylated by nerve growth factor (NGF), were identified. Approximately 100 patients are described in the literature worldwide,from diverse ethnic groups, including five of Moroccan Jewish origin. The prevalence of CIPA mutations, and the molecular basis of the disease in this small homogenous ethnic group, has not been previously described. We identified a novel nonsense mutation in two unrelated families of Moroccan Jewish descent, each with two affected siblings. Haplotype analysis revealed a possible founder mutation that may trace to a rural Jewish village in the Atlas Mountains. Genetic screening for the causative mutation among 300 unrelated Moroccan Jews did not reveal any carriers for the causative mutation, thus excluding high risk for CIPA in this ethnic sub- population.

Intragenic deletions of the *CDKL5* gene in female patients with infantile spasms and atypical Rett syndrome: A pilot study. *S. C. Reshmi, A. J. Whited, R. J. Alva, E. V. Haverfield, M. Dempsey, S. Das* University of Chicago, Department of Human Genetics, Chicago, IL.

Atypical Rett syndrome is a neurodevelopmental disorder associated with early-onset epileptic seizures and infantile spasms. The atypical Rett syndrome phenotype ranges from milder forms of the classic Rett syndrome with mild mental retardation and slower progression, to more severe forms that manifest at birth. Approximately 20% of patients with atypical Rett syndrome have mutations in the *MECP2* gene. Of patients in whom no mutation has been identified, approximately 3% have partial deletions in *MECP2*. Mutations in either *CDKL5* or *ARX*, both also mapping to the X chromosome, appear to have some phenotypic overlap with the severe form of atypical Rett syndrome with infantile spasms. We studied a series of female patients referred to our diagnostic laboratory for atypical Rett syndrome and/or infantile spasms and in whom no mutations were identified by *CDKL5* or *ARX* sequence analyses, for intragenic deletions and duplications of the *CDKL5* and *ARX* genes. Of 97 patients analyzed thus far, we have identified three individuals (3.1%) with intragenic deletions in exon 1 of the *CDKL5* gene. These deletions were detected by MLPA analysis and confirmed by real-time quantitative PCR. Exon 1 of the *CDKL5* gene is a non-coding exon and is located within the promoter region of the main *CDKL5* isoform 1. To date, deletions of this exon have not been reported in patients with atypical Rett syndrome/infantile spasms nor have they been described as variants/polymorphisms of the *CDKL5* gene. One of the original *CDKL5*-positive patients described with infantile spasms had an apparently balanced translocation involving the X chromosome. The breakpoint occurred in intron 1 of the *CDKL5* gene, resulting in separation of exon 1 from the coding region of the gene and absent gene expression (Kalscheuer et al., 2003). We speculate that a deletion in exon 1 of the *CDKL5* gene may also likely affect its normal expression and result in disease. We are in the process of further clarifying our exon 1 deletion finding to better determine its role in atypical Rett syndrome and infantile spasms.

An Overview of Molecular Abnormalities and Genotype-Phenotype Correlation in Cornelia de Lange Syndrome: Perspectives from the Molecular Diagnostic Laboratory. *E. V. Haverfield, A. J. Whited, R. J. Alva, L. Blumenfeld-Kouchner, A. I. Lozada, A. J. Reeder, L. L. Wysinger, M. A. Dempsey, S. Das* Department of Human Genetics, University of Chicago, Chicago, IL.

Cornelia de Lange syndrome (CdLS) is a rare developmental disorder characterized by distinctive facial features, growth retardation, hirsutism, and upper limb reduction defects. Mutations in the *NIPBL* and *SMC1A* genes have been identified in patients with CdLS with a frequency of ~50% and 3-5%, respectively. We have analyzed over 250 patients for abnormalities that cause CdLS through *NIPBL* and *SMC1A* full gene sequence analysis, as well as *NIPBL* deletion/duplication analysis by multiplex ligation-dependent probe amplification (MLPA), in our molecular diagnostic laboratory. We have identified over 40 novel pathogenic mutations in the *NIPBL* gene by DNA sequencing in 210 patients analyzed (23.8%). *NIPBL* deletion/duplication analysis identified 3 intragenic deletions and 1 intragenic duplication in 124 individuals analyzed, a detection rate of 3.2%. The *NIPBL* intragenic duplication, a mutation type that has not been described to date, was detected in a newborn female with a classic CdLS phenotype. The overall mutation detection rate in our patient cohort that was analyzed by both DNA sequencing and MLPA was 54.6% for mutations and deletions/duplications in the *NIPBL* gene. The rate of mutation detection in the *SMC1A* gene has been low and has been observed in 1 out of 79 patients analyzed (1.3%). Detailed clinical information on all patients analyzed for *NIPBL* and *SMC1A* is being collected via a questionnaire that is submitted to our laboratory with the patient sample at the time of test request. We will present the clinical findings in patients with and without abnormalities in the *NIPBL* and *SMC1A* genes. Our findings represent an update on the molecular basis of CdLS as well as provide a genotype-phenotype correlation of *NIPBL* and *SMC1A* mutations and disease severity. Our studies also illustrate that *NIPBL* intragenic deletions and duplications are a contributor to CdLS etiology.

Identification and characterization of NIPBL physiological splicing variants. *F. J. Ramos[1], M. Ciero[2], B. Puisac[2], M. C. Gil-Rodríguez[2], M. Arnedo[2], M. P. Ribate[2], J. C. de Karam[2], M. Ramos[2], S. Menao[2], A. Pié[2], J. Pié[2]* 1) Secc. Genética, Depto. Pediatría, Fac. Medicina, Universidad de Zaragoza, Zaragoza, Spain; 2) Laboratorio de Genética Clínica y Genómica Funcional. Depto. Farmacología-Fisiología, Fac. Medicina, Universidad de Zaragoza, Zaragoza, Spain.

INTRODUCTION: Cornelia de Lange Syndrome (CdLS) is a clinically heterogeneous inherited disorder characterized by distinctive dysmorphic facial features, growth and cognitive impairment, and limb malformations. In 2004, two independent groups, Krantz et al. and Tonkin et al., found mutations in a regulator of the cohesin complex, the NIPBL gene, located in 5p13.2, in patients with Cornelia de Lange Syndrome 1 (CDLS1, MIM 122470). NIPBL contains 47 exons and predicted to generate two isoforms. Northern-blot and in situ analyses showed that NIPBL was expressed in several tissues with different level of expression.The identification of multiple transcripts in this gene suggest the presence of alternative splicing, a feature that has not been yet studied. This is the first systematic analysis of the NIPBL splicing variants in human normal tissues. AIM OF THE STUDY: To determine the existence of alternative splicing in NIPBL gene. METHODS: We have amplified the NIPBL cDNA from fetal skeletal muscle, fetal brain, adult leukocytes and adult brain, in various overlapping fragments. PCR products were separated by electrophoresis on agarose gel. Additional bands of different length than expected were sequenced. RESULTS: Seven different splicing variants were found and all deletions observed were in frame. Some of them were expressed only in one tissue like NIPBL-43, NIPBL-45 and NIPBL-[E10,E12]. In contrast, NIPBL-12 and NIPBL-33/34 are present in all studied tissues. To investigate the significance of these variants we are quantifying them by real time PCR in different tissues. Preliminary studies have shown a low expression level of some transcripts. Although their functional significance is still unclear, we hypothesize that some splicing variants might have a biological role. *This work is supported by a grant from the Ministerio de Sanidad of Spain (Ref. PI061343) and the Diputación General de Aragón (Ref. B20).* .

Further support for the involvement of ASAH2L in Alzheimers disease. *R. Wang[1], S. S. Bassett[1], D. Avramopoulos[1,2]* 1) Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD; 2) McKusick Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

We have previously reported the identification of a new gene, ASAH2L, which showed evidence for involvement in the risk to develop Alzheimers Disease (AD). ASAH2L is created by a partial duplication of the ASAH2 gene, an event only observed in the human genome. It is located in a region strongly linked to AD and we previously showed that it has an expression profile consistent with a correlation of higher transcription with protection against neurodegeneration. We have now acquired an independent set of temporal lobe brain samples and replicated the expression results with stronger significance than the original study. Further, in order to explore whether this transcript is indeed translated into protein we sought to determine whether any of the two putative start codons present in the ASAH2L transcript can be used to initiate the translation of their corresponding non-overlapping open reading frames (ORF1 and ORF2). We generated constructs including, under a CMV promoter, the ASAH2L transcript merged to GFP at the C-terminus in two frames corresponding to each of the two ORFs. We transfected HEK 293 cells and showed that both ORFs are recognized by the translation machinery and produce GFP tagged proteins, and thus it is possible that they are also translated in the brain. The GFP tagged ORF1 protein was found to be localized in the mitochondria, suggesting a possible role in oxidative phosphorylation or apoptosis, while the GFP tagged ORF2 protein was localized in the cytoplasm. Further work is necessary to show that translation indeed occurs in the brain for ORF1 and/or ORF2 and to determine the nature of their putative neuroprotective functions.

Investigating the neuropsychological phenotype of adult FMR1 premutation allele carriers. *J. Hunter[1], A. Abramowitz[2], M. Rusin[3], M. Leslie[1], G. Novak[1], D. Hamilton[1], L. Schubeck[1], K. Charen[1], S. Sherman[1]* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, Georgia; 2) Department of Psychology, Emory University, Atlanta, Georgia; 3) Independent practice, Atlanta, Georgia.

Expansion of the CGG repeat in the 5 untranslated region of FMR1, the fragile X mental retardation gene, is responsible for a spectrum of disorders. Repeats greater than 200, termed full mutation alleles, are associated with the mental retardation syndrome, fragile X. Expanded repeats in the range of ~55-199, termed premutation alleles, are associated with a late-onset tremor-ataxia syndrome most commonly in carrier males and primary ovarian insufficiency in carrier females. The neuropsychological impact of carrying a premutation allele is presently unclear in younger adults. In this study, we analyzed neuropsychological scores for 138 males and 506 females ascertained from the general population and from families with a history of fragile X syndrome. Subjects were age 18-50 years and had varying repeat lengths. Neuropsychological scores were obtained from measures of general intelligence, memory, executive functioning, and attention. Principal component analysis followed by varimax rotation was used to create independent factors for analysis: general intelligence, verbal ability, visual processing, self-report attention, sustained attention, and perseveration. These factors were modeled for males and females separately using a general linear model that accounted for correlation among related subjects. All models were adjusted for potential confounders, including age at testing, self-report ethnicity, and household income level. Among males, no repeat length associations were detected for any factor. Among females, significant associations with repeat length and general intelligence ($p=0.01$) and self-report attention ($p=0.03$) were detected, with premutation carriers having significant deficits compared to non-carriers. No significant interactions between repeat length and age were detected which would indicate that these deficits increase with age.

Down-regulation of gene expression at the Prader-Willi/Angelman syndrome imprinted domain by a paternally transmitted transgene. *E. Y. Smith, C. R. Futtner, A. J. DuBose, S. J. Chamberlain, J. L. Resnick* Molecular Genetics, University of Florida, Gainesville, FL.

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are distinct neurological disorders resulting from improper gene expression from the imprinted domain on chromosome 15q11-q13, the PWS/AS locus. This locus is controlled by a bipartite imprinting center consisting of the PWS-IC and the AS-IC. The PWS-IC is proposed to be a positive acting element that promotes gene expression from the paternal allele. The AS-IC acts on the maternal allele to inactivate the PWS-IC, thus silencing the paternally expressed genes. The PWS-IC is located just 5 to and including exon 1 of *SNRPN* whereas the AS-IC is 35 kb upstream of *SNRPN*. Importantly, the AS-IC includes one of several alternative upstream exons of *SNRPN*.

The PWS/AS locus is well conserved in the mouse, although the murine AS-IC remains poorly characterized. As in humans, the mouse *Snrpn* locus includes several upstream exons. We have taken a transgenic approach to study the potential regulatory role of these alternative exons. To do so, we utilized a bacterial artificial chromosome (BAC) containing *Snrpn* with approximately 100 kb of 5sequence encompassing three alternative exons. In low copy number, this transgene expresses *Snrpn* only upon paternal inheritance, suggesting that the BAC contains a functional AS-IC capable of inactivating the PWS-IC upon maternal inheritance. Targeted deletions of all three upstream exons lead to biallelic expression, suggesting inactivation of the AS-IC. When the two most 5 exons are deleted, imprinting is again lost. Surprisingly, paternal transmission of this transgene results in silencing of the endogenous *Snrpn* gene. Preliminary data show other paternally expressed genes are down-regulated as well. We are currently analyzing the remainder of the PWS/AS domain to determine whether the entire locus is repressed in addition to determining if aberrant epigenetic imprints are present at the endogenous locus. This model presents an exciting new approach to study imprinting at the PWS/AS locus.

Prenatal phenotypic variation in Ellis-van Creveld syndrome. *R. Lebel[1,2], L. Seaver[1], A. Gregg[3], J. Edwards[3], M. Salley[4], J. Avery[1], P. Broome[1], R. Stevenson[1]* 1) Greenwood Genetic Ctr, Greenwood, SC; 2) SUNY Upstate Medical University, Syracuse, NY; 3) University of South Carolina School of Medicine, Columbia, SC; 4) South Carolina OB-GYN Associates, PA, Columbia, SC.

A 21 year old womans first pregnancy ended with a blighted ovum (age 19); she presented with skeletal dysplasia (short tubular bones and ribs) and cardiac anomaly by ultrasound at 21 weeks; amnio was normal (46,XX). Autopsy confirmed prenatal report, adding endocardial cushion defect and polydactyly, supporting conclusion of Ellis-van Creveld syndrome (EC). Nine years later, after delivery of 2 normal children, she presented at 18 weeks with ultrasound findings of polydactyly, short tubular bones and ribs. Delivery was induced. Cells from the male fetus did not grow in culture. Autopsy was not consistent with EC because the cardiovascular defect was minor and there was hydrocephaly but no nuchal cyst, pulmonary hypoplasia or frenulum. No alternative diagnosis was clear but Majewski syndrome (MS) and dyssegmental dysplasia (DD) were considered. Seven months later she presented with cystic hygroma at 12 weeks. CVS showed 46,XX, but 2 weeks later intrauterine demise was found and delivery induced. Autopsy further expanded the anomaly list; syndrome assignment was reconsidered. The Beemer-Langer syndrome (BL) and Mucolipidosis type II (ML) were considered, but it was concluded that all 3 fetuses were affected by EVC, representing a broad phenotypic spectrum and illustrating the difficulties of prenatal syndrome recognition.

The Phenotypic Spectrum of Trisomy 2: A Case with Full and A Case with Mosaic Trisomy 2. *E. Mihci, G. Velagaleti, R. Ensenauer, D. Babovic-Vuksanovic* Mayo Clinic College of Medicine, Department of Medical Genetics, Rochester, MN.

Complete trisomy 2 is extremely rare and most reported cases were found during the prenatal period. The outcome of such pregnancies is highly variable, but spontaneous abortions are common with trisomy 2 accounting up to 1.1% of all spontaneous abortions. Only the mosaic form of trisomy 2 is observed in live-born individuals. In such cases, the postnatal period is characterized by growth delay, multiple congenital anomalies (including microcephaly, cleft lip and palate, facial dysmorphism) and developmental delay. We present two cases of trisomy 2. The first case, a 2-1/2-year old girl, presented with history of diaphragmatic hernia, duodenal atresia, intestinal malrotation, microcephaly, atrial and ventricular septal defect, developmental delay, hypotonia and seizures. Peripheral blood chromosome analysis showed normal 46,XX karyotype. Her phenotype was somewhat reminiscent of Pallister-Killian syndrome and skin biopsy was done. Chromosomal analysis on tissue fibroblasts showed mosaic trisomy 2 (3 out of 100 evaluated cells). Second case was an acardiac fetus in a monozygotic twin pregnancy. The normal twin was a baby girl with a karyotype 46,XX. Chromosome analysis of the Acardiac fetus showed complete trisomy with the karyotype 47, XX,+2. In conclusion, trisomy 2 is a rare chromosomal anomaly which can present with a varied phenotypic spectrum, the severity of which could be dependent on level of chromosomal mosaicism. Chromosome analysis of acardiac fetuses may help understand the etiology in some cases. Since trisomy rescue is a known phenomenon, in cases of rare mosaic trisomy 2, the phenomenon of trisomy rescue should be considered and uniparental disomy testing might help explain the phenotypic features, particularly in cases of discordant monozygotic twins.

The influence of continental axes of orientation on patterns of human gene flow. *S. Ramachandran*[1,2], *N. A. Rosenberg*[3,4,5] 1) Organismic and Evol. Biology, Harvard University, Cambridge, MA; 2) Society of Fellows, Harvard University, Cambridge, MA; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 4) Center for Computational Medicine and Biology, University of Michigan, Ann Arbor, MI; 5) The Life Sciences Institute, University of Michigan, Ann Arbor, MI.

Jared Diamond (Guns, Germs, and Steel, 1998) argued that the east-west orientation of the Eurasian landmass facilitated the rapid spread of agriculture and other technological innovations across Eurasia, while the north-south orientation of the Americas led to a slower diffusion of technology in the New World. We test Diamonds hypothesis with 678 microsatellite loci typed in 68 human populations from Eurasia and the Americas. If the diffusion of technology is accompanied by gene flow, then we expect genetic differentiation in the Americas along lines of longitude to be greater than that in Eurasia along latitudinal lines. We find that genetic differentiation is greater in the Americas than in Eurasia. Longitudinal distance explains a sizeable portion of genetic distance in Eurasia, while latitudinal distance does not explain a significant proportion of Eurasian genetic variation. Genetic differentiation in the Americas occurs along both latitudinal and longitudinal axes, suggesting the possibility of a greater degree of geographic complexity of gene flow in the Americas. These results support the view that migration patterns influenced by continental orientation have played an important role in determining the structure of human genetic variation and, by extension, the distribution and spread of cultural traits.

Mapping of a novel Ménières disease locus to chromosome 1q32.1-q32.3. *C. A. Campbell[1,2], J. Webster[3], C. Li[4], D. A. Stephan[3], R. J. H. Smith[1,2]* 1) Otolaryngology, University of Iowa, Iowa City, IA; 2) Interdepartmental PhD Program in Genetics, University of Iowa, Iowa City, IA; 3) Neurogenomics Division, Translational Genomics Research Institute, Phoenix, AZ; 4) Dept of Biostatistics, Harvard School of Public Health, Boston, MA.

Ménières disease (MD) is a complex disorder of unknown etiology characterized by vertigo, sensorineural hearing loss and tinnitus. Its reported incidence in Caucasians is 1-2 per 10,000 (Morrison 1995), but most cases of MD are sporadic and only occasional families are identified with multiple affected persons (Oliveira 1992). The dearth of such families and the reduced penetrance of MD make classic linkage analysis difficult.

We identified a Chilean family segregating autosomal dominant MD over three generations and completed a genome-wide linkage scan using the Affymetrix GeneChip Mapping 50K array. Five family members had definite MD, one individual had possible MD, 5 individuals were unaffected, and 4 individuals were too young to classify. Multi-point parametric linkage analysis assuming dominant inheritance and using DNA-Chip Analyzer software (dChip) (www.dchip.org) identified probable linkage to chromosome 1q32.1-q32.3 with a maximum LOD score of 2.36. The candidate gene interval determined by haplotype reconstruction spans 8.3 Mb (201.71- 210.29cM) and includes 79 known genes. No deafness locus maps to this region. The next linkage peak greater than 1 in this family was a LOD score of 1.66 at 17p12. This region spans 382 kb (12.65 - 13.03cM) and includes 6 genes.

Our study is significant because it identifies a locus for MD on 1q32. Since the phenotypes associated with sporadic and familial MD are indistinguishable, the identification of the causative gene in this family may have relevance to the definitive diagnosis of MD in sporadic causes. Furthermore, since little is known about MD and its initiating factors, the identification of a genetic contribution to this disease may help to clarify disease pathogenesis and possibly lead to better therapies.

Differentiation of renal oncocytoma and chromophobe renal cell carcinoma by interrogation of CCND1 by FISH and IHC: evidence that one-third of renal oncocytomas harbor a CCND1 abnormality. *A. W. Carlson, W. R. Sukov, R. P. Ketterling* Dept. of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Renal oncocytoma (RO) is a kidney neoplasm with histologic features which can at times overlap with those of chromophobe renal cell carcinoma (ChRCC). As ChRCC is malignant and can be clinically aggressive, differentiating these tumors is important. Recent studies have shown cyclin D1 overexpression by immunohistochemistry (IHC) in a subgroup of renal oncocytomas. Fluorescence in situ hybridization (FISH) studies have also shown that oncocytomas may demonstrate rearrangement of the CCND1 locus. However, the frequency of cyclin D1 overexpression and CCND1 rearrangements and the clinical implications of these findings in RO or ChRCC has not been studied. We evaluated cyclin D1 overexpression by IHC and rearrangement of the CCND1 locus by FISH in formalin-fixed paraffin-embedded tissue sections from 63 RO, 36 ChRCC, and 25 non-neoplastic kidneys. Results of IHC and FISH for all 124 specimens were blinded until study completion. All 36 ChRCC and 25 non-neoplastic kidney specimens failed to show cyclin D1 overexpression or rearrangement of the CCND1 locus. Of the 63 RO specimens, 22 (35%) were abnormal for CCND1 by either IHC or FISH. Thirteen RO were abnormal for CCND1 both by FISH and IHC, 8 RO were abnormal for IHC only, and 1 RO was abnormal by FISH only. These results indicate Cyclin D1 overexpression and rearrangement of the CCND1 locus appears to be present in approximately one third of RO and absent in ChRCC, suggesting these tests may be helpful in distinguishing these two clinically disparate tumor types. In addition, these results suggest that the evaluation of CCND1 by both IHC and FISH may be warranted, since several cases had disparate results between these two methodologies. Further, since 8 RO demonstrated CCND1 overexpression by IHC but lacked a CCND1 rearrangement by FISH, the data indicates a genetic mutation, other than translocations or inversions, is responsible for the CCND1 overexpression in a subset of RO.

Sex Hormone Abnormalities in patients with Fibromuscular Dysplasia with Connective Tissue Features. *B. F. Griswold, L. Sloper, S. Basaria, J. M. Egan, N. B. McDonnell* National Institute on Aging Baltimore, Maryland.

We have identified a group of patients (n=28) who presented with arterial dissections and aneurysms as well as stenotic lesions with a diagnosis of fibromuscular dysplasia (FMD). Varying features of Ehlers-Danlos syndrome, such as atrophic scars, velvety or stretchy skin, joint hypermobility as evidenced by a high Beighton score, history of articular dislocations, uterine prolapse, joint pain, pectus deformities, pes planus and scoliosis were also present in this group of patients, and family history data suggested autosomal dominant inheritance with reduced penetrance. There was a female preponderance, 24 women and 4 men, consistent with prior observations that FMD affects women predominantly, leading to the hypothesis that sex hormones played a role in the penetrance of the disorder. As part of a longitudinal protocol studying the natural history of this disorder, laboratory analysis of sex hormone levels was completed. Of the 24 female patients aged 33-62, 15 were post-menopausal. Of the women subjects, 8/24 (0.33) had high levels of Sex Hormone Binding Globulin (SHBG) which included four post menopausal patients. Free testosterone was low in 36 percent; of women patients, and 4/24 (0.17) had low bioavailable levels of testosterone. Of the 8 patients found to have high levels of SHBG, five also had corresponding low free testosterone. None of the patients had liver function abnormalities or current birth control pill use which are known to increase SHBG. None of the premenopausal patients had low FSH or LH along with low estrogen which would suggest pituitary failure. By contrast, the four male patients had normal levels of testosterone and SHBG, however the sample size was too small to draw conclusions. Elevated SHBG and low testosterone in women with FMD may be a clue to pathways involved in the etiology of this disorder.

A comprehensive map of common copy number variation at 50bp resolution, and resulting biological insights. *D. F. Conrad[1], D. Pinto[4,5], L. Feuk[4,5], R. Redon[1], N. Carter[1], C. Lee[2,3], S. W. Scherer[4,5], M. E. Hurles[1]* 1) Sanger Institute, Cambridge, United Kingdom; 2) Brigham and Women's Hospital and Harvard Medical School, Cambridge, MA; 3) Broad Institute of Harvard and Massachusetts Institute of Technology, Cambridge, MA; 4) The Centre for Applied Genomics and Program in Genetics and Genomic Biology, The Hosptial for Sick Children, MaRS Centre, Toronto, Canada; 5) Department of Molecular and Medical Genetics, University of Toronto, Toronto, Canada.

Copy number variation (CNV) in the genome is extensive and yet is grossly under-ascertained, as there are only 1500 sites of common CNV presently known. We know that smaller CNVs are far more numerous than larger CNVs, and so improved CNV detection resolution can be expected to dramatically increase the numbers of known CNVs. The Genome Structural Variation Consortium has performed comparative genome hybridisation on a genome-wide set of tiling oligonucleotide arrays to discover the majority of common copy number variants >500bp in size in two populations with African and European ancestry. In addition we have generated data on a single chimpanzee to provide information on the ancestral state of observed variants. This array set covers the assayable portion of the human genome with 42,000,000 probes with a median spacing of ~50bp. These data reveal, as expected, that previous surveys captured only 5-10 percent of the CNVs within a single genome. The unparalleled resolution of these arrays precisely define the boundaries of over 10,0000 CNVs and so allow us to identify accurately functional sequences that are copy number variable, as well as providing new insights into the mechanisms generating chromosomal rearrangements. Current analyses suggest that our results represent a threefold increase in the number of known sites of common copy number variation. A custom CNV genotyping array has been designed off these discovery results and screening of the HapMap samples is underway.

Interaction between the NOS2A rs1060826 variant and smoking in neovascular age-related macular degeneration. *J. A. Ayala-Haedo[1], P. J. Gallins[1], P. Whitehead[1], K. L. Spencer[2], A. Argawal[2], E. Postel[3], J. L. Haines[2], M. A. Pericak-Vance[1], W. K. Scott[1]* 1) Miami Institute for Human Geno, University of Miami Miller School of Medicine, MIAMI, FL; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Duke University, Durham NC.

It has been previously demonstrated that SNPs in the NOS2A gene modulate the effect of smoking in neurodegenerative diseases. In particular, the rs1060826 synonymous SNP attenuates the protective effect of smoking in Parkinson disease (PD). Cigarette smoking is also a strong risk factor for age-related macular degeneration (AMD), with a demonstrated synergistic interaction with genotypes of the ARMS2 locus. The NOS2A gene is an attractive AMD candidate gene given its effect on smoking and its role in host defense and inflammation. The purpose of our study was to assess the possible main and interaction effects between rs1060826 genotype, AMD, and smoking. Using a Taqman assay, we genotyped rs1060826 in 260 cases of neovascular AMD (grade 5) and 145 unrelated controls with no macular changes (grade 1). Data were analyzed using a logistic regression model with rs1060826 genotype (dominant and recessive coding), age, sex, and smoking status (ever/never), along with a two-way interaction between rs1060826 and smoking. A significant interaction was detected between rs1060826 and smoking (p=0.03), and therefore we stratified the data set by rs1060826 genotype to examine modification of the effect of smoking by genotype. These stratified analyses demonstrated that the effect of smoking in AMD is stronger in carriers of the rs1060826 GG genotype (OR 4.1, 95% CI [1.9, 8.6]) than in those with the AG or AA genotypes (OR 2.1, 95% CI [0.94, 4.9]). The elevated risk of AMD in smokers with the GG genotype is similar to the effect seen in PD, where the GG genotype eliminates the protective effect of smoking. Our results support the hypothesis that SNPs in the NOS2A gene might modulate the effects of known disease risk factors. Our preliminary data suggests a more thorough analysis of the common variants in this candidate gene and their possible interactions with smoking and ARMS2 is necessary.

Integrative epigenetic regulation via MeCP2 mediated control over microRNA 137 in a mouse model of Rett Syndrome. *K. Szulwach[1], X. Li[2], R. Smrt[2], L. Li[1], Y. Li[1], Y. Luo[2], N. Santistevan[2], W. Li[1], X. Zhao[2], P. Jin[1]* 1) Dept Human Genetics, Emory University, Atlanta, GA; 2) Dept of Neuroscience, University of New Mexico, Albuquerque, NM.

Rett Syndrome (RTT) is an X-linked dominant progressive neurodevelopmental disorder caused by mutations in the gene encoding the DNA methyl-CpG-binding protein and transcriptional regulator, MeCP2. Identification of transcripts subjected to epigenetic regulation by MeCP2, particularly in the context of postnatal neurodevelopment, is critical toward understanding the molecular pathogenesis of RTT. microRNAs (miRNAs) function through the RNA interference (RNAi) pathway to post-transcriptionally regulate protein coding transcripts. Therefore, MeCP2 mediated epigenetic control over the expression of miRNA offers a means by which MeCP2 may contribute to the altered expression of protein coding genes, and thereby contribute to the molecular pathogenesis of RTT, without influencing mRNA transcription directly. We found that, within the postnatal neurodevelopmental context of adult neural stem cells (aNSCs), expression of specific miRNAs could be epigenetically regulated by MeCP2. We have demonstrated that one miRNA subjected to MeCP2 mediated epigenetic regulation, miR-137, modulates the proliferation and differentiation of aNSCs both in vitro and in vivo. Overexpression of miR-137 was found to promote the proliferation of aNSCs, whereas a reduction of miR-137 enhanced aNSC differentiation. Furthermore, miR-137 post-transcriptionally repressed the expression of Ezh2, a histone methyltransferase and a member of the Polycomb group (PcG) protein family important toward both stem cell function and neural development. Coexpression of Ezh2 rescued the phenotypes associated with miR-137 overexpression. These results demonstrate the integration of epigenetic regulation in adult neural stem cells via MeCP2 mediated control over miR-137 expression and downstream targeting of the epigenetic modulator Ezh2 by miR-137. Additionally, our data suggests that the loss of functional MeCP2 results in the altered expression of specific miRNAs, possibly contributing to the molecular pathogenesis of RTT.

Molecular features of karyotypically normal acute myeloid leukemia (AML). *A. Block[1], S. N. J. Sait[1], S. Kakati[1], P. Starostik[2], P. K. Wallace[3], M. Barcos[4], J. Marinaro[5], M. Wetzler[5], E. S. Wang[5], G. Deeb[4]* 1) Clinical Cytogenetics Lab, Roswell Park Cancer Inst, Buffalo, NY; 2) Molecular Diagnostics Lab, Roswell Park Cancer Inst, Buffalo, NY; 3) Laboratory of Flow Cytometry, Roswell Park Cancer Inst, Buffalo, NY; 4) Department of Pathology, Roswell Park Cancer Inst, Buffalo, NY; 5) Department of Medicine, Roswell Park Cancer Inst, Buffalo, NY.

Acute myeloid leukemia (AML) patients (pts) with a normal karyotype at diagnosis have been classified into an intermediate risk group, however, this subset of pts is heterogeneous in clinical outcomes. Since the accumulation of acquired genetic alterations and epigenetic changes in hematopoietic progenitor cells have been implicated in the development of AML, multiple submicroscopic genetic alterations with prognostic significance have been identified. In order to characterize molecular features of karyotypically normal AML, we combined analysis of fms-related tyrosine kinase 3 (FLT3) and nucleophosmin, member 1 (NPM1) mutation status in a group of 43 karyotypically normal AML pts treated at our institution. A 4 base pair insertion in NPM1 resulting in a reading frame shift was observed in 18/43 pts (9 female, 9 male; median age 71 yrs, range 34-88 yrs). 6/18 pts also had FLT3 internal tandem duplication (FLT3-ITD) and 2/18 pts had missense mutation of the aspartic acid of the FLT3 kinase domain (D835). FAB morphological classification included M1, M2, M4, M5a/b. One patient had a preceding myelodysplastic syndrome. Median WBC was 61.9 X 10^9/L (range 2.6-454.3). Based on available multiparameter flow cytometric analysis, $NPM1^+$ blasts lacked $CD34^+$ expression in 11/17 patients. FLT3 abnormalities alone were observed in 6/43 pts (1 female, 5 male; median age 56.5 yrs, range 34-81 yrs). Median WBC was 40.1 X 10^9/L (range 3.7-77.7) for these pts. Pts with NPM1 mutations in this study were older, presented with higher WBC, low/absent $CD34^+$ expression, FLT3 mutations, and without AML subtype specificity. Further identification of prognostic factors in karyotypically normal pts may optimize treatment and more precisely predict outcome.

Identification of aberrantly methylated genes in colon cancer that deregulate tumorigenic signaling pathways using methylated CpG island amplification and microarrays (MCAM). *K. D. Tsuchiya[1,2], S. Dzieciatkowski[1], J.-H. Lee[1], W. M. Grady[1,3]* 1) Clinical Research Div, Fred Hutchinson Cancer Research Ctr, Seattle, WA; 2) Dept of Labs, Children's Hosp and Reg Med Ctr, Seattle, WA; 3) Div of Gastroenterology, Univ of Washington School of Med, Seattle, WA.

Colorectal cancer (CRC) arises from the accumulation of mutations and epigenetic alterations in colon epithelial cells. It is well established that gene mutations promote CRC formation by deregulating signaling pathways. The tumor promoting consequences of mutations in genes such as APC have been demonstrated in cancer cell lines and in mouse models of intestinal cancer; however, the biological effects of most epigenetic events identified in CRC remain unknown. In addition, although many genes that are silenced by epigenetic alterations in CRC have been identified, evidence suggests that a large number remain to be discovered. The purpose of this study was to identify additional genes that are silenced by promoter methylation in CRC, and to assess whether genes regulating signaling pathways are commonly subject to aberrant DNA methylation in CRC. Genome-wide assays for aberrant DNA methylation were carried out on colon adenoma and adenocarcinoma cell lines by using Methylated CpG island Amplification followed by hybridization to microarrays containing probe coverage of promoter regions (MCAM). Methylated gene promoters identified by MCAM were validated by bisulfite sequencing of cell lines and primary colon tumors. MCAM identified a number of additional genes that are aberrantly methylated in colon neoplasm cell lines. A high percentage of these genes were confirmed to be heavily methylated in primary colon tumors. These genes included members of a variety of signaling pathways, including adrenergic receptor mediated signaling, PKC signaling, PI3K-AKT signaling, and others. The methylation of the majority of these genes is predicted to alter signaling in a pro-tumorigenic manner. Our results demonstrate that aberrant DNA methylation affects genes involved in a variety of signaling pathways in CRC, and that epigenetic alterations are likely a common mechanism for deregulating these pathways in CRCs.

Endophenotype-based approach identifies missense variant in *Transferrin* that influences A levels and risk for Alzheimer's disease. *A. Goate, J. S. K. Kauwe, J. Wang, K. Mayo, J. C. Morris, A. M. Fagan, D. M. Holtzman* Depts Psychiatry & Neurology, Washington Univ Sch Medicine, St Louis, MO.

Late-onset Alzheimers disease (LOAD) is the most common neurodegenerative disorder, affecting more than 5 million people in the United States alone. With the exception of apolipoprotein E epsilon 4 (*APOE 4*) no polymorphism has shown consistent and replicated association with LOAD. The creators of AlzGene, a publicly available online database, have used meta-analyses of published genetic association studies to address the problem of small sample sizes. In this study we have tested whether putative LOAD associated single nucleotide polymorphisms (SNPs) from the AlzGene meta-analysis are also associated with a novel quantitative endophenotype, cerebrospinal fluid (CSF) levels of 42 amino acid amyloid- (A42). Biomarker studies have shown that CSF A42 levels are correlated with LOAD status and A deposition, while genetic studies have shown that mutations causing early onset AD alter A42 levels. We genotyped 29 SNPs from 26 genes (from the AlzGene database on 12/01/07) in 313 individuals for whom CSF was collected after fasting. Genotypes were tested for association with normalized CSF A42/A40 ratio and CSF total A (CSF A40 plus A42) using analysis of covariance after adjusting for significant covariates. Alleles in *ACE, APOE, BDNF, DAPK1* and *TF* are associated with CSF A levels in a manner consistent with the previous association with LOAD. This suggests that these genes may influence risk for LOAD via an A dependent mechanism. Because the *TF* SNP (rs1049296) causes an amino acid substitution (P589S) we introduced the mutation into a cDNA and tested whether the SNP altered A42 levels *in vitro*. The minor allele of this polymorphism is associated with increased risk for LOAD (OR=1.18, CI:1.01-1.37), higher A42/A40 ratios in CSF (p=0.029) and higher A42/A40 ratios *in vitro* (p=0.0035). We conclude from this work that TF is a novel LOAD gene that influences risk via an A dependent mechanism. This work demonstrates the utility of this endophenotype-based approach in identifying SNPs that influence risk for LOAD.

BRD2, a JME susceptibility gene, is required for embryonic development in mouse. *E. Shang[1], X. Wang[3], D. J. Wolgemuth[2,3,4,5], D. A. Greenberg[1,6]* 1) Department of Biostatistics, Columbia University, New York, NY; 2) Department of Genetics and Development, Columbia University, New York, NY; 3) Department of Obstetrics and Gynecology, Columbia University, New York, NY; 4) The Herbert Irving Comprehensive Cancer Center, Columbia University, New York, NY; 5) The Institute of Human Nutrition, Columbia University, New York, NY; 6) New York State Psychiatric Institute, Columbia University, New York, NY.

Juvenile Myoclonic Epilepsy (JME) is one of the most common types of epilepsy, accounting for about 10% of all epilepsies. Linkage analysis and association studies have identified a susceptibility locus for JME as BRD2 on chromosome 6p21. We have generated a mutant mouse line lacking Brd2 function and showed that Brd2 is essential for embryonic development in mouse, especially for the development of the nervous system. Lacking the Brd2 gene causes embryonic lethality: most homozygous Brd2-/- embryos die by embryonic day 11.5. Prior to death, the homozygous embryos were notably smaller but the severest obvious abnormalities are seen in the developing brain where the gene is highly expressed. The neural structures of Brd2-/- mice are highly stunted and deformed, in contrast to other organs, which appear structurally intact. The heterozygous mice appear normal but are more sensitive to drug-induced seizure. We also observed spontaneous seizures in heterozygous individuals. The Brd2 knockout unambiguously demonstrates that the gene has a critical role in neurodevelopment.

Neurocognitive profile in older children with 22q11.2 Deletion Syndrome. *E. Chow[1,2], A. Ho[1], R. Higgins[3], S. Langlois[3], D. Young[1], A. Bassett[1,2]* 1) Centre for Addiction and Mental Health, Toronto, ON, Canada; 2) Dept Psychiatry, Univ Toronto, Toronto, ON, Canada; 3) BC Children's Hospital, Vancouver, BC, Canada.

22q11.2 deletion syndrome (22q11DS) is a genetic syndrome associated with deletions in chromosome 22. Approximately 25% of adults with 22q11DS develop schizophrenia (SZ) (Bassett et al, 2005). A comprehensive study on the neurocognitive profile of 22q11DS adults reported no difference in IQ but greater impairments in motor function, learning and memory, verbal fluency and social cognition in subjects with SZ than those without SZ (Chow et al, 2006). In this study, we compared performance between children with 22q11DS and their non-deleted siblings in cognitive domains similar to this study. Thirty children with 22q11DS (13 M 17 F; age M = 10.0 years, SD = 2.0 years; IQ M = 68.0, SD = 13.7), and 12 non-deleted siblings (6 M, 6 F; age M = 10.9 years, SD = 1.5 years; IQ M = 96.0, SD = 20.0) were included in the study. All subjects were assessed with the Connors Continuous Performance Test (CPT), the Picture Arrangement subtest of the Wechsler Intelligence Scale for Children III (WISC III), the Rey-Auditory Verbal Learning Test (RAVLT), Animals naming, the Purdue Pegboard Test, Theory of Mind (TOM), and Judgement of Line Orientation (JOL). Performance on the attention index of the CPT, Picture Arrangement subtest, 5-trial total recall of the RAVLT, bilateral dexterity in the Pegboard test, Animals naming, TOM, and JOL were compared between the subject groups. The two groups differed significantly on multivariate analysis ($F(7, 26) = 16.75$, $p = <0.001$), and post-hoc Tukey-Kramer's corrections for multiple comparisons yielded significant effects for 5 tests: Picture Arrangement ($p = <0.001$), RAVLT total recall ($p = 0.021$), Animal naming ($p = 0.002$), bilateral dexterity score ($p = <0.001$), and JOL ($p = 0.001$). Interestingly, 5 22q11DS subjects (17%) performed poorly in at least 4 of the 7 test variables. These individuals may potentially be at the most risk for developing SZ in adulthood; follow-up studies with this sample will be needed to assess whether this relationship will come true.

Comparative analysis of whole-genome genotyping arrays and candidate gene arrays for copy number variation detection. *K. Wang[1,3], B. Keating[2], J. Glessner[3], T. Cappola[4], M. Bucan[1], H. Hakonarson[3], D. Rader[4], M. Reilly[4], M. Li[5]* 1) Dept Genetics, Univ Pennsylvania, Philadelphia, PA; 2) Dept of Pharmacology, Univ Pennsylvania, Philadelphia, PA; 3) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 4) Dept of Medicine, University of Pennsylvania, Philadelphia, PA; 5) Dept of Biostatistics and Epidemiology, Univ of Pennsylvania, Philadelphia, PA.

Genome-wide and candidate gene association studies have been routinely used for gene mapping. In addition to SNP-based analysis, the analysis of copy number variations (CNVs) may provide novel and complementary insights into the genetic susceptibility of complex diseases. In this study, we aim to test the relative merits of using genome-wide approach and candidate gene approach for the detection of CNVs. We have assembled a coronary artery disease (CAD) case-control study of 421 acute CAD cases, 454 chronic CAD cases and 447 angiographically normal controls. We genotyped this cohort using the Affymetrix genome-wide 6.0 array with ~900K SNPs and ~900K non-polymorphic markers, as well as the Illumina ITMAT-Broad-CARE (IBC) array with ~50K densely spaced SNPs in ~2,000 candidate genes, including 500 priority 1 genes that are densely covered. Since the IBC array has much better coverage for these genes than the Affymetrix 6.0 array, our data provide a unique opportunity for validating CNVs detected in Affymetrix and for refining boundaries of small-sized CNVs. We adapted PennCNV, a hidden Markov model based algorithm, to both the Affymetrix and Illumina arrays. A total of 474 Affymetrix CNV calls can be covered by at least 10 SNPs in the IBC array. Of these, 225 Affymetrix CNV calls are larger than 100kb, and 119 (53%) can be validated by IBC; the rate of validation increases to 40/53 (76%) if we restrict the analysis to Affymetrix CNV calls that are larger than 500kb. Our results suggest that the combined analysis of two technical platforms can provide complementary information in validating CNVs. Results from our analysis can be directly used in subsequent association tests which may provide insights into the genomic architecture of human cardiovascular diseases.

Optimizing Bisulfite DNA Conversion Method for Methylated CpG Island Discovery and Screening. *E. Currie-Fraser, B. Finkelnburg, V. Boyd, M. Barker, M. Bozzini, S. Jankowski, L. Xu* Applied Biosystems, Foster City, CA.

DNA methylation at the 5 position of cytosine in CpG islands plays a critical role in the epigenetic regulation of gene expression. Typically methylation is inversely correlated with the transcription status of the gene. Bisulfite DNA conversion is one of the most used techniques for methylation studies because of its relative simplicity, whereas other methods are frequently cumbersome and require significant optimization. The bisulfite conversion method allows precise analysis of methylation in a target region by converting all nonmethylated cytosines into uracils, while methylated cytosines remain unchanged. The workflows described here provide an effective solution for methylation analysis with straightforward protocols. There are many different approaches to methylation analysis, and in this poster we describe 3 different options. We demonstrate that a candidate regions methylation state and genotype information for each CpG locus across the entire candidate region can be identified with confidence using an optimized approach, which requires small amounts of genomic DNA and generates high quality data. These workflows, therefore, are very useful for the analysis of samples where the amount of material is limited, and when analysis time is an important factor.

Cis-regulatory elements in the Epidermal Differentiation Complex (EDC): Towards understanding atopic dermatitis and psoriasis. *C. de Guzman Strong[1], K. Sears[2], J. Segre[1]* 1) National Human Genome Research Institute, Bethesda, MD; 2) University of Illinois at Urbana-Champaign, Urbana, IL.

The Epidermal Differentiation Complex (EDC) locus (1q21) harbors a set of genes that are specifically expressed upon epidermal differentiation and barrier formation. Atopic dermatitis (AD) and psoriasis are common skin inflammatory disorders that both share independent linkage to the EDC suggesting a role for these genes in disease etiology. Recently, mutations in filaggrin (FLG) in the EDC are strongly linked to familial ichthyosis vulgaris and are highly associated with cases of AD that often advance to asthma (atopic march). AD familial studies excluding FLG continue to demonstrate EDC linkage suggesting additional genetic variants within the EDC in AD pathogenesis. The proximity and density of genes in the EDC suggest coordinate regulation via cis-regulatory elements for temporal and spatial epidermal expression. We hypothesize that evolutionarily conserved noncoding sequences (CNS) function as cis-regulatory elements to coordinate transcriptional regulation of the EDC genes. A genomics approach using comparative multi-species sequence analysis (MultiPip) of the EDC loci from human, chimpanzee, rhesus, mouse, rat, dog, and opossum genomes has identified 43 CNS as potential regulatory elements. The use of the opossum genome as a stringent criterion in annotating CNS in the EDC has been confirmed based on the evolutionary conservation of dorsal to ventral patterning of epidermal barrier acquisition in the opossum. Our functional analysis of the CNS using dual luciferase reporter assays in differentiating keratinocytes has identified either enhancer or repressor activity in roughly 50% of the CNS. We are currently correlating our findings with Genetic Association Information Network (GAIN) psoriasis studies. Taken together, our results suggest a high proportion of regulatory activity in the CNS that may coordinate expression of the genes in the EDC and could pose as genetic variants contributing to either AD or psoriasis.

Disruptions of distant regulatory elements outside *FOXL2* in BPES syndrome: exploring the role of microdeletions and variants in Conserved Non-Coding sequences (CNCs). *E. De Baere[1], B. D'haene[1], C. Attanasio[2], D. Beysen[1], M. Friedli[2], B. Lorenz[3], P. Lapunzina[4], B. Lowry[5], T. de Ravel[6], W. Reardon[7], G. Pierquin[8], A. Trainer[9], R. Fisher[10], S. Del Pozo[11], W. Courtens[12], M. Field[13], P. Bouchard[14], B. Menten[1], A. De Paepe[1], S. E. Antonarakis[2]* 1) Ctr Med Genet, Ghent Univ Hosp, Belgium; 2) Dept of Genet Med and Dev, Univ of Geneva Med School, Switzerland; 3) Dept of Opthalmol, Univ Hosp Giessen, Germany; 4) S de Genet Med y Mol and CIBERER, ISCIII, Spain; 5) Dept of Med Genet, Alberta Children's Hosp, Canada; 6) Ctr Hum Genet, Leuven Univ Hosp, Belgium; 7) Nat Ctr Med Genetics, Our Lady's Hosp for Sick Children, Ireland; 8) Dept Hum Genet, Sart Tilman, Belgium; 9) Inst Hum Genet, Univ of Newcastle, UK; 10) St James's Univ Hosp, UK; 11) Dept of Ped, Hosp 12 de Oct, Spain; 12) Ctr Hum Genet, UCL, Belgium; 13) North Clin School, Univ of Sidney, Australia; 14) Dept of Endocrin, Hosp St-Antoine, France.

Blepharophimosis syndrome (BPES) is a development disorder caused by *FOXL2* mutations, deletions or long-range microdeletions. In 12% of patients however, the molecular defect remains unknown. The major aim of this study was to unravel the genetic defect in 40 patients without *FOXL2* mutations/deletions. For this we developed targeted arrays, quantitative PCR (qPCR) and sequencing of CNCs located in previously described 5' microdeletions. ArrayCGH and qPCR revealed 1 and 3 new microdeletions 5' of *FOXL2* respectively. High-resolution qPCR and sequencing of CNCs showed that subtle copy number changes or point mutations in CNCs do not play a major role in the causation of BPES. Second, we identified and delineated 11 new deletions using microsatellites, arrayCGH and qPCR, and further characterized 10 known deletions. Overall, deletions found in the *FOXL2* region are characterized by scattered breakpoints, suggesting NHEJ or FoSTeS as possible underlying mechanisms. In conclusion, our study emphasizes the importance of disrupted long-range transcriptional control in the molecular pathogenesis of BPES. Finally, it shows the need for exhaustive copy number screening of the *FOXL2* region in this development disorder.

Genomic regions influencing plasma levels of resistin in African-Americans and non-Hispanic whites from hypertensive sibships. *K. Ding[1], M. de Andrade[2], S. L. R. Kardia[3], S. T. Turner[4], T. H. Mosley,Jr[5], I. J. Kullo[1]* 1) Division of Cardiovascular Diseases, Mayo Clinic, Rochester MN; 2) Department of Biostatistics, Mayo Clinic, Rochester MN; 3) Department of Epidemiology, University of Michigan Ann Arbor, Ann Arbor MI; 4) Division of Nephrology and Hypertension, Mayo Clinic, Rochester MN; 5) Department of Medicine, University of Mississippi, Jackson MS.

Resistin, a proinflammatory cytokine produced by macrophages in adipose tissue, has been implicated in insulin resistance and plasma resistin levels have been associated with vascular disease phenotypes. We investigated genetic determinants of plasma resistin levels in 1480 African-Americans (AAs) and 1230 non-Hispanic whites (NHWs) belonging to sibships ascertained on the basis of hypertension. Plasma resistin levels were measured by solid-phase sandwich ELISA and adjusted for conventional risk factors, serum creatinine, alcohol use, and physical activity, prior to genetic analyses. Heritability of plasma resistin levels was calculated as the proportion of the total phenotypic variance due to additive genetic effects. Genome-wide linkage analyses were performed using ~360 autosomal microsatellite markers and a variance components approach. Association analyses were performed using 11 tag SNPs in the resistin gene (*RETN*), with adjustment for presence of sibships. Plasma levels of resistin were highly heritable: $h^2 = 0.61$ in AAs, and 0.58 in NHWs. Two adjacent linkage signals were noted on chr 19p13 in AAs (LOD = 5.28 and 5.64, respectively), one of which harbors *RETN*. Tentative evidence of linkage was present on chr 6 (LOD = 1.60) in NHWs. SNP rs1862513 in the promoter region ($P = 0.00001$) and SNP rs1477341 in the 3 flanking region ($P = 0.0001$) were associated with resistin levels in AAs. SNP rs1477341 was weakly associated with resistin levels in NHWs ($P = 0.03$). Conclusion. Plasma resistin levels are highly heritable. We identified two quantitative trait loci for plasma resistin levels on chr 19p13 in AAs, one of which harbors *RETN*, and two SNPs in *RETN* that were associated with resistin levels.

ROOTLESS SYNDROME : A CASE WITH A LARGE SPECTRUM OF DENTIN DYSPLASIA. *B. DEMEER[1], C. TOUGNE[2], G. MORIN[1], B. RICHARD[3], S. DE BROCA[2], B. ARVEILER[3], M. MATHIEU[1]* 1) Department of Genetics, University hospital, Amiens, France; 2) Department of Maxillofacial Surgery, University Hospital, Amiens, France; 3) Department of genetics, University Hospital, Bordeaux, France.

We report a 10 year old boy with generalized yellow discoloration of the teeth, unusual mobility and premature loss of teeth. Both primary and secondary dentitions were affected. The clinical shape of the crowns of the teeth appeared to be normal. On clinical examination neither ectodermal defect, nor skeletal or articular features were found. Panoramic radiograph features included rootless teeth, short and abnormal shaped root teeth. In this family, the probands grand-mother and father, one of his aunt and her two boys were also affected, expressing an autosomal dominant transmission. According to the clinical and radiological phenotype, the diagnosis of dentin dysplasia type I is likely. Hereditary dentin defects have historically been classified into two main groups : dentin dysplasia (DD) and dentinogenesis imperfecta (DGI). According to this classification system, based upon clinical and radiographic features, isolated inherited dentin defect are categorized as DGI types II and III, and DD types I and II. To date, mutations in DSPP-Dentin Sialophophoprotein- have been found to underlie the dentin disorders DGI types II and III and DD type II. Dentin dysplasia type I, also known as rootless teeth (OMIM 125400) or radicular dentin dysplasia, is a very rare autosomal dominant genetic disease of unknown aetiology, causing incomplete tooth formation that results in premature exfoliation of both the primary and permanent dentitions. Study of DMP1 gene -Dentin matrix acidic phosphoprotein- and DSPP gene, except a part of exon 5 of DSPP due to technical reasons, has been performed, and no mutation was found.

The putative type 2 diabetes association signals in the *NOSAP1* and *PKLR* gene regions on chromosome 1q are not confirmed by a large scale follow up study. *N. W. Rayner[1], I. Prokopenko[1], C. J. Groves[1], E. Zeggini[1], R. L. Hanson[2], B. D. Mitchell[3], W. Jia[5], M. Ng[6], P. Froguel[4], J. Chan[6], C. Bogardus[2], S. C. Elbein[7], A. R. Shuldiner[3], M. I. McCarthy[1] For the International Type 2 Diabetes Consortium* 1) Oxford, United Kingdom; 2) Phoenix, AZ, USA; 3) Baltimore, MD, USA; 4) Lille, France; 5) Shanghai, China; 6) Hong Kong, China; 7) Little Rock, AR, USA.

High density SNP mapping (mean density 4.3kb) of the well replicated chromosome 1q type 2 diabetes (T2D) linkage region (147.0-169.7Mb) identified two association signals in samples of European descent. The first resides in the *NOS1AP* (*CAPON*) gene region (e.g. rs7538490, OR 1.53 [95%CIs 1.28-1.81], $p=1.2x10^{-6}$) and the second within a region of extensive linkage disequilibrium (LD) that includes the *ASH1L* and *PKLR* genes (e.g. rs11264372, OR 1.35 [1.17-1.56], p $5.1x10^{-5}$).

We genotyped rs7538490 in four independent sets of European origin consisting of a total of 5509 T2D cases and 7843 controls, we also genotyped rs11264371 (r^2~1.0 with rs11264372) in the same four independent sets along with a fifth set giving a total of 6067 T2D cases and 9878 controls.

The replication in these UK case-control sets failed to demonstrate any detectable effect at either SNP. Meta-analysis of the combined replication sets showed no association with T2D at these two loci: rs7538490, OR 1.01 [0.96-1.07], p 0.63, rs11264371, OR 1.04 [0.99-1.11], p 0.14. We conclude that no convincing role in T2D susceptibility was observed for these SNPs in *NOSA1P* and the *ASH1L*/*PKLR* gene region, notwithstanding any differences in the ascertainment of the replication cases and the highly selected cases used for the original screen. All in all, this large, well powered, dense association study has failed to identify any common SNP variants that may be contributing to the replicated linkage signal and we are now investigating whether structural variants, and low frequency intermediate penetrance SNPs are responsible for the observed linkage signal.

New Haplotype Sharing Method for Genome-Wide Case-Control Association Studies Implicates Gene for Parkinsons Disease. *G. A. Satten[1], A. S. Allen[2]* 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) Department of Biostatistics and Bioinformatics and Duke Clinical Research Institute, Duke University, Durham NC.

The large number of markers considered in a genome-wide association study (GWAS) has resulted in a simplification of analyses conducted. Most studies are analyzed one marker at a time using simple tests like the trend test. Methods that account for the special features of genetic association studies, yet remain computationally feasible for genome-wide analysis, are desirable as they may lead to increased power to detect associations. Haplotype sharing attempts to translate between population genetics and genetic epidemiology. Near a recent disease-causing mutation, case haplotypes should be more similar to each other than control haplotypes. We give computationally simple association tests based on haplotype sharing that can be easily applied to GWASs while allowing use of fast (but not likelihood-based) haplotyping algorithms and properly accounting for the uncertainty introduced by using inferred haplotypes. We also give haplotype sharing analyses that adjust for population stratification. Applying our methods to a GWAS of Parkinsons disease, we find a genome-wide significant signal in a biologically-plausible gene that is not found by single-snp methods. Further, a missing-data artifact that causes a spurious single-SNP association on chromosome 9 does not impact our test.

Mechanisms and clinical significance of copy number changes (CNCs) detected by aCGH in a pediatric patient population. *E. L. Baldwin[1], E. C. Thorland[2], A. R. Brothman[3], C. L. Martin[1], D. H. Ledbetter[1]* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Cytogenetics, Department of Lab Medicine & Pathology, Mayo Clinic, Rochester, MN; 3) Departments of Pediatrics and Pathology, University of Utah Health Sciences Center, Salt Lake City, UT.

Significant data are accumulating on the frequency, size and location of submicroscopic copy number changes (CNCs) in normal and various disease-specific populations. However, there is still a lack of information on the mutation rate and mechanism of origin of these duplication and deletion events, as well as the factors contributing to their potential clinical significance. We have analyzed >1200 patients with developmental delay/mental retardation/autism by aCGH using a custom-designed oligonucleotide array with whole genome plus targeted coverage. This array design has been validated and clinically implemented in a multi-center consortium, and will accurately detect genomic imbalances >300 kb anywhere in the euchromatic genome. A subset of copy number gains (CNGs) and losses (CNLs) 300 kb-10 Mb in size with known inheritance was selected for analysis of mechanism and clinical significance. Of 65 imbalances, only 15% were mediated by flanking segmental duplications (seg dups), while 85% were not associated with seg dups and represent random chromosome breakage. Twenty-six imbalances were inherited from a normal parent and were considered benign CNCs, whereas 28 imbalances were *de novo* and considered likely pathogenic CNCs. For the benign CNCs, duplications were more frequent than deletions (61.5% vs. 38.5%). However, for pathogenic CNCs, deletions were significantly more frequent (82.1%). The average size of pathogenic CNCs was 2.5 Mb, while the average size of benign CNCs was 946 kb. For a subset of imbalances in the size range of 300 kb-3 Mb, we found an average of 2 genes for the benign CNCs compared to an average 9 genes for the pathogenic CNCs, consistent with the expectation that imbalances involving a larger number of genes are more likely to include dosage sensitive genes producing phenotypic effects.

Investigation of non-coding regulatory elements as targets of Type 2 Diabetes susceptibility regions. *P. Akan[1], C. Lindgren[2], I. Prokopenko[2], M. McCarthy[2], P. Deloukas[1]* 1) Wellcome Trust Sanger Institute, Genetics of Complex Traits in Humans, Hinxton Cambridge, CB10 1SA, UK; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism (OCDEM) Churchill Hospital, Old Road Headington, Oxford, OX3 7LJ, UK.

Type 2 Diabetes (T2D) is a complex metabolic disease characterised by elevated serum glucose levels, mainly caused by defects in insulin action, secretion or both. The manifestation of the disease does not follow Mendelian segregation however; twin studies suggest strong heterogeneous genetic component acting collectively with environmental risk factors for disease predisposition (average concordance rates are 58.8% and 26.8% in monozygotic and dizygotic twins respectively). The genetic component of the disease is highly heterogeneous; several loci in the genome contributing moderate levels to the disease. Over 10 linkage scans of T2D in multiple populations have given a signal at chr1q21-25. As part of the International 1q consortium, we have undertaken a systematic investigation of regulatory elements in this region which spans 26 Mb. We are applying chromatin immunoprecipitation (ChIP) methodology using 13 antibodies against a combination of modified histones and transcription factors that mark promoters, enhancers and insulators. ChIP experiments are being performed in human primary liver epithelial (THLE-2), primary skeletal muscle and pancreatic beta cells (Hap-5). ChIPed material is analysed using a custom-made microarray with 50 bp resolution covering the entire region. To date, we have identified 591 (117 intra-genic) potential regulatory elements; only 198 of them were within 2 kb of a known transcription start site. Moreover, we have found 124 potential promoter elements in the region (at least 10 kb away from any known transcription start site), their functional investigation is ongoing. Our present goal is to sequence such potential regions in multiple individuals with different case control status to establish their functional importance in disease progress.

Congenital Hepatic Fibrosis: A common feature in various ciliopathies. *L. Lukose[1], T. Heller[3], M. Parisi[4], P. Choyke[5], K. Daryanani[6], B. Turkbey[7], J. Bryant[1], G. Golas[1], K. O'Brien[1], A. Garcia[1], D. Adams[1], L. Guay-Woodford[7], P. Mohan[8], W. A. Gahl[1,2], M. Gunay-Aygun[1,2]* 1) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Intramural Program of the Office of Rare Diseases, DHHS; 3) NIDDK, Bethesda, MD; 4) University of Washington, Seattle, WA; 5) Molecular Imaging Program, NCI, Bethesda, MD; 6) NIH Clinical Center, Bethesda, MD; 7) University of Alabama, Birmingham, Al; 8) CNMC, Washington, DC.

Congenital Hepatic Fibrosis (CHF) is a unique, genetically-determined liver pathology, caused by defective remodeling and branching of the developing biliary and portal system referred to as ductal plate malformation (DPM). Although CHF is commonly associated with autosomal recessive polycystic kidney disease (ARPKD), it can be part of many other ciliopathies including Joubert syndrome and related disorders (JSRD), Bardet-Biedl (BBS), Meckel-Gruber (MKS), oral-facial-digital (OFD) syndromes, and skeletal dysplasias caused by ciliary defects. Through our ongoing NIH trial on ciliopathies (ClinicalTrials.gov, number, NCT00068224), we evaluated 110 CHF patients (85 ARPKD/CHF, 5 ADPKD/CHF, 10 JSRD/CHF, 10 unknown type PKD/CHF) some followed prospectively for up to 5 years. In contrast to the findings in cirrhosis, liver synthetic function in CHF was intact and liver enzymes were largely normal. Portal hypertension (PH) resulting in splenomegaly and esophageal varices was the most common clinical problem. Decreased platelet count due to hypersplenism, correlated inversely with spleen volume, making this parameter a reliable indicator of the severity of PH. The severity of kidney and liver disease were independent of each other, since creatinine clearance did not correlate with spleen volume. A subset of JSRD patients had a variant form of CHF with elevated hepatocellular and biliary enzymes. Most CHF patients, especially those with ARPKD had intra- and extrahepatic gross biliary dilatations. Longer follow up and accurate molecular diagnostic classification of this cohort of CHF patients will allow us to better define the liver phenotype of ciliopathies.

Hunter Syndrome: Functional/Cognitive Improvement in Severe Cases with Enzyme Replacement Therapy. *S. Root* Peds, Univ New Mexico Sch Med, Albuquerque, NM.

This paper describes two patients with Hunter Syndrome, aged 9 and 13. Both had cognitive decline, progressively losing functional skills. By the time enzyme replacement therapy was FDA-approved, both had lost functionality, losing most speech and ambulation. By two months on treatment, both showed resolution of their hepatosplenomegaly, with improved mood and affect. Both regained some speech, along with improved ambulation and use of hands. Patient A has had frequent hospitalizations with respiratory illnesses and/or sepsis, and had a tracheotomy by age 3. He began weekly enzyme replacement with multiple episodes of presumed infusion reactions, with red skin and hives appearing, then subsiding, with or without treatment. He was started on montelukast, and these episodes mostly disappeared. His liver and spleen shrank to normal. He now blurts out single words, appropriate to the situation. He is able to walk long distances. At school, he participates in class effectively, and even says a few words that others can understand. He can now complete a task once his teachers start it off with brief hand-over-hand work. Patient B never needed hospitalization, but had herniorrhaphies. Good health, but showed evidence of developmental delay, and before enzyme replacement therapy was approved he had lost all speech and was unwilling to walk very far. He used his hands like spades, unable to functionally separate his fingers. On therapy, his hepatosplenomegaly quickly resolved and his tongue shrank. He learned to catch and throw a ball accurately. He rarely uses a word, but understands much of what is said to him. His favorite activity is watching Tom and Jerry cartoons, and he can follow the plot. Hes able to walk for miles. On montelukast, his chronic cough and rhinorrhea disappeared. Enzyme replacement therapy has transformed the lives of both these children. It is not a cure, but has given them more function and their families hope. What is responsible for the improvementsremoval of mucopolysaccharides in the brain? Loss of hepatosplenomegaly? Improved joint function? Smaller tongue size? Is some due to the anti-inflammatory effects of montelukast? They and their families are pleased.

Realizing single molecule clinical genetics. *M. Boyce-Jacino, P. Deshpande, N. Fernandes, L. Changolkar, MD. Austin, S. Vijayan, H. Cao* BioNanomatrix Inc., Philadelphia, PA.

Advances in understanding genetic complexity from SNPs to gene duplications and rearrangements to regulatory changes in methylation have driven the need for increasingly sensitive and accurate methods of DNA analysis to ensure informative association of DNA variation with clinical status. Ideally, such methods would enable direct analysis of high molecular weight genomic DNA in native-state constructs. To this end, we have been developing a simple and robust approach to sorting single DNA molecules in a massively parallel fashion, enabling direct imaging of structural barcodes of individual long (100,000-200,000 bp) genomic DNA fragments in a continuous flow mode. Our approach utilizes a nanochannel chip capable of parallel sorting and single molecule analysis of megabase DNA molecules. The chip consists of an array of enclosed nanochannels which enable linearization and prevents individual molecules from folding back on themselves while inside the channel. The chip provides a linearized DNA molecule that is suspended in solution in its native helical form. The samples tested to date include native genomic DNA, bacterial artificial chromosomes and long range PCR products. We present results showing that our nanochannel device can be used to perform sizing of genomic DNA fragmented by radiation damage or apoptosis, to determine the distances between fluorescently labeled sequence-specific biomarkers for genomic mapping/structural variation detection, and to determine long range haplotypes. The device can even examine protein binding events for epigenetic studies on molecules that are up to 200 kbp and larger, at sub-kilobase resolution. Capabilities of the system and mapping results will be described.

Sacral agenesis, T-box genes, and independent evolution of short tails in Manx Cats. *K. J. Buckingham[1], M. J. McMillin[1], M. L. Feldkamp[2], M. J. Bamshad[1]* 1) Dept. of Pediatrics, University of Washington, Seattle, WA, USA; 2) Dept. of Pediatrics, University of Utah, Salt Lake City, UT, USA.

Tails in vertebrates are used for a wide variety of functions including balance, locomotion, and communication. Both within and among species variation in tail length is common and phylogenetic analyses suggest that shortening or loss of the tail has occurred multiple times independently. The evolutionary mechanism(s) that explains this observation is, as of yet, unknown. Tail length variation is particularly common among different breeds of domestic cat. Notably the tail of the Manx cat can be categorized into four phenotypes that range from absence of the tail (i.e., rumpy), to a minimal tail (i.e., rumpy riser), to a short tail (i.e., stumpy), to a full tail. The variable tail length of the Manx recapitulates that of mice heterozygous for deletions of the canonical T-box gene, *T*, which encodes the transcription factor Brachyury, a key regulator of notochord differentiation in all vertebrates. We resequenced *T* in several independent lineages of Manx cats and identified multiple small deletions, each predicted to cause a frameshift that leads to premature termination and truncation of the carboxy terminal end of Brachyury. Mutant alleles appeared to be largely lineage specific, all of the animals with shortened tails were heterozygous for *T* mutations, and none of the animals with a *T* mutation had a tail of normal length. One of these alleles was shared with American Bobtails, another cat breed with a short tail. These observations indicate that variable Brachyury dosage might be a general mechanism for influencing tail length in vertebrates. Moreover, Manx cats with shortened tails have a higher incidence of imperforate anus and vertebral defects such as sacral agenesis. A missense mutation predicted to substitute a conservative amino acid in the carboxy terminal domain of Brachyury was recently reported in a case of sacral agenesis and screening of a modestly sized cohort of cases for additional mutations is underway. These results suggest that *T* variants might also influence the risk for birth defects in humans.

New Mutations in GDAP1 gene are responsible for axonal autosomal recessive Charcot-Marie-Tooth disease (ARCMT2)in families from Sudan and Yemen. *H. Azzedine[1,2], M. A. M. Salih[3], E. Mikesova[1], S. A. Elmalik[4], M. M. Kabiraj[5], A. E. M. Ahmed[6], M. M. Mukhtar[7], E. LeGuern[1,8]* 1) INSERM U679, Hôpital de la Pitié-Salpêtrière, Paris, France; 2) National Centre for Neurogenetic disorders, CHU Angers, Angers, France; 3) Division of Pediatric Neurology, Department Of Pediatrics, College of Medicine, King Saud University, Riyadh, Saudi Arabia; 4) Department of Physiology, College of Medicine, King Saud University, Riyadh, Saudi Arabia; 5) Division of Clinical Neurophysiology, Department of Neuroscience, Armed Forces Hospital, Riyadh, Saudi Arabia; 6) Department of Physiology, Faculty of Medicine, University of Khartoum, Sudan; 7) Institute of Endemic Diseases, Faculty of Medicine, University of Khartoum, Sudan; 8) UF de génétique, Département de Génétique et Cytogénétique, Hôpital de la Pitié-Salpêtrière, Paris, France.

CMT is a pathological and genetic heterogeneous group of hereditary motor and sensory neuropathies characterized by slowly progressive weakness and atrophy, primarily in peroneal and distal leg muscles. Two major types have been distinguished on pathological and electrophysiological grounds: demyelinating and axonal CMT. We describe 3 consanguinous Sudanese and Yemeni families with ARCMT2. These consisted of 16 individuals aged 2-35 years and there parents. Five of them were affected. Onset was about 2 years with delayed walking, evolving into high steppage gait and distal lower limb muscle weakness and wasting. Cognitive development was normal, ambulation was preserved and no scoliosis was detected. Nerve conduction studies were compatible with axonal CMT. However, nerve pathology showed prominent loss of large myelinated axons and typical onion bulbs formations. These families were screened for 12 microsatellites markers covering the 2 more frequent ARCMT2 loci (CMT4A/2K and CMT2B1). Assignment of the families to the CMT4B/2K was established by homozygocity mapping. Sequencing of GDAP1 was performed in all members of the 3 families and 3 new mutations were identified. In our Knowledge, These are the first GDAP1 mutations reported in Sudanese and Yemeni families. The phenotype is of axonal type, compatible to the majority of previously reported studies.

Protective effect of *Glutathione S-Transferase T1* gene on melanoma risk in presence of *CDKN2A* mutations, *MC1R* variants and host-related phenotypes. *V. Chaudru[1,2], MT. Lo[1,2], F. Lesueur[3,4], K. Laud[5], H. Mohamdi[1,2], C. Marian[6], M. Barrois[3], A. Chompret[3], MF. Avril[7], F. Demenais[1,2], B. Bressac-de Paillerets[3]* 1) INSERM U794, CEPH, Paris, France; 2) Université dEvry, Evry, France; 3) Service de Génétique, IGR, Villejuif, France; 4) IARC, Lyon, France; 5) INSERM, U830, Institut Curie, Paris, France; 6) Lombardi Comprehensive Cancer Center, Washington, DC, USA; 7) AP-HP, Hôpital Cochin, Paris, France.

The effect of *CDKN2A*, the major high-risk melanoma susceptibility gene, has been shown to be modified by host-related phenotypes and variants of *MC1R* gene. The Glutathione S-transferase (*GSTs*) genes, implicated in detoxification of metabolites after UV exposure, are candidates for modulating *CDKN2A* penetrance. Few case-controls studies have investigated the effect of *GSTs* on melanoma risk, and have led to controversial results while these genes have not yet been studied in families segregating *CDKN2A* mutations. We examined the effect of *GSTP1*, *GSTM1* and *GSTT1* genotypes on melanoma risk in 25 French melanoma-prone pedigrees with *CDKN2A* mutations, in presence of *MC1R* gene variants, sun exposure, and host-related phenotypes. Logistic regression analysis, taking into account correlations among family members, was applied to 195 subjects genotyped for all investigated genes. No significant effect of null *GSTM1* allele and *GSTP1* variants (p.I105V, p.A114V) on melanoma risk was found. However, a significant protective effect of carrying at least one null *GSTT1* allele was shown: Odds-ratio (OR) adjusted for age, sex and *CDKN2A* = 0.41 (*P*=0.035) and OR adjusted for age, sex, *CDKN2A* and *MC1R* = 0.24 (*P*=0.001). Multiple logistic regression analysis showed that the factors influencing significantly melanoma risk associated with *CDKN2A* mutations were: *MC1R* and dysplastic nevi (increasing the risk) and *GSTT1* (decreasing the risk). This study demonstrates the multiplicity of genetic pathways involved in melanoma development and has important implication in melanoma risk assessment. Funded by Ligue Nationale Contre le Cancer and INCa.

Proper Analysis of Secondary Phenotype Data in Case-Control Association Studies. *D. Lin, D. Zeng* Dept Biostatistics, CB #7420, Univ North Carolina, Chapel Hill, NC.

Case-control association studies often collect extensive information on secondary phenotypes, which are quantitative or qualitative traits other than the case-control status. Exploring secondary phenotypes can yield valuable insights into biological pathways or identify genetic variants influencing phenotypes of direct interest. Indeed, recent months have seen an explosion of publications on genetic variants influencing human quantitative traits, such as height, body mass index, and lipid levels. All publications on secondary phenotypes have used standard statistical methods (e.g. least-squares estimation), which require random sampling. Because of unequal selection probabilities between cases and controls, the case-control sample is not a random sample from the general population. As a result, standard statistical analysis of secondary phenotype data can be very misleading: the estimates of genetic effects can be severely biased, the false-positive rates can be grossly inflated, and the statistical power can be substantially diminished. We present simple statistical methods that properly reflect the case-control sampling in the analysis of secondary phenotype data. The new methods provide unbiased estimation of genetic effects and accurate control of false-positive rates while maximizing statistical power. We demonstrate the pitfalls of the current methods and the advantages of the new methods in both simulated and empirical data. The relevant software is available at our website.

Method for Association Based on Hardy-Weinberg Disequilibrium. *S.-A. Bacanu, Li. Li, M. R. Nelson*
GlaxoSmithKline, Res Triangle Park, NC.

In many scenarios it is of interest to analyze markers that may deviate significantly from expectations under Hardy-Weinberg equilibrium (HWE) in study or population controls. While in cases having a disease or drug response of interest such disequilibrium can be induced for a genetic risk factor, in population or clinical controls (subsequently referred as controls) such deviations from HWE can be the result of several possible causes, including subtle stratification/admixture, active selection, genotyping errors and the possible presence of copy number variants nearby. To allow for analysis of markers in Hardy-Weinberg disequilibrium (HWD) we propose two novel HWD-based statistical tests. The first test assesses if the HWD statistic in cases is significantly increased compared to controls. The test adjusts the HWD 2 statistic in cases for the background HWD from controls. The second is a combined test of HWD and association. It computes the departures of the observed genotype frequencies in cases from the HWE frequencies estimated from controls. For both tests p-values are computed assuming the HWD 2 statistic is distributed as a non-central 2. The noncentrality parameter of the 2 distribution is estimated from the control sample and rescaled for the number of cases. We present the performance of the proposed statistical tests under a variety of scenarios involving combinations of stratified/unstratified cohorts and under the null/alternative hypothesis. The proposed tests are conservative even when analyzing markers in HWD and can increase power dramatically under many circumstances for markers in HWE. Consequently, we recommend the use of these novel tests in an exploratory analysis if not in the primary analysis itself.

Genome-wide association studies of 13 metabolic traits on the Pacific island of Kosrae suggest shared genetic architecture across populations. *J. K. Lowe[1,2,3], J. B. Maller[1,2,4], I. Pe'er[5], B. M. Neale[1,2,6], J. Salit[3], E. Kenny[3], J. L. Shea[1,2], R. Burkhardt[3], W. Ji[7], J.-N. Foo[7], R. P. Lifton[7], J. L. Breslow[3], M. Stoffel[3], M. J. Daly[1,2,9], D. M. Altshuler[1,2,9], J. M. Friedman[3,8]* 1) Broad Institute of Harvard & MIT, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Rockefeller University, New York, NY; 4) University of Oxford, Oxford, UK; 5) Columbia University, New York, NY; 6) King's College, London, UK; 7) Yale University, New Haven, CT; 8) Howard Hughes Medical Institute; 9) Harvard Medical School, Boston, MA.

Natives to the island of Kosrae, Federated States of Micronesia, exhibit a high prevalence of metabolic disorders such as obesity and diabetes compared to Caucasian populations. A strong founder effect, severe isolation, and substantial inbreeding greatly reduced genetic diversity on Kosrae, making it an attractive cohort for mapping genetic components of complex traits. We developed methods for association analyses in this highly related population, in which 2842 subjects fall into a single extended pedigree, and performed genome-wide analyses for 13 quantitative traits. A comparison of association results for plasma lipids in Kosrae and in published studies validates our approach.

We sought to assess the added value of this non-European founder population in light of extensive GWA studies in Europeans. Using >60 published associations for quantitative traits (lipids, height, BMI, TSH) discovered in European GWA studies, we evaluate: the proportion of loci with convincingly similar effects () in Kosrae; similarity in allele frequencies and the proportion where the risk allele is too rare to evaluate in Kosrae; potential for variable LD patterns to help delimit associations; and evidence for unrelated associations in the same gene in Kosrae. Although allele frequencies are largely comparable, ~13% of loci could not be evaluated due to low frequency on Kosrae. Over 80% of the remaining loci have the same effect in Kosraens & Europeans. These data suggest strong similarity in the genetic architecture of disease between an inbred population isolate and outbred Europeans.

From laser capture micro-dissection (LCM) to high-resolution SNP-CGH microarrays: genomic architecture in two neurofibromatosis type 1-associated glomus tumors. *A. Pemov[1], C. Park[1], C. R. Lee[2], J. L. Sloan[1], D. R. Stewart[1]* 1) NHGRI/NIH, Bethesda, MD; 2) Dept. of Pathology, NCI/NIH, Bethesda, MD.

Introduction. Neurofibromatosis type 1 (NF1) is a common autosomal dominant monogenic disorder of dysregulated tissue growth. The causative gene, *NF1*, encodes the tumor suppressor neurofibromin. Glomus tumors are rare, benign tumors of the glomus body, a thermoregulatory shunt in the fingertips. Multi-focal glomus tumors in patients with NF1 have been reported, suggesting a possible association. Previously, we found somatic inactivation of *NF1* in 2 of 3 glomus tumors from a single individual with NF1. To investigate the role of other genomic perturbations in 2 NF1-associated glomus tumors, we performed comparative genomic hybridization (CGH) analysis of tumor DNA. Given the small size of glomus tumors (<10 mm in diameter) it is a challenge to separate tumor cells from normal tissue and obtain high quality DNA in the amount sufficient for downstream analysis. To succeed, we coupled LCM-based tumor cell isolation with subsequent DNA analysis on Illumina HumanHap550 SNP-CGH microarrays, a high-resolution whole genome approach requiring a low amount of input DNA. **Results.** 500 ng of tumor DNA samples were processed, in parallel with the patient's germline (lymphocyte) DNA, on the arrays. Numerous copy-neutral regions of loss of heterozygosity (LOH) were identified in both tumor samples; however, the same LOH regions were also identified in germline DNA, indicating that no tumor-specific LOHs were present in the samples. Copy number (CN) analysis revealed no large-scale (>1 Mb) deletions or duplications in the tumor samples. High-resolution CN analysis (10 Kb - 1 Mb) identified several statistically significant loci present in at least 1 tumor DNA but not germline DNA. Follow-up qPCR validation identified several candidate genes and chromosomal loci for further analysis. **Conclusions.** 1. Global genomic architecture of the glomus tumor DNA closely resembles that of the patients germline DNA. 2. Combining LCM dissection with high-resolution SNP-CGH analysis, though technically demanding, is a powerful approach for studying tumorigenesis.

Genome wide scans for signature of positive selection of noncoding regions in primates. *O. Fedrigo[1,2], R. Haygood[1,2], J. Pavisic[1], G. A. Wray[1,2]* 1) Biology Department, Duke University, Durham, NC; 2) Institute for Genome Sciences and Policy, Duke University, Durham, NC.

It has been suggested that major trait differences between humans and chimpanzees are due to changes in gene regulation rather than changes in protein structure. We previously performed a genome wide scan for positive selection of 5 flanking regions (5 kb upstream of the transcription start site), which are known to be enriched in *cis*-regulatory sequences. However, gene products can also be post-transcriptionally regulated through processes such as translation efficiency, mRNA stability and mRNA subcellular localization. This additional level of regulation is another potential target for adaptation on the human lineage. We performed a similar survey on 5' and 3' untranslated regions (UTRs) using a lineage-specific Random Effect Likelihood model comparison to test for faster evolution along the human lineage and compared the results to signatures of positive selection on 5 flanking. Our results show that the three compartments are under different selective constraints but the 5 flanking regions are more similar to the 5 UTR regions than to the 3 UTR regions, consistent with their greater similarity in regulatory function. We also contrasted the signature of positive selection with PANTHER and GO ontology classifications and expression data from Novartis Gene Expression Atlas. Different ontology categories are enriched for signatures of positive selection for each compartment. We previously found that 5 flanking region of genes involved in neural development and function and in nutrition have been targeted by positive selection. In contrast, molecular transport, signaling, development and immunity ontology categories are enriched with signature of positive selection within UTRs. The results of this study show different trends between the three regulatory compartments, suggesting that natural selection has acted differentially on these compartments for fine tuning gene products during adaptation on the human lineage.

Using mtDNA and Y-chromosome for estimating group ancestry: Implications for case-control studies. *K. Stefflova[1], M. Dulik[2], A. Pai[2], A. Walker[1], T. Schurr[2], T. Rebbeck[1]* 1) Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA; 2) Archeology and Anthropology.

Population-specific genetic markers inherited either biparentally (autosomal) or uniparentally (mtDNA, Y-chr.) may provide valuable information about ancestry. This genetically defined ancestry was proven to be useful in genotype-disease association studies, helping to prevent incorrect statistical inferences caused by population stratification. We examined the possible role of mtDNA and the non-recombining portion of the Y-chr. (NRY) as ancestry informative markers (AIMs) for admixed groups (self-identified African Americans (AA) or European Americans (EA)) collected as part of a prostate cancer case-control study. We deeply typed both mtDNA (HVS-I, II, 36 coding SNPs) and the NRY (37 SNPs) in a group of 226 AA cases and controls and compared this group to 206 EA cases and controls, and 49 Senegalese. Based on both mtDNA- and NRY-defined group ancestry, we confirmed that there was no statistically significant difference between cases and controls (F_{st} for mtDNA/NRY: 0.00034/0.00393 and 0.00091/0.0049 for AA and EA respectively), suggesting that our matching strategy appropriately accounted for ancestry during participant ascertainment. We then assessed admixture contributed from maternal and paternal populations. We found a sex biased admixture for AA where 13.2% of mtDNAs and 34.5% of NRYs were of non-African origin. We also found a small amount of admixture in EA (~3% mtDNA, 1.5% NRY). By typing a set of 1,509 autosomal AIMs on a subset of AAs, we confirmed that this level of admixture is reflected in the autosomal region (m_{auto} found: 19.2%6.4%, m_{auto} calculated: 23.9%). Lastly, we have used these markers for inferring the history of the Philadelphian AA using our database of published world mtDNA and NRY variation (3,800 mtDNA, 1,400 NRY) with a focus on Africans and South AAs, and stratifying it according the ethnicity, language and geography. These data paint a comprehensive picture of ancestry of the Philadelphian population and serve as a necessary control in epidemiological association studies to protect against biases in the corresponding association estimates.

Haplotype functional analysis of *ENGRAILED 2* autism risk allele. *J. Choi[1,2,4], R. Benayed[2,3,4], N. Gharani[5], L. Brzustowicz[5], J. Millonig[1,2,3]* 1) Cell and Developmental Biology, University of Medicine and Dentistry of New Jersey, Piscataway, NJ; 2) Center for Advanced Biotechnology and Medicine, Piscataway, NJ; 3) Department of Neuroscience and Cell Biology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ; 4) Graduate School of Biomedical Sciences, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ; 5) Department of Genetics, Rutgers University Piscataway, NJ.

Previous studies in the Millonig and Brzustowicz labs have determined that the homeobox transcription factor, *ENGRAILED 2 (EN2)* is a likely susceptibility gene of Autism Spectrum Disorder (ASD). The common alleles of two intronic SNPs, *rs1861972* (A/G) and *rs1861973* (C/T) are significantly associated with ASD individually and as a haplotype. Functional analyses including luciferase reporter assays and Electrophoretic Mobility Shift Assays demonstrated the associated A-C haplotype results in significantly increased expression of luciferase as well as specific binding of protein factors. These results indicate that the A-C haplotype is a functional variant contributing to increased risk for ASD. The aim of the present study was to examine whether both associated alleles contribute to this functional difference. To do this, we transfected a series of luciferase constructs into primary neuronal cultures of mouse cerebellar granule cells. The A-T and G-C haplotype constructs were tested, which have a single associated allele for either *rs1861972* or *rs1861973*. Both rare haplotypes significantly decreased gene expression disabling the A-C haplotype activator function. Oligonucleotide constructs demonstrated that each allele was sufficient for transcriptional activity but the *rs1861973* C allele modified the functional effect of the *rs1861972* A allele. These data collectively demonstrate both alleles of the associated A-C haplotype are functional. To further support the haplotype function of the risk alleles, evolutionary conservation of these alleles were investigated in primate species. The results indicate the A-C haplotype is ancestral and evolved together, implying the A-C haplotype is an important functional unit.

Association of the *CLOCK* gene to Alcohol Dependence and substance abuse in the Irish Affected Sib Pair Study of Alcohol Dependence (IASPSAD) sample. *G. Kalsi[1], P.-H. Kuo[2], F. Aliev[1], J. Alexander[1], D. G. Patterson[3], D. Walsh[4], D. M. Dick[1], C. A. Prescott[5], K. S. Kendler[1], B. P. Riley[1]* 1) Dept of Psychiatry, Virginia Commonwealth Univ, 800 East Leigh St, Richmond, VA 23298; 2) Institute of Clinical Medicine, College of Medicine, National Cheng Kung University, Taiwan; 3) Shaftsbury Square Hospital, Belfast, Northern Ireland, UK; 4) Health Research Board, Dublin, Ireland; 5) Department of Psychology, University of Southern California, Los Angeles CA, USA.

The *CLOCK gene* is a transcription factor involved in controlling chronobiological rhythmicity. Drugs of abuse can disrupt the circadian molecular mechanism essential for an organism to anticipate and adapt effectively to daily environmental cues. We examined the role of *CLOCK* gene in 575 independent cases selected from the Irish Affected Sib Pair Study of Alcohol Dependence (IASPSAD) sample and 530 controls screened for heavy drinking. Genotyping was conducted using an Illumina custom array of 1350 SNPs in candidate genes. Ten SNPs in the *CLOCK* gene were tested. The data produced 3 non-polymorphic SNPs and four showed redundancy in terms of LD information. To complete a minimum tagging set of 6 SNPs, three additional SNPs were selected using Tagger and genotyped using Taqman (ABI) assays. Association tests for single marker and haplotype analyses were conducted using Haploview v4.0. A case-only regression analysis of substance abuse symptoms as quantitative phenotype was conducted in WHAP. Single marker results reveal that 3 of the 6 tSNPs support association with AD, the most significant producing p=0.0033 (rs12649507). Multiple testing correction produced P=0.014. Haplotype analysis produced two 4-marker haplotypes; the most significant haplotype yielded p=0.003. The second haplotype demonstrates nominal significance (p=0.021). The case-only analysis using quantitative measures produced 1 tSNPs yielding nominal significance for association to substance abuse symptoms (p=0.01). Our study is the first to provide evidence for a role for *CLOCK* gene in AD and a comorbid phenotype of substance abuse. The expression of *CLOCK* gene is being explored in post-mortem brain samples.

An integrative genomics approach to biomarker discovery in breast cancer. *C. Hicks[1], R. Asfour[2], L. Miele[3]* 1) Preventive Medicine and Epidemiology & Surgery, Loyola Univ, Maywood, IL; 2) Department of Mathematics and Statistics, Loyola University, Chicago; 3) The Cardinal Bernardin Cancer Center, Loyola University Medical Center.

Recent advances in high-throughput genotyping have made it possible to conduct large-scale genome-wide association studies (GWAS)to identify gene variants associated with risk for breast cancer and a variety of other common human diseases. Over the last several years, many gene variants and genes associated with breast cancer have been identified using GWAS. However, the full breadth of the goals of high-throughput genotyping and GWAS to dissect the genetic architecture of breast cancer is rapidly running into several bottlenecks in translating findings and hypothesis from GWAS to clinical practice. One of the significant bottlenecks is the inability of GWAS to identify causal pathways and to elucidate the functions of identified gene variants and genes. This knowledge gap between gene discovery and function has significant impaired our ability to develop more effective strategies for early therapeutic intervention. In this study, we have conducted an integrative genomic analysis to identify causal pathways and to infer the causal association between gene expression and the disease. Our working hypothesis was that gene variants associated with breast cancer are mapped to multiple genes interacting within pathways, and that genes within these pathways are expressed in breast cancer subjects. We tested this hypothesis using 200 genes and 800 gene variants associated with breast cancer, derived from 59,890 breast cancer cases and 79,051 controls. We have shown through pathway analysis that genes with multiple gene variants interact within pathways. Using two publicly available gene expression data sets, we show the causal association between gene expression and the disease. In addition, we identify a novel set of genes that are regulated by genes identified from GWAS. Our analysis demonstrates that integrative genomics leveraging information from GWAS with gene expression data provides a unified approach to identification of causal pathways and modeling complex gene regulatory networks.

Sudden and premature death in adults with 22q11.2 Deletion Syndrome. *A. S. Bassett[1, 2,3], E. W. C. Chow[1,2], J. Husted[1,5], K. A. Hodgkinson[1,4], E. Oechslin[3], L. Harris[3], C. Silversides[3]* 1) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 3) Toronto Congenital Cardiac Centre for Adults, University of Toronto, Peter Munk Cardiac Centre, University Health Network/Toronto General Hospital, Toronto, Ontario, Canada; 4) Department of Genetics, Memorial University of Newfoundland, St. John's, Newfoundland, Canada; 5) Department of Health Studies, University of Waterloo, Waterloo, Ontario, Canada.

Background: 22q11.2 Deletion Syndrome (22q11.2DS) is a common but under-recognized microdeletion syndrome with multisystem expression including congenital heart defects (CHD) and schizophrenia. Little is known about longevity in adults with the syndrome. Methods: We prospectively followed 264 subjects; 102 adults (> 17 years) with 22q11.2DS (44 M, 58 F; mean age 33.6 SD 10.9 years) and their 162 unaffected siblings (77 M, 85 F; mean age 36.1, SD 12.2 years). We compared survival between groups using Kaplan-Meier estimates. Findings: Twelve (11.8%; 4 M, 8 F) individuals with 22q11.2DS died at median age 41.5 (range 18.1-68.6) years, four of whom had major CHD and seven schizophrenia. No siblings died ($p<0.0001$). Six (50%) deaths were sudden, unexpected and presumed arrhythmic in origin: two in patients with complex CHD, two in patients with repaired simple congenital cardiac lesions and two in patients with no cardiac history. Survival to ages 40 and 50 years was 89.9% and 73.9%, respectively. Interpretation: Individuals with 22q11.2DS who survive childhood have diminished life expectancy and increased risk of sudden death. Further studies, including detailed post mortem examinations, are needed to facilitate research into pathophysiological mechanisms that may help identify preventive strategies. 22q11.2DS may represent another cause of sudden adult death syndrome.

Common DNA sequence variants at thirty loci contribute to polygenic dyslipidemia. *S. Kathiresan[1, 2, 3], C. Willer[4], G. Peloso[3, 5], S. Demissie[3, 5], LOLILOP, SUVIMAX, InCHIANTI, DGI, FUSION, SardiNIA, Rosetta, ISIS, METSIM, FINRISK, MDC, and FHS* 1) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 2) Ctr for Human Genetic Research and Cardiovascular Research Ctr, Massachusetts General Hospital, Boston, MA; 3) Framingham Heart Study, Framingham, MA; 4) Ctr for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI; 5) Department of Biostatistics, Boston University School of Public Health, Boston, MA.

Low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol and triglycerides are quantitative risk factors for cardiovascular disease and variability in these traits is largely polygenic in origin. To map DNA sequence variants that impact blood lipoprotein concentrations, we conducted genome-wide association screens in four studies (n=11,024 from Framingham Heart Study, LOLIPOP, SUVIMAX, and InCHIANTI). We performed a meta-analysis including previously published scans [total n=19,840 composed of 11,024 new scans and 8,816 previously-published, >2.4 million single nucleotide polymorphisms (SNPs, directly genotyped and imputed)] along with replication in up to 19,826 additional individuals. We identified SNPs at 30 loci (11 newly-identified) as reproducibly associated with LDL cholesterol, HDL cholesterol, and/or triglycerides ($P<5 \times 10^{-8}$ for each locus). Newly identified common SNPs include those primarily associated with LDL cholesterol (near or in ABCG5-ABCG8, LPA, TCF1, and TIMD4); HDL cholesterol (near or in ANGPTL4, c9orf52, FADS gene cluster, HNF4A, LCAT, and PLTP); and triglycerides (near or in FADS gene cluster, PLTP, and AMAC1L2). At eight of the 30 loci, SNPs associated with blood lipoproteins were strong cis-acting regulators of gene expression in liver ($P<5 \times 10^{-8}$ for each genotype-expression association; 955 liver samples studied). The proportion of individuals with dyslipidemia (i.e. exceeding clinical cut points of high or low lipoprotein levels) increased across an allelic dosage score composed of common SNPs. These results support the hypothesis that the cumulative effect of multiple common SNPs contributes to polygenic dyslipidemia.

Complex chromosomal rearrangements detected by high-resolution whole-genome copy number analysis: implications for phenotypic variability in patients with recurrent abnormalities. *P. R. Gonzales, E. C. Thorland*
Cytogenetics Laboratory, Mayo Clinic, Rochester, MN.

Traditional cytogenetic methods have been successful at detecting abnormalities in children with mental retardation, developmental delay and multiple congenital anomalies. However, these techniques are limited in resolution and are not sufficient to determine if additional unrecognized complexity is present at the breakpoints. With the recent availability of high-resolution, whole-genome dosage analysis platforms, additional complexity is being recognized at a significant rate. A series of patients with known chromosome abnormalities was screened using the Illumina Infinium Human 1M BeadArray. Four of these cases demonstrated unexpected complexity at the site of rearrangement not appreciated with previous analyses. Case 1 had a terminal 4p deletion, consistent with Wolf-Hirschhorn syndrome. Further characterization on the 1M array revealed a 13.3 Mb terminal deletion in addition to a ~200 kb region of normal copy number and a ~600 kb duplication. Case 2 had an unbalanced 5;19 translocation, consistent with Cri-du-chat syndrome. Array analysis confirmed a 12.2 Mb terminal deletion of 5p followed by a ~600 kb duplication. Case 3 had a 20p deletion by subtelomere FISH analysis and had a chromosomal banding pattern suggestive of a complex rearrangement. Array analysis confirmed a 1.2 Mb terminal deletion of 20p followed by a ~7.3 Mb duplication. Case 4 had a cryptic 22q deletion, consistent with 22q13.3 deletion syndrome. Array analysis confirmed a 4.9 Mb terminal deletion of 22q, followed by a duplication of ~1.3 Mb. These results demonstrate that apparently simple chromosome rearrangements are often more complex at the molecular level than appreciated by traditional cytogenetic techniques. These unexpected complexities may be one factor contributing to the often considerable phenotypic variability that is observed in many of the common syndromes associated with terminal deletions and unbalanced translocations. Additional analysis is ongoing to determine the overall rate of these complex abnormalities and the mechanisms that likely contribute to these complex rearrangements.

Overloading of lipid rafts impairs SNAREs function leading to membrane traffic jam in lysosomal storage disorders. *A. Fraldi, F. Annunziata, A. Lombardi, C. Spampanato, A. Fedele, A. Ballabio* Telethon Institute of Genetics and Medicine (TIGEM), Naples, Italy.

In spite of the heterogeneity in the nature of primary storage in lysosomal storage disorders (LSDs), secondary accumulation of lipids represents a common feature of these diseases. Cholesterol and glycosphingolipids are the major constituents of lipid rafts, a liquid-ordered phase which forms a dynamic platform within cell membrane bilayers functioning in membrane trafficking and signal transduction. Lipid rafts can be isolated as detergent resistant microdomains (DRMs). An increase in the amount of DRMs and of cholesterol was observed in lysosome membranes of cells derived from a mouse model of Multiple Sulfatase Deficiency (MSD), a very severe form of LSD. As a consequence, we detected changes in protein composition/distribution within MSD lysosomal membranes associated to increased lipid rafts-mediated trapping of membrane proteins. Depletion of cholesterol from MSD lysosomal membranes reconstituted a normal protein distribution demonstrating that the abnormal pattern is cholesterol-dependent. The function of membrane proteins can be affected by their aberrant distribution. We focused on SNAREs proteins, which constitute the minimal machinery for membrane fusion. Syntaxin7 and VAMP7, two SNAREs proteins involved in the endo/lysosome fusion events, accumulate in lysosomal membrane rafts regions of MSD cells. Therefore, we hypothesized the formation of unproductive/dysfunctional complexes containing syntaxin7 and VAMP7 (and most likely other specific SNAREs) with consequent inefficient fusion process. Supporting this hypothesis, we found that while the amount of syntaxin7/VAMP7 steady-state complexes increased in MSD MEFs, the dynamics of SNAREs complex formation between VAMP7 and syntaxin7 was instead reduced, as revealed by FRAP analysis. Moreover, trapping of SNAREs proteins in rafts regions also results in inefficient re-distribution of SNAREs between cell membranes. In conclusion, we postulate that abnormal lipid storage in LSDs results in profound changes in the dynamics of endo/lysosomal membranes leading to membrane traffic jam and global lysosomal dysfunction.

Functional interactions between *cis*-regulatory SNPs involved in lactase persistence. *C. C. Babbitt[1], A. S. Swearingen[1,2], A. Ranciaro[3], S. A. Tishkoff[3,4], G. A. Wray[1,2]* 1) Institute for Genome Science & Policy, Duke University, Durham, NC; 2) Department of Biology, Duke University, Durham, NC; 3) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 4) Department of Biology, University of Pennsylvania, Philadelphia, PA.

The ability to digest milk as adults (lactase persistence, LP) is a phenotype driven by distinct *cis*-acting variants in ethnically distinct human populations. Several recent studies have identified regulatory SNPs that are important for *lactase* (*LCT*) transcription. Some of these SNPs appear to have arisen independently in different human populations. Understanding how these variants interact may elucidate the functional basis of LP, as well as help to understand how this phenotype is driven by convergent genotypic changes. In order to identify the functional interactions between these *cis*-acting SNPs, we used *in vitro* constructs containing the previously identified SNPs of interest in the adjacent *MCM6* intron 13 region and a proximal *LCT* core promoter region in Caco-2 cells. Using a site-directed mutagenesis approach, we created different combinations of these functionally implicated activating SNPs. Our data show unexpected epistatic interactions between SNPs that are different between populations. Specifically, SNPs that activate transcription individually depress transcription when present together in the same haplotype. Determining the nature of interactions between polymorphisms characterized in the region with transcription factors may elucidate the mechanism by which the LP trait arose, and increase our understanding of *cis*-regulation in association with the recent adaptations to nutritional changes of *Homo sapiens*.

The factors related to attitudes toward genetic testing: Nationwide surveys on attitudes towards genome research of the public and scientists in Japan. *Z. Yamagata[1], A. Nagai[1], K. Muto[2], A. Tamakoshi[3], K. Kato[4], T. Maeda[5], I. Ishiyama[6], T. Shirai[4]* 1) Department of Health Sciences, University Yamanashi, Chuo, Japan; 2) The University of Tokyo, Tokyo, Japan; 3) Aichi Medical University, Aichi, Japan; 4) Koyoto University, Kyoto, Japan; 5) The Institute of Statistical Mathematics, Tokyo, Japan; 6) Teikyo Gakuen Junior College, Yamanashi, Japan.

Purpose: National surveys were conducted to assess attitudes toward genomic studies related to medicine in public and scientists, especially we focus on factors related to attitudes toward taking susceptibility testing with common diseases or pharmacogenomic testing. Methods: Three mail surveys were conducted; 4,000 people (age, 20-69) sampled from Japanese general population in 2005 and 3,000 people in 2008, and 2000 scientist of molecular biology and human genetics in 2007. Questionnaires include pros and cons of the promotion of genomic studies related to medicine, level of scientific literacy in genomics, demographic and socioeconomic background, and knowledge and attitudes toward genetic testing. We analyzed factors related to the attitudes toward taking genetic testing using logistic regression models. Results: More than half of the respondents are interested in taking susceptibility testing with common diseases. However, the number increases in case of pharmacogenomic testing. Scientists were more denial than the public about susceptibility testing but more supportive about pharmacogenomic testing. More people wanted to take genetic testing than 2005 in 2008 in public. Multivariate analysis revealed that taking genetic testing was related to young age, interest in the genome research, good image on genome and a high genomic literacy score.

Opportunities and obstacles of population-based genome resequencing. *X. Liu[1], T. J. Maxwell[1], L. Bull[2], K. E. Lohmueller[3], T. J. Rea[4], D. M. Muzny[2], D. A. Wheeler[2], O. Hall[2], J. S. Pankow[5], A. R. Templeton[6], A. G. Clark[3], R. A. Gibbs[2], E. Boerwinkle[1], C. F. Sing[4]* 1) Human Genetics Center, UTHSC-Houston, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Dept. of Molecular Biology and Genetics, Cornell University, Ithaca, NY; 4) Dept. of Human Genetics, University of Michigan, Ann Arbor, MI; 5) Dept. of Epidemiology, University of Minnesota, Minneapolis, MN; 6) Dept. of Biology, Washington University, St. Louis, MO.

Emerging technologies are bringing population-based DNA re-sequencing of human genomes ever closer. We have undertaken population-based resequencing of select candidate genes in a large bi-ethnic sample of 15,000 individuals. The data presented in this early abstract includes two genes, KCNJ11 and HHEX, resequenced in 1786 individuals. Introns, exons, and flanking regions being resequenced span 5.4 kb in KCNJ11 and 7.7 kb of HHEX. In this subsample, there were 85 and 148 SNPs in KCNJ11 and HHEX, respectively, with 23 and 2 non-synonymous SNPS. The proportion of rare SNPs (MAF<1%) increased disproportionately as the sample size increased, and reached 80-90%; for KCNJ11 and HHEX, respectively. The proportion of SNPs that are singletons (%s) and a test of neutrality based on singletons (as measured by D*) were influenced by sample size (n) and differed markedly between the two genes, e.g. when n=100 (or 1600), %s=32(39), D*=-1.75(-6.91) for KCNJ11; and %s=49(39), D*=-4.04(-8.47) for HHEX. This perhaps reflecting the effects of natural selection. The coverage of large sample resequencing projects is typically sparse. This has necessitated the development of methods for estimating basic population genetics parameters in the presence of sparse or missing data. For example, the estimate of Watterson's population mutation rate, , is biased downward because it overestimates the effective sample size in the presence of missing data. In summary, population-based resequencing of human genomes provides great opportunities for unveiling the role of rare variants in the genetic architecture of common disease, but novel methods are necessary to overcome the obstacles inherent in these new data.

UNDERSTANDING THE FULL SPECTRUM OF GENETIC VARIANTS2ND PHASE ENCODE RE-SEQUENCING IN 712 INDIVIDUALS FROM 10 ETHNICITIES. *F. Yu, D. Wheeler, Y. Ren, S. Scherer, D. Muzny, L. Nazareth, R. Gibbs* Human Genome Sequence Center, Baylor College of Medicine, Houston, TX.

The SNP data set characterized by phases I and II of the International HapMap Project has produced an unprecedented understanding of the linkage disequilibrium structures of the human genome, facilitated mapping loci for complex diseases, and helped elucidate signals of natural selection. HapMap studies did not capture most rare (MAF<5%) variants, which limits the potential advance in medical genetics. This large scale ENCODE re-sequencing project aims to interrogate the full spectrum of genetic variants in an unbiased manner, and enables modeling for the 1000 Genome Project. In the former ENCODE Project; ten 500kb genomic regions were directly re-sequenced in 48 samples from CEU, CHB/JPT, and YRI. SNPs were identified using automated software and validated in the HapMap samples. We set out to further extend this effort by sequencing 1Mb sequences in 712 individuals from 10 diverse ethnicities. We discovered 10,076 SNPs, among which 7,949 were novel (i.e. not present in dbSNP). We carried out quality analysis to assess a) reliability in singleton discoveries, and b) sensitivity and specificity for other variants. In the QC+ data set, the overall false positive rate is 3.2%, with the singletons having a slightly higher false positive rate of 4.3%. This data set has been released in May 2008; along with the genotyping data set obtained from 1260 HapMap individuals by Broad Institute and Sanger Institute. This is the deepest direct PCR, re-sequencing study so far, carried out on random genomic regions in control samples. It presents a tremendous opportunity for studying the population specific features, including the patterns of LD, prevalence and distribution of rare SNPs, and demographic history, in much broader geographical scope.

Metagenomic analyses of the microbial communities in cheese and their temporal variations. *D. Serre* Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH.

Metagenomics is the study of genomes recovered from environmental samples. Here I use massively parallel DNA sequencing to characterize the microbial communities living in cheese, a human-made, cultural ecosystem. Cheeses display tremendous variation in appearance, pungency and palatability depending critically on the species of bacteria and molds as well as the environmental conditions used to manufacture and age fine cheeses. In addition to its economical importance, cheese production is also a concern for public health, with thousands of people becoming sick every year after eating improperly manufactured cheese. As a first attempt to describe the microbial populations and their temporal variations, I extracted DNA from cheese at four time points: immediately after insemination (day 1), at the day of sale (day 30), at the expiration date (day 90) and at day 180. I amplified short fragments of 16S and 18S ribosomal RNA genes using universal primers and obtained 100,000 sequence reads from each sample. The analysis shows that, starting from an environment relatively free of microorganisms before being inseminated with a few bacterial species, the microbial diversity increases dramatically to include multiple species belonging to several orders of bacteria and fungi. The microbial composition at the different time points reflects the changes in the environment (e.g., in pH, nutrient content and presence of oxygen) and the interactions between the different microorganisms. This study illustrates the potential of this high-throughput sequencing to study the complex microbial interactions in a changing model ecosystem.

A child with a der(Y)t(X;Y) resulting in Xp duplication and Yq deletion detected by FISH and characterized by arrayCGH. *M. Sathanoori[1], L. Gole[2], A. Goldstein[3], J. Hu[1], U. Surti[1,2]* 1) University of Pittsburgh School of Medicine, Pittsburgh, PA; 2) University of Pittsburgh, Pittsburgh, PA; 3) University of Pittsburgh Medical Center, Pittsburgh, PA.

An 11-year-old male was referred to the neurology department for follow-up due to the finding of vermis hypoplasia on prenatal ultrasound that apparently self resolved. He was noted to have autistic features, mental retardation, stuttering, and global developmental delay. No mutation was detected in the FMR1 gene. His physical examination showed many café-au-lait spots on his skin, but he lacked a second clinical feature for a possible diagnosis of neurofibromatosis 1 (NF1). A complete ophthalmology evaluation, and brain MRI was normal making NF1 unlikely. He also has IgA deficiency. Chromosome analysis detected a der(Y) with a deletion of the Yq heterochromatin region. Fluorescence in situ hybridization (FISH) showed two copies of the Xp/Yp probe, one on either end of der(Y) suggesting duplication and no signal for the Xq/Yq probe suggestive of a deletion of the Yq region. The arrayCGH results using 105K oligo array chip (SignatureGenomics, Spokane, WA), showed a copy number gain at the Xp22.33p22.2 region which includes ~2.6MB of the pseudoautosomal region (PAR) and ~13.25Mb on the non-PAR region resulting in functional partial disomy for Xp, and a copy number loss at the Yq11.221-Yqter (~11.2 Mb) resulting in partial nullisomy for Yq. The arrayCGH results confirm the cytogenetic findings and the der(Y) may be the result of an unbalanced X;Y translocation. A review of the UCSC genome browser showed that the Xp duplicated interval (~16Mb) contains at least 61 genes that include SHOX, STS, KAL1, TBL1, MID1, AMELX, and the Yq deleted interval (~11Mb) contains at least 17 genes that include the DAZ genes responsible for azoospermia or oligospermia. Partial duplications of Xp in males are rare and cases identical to our patient have not been reported. Testing on the father and the brother that is pending may give more insight into the phenotypic consequences of this chromosome abnormality.

Analysis of ABCB4 mutations in children with non-hemolytic cholelithiasis. Does development of cholelithiasis due to ABCB4 deficiency depend on hormonal load during puberty? *M. Hrebicek[1], J. Bronsky[2], M. Bouckova[1], L. Dvorakova[1], V. Valtrova[2], J. Nevoral[2], M. Jirsa[3]* 1) Institute of Inherited Metabolic Disorders, Prague , Czech Republic; 2) Pediatric Clinic, 2nd Medical Faculty, Prague, Czech Republic; 3) Institute of Clinical and Experimental Medicine,Prague, Czech Republic.

Deficiency of ABCB4 (MDR3), the phospholipid export pump of biliary membrane, results in a variety of hereditary cholestatic disorders including progressive familial intrahepatic cholestasis type 3 (PFIC-3). ABCB4 deficiency is also associated with recurrent gallbladder and intrahepatic cholesterol cholelithiasis due to low bile phospholipids before the age of 40. The development of symptoms may be conditional - episodes of cholestasis after oral contraceptives in females are characteristic. Patients with severe phenotypes carry *ABCB4* mutations on both alleles, while patients with milder and late-onset forms can only be heterozygous.

We have studied *ABCB4* mutations by direct sequencing of PCR products in a group of 23 children in whom non-hemolytic translucent cholelelithiasis developed before the age of 12. None of the patients carried *ABCB4* mutations, only known polymorphisms were found, frequency of which did not differ from the control population. At the same time we have identified heterozygosity for *ABCB4* mutations in members of 3 families with cholestatic disease and/or cholelithiasis (heterozygosity for missense or premature-stop mutations).

Hormonal load is very often the precipitating moment for symptoms of ABCB4 deficiency - such as transient cholestasis in pregnancy or cholestasis after hormonal contraceptives. We hypothesize that low (or nil) incidence of ABCB4 deficiency among pre-pubertal patients with cholesterol cholelithiasis is due to the absence of hormonal load, that leads to the presentation at later age. This is further supported by male to female ratio of 1:3 among adult patients with cholelithiasis due to ABCB4 deficiency.

Parametric Linkage Analysis in Tourette Syndrome: Analysis of A Two Generation Family with 9 Affected Individuals. *A. G. Ercan-Sencicek[1,2], C. E. Mason[2,3], D. L. Pauls[4], M. W. State[1,2]* 1) Child Study Center, Yale University, New Haven, CT; 2) Department of Genetics, Yale University, New Haven, CT; 3) Program on Neurogenetics, Yale University, New Haven, CT; 4) Psychiatric and Neurodevelopmental Genetics Unit, MGH, Harvard University, Boston, MA.

Tourette Syndrome (TS) is a developmental neuropsychiatric disorder characterized by chronic motor and phonic tics. There is substantial evidence for a complex genetic contribution to TS, but specific risk alleles have proven difficult to characterize. While the majority of gene-discovery efforts have concentrated on common variants, we have focused our attention on rare outlier individuals and families (Abelson et al 2005, State et al 2003). We have identified a 2-generation pedigree transmitting TS and related conditions in 9 affected individuals in what appears to be a Mendelian fashion. The pedigree consists of an affected father and 8 affected offspring. Given strong evidence for a shared etiology of TS, Chronic Tics (CT) and Obsessive-compulsive disorder (OCD), we assigned affected status to family members who presented with any of these three conditions. There was a history of 7 miscarriages from this parental union raising the possibility of dominant inheritance. All available family members were genotyped using the GeneChip Human Mapping 100K array. Parametric linkage analysis was conducted using the Allegro program under an autosomal dominant model. Copy number variants (CNVs) were evaluated using The Human1M BeadChip. Only a single locus was identified that approached the maximum theoretical LOD score for this pedigree of 2.1 (LOD=2.05) The result was confirmed via fine-mapping with 20 micro-satellite markers in the putative linkage interval. This 8.7 Mb region on chromosome 15q21 (D15S126 to D15S998) contains 40 brain-expressed genes. CNV analysis shows no shared structural variation among affected individuals. We are currently sequencing all candidate transcripts in the region in an effort to identify a functional mutation segregating with TS and related conditions.

Genotype to phenotype and beyond: NCBIs new resources to support evaluation of rare variants. *D. Maglott, M. DiCuccio, L. Forman Neall, M. Johnson, L. Phan, K. Pruitt, D. Shao, S. Sherry, A. Shkeda, R. Tully, M. Ward, G. Yu*
Natl Ctr Biotechnology Info, NIH/NLM, Bethesda, MD.

As sequence information becomes more readily available, it is increasingly important to be able to identify variants and interpret their significance. This presentation reviews several tools, viewers, and resources that support these needs.

Genome Workbench is an integrated application for viewing and analyzing sequence data. It can be used to align reads, identify variants, and compare them to records in dbSNP. Newly discovered variants can readily be accessioned and archived by using one of the new web-based resources that facilitate submissions to dbSNP based on HGVS nomenclature. Both single and batch methods are supported. These tools align the reference sequence in the HGVS name to the genome, identify the placement, support review by linking to other viewers including our new sequence viewer, and transform the information about the location of the variant into a submission to dbSNP. An id (ss#)is assigned to each variant, which will be clustered with other submissions of the same variant under a reference id (rs#). Attributes of each variant can also be submitted, such as links to data in OMIM, PubMed, or a pertinent web site, and frequency of observations and clinical interpretation. These enriched submissions allow display of variants and their clinical attributes that appear in a new variation viewer (VarVu), accessible from Entrez Gene, dbSNP, and OMIM. Submitters sites are also directly accessed from this viewer.

New gene-specific genomic RefSeq standards, RefSeqGene (www.ncbi.nlm.nih.gov/RefSeq/RSG) provide a stable numbering system for reporting variants on genomic sequence coordinates. These sequences are being developed in collaboration with locus-specific databases and other stakeholders Suggestions can be emailed to rsgene@ncbi.nlm.nih.gov. These resources, which are being integrated with OMIM, GeneReviews, and GeneTests, reflect NCBIs commitment to supporting clinicians and medical geneticists.

IMPACT OF LOW-COST INDIVIDUAL GENOME SEQUENCING ON GRADUATE GENETIC COUNSELING EDUCATION: AN EXPLORATORY STUDY. *A. Biser* Sarah Lawrence College, Human Genetics, Bronxville, NY.

Through the financial incentives from the public and private sectors, improvements in the cost and effectiveness of DNA sequencing technology have made the concept of low-cost individual genome scans an expected and imminent reality. Together with the continued identification and characterization of genetic factors made possible by the completion of the Human Genome Project, such individual sequencing technology could be made clinically available - used to assess ones risk for not only single gene conditions, but also common complex conditions. The use of this technology would shift the existing paradigm of clinical genetics to clinical genomics and consequently have significant implications for the education of those involved in the delivery of genetic services, namely genetic counselors. Genetic counseling training program directors and board members of the American Board of Genetic Counseling (ABGC) were surveyed to investigate if and what revisions the nations genetic counseling training programs could undergo with respect to curricular content, clinical training, and professional training to better prepare graduates for the advent of personalized genomic medicine. According to respondents, feasible modifications to the curricular content consist of putting a greater emphasis on course work in the areas of ELSI issues, common complex conditions, and health education. Clinical training would emphasize more specialty and virtual methods of counseling; while significant considerations for professional training include generating more focused efforts on professional recruitment, specialization, and variations in academic degree-level restructuring.

Shwachman-Diamond Symptoms in a Patient with Microdeletion of Chromosome Region 6p24.3 to 6p25.1. *R. Mendoza-Londono[1], L. Dupuis[1], L. Steele[2], D. J. Stavropoulos[1,2]* 1) Div. Clinical and Metabolic Genetics and; 2) Dept. Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, ON, Canada.

Shwachman-Diamond syndrome (SDS, MIM 260400) is an autosomal recessive condition characterized by pancreatic insufficiency, hematologic defects, skeletal abnormalities and short stature. The majority of patients with the clinical phenotype have mutations in the *SBDS* gene on 7q11, but in a small proportion of cases no mutations have been found, suggesting that there is genetic heterogeneity. We describe an 8-year-old-male referred for evaluation because of history of short statute, pancreatic insufficiency, multiple infections, IgA deficiency, delayed tooth shedding, seizures and mild developmental delay. He was the product of non-consanguinous parents of English and French Canadian descent. On examination he had proportionate short stature with height and weight below the 3rd centile for age and normal head circumference. He had mild dysmorphic features. Extensive testing including chromosome analysis, cystic fibrosis testing by sweat chloride and sequencing of the *CFTR* gene, thyroid function tests and growth hormone levels were normal. Full sequencing of the *SBDS* gene did not detect any mutations. Array comparative genomic hybridization (aCGH) revealed a de-novo deletion of ~2Mb at chromosome region 6p24.3 to 6p25 involving 10 BAC clones. This genomic region harbors 7 genes including the bone morphogenetic protein 6 (*BMP6*), the gene *C6orf151*, and Neurintin 1 (*NRN1*). BMP6 belongs to the transforming growth factor beta superfamily of regulatory molecules and it is known to be expressed in multiple tissues including developing skeleton and injured brain. *C6orf151* codes for a U11/U12 small nuclear ribonucleoprotein of 48 kDa that is involved in mRNA processing and splicing. NRN1 is a neuronal protein that modulates neurite outgrowth. Our patient constitutes the first description of haploinsufficiency for genes located in this small region of chromosome 6p24. We hypothesize that one of these genes may be responsible for the Shwachman-Diamond-like symptoms present in our patient.

20p12.3 microdeletion predisposes to Wolff-Parkinson-White syndrome with variable neurocognitive deficits. *L. Potocki[1], J. V. Thakuria[4], G. F. Cox[4], X. Wang[1], W. Bi[1], M. S. Bray[1], S. W. Cheung[1], A. C. Chinault[1], B. A. Boggs[1], J. R. Lupski[1], P. Stankiewicz[1], J. A. Towbin[2], I. Hansmann[5], S. Sood[3], T. Ai[3], A. Pursley[1], X. H. Wehrens[3], J. F. Martin[6], J. W. Belmont[1], S. R. Lalani[1]* 1) Dept of Molecular and Human Genetics; 2) Dept of Cardiology; 3) Dept of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX; 4) Division of Genetics, Childrens Hospital Boston, Boston, MA; 5) Institut für Humangenetik und Medizinische Biologie, Halle/Saale, Germany; 6) Texas A&M System Health Science Center, Houston, TX.

Wolff-Parkinson-White syndrome (WPW) is a bypass reentrant tachycardia that results from an abnormal connection between the atria and ventricles. Mutations in PRKAG2 have been described in patients with familial WPW syndrome and hypertrophic cardiomyopathy. Based on the role of bone morphogenetic protein (BMP) signaling in the development of annulus fibrosus in mice, it has been proposed that BMP signaling through the type 1a receptor and other downstream components may play a role in preexcitation. We identified four individuals with WPW syndrome, variable dysmorphisms and neurocognitive delay and used targeted and genome-wide array comparative genomic hybridization (CGH), and candidate gene sequencing to identify the underlying genetic basis of preexcitation in these individuals. The array CGH identified non-recurrent deletions of 20p12.3, involving BMP2 in all four individuals analyzed. With the exception of one maternally inherited deletion, all occurred de novo, and the smallest of these, harbored only the BMP2 gene. In two individuals with additional features of Alagille syndrome, deletion of both JAG1 and BMP2 were identified. Deletion of this region has not been described as a copy-number variant in the Database of Genomic Variants and has not been identified in 13,321 individuals from other cohort examined by array CGH in our laboratory. Our findings demonstrate a novel genomic disorder characterized by deletion of BMP2 with variable cognitive deficits and mild dysmorphic features and show that individuals bearing microdeletions in 20p12.3 often present with WPW syndrome.

A wavelet thresholding based association test for improving adaptability. *R. Jiang, J. Dong, Y. Dai* Dept Mathematical Sci, Michigan Technological Univ, Houghton, MI.

Association studies are often used in finding susceptibility genes for complex diseases. If a single SNP has enough LD information, then methods based on a single SNP will have more power than multilocus methods. Otherwise, multilocus methods will be more powerful than single locus ones. Similarly, if the genetic information about the disease have already been captured by genotypes, using haplotype based methods will only increase the degrees of freedom and reduce their power. Otherwise haplotype based methods will provide more power to detect disease susceptibility genes. The difficulty here is to determine when we should apply multilocus methods rather than single locus ones, and for multilocus methods, when we should use genotype based methods rather than haplotype based methods. We need a method which can automatically adapt to the situation, and always be able to provide the best choice. This is accomplished by a new wavelet thresholding method that we propose in this paper. We first translate the multilocus genotype data into wavelet coefficients by discrete wavelet transform.. Then we apply thresholding on these coefficients. A coefficient is kept if its magnitude is greater than the thresholds. The scale-dependent thresholds are chosen by an empirical Bayes method. The thresholding procedure is adaptive, and it makes sure that no degrees of freedom is wasted. Finally, a score statistic is constructed using these remaining wavelet coefficients. Several association tests are compared with the proposed method. The new method has correct type I error, and it is more powerful than the existing tests under different scenarios.

ARX gene and Otahara syndrome: beyond polyalanine tract expansions. *E. Bettella[1], S. Sartori[1], L. Giordano[2], F. Darra[3], R. Polli[1], S. Russo[4], B. Dalla Bernardina[3], A. Murgia[1]* 1) Department of Pediatrics, University of Padua, Padua, Italy; 2) Department of Child and Adolescent Neuropsychiatry, Spedali Civili, Brescia, Italy; 3) Department of Child Neuropsychiatry, Policlinico G.B. Rossi, Verona, Italy; 4) Laboratory of Molecular Genetics, Istituto Auxologico Italiano, Milan, Italy.

Expansions of the first polyalanine tract of the Aristaless-related homeobox gene (ARX) protein are known to be associated with X-linked infantile spasms syndrome and epileptic dyskinetic encephalopathy. Longer expansions of the same polyalanine tract have been recently reported as a cause of early infantile epileptic encephalopathy with suppression burst pattern, also known as Otahara syndrome and a possible relationship between length of this repeat region and the severity of the epileptic phenotype has been suggested. We report three cases of Otahara syndrome: two related boys of 18 and 24 months of age, born to monozygotic twin sisters whos deceased younger brother was also described as affected by neonatal-onset epileptic encephalopathy. A third unrelated 16 year-old male subject, a sporadic case, had a clinical history of neonatal epilepsy which characteristics had evolved with time from Otahara to atypic West syndrome. His current epileptic profile is that of a Lennox-like syndrome with persistence of massive myoclonic, partial and tonic seizures; he has developed spastic tetraparesys and is cognitively severely impaired. The three patients carry two different previously unreported missense mutations of the ARX gene, both insisting on the region corresponding to the Aristaless domain, in exon 5. The two carrier mothers of the familial case, reported as completely asymptomatic, showed a balanced pattern of X-inactivation. This report further confirms the striking pleiotropy attributed to the ARX gene and demonstrates the involvement of mutations other than longer polyalanine tract expansions, in the pathogenesis of cryptogenic epileptic encephalopathy with very early onset, such as Otahara syndrome.

microRNA genomic variations in psychiatric diseases. *L. Cheng[1], J. Reid[2], O. Alvi[2], A. Lucas[2], L. Lewis[2], O. Hall[2], L. Nazareth[2], D. Wheeler[2], D. Muzny[2], D. Zhang[1], E. Gershon[1], R. Gibbs[2], C. Liu[1]* 1) Department of Psychiatry, University of Chicago, Chicago, IL; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

MicroRNAs (miRNAs) are short (19~25 nucleotides) single-stranded non-coding RNAs that are generated from endogenous hairpin-shaped transcripts, precursor miRNAs. miRNAs function as guide molecules in post-transcriptional gene silencing by base pairing with target mRNAs, which lead to mRNA cleavage or translational repression. With >400 members in human, miRNAs are one of the largest gene families, accounting for ~1% of the genome. Since miRNAs are abundant in brain and playing important role in brain development and function, and they can regulate the expression of many genes of neurological interest simultaneously, variants in miRNA genes have the potential to play a role in complex psychiatric diseases such as schizophrenia and bipolar disorder. We present here results on the deep resequencing of known human miRNA precursors and variants identification in 281 brain-significant miRNAs. We have sequenced the genomic DNA region of these 281 miRNAs in 282 samples including 94 HapMap (CEU, YRI, JPN and CHB) samples and 188 Stanley Medical Research Institute (SMRI) and NIMH Genetic Initiative Bipolar, Schizophrenia, Major depression and control Caucasian samples. A total of 748 SNPs have been detected, of which 103 SNPs were located in miRNA precursors. Nominally significant associations have been detected for 33 SNPs between disease/control comparison and none of these associations withstood multiple testing corrections. For those SNPs in miRNA precursors, the change in folding energy of the variant precursor were calculated and these SNPs were found tend more towards stabilizing than destabilizing the precursor. Further investigations of common and rare variant associations of the identified variants in large sample psychiatric diseases are ongoing.

Acute Intermittent Porphyria: Generation of a Knock-In Mouse Model with Biochemical and Clinical Phenotype. *M. Yasuda[1], D. F. Bishop[1], W. Edelmann[2], R. J. Desnick[1]* 1) Gen & Genomic Sci, Mount Sinai Sch Med, New York, NY; 2) Department of Cell Biology, Albert Einstein College of Medicine, Bronx, NY.

Acute Intermittent Porphyria (AIP) is an autosomal dominant disorder of heme biosynthesis, due to the half-normal activity of Hydroxymethylbilane Synthase (HMBS). Patients with AIP are prone to life-threatening, acute neurological attacks that are precipitated by various drugs, fasting, and hormonal changes. Previously, *Lindberg et al. (Nat Genet 12:195, 1996)* generated a mouse model in which phenobarbitol induction increased plasma aminolevulinic acid (ALA) and porphobilinogen (PBG), but lacked acute symptomology, presumably due to its ~30% residual HMBS activity. To investigate the pathogenesis of this hepatic encephalopathy and to develop novel treatments, efforts were directed to generate a more severely affected mouse. Mice heterozygous for R167Q and R173Q mutations, which had ~7.5% and ~1.5% of wild-type HMBS activities *in vitro*, respectively, were obtained and bred to homozygosity. R173Q mice were embryonic lethals, while homozygous R167Q mice were viable, but runted and only ~65% survived to adulthood. The mice had an early-onset profound ataxia that progressed from postnatal day (P)6-P20 and then became milder, enabling them to successfully breed. While their neurodevelopment appeared grossly normal (e.g. eye opening, ear twitch), delayed onset and impaired performance were seen for tasks requiring postural skills and complex motor coordination (e.g. rearing, running). Compared to wild-type, the mice had markedly elevated urinary ALA (~3-6 fold) and PBG (~10-30 fold), without phenobarbitol induction. The plasma uroporphyrinogen I/III ratio was increased by ~20 fold and coproporphyrinogen I was elevated by ~2 fold. Mean hepatic and erythrocyte HMBS activities were ~8% and ~17% of normals, respectively. The marked biochemical and clinical phenotype of these mice will facilitate studies of the pathogenesis of the neurotoxicity of AIP and novel therapeutics.

PCSK2 Polymorphisms Modulate the Proinsulin/Insulin Ratio and -Cell Function in an Ashkenazi Population. *J. Wasson[1], R. J. Neuman[2,3], S. Lingwei[2], G. Atzmon[4], T. Budagov[4], N. Barzilai[4], I. Blech[5], B. Glaser[5], D. Avramopoulos[6], J. A. McGrath[6], A. E. Pulver[6], M. A. Permutt[1]* 1) Department of Medicine, Washington University School of Medicine, St Louis, MO; 2) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO; 3) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 4) Department of Medicine (Endocrinology), Albert Einstein College of Medicine, Bronx, NY; 5) Endocrinology and Metabolism Service, Hadassah-Hebrew University Medical Center, Jerusalem, Israel; 6) Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore.

In a case-control SNP association study of 85 selected pancreatic -cell genes, we observed highly significant association between some PCSK2 variants (7 out of 45 tested) and type two diabetes (T2D) in the Ashkenazi population. PCSK2 is responsible for the processing of proinsulin to insulin in the -cell and TCF7L2 is a transcription factor that affects the expression of PCSK2. Significant association between specific polymorphisms in TCF7L2 and T2D has been demonstrated in multiple populations, including Ashkenazi. TCF7L2 polymorphisms have been shown to modulate proinsulin levels and -cell function in a UK population. Our hypothesis is that genetic variants in these two genes affect the efficacy of proinsulin processing in the Ashkenazi which will be reflected in abnormal proinsulin/insulin ratios. The proinsulin/insulin ratio may be predictive of T2D. 1000 non-diabetic control Ashkenazi DNA samples were genotyped for SNPs rs2021786 in PCSK2 and rs7903146 in TCF7L2. 1000 corresponding Ashkenazi serum samples were assayed for proinsulin and insulin. Correlations between the SNP genotypes, quantitative traits and proinsulin/insulin ratios are now being analyzed.

Posttraumatic Stress Disorder and *SLC6A3* Haplotypes. *BZ. Yang[1,4], F. Ozbay[5], A. M. Rasmusson[6,7], H. R. Kranzler[8], J. Gelernter[1,2,3,4]* 1) Dept Psychiatry, Yale Univ Sch Medicine, West Haven, CT; 2) Genetics, Yale Univ Sch Medicine, West Haven, CT; 3) Neurobiology, Yale Univ Sch Medicine, West Haven, CT; 4) VA CT Healthcare Center, West Haven, CT; 5) Mount Sinai School Med, NY; 6) Nat'l Center for PTSD, Women's Health Science Division, VA Boston Healthcare System; 7) Boston Univ School of Med; 8) Univ CT Health Center, Farmington, CT.

Posttraumatic stress disorder (PTSD) has a heritability of about 38%. The molecular genetic basis for PTSD has been understudied compared to other psychiatric disorders, but its importance is increasingly recognized. Among the few published reports, there has been one report of association of PTSD to a variant in *SLC6A3*, which encodes the dopamine transporter protein. We collected a population-based case-control sample of 401 European-American subjects, including 182 subjects with PTSD (66% male) and 219 controls (46% male). We genotyped four *SLC6A3* markers, one each in intron 8 (M1), exon 9 (M2), intron 9 (M3) and a VNTR (M4) in the 3UTR, and conducted haplotype association analysis using score statistics adjusted by sex as a covariate. We found: (1) A significantly associated haplotype of M1-M2-M3 (global p-value = 3.46×10^{-9}), with two specific individual haplotypes being associated to PTSD. One of these haplotypes is protective (7-2-2, simulated p-value = 5×10^{-5}) with frequencies of 11.0% and 1.7% in the control and PTSD patient groups, respectively. The other is a risk haplotype (6-2-2, simulated p-value = 0.00195) with frequencies of 60.2% and 73.8% % in the control and PTSD patient groups, respectively. (2) A significantly associated haplotype of M2-M3-M4 (global p-value = 0.011), with one individual haplotype associated with phenotype (2-2-9, simulated p-value = 0.017) and frequencies of 10.3% and 15.4% in the control and PTSD patient groups, respectively. (3) Haplotype association analysis of all four markers was also significant (global p-value = 2.7×10^{-5}), with an individual haplotype (6-2-2-9, simulated p-value = 0.0015) having frequencies of 7.3% and 14.8% in the control and PTSD patient groups, respectively. We conclude that variants in SLC6A3 modulate risk for PTSD.

Association of Cleft Lip/Palate with Mutations in *FGFR2* Found in Breast Cancer Patients. *B. N. Erickson[1], K. Christensen[3], M. L. Marazita[4], J. C. Murray[1,2]* 1) Molecular and Cellular Biology, University of Iowa, Iowa City, IA; 2) Pediatrics, University of Iowa, Iowa City, IA; 3) Epidemiology, University of Southern Denmark, Odense, Denmark; 4) Oral Biology, University of Pittsburgh, Pittsburgh, PA.

Background: Understanding the lifelong clinical course of children born with congenital malformations is important to anticipate and prevent treatable causes of morbidity and mortality. Epidemiologic data has shown an increased incidence of breast cancer in women born with non-syndromic cleft with or without cleft palate (CL/P). Population studies have linked breast cancer risk to a CL/P candidate gene, *FGFR2*. **Objective:** Investigate single nucleotide polymorphisms (SNPs) in *FGFR2* for evidence of association in CL/P families. **Methods:** Seven SNPs in a highly conserved region of intron 2 in *FGFR2* were genotyped using TaqMan assays. We genotyped 221 unrelated, multiplex Filipino families (5903 individuals), 516 unrelated Danish families (2293 individuals), and 359 unrelated Iowa families (1259 individuals). Family based association testing for individual SNPs (FBAT) and haplotypes (HBAT) were used to identify association between CL/P and *FGFR2* SNPs. **Results:** FBAT analysis found no individual SNP in association with CL/P. HBAT found the CC haplotype at rs3750817 and rs2981582 is significantly associated with CL/P (p=0.0075) When a third SNP is added to the HBAT analysis (CCT haplotype at rs3750817, rs2981582 and rs7896565), significant association with CL/P was observed (p=0.0067). **Conclusions:** This study provides evidence that SNPs in *FGFR2* are associated with CL/P. Haplotypes of SNPs previously associated with breast cancer (rs3750817 and rs2981582) along with rs7896565 were significantly associated with CL/P. This work provides some evidence that SNPs in intron 2 of *FGFR2* are associated in both CL/P and breast cancer. Future work will continue to narrow in on the region of *FGFR2* association with CL/P and cellular studies may provide clues as to how CL/P relates to breast cancer risk later in life.

Visualization of multidimensional genetic likelihoods. *B. Nouanesengsy, S. Seok, V. Vieland* Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital, Columbus, OH.

Once a linked and/or associated locus is discovered for a given disease, information on multiple genetic parameters can be gleaned via exploration of the corresponding likelihood surface. For instance, it then becomes possible to estimate parameter such as the disease allele frequency or the associated penetrances. Even more interestingly, we have previously shown that the shape of this likelihood surface contains information that can be used to distinguish linked or associated subsets of families within heterogeneous data sets, beyond the information contained in summary statistics such as the size of the maximum by-pedigree lod score. However, optimal methods for exploiting this information remain to be explored. Here we present an approach using data visualization, building on an earlier prototype (LiViT), and our PPL software package Kelvin, which can be used to output arbitrarily fine-grained grids of likelihood points across the multidimensional space (currently up to 11 parameters at a time). LiViT showed a subset of the likelihood space over a limited number of dimensions, forcing the user to repeatedly change parameters and keep a mental record of previous views. Our new approach highlights local maxima and local minima, overlapping them with level sets (points consisting of contour lines). After sampling, all points are projected to a 2D space using multidimensional scaling (MDS). MDS uses the pair-wise distances of all input points to show the structure of the data in two-dimensional space. The final points on the 2D space are used to identify geometric features such as curvature and gradient (steepness of the function) in the vicinity of critical points. We show examples of different surfaces and their 2D projections, illustrating ways in which the human eye can be used to efficiently extract genetic pattern information when high-dimensional data are displayed in appropriate fashion.

Genetic variants associated with substance dependence affect nAChRs mRNA expression. *J. Wang, C. Cruchaga, J. Budde, L. Bierut, A. Goate* Dept Psychiatry, Washington Univ, St Louis, MO.

Cigarette smoking and alcohol dependence (AD) share genetic vulnerability. Several studies reported that variants in the CHRNA5-CHRNA3-CHRNB4 gene cluster are associated with nicotine dependence (ND) and increased risk for lung cancer. We have also reported that a different group of variants within this gene cluster demonstrate association with AD. There is extensive linkage disequilibrium across the gene cluster making it difficult to determine which gene(s) affects risk for substance dependence (SD). In this study, we examine whether the variants associated with SD affect gene expression. Brain tissue from the frontal cortex of 48 unrelated, non-demented elderly European Americans were obtained from the Alzheimers Disease Research Center at Washington University. Another set of frontal cortex samples derived from 31 unrelated, non-alcoholic European Australians and 28 alcoholic European Australians were obtained from the Australian Brain Donor Program. Real-time data were analyzed using the comparative Ct method. We used ANOVA to test for evidence of differential expression in samples of different genotype. Quantitative real-time PCR analysis shows that variants associated with AD affect CHRNA5 mRNA expression but not CHRNA3 or CHRNB4. Subjects homozygous for the minor allele show 2.9-fold increase in CHRNA5 mRNA levels. Genetic variants associated with increase risk for ND do not affect mRNA expression of the genes in this cluster. The variants associated with reduced risk for ND are weakly associated with CHRNA5 mRNA levels. However, a stepwise discriminant analysis of CHRNA5 mRNA levels suggests that this association is driven by linkage disequilibrium with variants that show association with AD. In contrast, increased risk for ND is associated with a missense variant in CHRNA5 that decreases response to a nicotine agonist. The protective allele for ND does not alter the coding sequence or expression levels of any gene in the cluster. These results reveal that although variation in CHRNA5 influences risk for both AD and ND, different polymorphisms and different mechanisms of action are responsible for these effects on risk.

Fine mapping of SORL1 using memory traits to understand the genetics of Alzheimer disease. *R. Cheng[1], J. H. Lee[1], V. Santana[1], J. Williamson[1], R. Lantigua[1], M. Medrano[2], J. Jimenez[3], E. Rogaeva[4], Y. Stern[1], P.St. George-Hyslop4[4], R. Mayeux[1]* 1) Sergievsky Center/Taub Institute, Columbia Univ, New York, NY; 2) Universidad Tecnologica de Santiago, Santiago; 3) Department of Internal Medicine, Univ of Puerto, San Juan; 4) Centre for Research in Neurodegenerative Diseases, University of Toronto, Toronto, Ontario.

Neuronal sortilin-related receptor SORL1 gene has been shown to be associated with Alzheimer disease (AD) in multiple populations. To date, we and others have reported single nucleotide polymorphism (SNP) allelic and haplotype association between SORL1 and AD in multiple family, epidemiologic, and autopsy samples. We and others also have shown that suppression of SORL1 expression results in increased in A levels. If true, this relation can be extended to certain memory traits, since memory impairment precedes AD. We examined the relation between memory traits and 29 SNPs from the SORL1 gene using 1,064 family members from 210 families of Caribbean Hispanics. FBAT was used for allelic and haplotype association analysis. We found significant association for three sets of SNPs 2-4, 8-10, and 15-18, and weak associations were observed for SNPs 26 and 29. Unlike for the AD phenotype, the association with SNPs 8-10 weakened somewhat and that with SNP 13-16 strengthened. Further, the SNP association differed by memory trait. Verbal memory traits were similarly associated for the three sets of haplotypes. On the other hand, Benton recognition test revealed a different pattern of association, suggesting that this test invokes visuospatial functions and stimulates different brain parts. Here we show a systematic ways to dissect the AD and subcomponents to see how genes contribute to AD, a complex trait. In sum, our results showed that association between memory traits and some of SNPs from SORL1 gene are not uniform. However, these findings need to be replicated.

Experience with Porphyria Molecular Diagnostic Testing. *D. Doheny, I. Nazarenko, D. Kwan, K. Astrin, M. Balwani, R. J. Desnick* Dept Genetics & Genomic Scienc, Mount Sinai Sch Medicine, New York, NY.

The Mount Sinai Porphyria Molecular Testing Laboratory is a CLIA and New York State-approved laboratory for the molecular diagnosis of the porphyrias, the inborn errors of heme biosynthesis. These include the hepatic porphyrias: Acute Intermittent Porphyria (AIP; mutations (muts) in hydroxybilane synthase, HMBS), Hereditary Coproporphyria (HCP; muts in coproporphobilinogen oxidase, CPOX), and Variegate Porphyria (VP; muts in protoporphobilinogen exidase, PPOX), and the cutaneous porphyrias: Congenital Erythropoietic Porphyria (CEP; muts in uroporphyrinogen III synthase, UROS), Porphyria Cutanea Tarda (PCT) and its rare recessive form, Hepatoerythropoietic Porphyria (HEP; muts in uroporphyrinogen decarboxylase, UROD), and Erythropoietic Protoporphyria (EPP; muts in ferrochelatase, FECH). Although biochemical testing is usually diagnostic in symptomatic patients, such testing usually will not identify asymptomatic individuals. In contrast, identification of a specific mut is the gold standard for porphyria diagnosis. For each gene, all exonic, exon-intron and promoter regions are PCR-amplified and sequenced. Since 2006, our laboratory has diagnosed >100 probands and >115 affected relatives in 65 families. Among these, 64% have a hepatic porphyria (71% AIP, 15% HCP, & 14% VP) and 36% have a cutaneous porphyria (20% CEP, 37% PCT, 5% HEP, & 38% EPP). We identified 29 previously unreported mutations: in AIP, L170P, A252P, G280G, Q332X, A347P, 143delG, IVS6+1G>A; in HCP, E153V, H258R, R352C, Q165X; in VP, R168L, A467P, Y451X, IVS11+1G>C; in PCT, Q9H, P44L, D79N, G210D, H331R, R332C, 818del10, IVS10+6G>A; in HEP, V166A; & in EPP, S151F, K379X, 663delGAG, 901delTG, 1135delA. After mut database queries, >100 alleles are assessed for novel muts to rule out polymorphisms. Expression studies can be performed for missense muts to determine dysfunction. In all biochemically clearly proven patients, muts were identified. The availability of mut analysis for these porphyrias provides definitive diagnosis for patients, allowing for appropriate treatment and pre-symptomatic testing of at-risk relatives as well as prenatal testing.

Correlation of human embryo microRNA expression with infertility diagnosis. *B. R. McCallie, J. C. Parks, A. M. Janesch, M. G. Katz-Jaffe* Colorado Foundation for Fertility Research, Lone Tree, CO.

MicroRNAs (miRNAs) are short, non-coding regulatory RNAs that are an integral component in the regulation of protein expression. Loss of complete miRNA function within mice leads to embryonic lethality suggesting that miRNAs have a prominent role in development. Recent data has also pointed to the importance of key miRNAs during mouse embryo implantation. Implantation failure has been documented as a significant contributor to human infertility, thus the aberrant expression of key human embryonic miRNAs may also be associated with infertility diagnosis. To obtain insight into miRNA expression during human embryonic development, we performed real-time quantitative PCR (RT Q-PCR) on individual human blastocysts for 12 miRNAs documented to be expressed in either mouse embryos or human embryonic stem cells. We further analyzed the association of miRNA expression with human infertility diagnosis. Cryopreserved individual human blastocysts (n=18; including n=6 fertile controls; n=6 male factor infertility; n=6 polycystic ovarian syndrome) donated with patient consent and IRB approval were thawed and total RNA was isolated. Following reverse transcription, RT Q-PCR was performed in duplicates using Taqman probes. Twelve miRNA probe sets were analyzed relative to the expression of the control probe, RNU48. A miRNA expression profile of these 12 probe sets was observed in all samples. In comparison to blastocysts derived from fertile controls, statistical analysis revealed significant downregulation of 5 miRNAs in blastocysts derived from patients with male factor infertility including let-7a, let-7c, miR-21, miR-24 and miR-92 ($P < 0.05$). Blastocysts derived from patients with polycystic ovarian syndrome showed significant downregulation of 9 miRNAs including let-7a, let-7c, miR-19a, miR-19b, miR-21, miR-24, miR-34b, miR-92, miR-93 and miR-301 ($P < 0.05$). To our knowledge, this study has shown for the first time, the expression of miRNAs during human blastocyst development and the potential association with human infertility. Aberrant expression of embryonic miRNAs in correlation with infertility diagnosis could be a contributing factor to implantation failure.

Evaluation of seven CNV detection methods using whole genome SNP arrays from myopia samples. *Y. J. Li[1], A. Dellinger[1], M. Seielstad[2], L. K. Goh[3], T. L. Young[1,3], S. M. Saw[4,5]* 1) Ctr Human Gen, Duke Univ Med Ctr, Durham, NC; 2) Genome Inst. of Singapore; 3) Duke-NUS Graduate Med School, Singapore; 4) National Univ. of Singapore; 5) Singapore Eye Research Inst.

Methods for detecting copy number variants (CNVs) using genome wide single nucleotide polymorphism (SNP) arrays are relatively new and their performance is uncertain. We compared seven CNV detection methods: CBS, GLAD, CNVFinder, cnvPartition, PennCNV, QuantiSNP, and Nexus CGH. The Illumina 550K SNP array data from the Singapore Cohort study Of the Risk factors for Myopia (SCORM) were used. Calls from each analyses were compared to known CNVs in HapMap Asians and to all experimentally confirmed HapMap CNVs. Sensitivity, specificity, and kappa values were used for method comparison. Ten buccal DNA samples with genotype call rates > 99.9% were used to obtain CNVs based on two parameter settings in each method -default and optimized parameters with the highest agreement of CNV calls among samples. All methods were adjusted to generate a similar number of CNV SNPs in order to make fair comparisons among methods. The same optimized parameters for each method were applied to 13 buccal, 7 saliva, 1 blood, and 5 amplified buccal derived DNA samples from another set of 13 individuals. CNV calling using these samples was compared in order to examine the impact of different DNA sources on CNV discovery. At default parameters, CNVFinder called twice as many CNV SNPs relative to the other methods, with large variations in calls and in kappa between samples. The programs cnvPartition and PennCNV showed slightly better sensitivity and kappa than other methods under the fixed number of CNV SNPs calls. For the buccal samples, cnvPartition and PennCNV had the best overall performance with moderate numbers of CNV calls (at least 3 consecutive CNV SNPs) and good kappa values. Nexus and QuantiSNP had the highest call rates of CNVs (average 40 and 61 CNV per sample, respectively), with the highest sensitivities, but low specificity and kappa. Amplified buccal DNA resulted in higher CNV calls than other DNA sources and was unreliable. In conclusion, cnvPartition and PennCNV out-perform the other methods.

A novel mtDNA mutation, 1630A>G, in the tRNA Val gene is associated with a neuromuscular phenotype. *A. Yatsenko[1], S. Zhang[1], O. Abdul-Rahman[2], H. Zimmerman[2], A. N. Pursley[1], L. J. Wong[1]* 1) Dept MH Genetics, Baylor Col Med, Houston, TX; 2) Dept Preventive Medicine University of Mississippi Med Cent, Jackson, MS.

More than 50% of deleterious mitochondrial DNA (mtDNA) mutations are in the tRNA genes, including the most common, 3243A>G in the tRNA Leu(UUR) gene responsible for 80% of MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes) and 8344A>G in the tRNA Lys gene responsible for MERRF (myoclonic epilepsy with ragged red fibers). However, mutations in the tRNA Val gene are rare. To date, only 3 mutations have been described to have clinical phenotype ranging from MELAS to Leigh syndrome. Here we describe a novel heteroplasmic variant, 1630A>G, in a 2-year old girl with developmental delay, short stature, midfacial hypoplasia, hypotonia with diffuse necrotizing myopathy, physical intolerance, fatigue, and muscle weakness. This variant is located at the first base-pair of the stem region adjacent to the anti-codon loop of the tRNA Val. To clarify the clinical significance of this variant, the levels of mutant heteroplasmy in various tissues including muscle, blood, urine, buccal swab, and hair follicles from the proband and probands asymptomatic matrilineal relatives were analyzed. Using allele-specific qPCR ARMS (amplification refractory mutation system), we detected 90-99% of mutant heteroplasmy in all tissues available from the proband. Interestingly, a range of ~35-70% heteroplasmy of the mutation was detected in multiple tissues of the patients asymptomatic mother. The 1630A>G variant was not detected in various tissues from the probands unaffected sibling. This variant has not been reported in 2700 individuals examined in the Polysite and Mitomap databases. The A-T pair at this corresponding position was found in 13 out of the 22 mitochondrial tRNAs. Its close vicinity to the anticodon loop makes it important in maintaining the secondary and tertiary structures of tRNA for anticodon-codon recognition and binding. This important role, and the co-segregation of high mutant heteroplasmy with the disease, suggests the1630A>G variant is pathogenic. To understand the clinical significance of the 1630A>G change, functional studies will be necessary.

Nonhomologous End Joining (NHEJ) and Fork Stalling and Template Switching (FoSTeS) as possible mechanisms responsible for the nonrecurrent *MECP2* duplications in neurodevelopmentally delayed males. *C. M. B. Carvalho[1], F. Zhang[1], P. Liu[1], A. Patel[1], T. Sahoo[1], C. A. Bacino[1], S. Peacock[1], A. Pursley[1], J. Tavyev[2], M. Ramocki[2], M. Nawara[4], E. Obersztyn[4], A. V. Morgante[5], H. Y. Zoghbi[1,2], S. W. Cheung[1], J. R. Lupski[1,2,3]* 1) Mol & Hum Gene; 2) Pediatrics, Baylor Col of Med, Houston, TX; 3) Texas Childrens Hospital, Houston, TX; 4) Med Gene, Inst of Mother and Child, Warsaw; 5) USP, Brazil.

Nonrecurrent duplications including the *MECP2* gene are one of the most common genomic rearrangements identified in neurodevelopmentally delayed males. Recently, a replication-based mechanism, Fork Stalling and Template Switching (FoSTeS), has been proposed for generating nonrecurrent rearrangements. To investigate the mechanism underlying *MECP2* duplication, we designed a 4 Mb tiling path oligonucleotide microarray that interrogates the *MECP2* genomic interval. We analyzed 28 males, each one carrying different sized duplication, varying from ~250 kb to ~2.6 Mb. Interestingly in 71% of the duplications the distal breakpoint occurred in the same 215 kb region, located 47 kb upstream to *MECP2*, a region characterized by complex architecture. In 2/28 patients, interspersed stretches of DNA of normal copy number were found within the duplicated sequence, whereas in 4/28 patients a triplicated genomic region was contained within the duplication. The presence of such complex rearrangements is characteristically observed in rearrangements generated by FoSTeS. We sequenced the breakpoints in 4 patients; 3 of them had microhomology at their breakpoint junctions suggesting the occurrence of NHEJ mechanism or, alternatively, FoSTeSX1. The fourth sample presented a complex breakpoint junction, including an inversion, suggesting that FoSTeS occurred at least 4 times to generate such a complex rearrangement (FoSTeSX4). In conclusion, we observe LCRs in the *MECP2* vicinity are probably generating an unstable non-B DNA structure, potentially facilitating a FoSTeS event during the replication process in at least 6/28 patients with complex duplications of *MECP2*.

Predictive diagnostic testing for von Hippel-Lindau Disease: Five year follow-up. *A. Rasmussen[1, 2], E. Alonso[2], A. Ochoa[2], I. De Biase[1], P. Yescas[2], A. L. Sosa[2], Y. Rodríguez[2], M. Chávez[2], S. Bidichandani[1]* 1) Dept Biochemistry, Oklahoma Univ Health Science, Oklahoma City, OK; 2) Instituto Nacional de Neurología y Neurocirugía, Mexico City, Mexico.

Von Hippel-Lindau disease (VHL) is a hereditary cancer syndrome caused by germline mutations in the VHL gene. Presymptomatic genetic testing, including children at risk, has been recommended to reduce morbidity and mortality. We tested 109 individuals from 17 families (10 definite and 7 possible VHL) for VHL mutations, 25 individuals were symptomatic and 84 asymptomatic and 43 were children under the age of 18. We identified mutations in 9/10 definite families and 3/7 possible VHL families. After delivery of the test results, the 36 mutation carriers (16 asymptomatic, 20 symptomatic) undertook an initial tumor screening, in which we identified one or more VHL tumors in 7/16 previously asymptomatic mutation-carriers. To date, these families have 5 years of follow-up. Of the 12 families where a mutation was identified, only 7 have continued surveillance (53.8%). This is in spite of very high test uptake (100% of individuals counseled). Seven mutation-carriers (3 asymptomatic and 2 children) developed a total of 26 new tumors; three died of complications. Detailed socio-demographic information for 32 adults (age 18-54y) was available. Gender, religiosity, education, income, marital status and having or not having children do not modify the likelihood of continuing the tumor surveillance (p=0.34-0.92). Adequate follow-up was also independent of pre-test anxiety or depression (p=0.38-0.76), and there was no relation with severity of the disease or number of family members affected. The only predictors of follow-up adherence were the behavior of the rest of the family, with 90.6% of the individuals being concordant regarding their surveillance decisions (p=0.038), and if the family had a female as a leader (p=0.031). Studies of long-term follow-up of patients undergoing genetic testing for hereditary cancer are needed to adapt the counseling and surveillance practices to the needs of a specific population. Doing so will result in improved treatment and quality of life for these families.

Using Free Online Genetics Information Resources for Ethics, Law, Patenting, and Policy: An Introduction to the Services of the National Information Resource on Ethics and Human Genetics--A NHGRI Project. *D. M. Goldstein, L. J. Bishop* Kennedy Institute of Ethics, Georgetown University, Washington, DC.

Attendees will learn effective search tips and strategies for using free databases and other research and reference tools from the National Information Resource on Ethics and Human Genetics. These include the GenETHX database of more than 40,000 bibliographic records (many with abstracts, tables of contents, and links to full text); the *Bioethics Thesaurus for Genetics* (a controlled searching vocabulary utilized in GenETHX since 2007); annotated bibliographies - called *Scope Notes* - on several topics; and *QuickBibs* (self-renewing database searches). In addition, information will be provided about the DNA Patent Database that tracks applications and granted patents on human dna-related discoveries; links to full text are available. This session is focused on providing an overview and orientation to support scholarship and practice in the area of ethics and human genetics and will equip attendees with ready and practical knowledge. Additional information will be shared about the free, online services of the National Reference Center for Bioethics Literature, a companion library resource at Georgetown University, which is supported by the U.S. National Library of Medicine. Presenters: Laura J. Bishop, Ph.D., Research Associate, and Doris Mueller Goldstein, M.L.S., M.A., Director, Library and Information Services, Kennedy Institute of Ethics, Georgetown University. **http://genethx.georgetown.edu** [This abstract pertains to an **ancillary meeting**.].

Analysis of genome-wide scans identifies potential novel common susceptibility loci for central obesity. *C. Lindgren[1], I. Heid[2], J. Randall[1], C. Lamina[2] for the GIANT Consortium* 1) WTCHG, University of Oxford, United Kingdom; 2) German Research Center for Environmental Health, Neuherberg, Germany.

To date, two common variants with a robust association to overall obesity predisposition have been reported (*FTO* and *MC4R*). In contrast, no specific associations have been reported to central obesity (in particular the amount of visceral/abdominal fat), which is especially relevant to metabolic disease. Separating genes influencing central adiposity (waist circumference (WC) and waist-hip ratio (WHR)) from those influencing overall adiposity (weight/body mass index (BMI)), is difficult as these traits are highly correlated (r^2~0.7). To identify common genetic variants and pathways influencing individual patterns of fat distribution and central obesity, our plan is to apply large-scale GWA-meta-analysis to widely-available anthropometric measures of central obesity looking particularly for signals with a disproportionate effect on central, rather than overall, adiposity. Such signals will then be characterised using more specific fat-distribution measures (e.g. DXA). As a first step, we have performed a meta-analysis of 13 genome-wide association scans informative for WC and WHR. In total ~2.5 million SNPs (directly-typed or imputed) were tested for association in ~28,000 individuals of European ancestry. The previously reported associations with overall adiposity of *FTO* and *MC4R* were replicated for WC ($p<5x10^{-13}$ and $p<2x10^{-8}$), but these loci were less associated to WHR ($p<5x10^{-6}$ and $p<2x10^{-4}$). In all, we identify 19 independent loci with suggestive evidence of association to WC and a further 9 to WHR ($p<5x10^{-6}$): none of these has been previously reported to be associated with overall obesity. Of these, 5 of the WC- and 9 of the WHR-signals show a disproportionate lack of evidence of association to BMI ($p>0.01$), indicating that some of these are likely to be variants influencing central adiposity, and targets for further replication and characterization using fat-distribution specific measures. Overall, our results indicate potential for common variants which influence central obesity (WC/WHR) distinct from those with an effect on overall obesity (weight/BMI) in humans.

Fragile X Mental Retardation Protein Regulates Adult Neurogenesis. *G. Shan[1], Y. Luo[2], R. Smrt[2], X. Li[2], R. Duan[1], B. Barkho[2], W. Li[1], X. Zhao[2], P. Jin[1]* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Dept of Neurosciences, University of New Mexico, Albuquerque, NM.

Adult neurogenesis is regulated at multiple levels and may play a role in learning, depression, and neurodegenerative disorders. Fragile X syndrome, one of the most common forms of inherited mental retardation, is caused by the functional loss of fragile X mental retardation protein (FMRP). FMRP is a selective RNA-binding protein that forms a messenger ribonucleoprotein (mRNP) complex associating with polyribosomes. Recently, the role of Fmrp in stem cell biology has been explored in Drosophila, and Drosophila Fmrp was found to be required for the maintenance of germline stem cells. However, whether FMRP is involved in the regulation of other stem cells, particularly adult NSCs, given the mental retardation phenotype associated with fragile X syndrome, is not fully clear. Here we show that loss of Fmrp led to increased proliferation and altered fate specification of aNSCs both in vitro and in vivo. Fmrp-deficient aNSCs displayed decreased neuronal differentiation but increased glial differentiation. Furthermore, we identified specific mRNAs regulated by Fmrp in stem cell proliferation and differentiation, including GSK3, a negative regulator of -catenin and the canonical Wnt signaling pathway that has been implicated in adult neurogenesis. The loss of Fmrp resulted in reduced -catenin levels and a defective Wnt signaling pathway. Our data demonstrate that FMRP has profound regulatory roles in adult neurogenesis, providing a link between adult neurogenesis and human mental retardation.

DNA Methylation Profiling of Major Depression. *F. Haghighi[1,2], A. H. O'Donnell[3], J. R. Edwards[4], Y. Xin[1], B. Chanrion[2], P. Graham[1], V. Arango[1], A. J. Dwork[1], J. J. Mann[1,2], T. H. Bestor[3]* 1) Molecular Imaging & Neuropathology, NYSPI; 2) Psychiatry, Columbia University; 3) Genetics & Development, Columbia University; 4) Columbia Genome Center, Columbia University, New York, NY, USA.

Emerging evidence suggests that DNA methylation plays an expansive role in the central nervous system, linking this epigenetic process to neurogenesis and neuronal plasticity. Epigenetic processes may also play a key role in the etiology of neuropsychiatric disorders, possibly through abnormal genomic methylation patterns that regulate genes involved in brain development or physiology. The aim of the present study is to explore the epigenetic profile of major depressive disorder (MDD). Using experimentally and computationally validated methods, genomic DNA from the prefrontal cortex (PFC) of normal and depressed subjects is fractionated into methylated and unmethylated compartments, and then paired-end libraries are constructed followed by high-throughput sequencing via the 454 platform. To analyze and annotate these data, we developed an in-house database and a suite of analytic tools to detect potential disease-specific DNA methylation profiles. We limited our study to the PFC due to converging evidence from neuroimaging studies implicating this region in MDD pathogenesis and our own work showing that genomic methylation patterns differ markedly across regions of the human brain. We characterized the DNA methylation status of 19-26% of CpGs genome-wide for 1 normal control and 2 MDD cases. Our initial efforts focused on gene promoters where extant DNA methylation is shown to be associated with gene expression. We identified candidate genes including those of serotonergic and dopaminergic pathways, neurotransmitter release, receptor functioning, and synaptogenesis. Subsequent to bisulfite sequencing validation of these differentially methylated regions, we are expanding our analysis of these regions to a large sample of PFC tissue from 60 controls and MDD cases with comprehensive clinical and toxicological profiles. These DNA methylation abnormalities may have clinical utility as biomarkers, and evaluation of the frequency of these alterations may point to new pathways involved in MDD.

Curcumin facilitates a transitory cellular stress response in *Trembler-J* mice. *M. Khajavi[1], J. Saliba[1], G. Jackson Snipes[2], J. Lupski[1, 3, 4]* 1) Dept Molec & Human Genetics; 2) Department of Pathology; 3) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 4) Texas Childrens Hospital, Houston, TX.

The molecular cause of Charcot-Marie-Tooth disease type 1 (CMT1) in the majority of patients is a duplication of a 1.4 Mb region on the short arm of chromosome 17 containing the dosage sensitive peripheral myelin protein 22 gene (*PMP22*). Alteration in *PMP22* gene expression can have profound effects on the development and maintenance of peripheral nerves. Consequently, the regulation of *PMP22* gene expression has been the focus of one therapeutic strategy for CMT1 (Sereda et al., 2003; Passage et al., 2004). These therapeutic approaches show promise in animal studies, but they are not feasible for other genetic causes of CMT because such molecular strategies only apply to *PMP22* over-expression. Many myelin gene mutants (e.g. *MPZ* and *PMP22*) cause severe disease (Dejerine-Sottas neuropathy, DSN; congenital hypomyelinating neuropathy, CHN) apparently by protein accumulation within the ER, causing Schwann cell apoptosis, and subsequently peripheral neuropathy. We have recently shown that oral administration of curcumin significantly decreases the percentage of apoptotic Schwann cells and partially mitigates the severe neuropathy phenotype of the *Trembler-J* (*TrJ*) mouse model in a dose-dependent manner. To identify specific molecular and cellular pathways through which curcumin functions in *TrJ* mice, we performed comparative expression profiling in sciatic nerves of curcumin treated and untreated *TrJ* mice. Administering curcumin induces the expression of multiple heat shock proteins including *Hsp70* while reducing ER stress sensors in sciatic nerves of *TrJ* mice. We further tested if *Hsp70* levels could influence the severity of the *TrJ* neuropathy. Notably, reduced dosage of the *Hsp70*, strongly potentiates the severity of the *TrJ* neuropathy, providing further evidence for the importance of ER associated degradation (ERAD) pathways in the pathogenesis of CMT. Together, these data provide further insights into the pathological disease mechanisms caused by myelin gene mutations and open new avenues for the use of curcumin as a therapeutic approach for ER-retained mutants.

High throughput approaches to fine mapping in regions of confirmed association. *P. Deloukas on behalf of the Wellcome Trust Case Control Consortium* Human Genetics, Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Last year we reported the identification of multiple disease loci as part of two studies: (i) a genome wide association study of seven common disease phenotypes in 14000 British Caucasian samples (2000 per disease) and (ii) a scan of non-synonymous SNPs across four additional diseases. New loci were confirmed in independent samples. However, in almost all instances the true causative variant(s) remain unknown. Acquiring the full spectrum of sequence variation across a region of association is the first step towards identification of causative variants. For a systematic analysis it is necessary to consider the entire recombination interval surrounding the focal SNP which often corresponds to several hundred kilobases of sequence. New highly parallel sequencing technologies offer the possibility to undertake such studies. In a pilot study we considered 16 loci totalling 2.7 Mb selected to be involved in multiple diseases, representing small / large regions, gene "oases" / "deserts" and regions with residual uncertainty regarding the causal gene. We defined recombination intervals for each locus; these were then PCR amplified using 5- and 10-kb amplicons in 32 CEPH individuals. PCR products for each individual were pooled and sequenced using Solexa/Illumina to a theoretical depth of 44x with the aim to obtain 20x sequence coverage. PCR coverage was on average ~90%, but fluctuated per locus, particularly in relationship to GC content. Sequence coverage correlates very well with PCR, 70-80% per locus. We identified 7024 SNPs (46% new) with the MAQ algorithm at minimum 10x coverage and 844 small indels (79% new). We obtained 99.2% concordance with SNP genotypes in HapMap - 73% of the discordant SNPs were validated in another sequenced sample. A fine mapping pilot is underway in three of the diseases (14 loci) in which 7819 SNPs are being typed across 8000 samples using the iSELECT platform. In parallel, we explore imputation-based' approaches to fine mapping in the resequenced loci. We are now proceeding to sequence loci totalling 2Mb for each disease across 80 samples representing cases and controls making start with Crohns disease.

Mitochondrial Sequence Variation has a Major Influence on the Human Transcriptome. *J. E. Curran, M. P. Johnson, J. Charlesworth, T. D. Dyer, H. H. H. Göring, E. K. Moses, J. Blangero* SW Foundation Biomedical Research, San Antonio, TX.

The mitochondria are the major site of cellular respiration and energy metabolism and appear to play a significant role in regulation gene transcription. In this study, we present the first exhaustive investigation of the influence of mitochondrial sequence variation on the human transcriptome. We have resequenced the entire mitochondrial genome using the mitoSEQr resequencing system in a sample of 384 observed maternal lineages within the San Antonio Family Heart Study (SAFHS), identifying more than 800 variants. Mitochondrial sequence was then imputed for matrilineal descendents, using the known pedigree structure, providing a total of 1,240 individuals for association analyses. Using genome-wide transcriptional profiling of lymphocyte samples from these SAFHS individuals, we measured expression in over 20,000 transcripts. For each transcript, we calculated a global test for mitochondrial genome-wide significance for association between expression levels and mitochondrial sequence variation using SOLAR. We identified over 2,200 transcripts (more than twice that expected by chance) exhibiting nominal evidence of mitochondrial regulation. Control of multiple testing across transcripts produced a set of approximately 350 transcripts that are highly likely to exhibit mitochondrial regulation. Among these are several expected cis-effects on mitochondrial transcripts such as *MTCO1* (mitochondrial genome-wide $p=4\times10^{-34}$). However, many dramatic novel trans-effects on the nuclear genome were identified including substantial mitochondrial sequence variation effects on the transcription of *CENPN* ($p=1\times10^{-70}$), *PRPH* ($p=2\times10^{-64}$), *CBX1* ($p=1\times10^{-61}$), and *TRIM65* ($p=2\times10^{-43}$) among many others. Pathway analysis revealed several functional categories in which potentially mitochondrially-regulated genes were significantly enriched including cell division ($p=3\times10^{-7}$), cell stage ($p=7\times10^{-7}$), organism survival ($p=9\times10^{-6}$), apoptosis ($p=1\times10^{-5}$), DNA binding ($p=3\times10^{-5}$), and oxidative stress ($p=3\times10^{-4}$). Overall, our data reveal a prominent role for mitochondrial sequence variation in the regulation of the human transcriptome.

A novel association between a *TNF* haplotype and serum ferritin in symptomatic hereditary haemochromatosis.

J. M. Brew[1,2], H. Rodgers[2], D. N. Azmanov[2], E. J. Walker[2], M. Bassett[3], S. R. Wilson[4], J. A. Cavanaugh[2] 1) John Curtin School of Medical Research, ANU, Canberra, Australia; 2) Medical Genetics Research Unit, ANU Medical School, Canberra, Australia; 3) ACT Health, Canberra, Australia; 4) Mathematical Sciences Institute, ANU, Canberra, Australia.

Hereditary haemochromatosis (HH) is a late onset disorder of excess iron storage that is one of the most common inherited disorders of Caucasians. The C282Y (Y) mutation and the H63D mutation in *HFE* are described in the development of ca. 85% of HH cases. However penetrance is incomplete and genetic factors in addition to *HFE* affecting iron homeostasis have been estimated to account for ca. 20-45% of the variation in iron stores in HH, but as yet no modifier genes have been identified. We studied 99 anonymous male controls and 72 YY homozygous males; 52 presented with clinical signs/symptoms consistent with haemochromatosis and 20 were asymptomatic relatives or individuals identified by incidental biochemical diagnosis. Whilst both patient groups had significantly higher mean $\log_{10}$ serum ferritin (SF) than controls ($p<0.0001$, both groups), symptomatic YY homozygotes had significantly higher pre-treatment SF than asymptomatic YY homozygotes ($p=0.0054$) - a result which has not been shown before. We then tested a reported association between the -308A promoter polymorphism in the pro-inflammatory cytokine *TNF* and serum ferritin (SF) levels and extended the analyses to include 3 other promoter SNPs, -1031, -863 and -857. A novel *TNF* 2-1-1-1 promoter haplotype (that does not include the -308A polymorphism) was associated with higher SF values in symptomatic YY individuals ($p=0.024$) with a similar trend observed in both asymptomatic patients and controls. To test whether this difference in SF could be correlated to levels of *TNF*, real-time PCR analyses were performed. Results failed to identify any differences in expression of *TNF* between samples with the 2-1-1-1 haplotype and those without. Ongoing experiments are aimed at extending the haplotype to identify regions containing elements that influence serum ferritin levels and subsequent clinical presentation.

Copy number variations (CNVs) in well-defined region of Xp22.31 are associated with syndromic phenotypes and intellectual disability. Further delineation of a new microdeletion/duplication syndrome. *G. Scharer[1], D. Manchester[1], G. Bellus[1], L. Pickler[1], M. Saenz[1], M. Raymond[1], K. McKelvie[1], M. Stillberger[1], J. March[1], B. Lund[2], M. Springer[2], K. Swisshelm[2]* 1) Dept. of Pediatrics, Div. of Clinical Genetics & Metabolism, The Children's Hospital/UCD, Aurora, CO; 2) CGL, Dept. of Pathology/UCDHSC, Denver, CO.

Syndromic and non-syndromic intellectual disability (ID) has long been linked to multiple genetic loci on the X-chromosome, while DNA microarray technology now permits the definition of the critical region of new microdeletion/duplication syndromes. Here we report for the first time overlapping symptoms in 5 patients with CNVs (1 deletion, female; 4 duplications, 2M/2F) in a well-defined region of Xp22.31 (6.8-8.2 Mb) flanked by Low-Copy Repeats as previously reported by *Wagenstaller et al.* in 2007. CNVs were detected by array based comparative hybridization (aCGH) and confirmed by fluorescent *in-situ* hybridization (FISH). All patients had various degrees of ID with moderate-severe speech delays being the most common finding. Two patients (dup) had behavioral anomalies consistent with autistic-spectrum disorder. Two patients were diagnosed with multiple congenital anomalies, one of whom carried an additional deletion on 2p21; the other had a history of multiple prenatal substance exposures. While growth was generally not affected, one patient (dup) presented with microcephaly, and another (del) had macrocephaly. Dysmorphic features were noted in every patient, including prominent forehead, broad/depressed nasal bridge with lateral nasal build-up, short palpebral fissures, low-set ears, and moderate 2-3 toe syndactyly. One patient (dup) presented with mild facial asymmetry and leg length difference causing motor delays. Neurologic exam was notable for hypotonia in all 5 patients; one patient (del) had nystagmus and mild gait ataxia. While this is a small patient sample, evidence is mounting that CNVs in a defined region of Xp22.31 are associated with distinct phenotypes of syndromic ID and patients presenting with syndromic ID should be screened for chromosomal imbalances in Xp22.31 either by aCGH or by FISH as a first line screening test.

Meta-analysis of genome-wide association data for weight in ~32000 individuals. *J. C. Randall[1], C. M. Lindgren[1], E. K. Speliotes[2], S. Li[3], GIANT Consortium* 1) WTCHG, University of Oxford, Oxford, UK; 2) Broad Institute, Harvard and MIT, Boston, MA, USA; 3) MRC Epidemiology Unit, Cambridge, UK.

Adult weight is highly heritable (~70%), but the genetic variants that predispose to it are not well known, and loci identified thus far have had modest effects. To increase power to detect such effects, we performed a meta-analysis of 13 GWA studies as part of the GIANT consortium. Populations studied are of European ancestry and constitute a total of ~32000 individuals. Weight data was stratified by gender and inverse-normal transformed. Imputation was used to obtain a set of probable genotypes for unobserved loci using the CEU HapMap reference panel and combined with directly genotyped data yielding ~2.5M SNPs in total for analysis. SNPs were tested for association in each stratum using an additive model with age as a covariate. Meta-analysis of those results was then performed for male, female, & combined subsets, and summary statistics were generated for each SNP. A T-test was used to assess the heterogeneity of the effect estimates between genders. Preliminary analysis has identified 54 independent loci with suggestive evidence of association with weight ($p5x10^{-6}$). Of these, 12 loci have previously been shown to be associated with BMI and 11 with height, including *FTO* ($p3x10^{-16}$), *HMGA2* ($p3x10^{-11}$), *MC4R* ($p3x10^{-9}$), and *GDF5* ($p4x10^{-7}$). Of the 31 remaining loci, 29 had weak association ($5x10^{-6}$p0.05) with BMI and/or height, while 2 appear to be associated with weight alone. Significant sexual dimorphism ($p1x10^{-4}$) was found in 16 out of the 54 loci. Of these 16 loci, 5 had an opposite effect direction for each gender, 3 had a significant effect in one but no effect in the other, and 8 had an effect in the same direction but of a different magnitude in each (including *MC4R*). These results are consistent with previously known associations for obesity and height, and the additional loci found to be associated in this study continue to support the hypotheses that multiple common variants influence body weight, that GWA analysis with large numbers of individuals can identify such variants, and that some variants have a sexually dimorphic effect.

The effect of chr16p11.2 microdeletions and microduplications on gene expression in Autism Spectrum Disorders. *M. Kusenda[1,2], Y. Seungtai[1], M. Wigler[1], J. Sebat[1]* 1) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY 11724; 2) Graduate Program in Genetics, Stony Brook University, Stony Brook, NY 11794.

Studies of genome copy number variation in Autism Spectrum Disorders (ASDs) have shown that *de novo* structural mutations play an important role in disease etiology. One of the most frequent of such mutations is a recurrent ~500 Kb deletion at 16p11.2, occurring in approximately 1% of cases, and in 0.01% of the general population. The deleted region contains more than twenty five genes, and we hypothesize that hemizygosity of one or more of these changes contributes to the autistic phenotype. Thus it is important to determine how gene function is altered by this mutation. We analyzed genome wide expression data from Epstein Barr Virus (EBV) transformed Lymphoblast cell lines, on eight families with *de novo* or inherited mutations of 16p11.2. Using RNA expression profiling by Affymetrix Human Genome U133 Plus 2.0, we examined differential gene expression in individuals with 1, 2 or 3 copies of the genomic region. Copy number variation of several genes within the region resulted in consistent expression changes (adjusted P-value < 0.005), and the most significant was aldolase A (ALDOA). This finding is interesting in light of studies that have implicated this gene in mental retardation. Data generated by this study will give insight into dosage sensitive genes within the risk variant, and may help pinpoint genes which are relevant to pathology of autism.

Regulatory genetic variants upstream of the SNCA gene. *O. Chiba-Falek[1], C. Linnertz[1], L. Saucier[1], K. Cronin[1], K. Hayden[2]* 1) Institute for Genome Sciences & Policy, Duke Univ, Durham, NC; 2) Dept of Psychiatry and Behavioral Sciences, Duke Univ, Durham, NC.

In the last decade, evidence has emerged implicating alpha-synuclein (*SNCA*) in the development of Parkinsons disease (PD), raising the critical question of what role *SNCA* plays in the molecular pathogenesis of sporadic PD. Evidence has accumulated suggesting that the role of *SNCA* in PD may be mediated through alteration of *SNCA* expression. Association studies demonstrated that genetic variability across the *SNCA* locus, including its promoter/enhancer region, is associated with susceptibility to sporadic PD. Pinpointing the biologically relevant variation within the associated *SNCA* region, however, is quite challenging, as the implicated genetic variants are in high linkage disequilibrium with each other. Thus, the causal genetic variant/s remains elusive. We hypothesized that regulation of SNCA expression levels is important in the development of sporadic PD, and, hence, regulatory variants controlling *SNCA* transcription might be PD causative. In order to explore the regulation of *SNCA* expression and to identify the regulatory genetic variant/s, we first identified genetic variations within non-coding conserved regulatory elements upstream of the *SNCA* gene. We then determined the correlation between those candidate genetic variants upstream of the *SNCA* gene and SNCA-mRNA levels in vivo in a variety of human post mortem brain tissues from unaffected individuals. Finally, we are currently confirming, in vitro, the functional consequence of the candidate genetic variants by Luciferase reporter assays. This study advances our understanding regarding the molecular mechanism modulating *SNCA* gene expression. The current evidence relating over-expression of *SNCA* to PD emphasizes the importance of this study for the identification of new therapeutic approaches for PD targeting the reduction of *SNCA* levels. Furthermore, our study serves as a general model of how to pinpoint a causal genetic variant from a set of variants with high LD scores that have been associated with complex traits and demonstrates a mechanism to elucidate the precise molecular bases of the underlying effects.

The serotonin receptor gene HTR5A affects plasma triglyceride levels in humans and mice. *Y. Zhang[1], E. M. Smith[1], L. J. Martin[2], J. Charlesworth[3], E. Moses[3], J. Blangero[3], J. Lazar[1], Z. Lazarova[1], A. H. Kissebah[1], S. Mirza[1], M. Olivier[1]* 1) Dept Physiology, Medical Col Wisconsin, Milwaukee, WI; 2) Children's Hospital, Cincinnati, OH; 3) Southwest Foundation for Biomedical Research, San Antonio, TX.

Serotonin (5-HT) has been implicated in the development of obesity, but has not been shown to regulate lipid metabolism or plasma lipid levels. One of the genes for a 5-HT receptor, HTR5A, is located in a quantitative trait locus on human chromosome 7q36 (LOD = 3.7) linked to plasma triglyceride (TG) levels in an obese cohort. Initial fine-mapping using 1000 SNPs across the 5 Mb interval uncovered association between sequence variants in the gene and TG levels. Resequencing of all exons and 3 kb of the promoter region uncovered 13 SNPs within the 20 kb gene interval. Association analysis demonstrated that four of these SNPs were associated with TG levels ($p<0.002$). Subsequent BQTN analysis identified a SNP (rs3734967) with substantial posterior probability ($p=0.59$), suggesting that this variant may be causal. This SNP, which is 2kb upstream in the promoter, accounts for ~5% of the observed linkage in the QTL region in our cohort. Each copy of the G allele, on average, increases TG levels by 8-9%. Since HTR5A is exclusively expressed in the brain, we tested the effect of the two alleles of rs3734967 on transcription factor binding using two human glioma cell lines in gel-shift assays. We detected significantly altered binding of nuclear proteins to the A allele when compared to the G allele of the variant. Mass spectral analysis revealed differential binding of multiple DNA binding proteins including transcription activators (STAT1 and STAT3) and DNA helicases. Finally, plasma TG levels of htr5r KO mice (B6.129-Htr5atm1Dgen) are significantly lower ($p=5\times10\text{-}4$) when compared to heterozygous littermates at 6 wks of age, suggesting that HTR5A affects plasma TG levels in both humans and mice. These results, for the first time, implicate serotonin in obesity-related lipid homeostasis, and may allow the development of alternative pharmacological lipid-lowering therapies to prevent the cardiovascular complications of obesity.

Large-scale investigation of xenobiotic metabolism candidate genes and related pathways in amyotrophic lateral sclerosis(ALS) identifies associations in KLHL1 and VIL2. *E. Rampersaud[1], Y. Yang[2], W. Chen[2], M. Saeed[1], H. Khan[2], J. Armstrong[2], M. Zheng[2], D. Ma[1], R. Sufit[2], S. Heller[2], Y. Jianhua[2], N. Siddique[2], J. L. Haines[3], M. A. Pericak-Vance[1], T. Siddique[2]* 1) Miami Inst. Human Genomic, University of Miami; 2) Department of Neurology, Northwestern University; 3) Center for Human Genetics Research, Vanderbilt University.

Amyotrophic lateral sclerosis(ALS) is a fatal neurodegenerative disorder for which there are no known preventative treatments.It has long been suspected that toxicity from exposure to xenobiotic (natural or artificial substances foreign to the body) and endogenous compounds plays a role in the etiology of sporadic ALS (SALS).However, it is unclear whether genetic variability modifies the level of toxicity of such compounds.We performed the largest association analysis to date of 5,266 SNPs in 1,366 genes involved in xenobiotic metabolism and related pathways in 343 unrelated individuals with SALS, 368 neurologically normal unrelated controls and 195 singleton trio families.The genotype callrate of these SNPs was 95% the average MAF was 0.30.No evidence of population stratification was detected.SNPs were tested for departure from Hardy Weinberg Equilibrium (HWE) and association analyses in the combined dataset of cases, controls and trios was carried out with the UNPHASED software.Three common correlated SNPs (rs7985162,rs2161760,rs1424313;r^2>0.9)in intron 6 of the Kelch-like 1 gene (KLHL1) on chr13 were the most strongly associated with SALS (P~10^{-6}, P=0.025 after stringent Bonferroni correction testing for all 5,266 SNPs).Also of interest were 5 SNPs (rs7760064,rs2306746, rs3102990,rs7754951, rs3127196,P<0.001)in intron 9 in the Ezrin gene (VIL2) on chr6.In an independent study of SALS in British and German samples, rs2171209 in VIL2 was associated with SALS (genotypic P=0.0048) and this SNP is in moderate LD (r^2>0.30) with 3 of the VIL2 SNPs associated with SALS in our study (rs2306746, rs3102990,rs3127196,P<0.001).The significance of our findings for KIHL1 and the confirmation of our results for VIL2 strongly implicate these genes, and further indicate that genetic susceptibility in genes related to toxin exposures increases SALS risk.

Joint Analysis of Germline p53 Mutation, MDM2 SNP309, and Gender on Cancer Risk in Family Studies of Li-Fraumeni Syndrome. *C. C. Wu[1], R. Krahe[2], G. Lozano[2], S. Shete[1], C. I. Amos[1], L. C. Strong[2]* 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Dept Genetics, Univ Texas MD Anderson CA Ctr, Houston, TX.

Li-Fraumeni syndrome (LFS) is a rare familial cancer syndrome characterized by a high frequency of early-onset and diverse tumor types and an increased frequency of multiple primary tumors. Germline p53 mutations have been identified in most LFS families. Recently, a high-frequent genetic variant of single-nucleotide polymorphism (SNP) 309 in the MDM2 gene, a direct negative regulator of p53, was shown to be a modifier of cancer risk in p53 mutation carriers. Independent reports showed a significantly earlier age of cancer onset for the SNP309 G-allele carriers than homozygous T-allele carriers by 7 to 15 years on average. However, mathematical modeling of family studies allowing for multivariate interactions between p53 mutation, SNP309, and gender on cancer risk has not been explored. We propose the use of joint segregation and linkage analysis on the basis of Cox proportional hazards regression to assess joint effects of p53 mutation, SNP309, and gender on age of cancer onset. We first analyzed 6 extended LFS pedigrees ascertained through childhood sarcoma patients with germline p53 mutations and included all invasive cancers, except non-melanoma skin cancer and in situ carcinoma, as a single combined phenotype. Using p53 as a linked marker in the analysis, our results showed strong evidence of linkage disequilibrium (LD) between the putative trait locus and p53 locus. The LOD-Score difference of 1.5 is considered evidence for a better model. In our analysis, the highest LOD-Score for the model with LD is higher by 3.07 than that for the corresponding model without LD, suggesting a far better fit. A bigger sample comprising 22 extended kindreds with p53 germline mutations ascertained through clinical LFS phenotype is currently available for analysis. This sample includes 133 p53 mutation carriers with MDM2 SNP309 genotypes. Currently, we are quantitatively assessing the marginal and joint effects of germline p53 mutations, MDM2 SNP309 and gender on age of cancer onset in these 22 pedigrees.

Two New Mutations in FBN 1 Gene Associated With Marfan Syndrome in Puertorrican Population. *N. Ramirez[1], A. S. Cornier[2,5], J. Flynn[1], C. Burgos[2], N. Arciniegas[3], S. Carlo[2,4]* 1) La Concepcion Hospital, Dept. of Orthopedics, San German, Puerto Rico; 2) La Concepcion Hospital, Molecular Medicine Dept.,San German, Puerto Rico; 3) La Concepcion Hospital, Dept. of Pediatrics, San German, Puerto Rico; 4) Ponce School of Medicine, Dept. of Biochemistry, Ponce, PR; 5) Univ. of Puerto Rico School of Medicine, Dept. of Internal Medicine, Rio Piedras, PR.

Marfan syndrome is a connective tissue disorder with clinical variability. It mainly involves the ocular, skeletal, and cardiovascular systems. Mutations in the FBN1 gene and TGFBR2 gene had been associated with wide phenotypic variability in Marfan Syndrome, ranging from isolated clinical manifestations to severe and rapidly progressive disease. Puerto Rico is a small island in the Caribbean with unknown prevalence and incidence of Marfan Syndrome. Several Patients are diagnosed in the genetic clinics. We are reporting two new mutations associated with clinical diagnosis of Marfan in Puertorrican population. Molecular genetic testing of the FBN 1 gene detects 70-90% of mutations and is available in clinical laboratories.DNA sequencing of the FBN 1 gene had revealed two novel sequence variants: Heterozygous 6515_6516delTTinsG in exon 53 results in a premature stop codon (V2172fsX12), and 4505G>A (C1502Y) in exon 36. These mutations have never been reported before. Marfan findings in these patients includes dilatation of the aorta, mitral valve prolapse and triscuspid valve prolapse.Other features inludes ectopia lentis, lens dislocation and specific skeletal features. Amongs the skeletal system involvement presented with bone overgrowth and joint laxity and the extremities are disproportionately long for the size of the trunk (dolichostenomelia). Overgrowth of the ribs can cause pectus excavatum or pectus carinatum were present. Minimal Scoliosis was found in both patients.

Recurrent translocation t(4;11)(p16.2;p15.4) mediated by homologous low-copy repeats in three families with autistic spectrum, multiple congenital anomalies, and dysmorphic features. *Z. Ou[1], P. Stankiewicz[1], A. Patel[1], T. Sahoo[1], AC. Chinault[1], R. Shippy[2], J. Collins[2], JR. Lupski[1], SW. Cheung[1]* 1) Dept Molec & Human Gen, Baylor Col Med, Houston, TX; 2) Affymetrix, Santa Clara, CA.

To date, only two recurrent constitutional non-Robertsonian translocations have been described. The most common translocation t(11;22)(q23.3;q11.21) is mediated by AT-rich cruciform structures and the t(4;8)(p16.2;p23.1) translocation is mediated by the olfactory receptor-gene cluster low-copy repeats (LCRs). We describe three unrelated families with an unbalanced translocation der(4)t(4;11)(p16.2;p15.4) identified by targeted array CGH (CMA V5, V6.1, and V6.2) and verified by FISH. The patients phenotypes include autistic spectrum, multiple congenital anomalies, and dysmorphic features. Using SNP arrays (Affymetrix 6.0), the breakpoints were mapped at 3.55 Mb, 3.58 Mb, and 3.4 Mb in 11p15.4, and at 4.15 Mb, 3.85 Mb, and 3.9 Mb in 4p16.2, respectively. Sequence analysis of the breakpoint regions revealed the presence of large (~300 kb) LCRs of 94-98% interchromosomal sequence identity; the translocation breakpoints mapped within homologous subunits and thus were mediated by these LCRs. Interestingly, a similar paternally inherited translocation t(4;11) with breakpoints mapping at 3.4 Mb in 11p15.4 and at 4.6 Mb in 4p16.2 has been reported by Russo et al. (2006) in a patient with features of both Wolf-Hirschhorn and Beckwith-Wiedemann syndromes. In addition, we identified a pericentric inversion inv(11)(p15.4q25), and using CMA V6.1 and the SNP arrays defined the breakpoints within the same LCR in 11p15.4. The other breakpoint was located in a LCR-free region. Our data indicate that the LCR in 11p15.4 is a novel genomic instability region that can mediate the third recurrent constitutional non-Robertsonian translocation t(4;11)(4p16.2;11p15.4) and can stimulate the formation of other chromosomal aberrations in humans. The frequency of this NAHR mediated rearrangement compared to the other two reported recurrent translocation awaits single sperm PCR analysis of the recombination event and further chromosomal studies of patients with the resulting imbalances.

Autosomal Dominant Large Fontanelles - Prenatal Diagnosis and Postnatal Outcome. Report on Two Families.

M. Szak[1], N. Martin[1], A. Toi[2], D. Chitayat[1] 1) Prenatal Diagnosis, Mount Sinai Hospital, Toronto, ON, Canada; 2) Dept. of Diagnostic Imaging, Mount Sinai Hospital, Toronto, ON, Canada.

Very large anterior fontanelles are known to be associated with a variety of conditions and can be misinterpreted as acrania on fetal ultrasound. Obtaining detailed family history and parental examination to rule out cleidocranial dysplasia (CCD) are of utmost importance for accurate diagnosis. We report two families with a history of very large and delayed closure of the anterior fontanelles that is consistent with an Autosomal dominant mode of inheritance and diagnosed through the prenatal finding of a very large anterior fontanelle on 2D and 3D ultrasounds. Family 1: Our patient was a G3P2L2 mother. Fetal ultrasound showed absent cranial bone ossification at 13.1 weeks gestation. Fetal ultrasound at 16 weeks gestation showed a prominent anterior fontanelle measuring 1.9cm. Family history was significant for very large anterior fontanelles and splayed sagittal sutures detected on the father, the couples son and the paternal grandmother. Physical examination of the father showed OFC2 SD, height at 25-50th percentile, and slopped shoulders. Although his features were not consistent with CCD we performed molecular analysis for the RUNX2 gene on the father and no mutation was detected. The pregnancy is ongoing. Family 2: The patient was born to a G3P2SA1L2 mother. Fetal ultrasound at 18.5 weeks gestation revealed an absent/hypoplastic nasal bone, a large anterior fontanelle and bilateral 5th finger clinodactyly. Delivery was at 38.5 weeks gestation via a planned repeat c-section. Physical examination at 6 months of age revealed macrocrania and a very large anterior fontanelle. Detailed family history revealed that father was also born with a very large anterior fontanelle that eventually closed at 3 years of age. He has no findings consistent with CCD. To the best of our knowledge these families present a novel condition with large anterior fontanelle and absent/hypoplastic nasal bone, which was detected prenatally and confirmed postnatally. Making the diagnosis is of utmost importance to avoid false diagnosis of acrania and to lower parental anxiety.

Linking Collagen Genotypes to Clinical Phenotypes. *D. Bodian[1], M. Balaraman[2], B. Brodsky[2], T. Klein[1]* 1) Genetics Dept, Stanford University, Stanford, CA; 2) Department of Biochemistry, University of Medicine and Dentistry of New Jersey-Robert Wood Johnson Medical School, Piscataway, NJ.

Type I collagen is the major protein in bone, skin, tendon, sclera, and blood vessels and is responsible for the structural integrity of these tissues. The most common disease associated with mutations in type I collagen is osteogenesis imperfecta (OI), or brittle bone disease. OI presents in a wide range of clinical severities and the relationship between genotypes, molecular phenotypes, and clinical phenotypes is poorly understood. Although it is known that the phenotype depends on the nature of the mutation and its location with the gene, it is not currently possible to reliably predict the disease severity from the mutation. The ability to make such a prediction to guide genetic counseling decisions is becoming critical as diagnostic strategies move to direct sequencing of the genes. We are developing a computational method to predict the lethality of OI-associated collagen mutations using a divide-and-conquer approach. Mutations likely to share a mechanism of lethality were identified and each set was modeled separately. Models were validated both computationally, using independent test sets of mutations, and experimentally. The computational and experimental results together lend insight into the effect of mutations on the structure and function of collagen and the etiology of OI.

RNAi knockdown reveals an important role for glycerol kinase genes in development and metabolism of *Drosophila*. *P. J. Wightman[1], G. R. Jackson[2], K. D. Dipple[1,3]* 1) Department of Human Genetics, David Geffin School of Medicine at UCLA, Los Angeles, CA; 2) Department of Neurology, David Geffin School of Medicine at UCLA, Los Angeles, CA; 3) Mattel Children's Hospital at UCLA, Los Angeles, CA.

In humans, glycerol kinase deficiency [GKD; MIM 307030] can be asymptomatic or symptomatic ranging from mild to severe phenotypes. The lack of genotype/phenotype correlations in GKD patients however has led us to hypothesize the existence of modifier loci. We have created a *Drosophila* model for GKD using the UAS/GAL4 system for RNAi-mediated knockdown of the two closest *Drosophila* homologues (CG7995 and CG18374) to the human glycerol kinase gene (*GK*, Xp21). Using ubiquitous, fat body and muscle GAL4 drivers, RNAi knockdown of CG7995 and CG18374 identified phenotypes ranging from larval lethality, pupal lethality, adults with wing abnormalities to adults with shortened life span. Lines that survived to adulthood died at a rate similar to starvation when placed on a glycerol-only food source. This inability to metabolize glycerol was observed for knockdowns of both *GK* homologues, indicating that both are essential for normal glycerol metabolism. As expected, elevated glycerol levels and decreased glycerol kinase transcript levels were detected in multiple knockdown lines that survived to adulthood. Pupal lethality of RNAi lines using a fat body driver was rescued using transgenic lines for both *GK* homologues. These rescued flies had shortened lifespan, indicating that normal *GK* expression levels are necessary for normal lifespan. Thus, we demonstrate a genetically tractable model of GKD that can be used to screen for modifier loci.

Localization of a Dominant Genetic Susceptibility Factor in Familial Malignant Mesothelioma. *J. E. Below[1], A. Pluzhnikov[1], K. Aquino-Michaels[2], M. Nasu[2], V. Paz[1], B. Mossman[3], H. Pass[4], J. R. Testa[5], M. Carbone[2], N. J. Cox[1]* 1) University of Chicago, Chicago, IL; 2) University of Hawaii, Honolulu, Hawaii; 3) University of Vermont, Burlington, VT; 4) New York University, New York, NY; 5) Fox Chase Cancer Center, Philadelphia, PA.

Malignant mesothelioma (MM) is the primary, yet rare cancer of the pleura, and is generally found in populations with asbestos exposure1. The prognosis of MM patients is poor due in part to a prolonged latency period (frequently greater than 25 years) from initial exposure to clinical diagnosis1, and the highly malignant nature of the cancer. Upon diagnosis the median survival time is 10 months2, and early detection remains the best approach for reducing morbidity and mortality. An American family with no known asbestos exposure, but a markedly high rate of MM has been identified. All available family members have been genotyped using the Affymetrix Genome-Wide Human SNP Array 6.0. Prior to linkage analyses, familial relationships were checked and corrected using PLINK3. Parametric linkage analyses based on a 0.2 cM SNP map assume a rare dominant model with age-dependent liability classes modeling the expected change in penetrance for different age groups. Preliminary findings indicate that a region on chromosome 6 shows genome-wide significance for linkage (LOD score >3.4). We report details of these analyses, and the results of sequencing and copy number analysis in the disease-linked region on chromosome 6. 1. Testa, J.R. & Jhanwar, S.C. Textbook of pleural diseases, 120-130 (Arnold, London, New York, 2003). 2. Emri, S. et al. Prognostic significance of flow cytometric DNA analysis in patients with malignant pleural mesothelioma. Lung Cancer 33, 109-14 (2001). 3. Purcell, S. PLINK v0.991. (2007).

Generation of a BAC transgenic mouse model for FXTAS. *Y. Li, P. Jin* Dept Human Genetics, Emory Univ, Atlanta, GA.

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a progressive neurodegenerative disorder recognized in fragile X premutation carriers. Using Fruit fly, we have previously demonstrated that elongated noncoding CGG repeats in FMR1 allele as the pathogenic cause of FXTAS. To further develop robust FXTAS mouse model and study the molecular basis of rCGG-mediated neurodegeneration, we have used two-step BAC modification protocol with PLSD53SC-AB shuttle vector to modify a BAC containing the full length of calbindin genomic sequence by which the transgene expression would be Purkinje cell-specific. The precise manipulation resulted in the replacement of Calbindin exons by transgene containing EGFP coding region with (CGG)90 in the 5-UTR in the modified BAC bone. The modified BAC has been used to generate transgenic mice and could express the (CGG)90-EGFP specifically in mouse Purkinje cells driven by regulatory elements from mouse endogenous Calbindin gene independent of chromosomal location of the transgenic BAC, while the endogenous FMRP1 levels are not affected with overexpression of rCGG repeats. Development of this mouse model will provide new tool to further understand the molecular basis of FXTAS.

High population attributable risk (PAR): the PAR-adox of genome-based personalized medicine. *A. C. J. W. Janssens, C. M. van Duijn* Dept Epidemiology, Erasmus MC, Rotterdam, Netherlands.

Population attributable risk (PAR) is increasingly used in genetic association studies to demonstrate the population health impact of a genetic susceptibility gene and of combinations of multiple susceptibility genes (genetic profiles). PAR is the percentage of cases that is attributable to a risk factor, and hence the percentage of cases that can be prevented when the adverse effects of the risk factor are eliminated. Several alternative formulas are available for the calculation of PAR, but the simplest ones, assuming independent effects of susceptibility genes, are generally used. The properties of the PAR for evaluating genetic profiles are not well understood. Our studies of the performance of the PAR for the evaluation of genomic profiles show three important characteristics. First, the PAR estimates easily approach 100% when multiple genes are combined, even when the heritability of disease is low. This is not explained by the risks associated to the profile but by the joint frequency distribution of the risk alleles. Second, our evaluation suggests that a high PAR often comes with low predictive value when the effects of single genes are small. This discrepancy is explained by an inflation of the odds ratios of genetic profiles when rare profiles are used as baseline. Third, our study suggests that a high PAR of genetic profiles in complex diseases often implies that genetic screening is NOT efficient but rather asks for a population-based approach targeting the full population rather than genetically determined high-risk groups. In sum, we show that the PAR is very poorly related to the predictive value of a genetic test and that a high PAR does not imply that a genetic test will be useful.

Specific telomere length changes in length in chronic myeloid leukemia. *O. Samassekou[1], J. Herbert[2], A. Ntwary[1], B. Xiong[1], E. Bouchard[1], CC. Grenier[3], J. Y.[1]* 1) Dept Medical Genetics, Sherbrooke Univ (CHUS), Sherbrooke, PQ, Canada; 2) Banque des cellules leucémiques, Montréal, PQ, Canada; 3) Dept pédiatrie, Sherbrooke Univ (CHUS), Sherbrooke, PQ, Canada.

Chronic myeloid leukemia (CML) is a neoplasia characterized by a proliferation of a myeloid cell lineage and a translocation t(9;22). As most of the cancers, the telomere length in CML cells is shorter than normal blood cells. However, currently no data are available about the specific telomere length in CML. We studied the telomere length on each chromosome. After obtaining metaphases from CML cells, in situ hybridization with peptide nucleic acid probes was performed. The telomere length of each chromosome arm was measured according to the fluorescence intensity. We surprisingly noticed a lengthening of the telomere on the short arm of a chromosome X. This lengthening was confirmed by telomere restriction fragment technique. In addition, we showed a shortening of the telomere on the long arm of a chromosome 21. We measured the telomerase activity by real time polymerase chain reaction. We found an increase of telomerase activity in all samples. However, this augmentation could not explain the huge difference between short and long telomeres on one hand, and between the homologous chromosomes on the other hand. Then, we studied sister telomere exchange and found an increase of the exchange events in leukemia cells. Besides, the action of the telomerase to maintain telomere length, the alternative lengthening telomere (ALT) might be another mechanism to conserve telomere length in CML. It is important to take into account together the two mechanisms maintaining telomere length when targeting the telomerase by therapeutic agents because the telomerase activity can hide the ALT mechanism. The telomere change in length associated with specific chromosomes could be used as a marker for the follow up of patients and serve for a better understanding of telomere biology.

TP53 R72P polymorphism and childhood leukemia susceptibility. *T. Do, E. Ucisik-Akkaya, C. Davis, B. Morrison, M. T. Dorak* Genomic Immuoepidemiology, HUMIGEN LLC, the Institute for Genetic Immunology, 2439 Kuser Rd., Hamilton, NJ.

Genomic and immunologic surveillance mechanisms are crucial in protection from cancer. TP53 is one of the major regulators of genome surveillance. Inherited TP53 mutations cause familial cancer. Among the natural sequence variants of TP53, the exon 4 SNP rs1042522 (R72P) has been reported to modify the risk for solid tumors. To investigate its relevance in childhood acute lymphoblastic leukemia (ALL) susceptibility, we genotyped 114 cases with childhood ALL and 389 newborn controls from Wales (UK). Homozygosity for R72P showed increased risk for childhood ALL with no sex specificity (OR = 2.9, 95% CI = 1.5 to 5.6; P = 0.002). The additive model confirmed the gene-dosage effect (P = 0.002). TP53 association was independent from other associations found in the same sample, in particular the HLA complex and NKG2D associations. We then examined the intron 1 polymorphism known as SNP309 (rs2279744) within the MDM2 gene, which encodes a negative regulator of TP53. Although MDM2 SNP309 is associated with adult cancer risk with sex effect, it did not show any association with childhood ALL, even after stratification by sex. There was no statistical interaction between MDM2 and TP53 SNPs except that the risk conferred by TP53 R72P homozygosity was greater for girls if they had the wildtype MDM2 genotype (OR = 7.1; P = 0.02) as opposed to the variant-positive genotype (OR = 1.4). We also genotyped 12 SNPs in HLA complex genes whose products interact with TP53 and/or belong to genomic surveillance/apoptosis pathways (DDR1, IER3, LTA, BAT3, DAXX). No interaction test reached statistical significance for the HLA complex variants and TP53 R72P. Only the 5 end haplotype tagging SNP of DAXX (rs2073524) showed a suggestive interaction (P = 0.05). In females, the risk association with TP53 R72P homozygosity got stronger in the presence of homozygosity for the DAXX variant allele (OR = 12.6, P = 0.001). Our results suggested that TP53 R72P polymorphism is one of the stronger modifiers of risk for childhood ALL susceptibility and might interact with its regulator MDM2 in females.

A two-stage analysis using Random Forests and association testing identifies novel epistatic relationships with *PTPN22* in rheumatoid arthritis. *P. P. Ramsay[1], F. B. S. Briggs[1], E. Madden[1], M. F. Seldin[2], P. K. Gregersen[3], L. A. Criswell[4], L. F. Barcellos[1]* 1) Univ of California, Berkeley; 2) Univ of California, Davis; 3) The Feinstein Institute for Medical Research, NY; 4) Univ of California, San Francisco.

Studies of rheumatoid arthritis (RA) have consistently shown strong associations for both *HLA-DRB1* and *PTPN22*; however, the discovery of additional disease loci and complex genetic interactions is critical to further our understanding of disease pathogenesis. To identify novel gene x gene interactions in RA, we developed a two-stage analytical approach that incorporates the Random Forests (RF) algorithm and a series of association tests to uncover novel epistatic interactions. We utilized this methodology to reveal interactions with variation in the *PTPN22* locus that confer risk for RA. Multipoint identity-by-descent probabilities were determined using 292 affected RA sib-pairs for 379 microsatellite markers (MSMs) across the genome, and then used to identify predictors of *PTPN22* 1858T carrier concordance with RF. RF is a prediction technique based on a collection of classification trees grown on bootstrap samples of data using a random subset of predictors to define the best split at each node. Analyses produce a single measure of importance for each predictor. The six most important MSMs were then evaluated in 677 anti-CCP positive RA cases and 750 controls. SNPs within 5Mb of each MSM were tested first in a case-only analysis (12,367 SNPs) resulting in 21 SNPs ($p<0.001$) for follow-up which were tested for effect modification of *PTPN22* in RA cases and controls using Breslow-Day test for homogeneity. Finally, 19 SNPs ($p<0.05$) were tested for epistatic interactions using logistic models. Significant interactions ($p<0.05$) were investigated in stratified analyses. In *PTPN22* 1858T positive individuals, the presence of specific SNP alleles within four loci: *CDH13* (OR=3.82), *PRKCH* (OR=1.77), *WWOX* (OR=2.27) and *SLC35F4* (OR=1.88) significantly increased risk for RA. Our results underscore the important role of complex interactions in susceptibility to RA and the need for comprehensive analytical strategies to define them.

Severe glutathione synthetase deficiency: Long-term manifestations in two adult brothers. *K. O'Brien[1], J. Sloan[2], A. Gropman[1], E. Baker[3], T. Pierson[4], K. Fischbeck[4], I. Macdonald[5], W. Gahl[1], C. Venditti[2]* 1) MGB/NHGRI/NIH; 2) GDRB/NHGRI/NIH; 3) DRD/CC/NIH; 4) NINDS/NIH; 5) NEI/NIH.

Glutathione synthetase deficiency (GSSD) is a rare disease due to deficiency of glutathione synthetase (GSS), resulting in glutathione depletion, 5-oxoprolinuria, hemolytic anemia, and metabolic acidosis. Clinical manifestations in two adult brothers are described and compared to other patients reported with severe GSSD in order to better understand the natural history of this disorder. Two Caucasian siblings with GSSD have been followed at the NIH for more than 30 years. The older sibling was identified at 22 months of age based on typical laboratory findings; his younger brother was diagnosed as a neonate and has been treated with vitamins C and E, and alkali replacement since 2 days of life. The brothers have missense and frameshift mutations in the GSS gene. Patient 1, age 33 y, has experienced significant deterioration over the past 6 years. Previously, he was ambulating independently and working full time. Now, he is wheelchair bound, with worsening spasticity, imbalance, and dysarthria, and cannot function independently. Patient 2, age 30 y, also experienced a decline. He has developed psychosis, including paranoia, hallucinations, delusions, and motor symptoms. He ambulates with a walker and resides in an assisted living facility. A 3.0 T brain MRI/MRS revealed diffuse white and gray matter atrophy in both the cerebrum and cerebellum, ventricular enlargement, gray matter heterotopia, and a malformed cerebellum. NAA was low in 3 locations studied by MRS. These men are among the oldest known patients with severe GSSD. Over the past 6 years, both have experienced neurological decline with differing manifestations despite stable biochemical parameters. The malformed cerebellum and heterotopia seen in patient #2 are similar to findings reported in others, albeit rarely, and suggest that CNS malformations can be a feature of the disorder. The differing neurological manifestations of these two siblings also indicate that modifier genes may influence the phenotype of GSSD and highlight the importance of oxidant homeostasis in the CNS.

Modulation of recombinant protein secretion in different cell types by varying signal peptides. *A. A. Li, M. A. Potter* Department of Pathology and Molecular Medicine, McMaster University, Hamilton, Ontario, Canada.

Genetically engineered cells which express and secret therapeutic proteins can be implanted into recipients after enclosure in alginate-L-lysine-alginate (APA) capsules which provide an immune isolation of the cells. This approach has been used for gene therapy of several genetic conditions including lysosomal storage diseases, haemophilia and cancers. Efficient secretion of therapeutic protein is a prerequisite of APA microcapsule technology. In this study, we investigated whether different signal peptides and protein transduction domains would have an impact on the secretion of expressed proteins in different types of cells: mouse myoblasts (C2C12), canine epithelia cells (MDCK) and human kidney epithelia cells (293) which are widely used in microencapsulation technology. Signal peptide of human melanotransferrin p97, human factor VII, BM40 or an 11 amino acid protein transduction domain TAT has been reported to substantially enhance the secretion of some proteins which otherwise accumulated in endoplasmic reticulum. We cloned each signal peptide in-frame with a marker gene (luciferase) in pC3B vector derived from pcDNA3.1 and transfected C2C12, MDCK and 293 cells. Luciferase activities were measured in culture medium and cell lysates. Our results showed that signal peptide from p97 had the highest secretion of luciferase in 293 cells, then MDCK cells and the least in C2C12 cells. The same pattern was observed in BM40 targeted secretion, but the secretion efficiency was about half of p97 signal peptide. Although signal peptide of FVII has shown efficient secretion of other proteins, there was no improvement in secretion of luciferase in the three transfected cell lines used here. TAT showed a strong ability in retaining the protein intracellularly. Even when p97 signal peptide was fused upstream of TAT, no protein was secreted, indicating the strong retention signal of TAT exceeded the ability of p97 signal peptide to export the protein. In conclusion, it is difficult to predict a prior effect of signal peptides and protein transduction domains on protein secretion in different cell typeseach must be tested empirically.

Variation in *ABCA12* is associated with blood pressure and partially accounts for the BP linkage on 2q in the Old Order Amish. *Y. Wang[1], P. F. McArdle[1], X. Shi[1], C. M. Damcott[1], Y. C. Chang[1], B. D. Mitchell[1], A. R. Shuldiner[1,2], N. I. Steinle[1]* 1) Dept Medicine, Univ Maryland, Baltimore, MD; 2) Geriatrics Research and Education Clinical Center, Veterans Administration Hospital Medical Center, Baltimore, MD.

We previously detected strong evidence for linkage of a QTL influencing variation in blood pressure (BP) to a region on chromosome 2q in the Old Order Amish (DBP LOD=3.36; p=0.00004). Peak evidence for linkage occurred between chr2:181,883,021 and 220,376,982 (dbSNP build 126). Linkage of BP to this same region has also been reported in the Framingham Heart Study. To fine map this region, we genotyped 3,052 tag SNPs in 846 Amish subjects for association testing. These SNPs covered 58.5% of the common variation (MAF0.05, r20.8) in this region in Caucasians based on the most recent HapMap data. A total of 2,831 SNPs passed QC and were analyzed. The most strongly associated SNPs (p<0.0005) were in *SLC4A3* (rs684428, synonymous), an anion exchanger, and *ABCA12* (rs10498030, synonymous), an ATP-binding cassette. The coverage of common variations in *SLC4A3* and *ABCA12* were 66.7% and 60.4% respectively. We repeated the original linkage analysis by adding the *ABCA12* SNP genotype as a covariate and found that the magnitude of the lod score was reduced, with this SNP accounting for 24% of the original DBP linkage. None of other top DBP associated SNPs (0.0005p<0.005), including the *SLC4A3* SNP, resulted in a reduction of linkage as great as the *ABCA12* SNP, suggesting that rs10498030 partially explained the DBP linkage to 2q in the Amish. We conclude that more than one gene in this region may be responsible for the original linkage signal and that further studies of common variation as well as rare variants and copy number variants in *ABCA12* and across the region are warranted to identify the causative variants.

Small-molecule screening as a novel strategy for developing therapeutics for Gaucher disease. *O. Motabar[1], D. Urban[1], O. Goker-Alpan[1], W. Zheng[2], J. Inglese[2], C. Austin[2], E. Sidransky[1], E. Goldin[1]* 1) Section on Molecular Neurogenetics, Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Chemical Genomics Center, NHGRI, NIH, Bethesda, MD.

Gaucher disease is caused by mutations in the gene encoding the lysosomal enzyme glucocerebrosidase (GBA). Most GBA mutations result in a defective protein, impaired in stability, intracellular transport efficiency or activity. The identification of small molecules with therapeutic potential that are amenable to chemical optimization may provide simple, more effective and less expensive therapy for patients with Gaucher disease Small molecules may act either by activating the enzyme or by serving as pharmacological chaperones. We initially identified new leads for treatment of Gaucher disease by screening chemical libraries assembled by the NIH Chemical Genomics Center using wildtype glucocerebrosidase (GC). A quantitative high-throughput screening assay was used to screen a collection of 62,000 compounds, identifying three different structural classes that inhibited GC at nanomolar concentrations. Representatives of these compounds were found to be effective in cell culture models. It was decided to also screen mutant GC, using preparations from patient tissue samples. In these tissue samples, the pH optimum was approximately 5.0 for both wild-type and mutant tissue samples, while the Vmax was lower for the mutant enzyme than for the wild-type. An N370S homozygote with sufficient activity was selected for the compound screen. This study will enable us to pinpoint the functional units in the protein and to design potent drugs for patients with Gaucher disease.

The functional consequences of genetic variation on *tyrosine hydroxylase* (*TH*) expression. *L. R. Warner*[1,2], *C. C. Babbitt*[1], *A. E. Primus*[1], *G. A. Wray*[1,3] 1) Institute for Genome Sciences & Policy, Duke University, Durham, NC; 2) Developmental Biology Program, Duke University, Durham, NC; 3) Department of Biology, Duke University, Durham, NC.

Tyrosine hydroxylase (TH) is the rate-limiting enzyme in catecholamine synthesis and variations in the promoter region of *TH* have been implicated in disease states. However, the impact of variation in *cis* between humans and other primates, as well as within humans, is not well understood. Our study investigated naturally occurring haplotypes in *Homo sapiens*, *Pan troglodytes*, *Gorilla gorilla*, and *Macaca mulatta*. We used a dual luciferase reporter system in two neuroblastoma cell lines to assay differences in expression level based on sequence differences within the 2 kb region upstream of the *TH* translation start site. We observed several significant differences in expression between haplotypes from primate species, but the most striking difference was observed between human haplotypes. We identified two SNPs in humans that regulate the expression of *TH* in a specific cellular environment. Transcription factor binding algorithms predict an allele specific change in transcription factor binding at the two SNPs sites. Using a site-directed mutagenesis approach on the two SNPs of interest we have obtained informative results regarding the genetic basis of TH functionality. In sum, *TH* expression within humans is modulated by *cis*-regulatory sequence variants, highlighting the functional importance of natural genetic variation in *cis*.

A high density mapping study identifies association to the SLAM locus in SLE. *P. Goyette[1], D. S. Cunninghame Graham[2], T. J. Vyse[2], P. R. Fortin[3], A. Sharpe[4], C. Terhorst[5], J. Wither[6], Canios. GenES Investigators[4], J. D. Rioux[1]* 1) University of Montreal and Montreal Heart Inst, Montreal, Canada; 2) Molecular Genetics and Rheumatology, Imperial College Faculty of Medicine, London, UK; 3) University of Toronto Lupus Clinic, Centre for Prognosis Studies in the Rheumatic Diseases, Toronto Western Hospital, University Health Network; Department of Medicine, University of Toronto, Canada; 4) Harvard Medical School, Pathology, NRB-837, Boston, USA; 5) Division of Immunology, BIDMC, Harvard Institute of Medicine, Boston, USA; 6) Arthritis Centre of Excellence; Division of Genetics and Development, Toronto Western Hospital Research Institute, University Health Network; Departments of Medicine and Immunology, University of Toronto, Canada.

Systemic lupus erythematosus (SLE) is a complex disease trait of unknown aetiology. Genome-wide linkage studies in SLE have identified several linkage regions, including 1q23, which contains the signalling lymphocyte activation molecule (SLAM) locus. In mice there is a syntenic linkage region, Sle1. The SLAM genes are functionally related cell-surface receptors, which regulate signal transduction in immune cells. A recent association study in UK/Canadian SLE families identified the SLAMF7-LY9 region as contributing to SLE susceptibility. The strongest association, rs509479, resulted in a M602V amino acid change in LY9 which has potential functional consequences. We undertook a high density association study including 272 SNPs capturing the genetic variation at the SLAM locus as well as missense polymorphisms in SLAM genes. The analysis was performed in 671 UK cases, and initial results reveal two areas of SLE associations at the SLAM locus: the SLAMF6-VANGL2 region and the previously reported LY9-SLAMF7 region. We are currently performing an independent replication study using a cohort of 270 Canadian trios, collected through the GenES/CaNIOS Consortium. If the association to this region is confirmed these results, in combination with the discoveries from genome-wide association studies (GWAS), will provide additional evidence that genetic variation in genes with key functions in adaptive immunity are involved in the pathogenesis of SLE.

Genetic and functional studies of mutations in PPP1R3F, a novel PP1 regulatory subunit, in X-linked mental retardation. *J. Wang[1], F. Abidi[2], A. Hackett[3], A. Adamczyk[1], C. Skinner[2], K. Holden[2], F. L. Raymond[4], P. Tarpey[5], M. Stratton[5], J. Gecz[6], R. Stevenson[2], C. Schwartz[2], T. Wang[1]* 1) Johns Hopkins University, Baltimore, MD; 2) Greenwood Genetic Center, Greenwood, SC; 3) University of Newcastle, NSW, AU; 4) University of Cambridge, UK; 5) Wellcome Trust Sanger Institute, UK; 6) University of Adelaide, Adelaide, AU.

Mental retardation (MR) is a common cause of severe handicap in children and young adults affecting 2-3% of the general population. Genetic causes for mental retardation are heterogeneous involving many cellular pathways and processes. Phosphorylation of key synaptic proteins is essential for the induction and maintenance of LTP and LTD, two cellular models of learning and memory. Protein phosphatase 1 (PP1) plays an important role in the regulation of protein phosphorylation in neurons. PP1 activity and specificity are determined by numerous interacting regulatory subunits. Using a combination of cDNA microarray and candidate gene approach, we identified PPP1R3F, a putative PP1 regulatory subunit, as a candidate gene for X-linked mental retardation (XLMR). We conducted a mutation survey in a cohort of male probands (~400) and identified four synonymous and six nonsynonymous coding variants (nsCV). Four nsCV involve highly conserved residues in predicted functional domains, segregate with MR phenotype, and are absent in 500 normal males. On Northern blot, PPP1R3F showed abundant transcripts in brain, fetal brain, testis, and skeletal muscle. Using coimmunoprecipitation (CoIP) and a yeast two-hybrid (Y2H) assay, we detected strong interaction of PPP1R3F with both PP1-CA and PP1-CC subunits, confirming that PPP1R3F is a novel PP1-interacting protein. On immunoblot, these mutations generate stable protein in transfected HEK293 cells. In preliminary CoIP studies, at least two mutants showed a reduced interaction with PP1-CA, which are being replicated using Y2H assay. Results suggest that PPP1R3F mutants have a causative role in cognitive impairment in patients with XLMR. Further studies of these mutants will help to understand the role of PPP1R3F in the modulation of PP1 activity and in cognitive development and function in humans.

***CSMD1* Genetic Variation and Human Dextrality: Whole Genome Association Results.** *T. Lencz[1,2,3], P. DeRosse[1,2], K. E. Burdick[1,2,3], J. M. Kane[1,2,3], A. K. Malhotra[1,2,3]* 1) Center for Translational Psychiatry, Feinstein Institute for Medical Research, Manhasset, NY; 2) Dept Psychiatry Research, Zucker Hillside Hosp, Glen Oaks, NY; 3) Dept. of Psychiatry & Behavioral Sciences, Albert Einstein College of Medicine, Bronx, NY.

Background - Left-handedness (or, more broadly, nondextrality) is a moderately heritable trait that has been associated with increased risk for several psychiatric, neurologic, and learning disorders. As such, nondextrality may represent an easily assessed phenotype reflecting neurodevelopmental processes related to cerebral asymmetries. To date, however, only a single candidate gene study for handedness has been reported, and a small number of linkage studies have yielded equivocal results. The present genomewide association study provides a hypothesis-free method to examine the genetic underpinnings of nondextrality.

Methods - Handedness was assessed using the Edinburgh Handedness Inventory in 396 Caucasian individuals as part of a case-control study of schizophrenia at the Zucker Hillside Hospital. Sixty-four subjects (16%) were nondextral (laterality score <0.70). Genotyping was performed using the Affymetrix 500K microarray; QC yielded ~325K high-quality, common (MAF0.05) autosomal SNPs. The significance threshold for chi-square tests was defined a priori as p<4.2*10-7.

Results - One SNP (rs4639542) was significantly associated with nondextrality under additive, recessive, and allelic models. This SNP lies within an intron in *CSMD1*, the third largest gene in the human genome. The minor (C) allele demonstrated an odds ratio of 2.86 (95% CI=1.92-4.27) for nondextrality; CC homozygosity yielded 7-fold increase in risk. Results were consistent irrespective of subject sex or diagnosis.

Conclusions - *CSMD1* is a complement regulatory gene on chromosome 8p23.2 and is highly expressed in the brain. As such, this gene is a plausible neurodevelopmental candidate, and may also provide explanation of the previously reported association of left-handedness and autoimmune disorders.

MDB: A multicentric web-based database to study human malformative phenome. *JC. Fournet[1,2], F. Arbabzadeh[1,2], P. Sawicki[1], D. Bouron-Dal Soglio[1], H. Kabbara[2], E. Lemyre[3], LL. Oligny[1]* 1) Department of Pathology, Sainte-Justine Hospital, Montreal, QC, Canada; 2) Research Center, Sainte-Justine Hospital, Montreal, QC, Canada; 3) Genetics, Department of Pediatrics, Sainte-Justine Hospital, Montreal, QC, Canada.

Human developmental anomalies are still poorly described by a open free-access web-based database. Our purpose was to construct a user-friendly database dedicated to human developmental anomalies in order to describe statistically malformative combinations (sequences, associations, complexes, syndromes, diseases). We constructed a MySQL database describing the different entities involved in malformative pathology (called MDB for Malformation DataBase): developmental anomalies, malformative sequences, malformative associations, malformative syndromes, malformative diseases, chromosomal anomalies, malformation genes. We built an ontology of human developmental anomalies according to the OBO consortium (Open Biomedical Ontologies at http://www.obo.org). In a pilot series, we entered 200 cases of foetus with malformation from the autopsy series of the Department of Pathology of Sainte-Justine Hospital (Montreal, QC, Canada) observed from 2001 to 2007. The MDB Malformation DataBase website can be accessed at URL http://www.malformations.org. This pilot series permitted us to validate the structures and functions of our database. It permits to easily generate statistical data as frequencies of developmental anomalies by organs, by syndromes or by diseases. For malformative combinations, the database will permit us to study and quantify aggregations of developmental anomalies in malformative combinations and to give them a graphic representation (data visualization). It will permit to classify observed foetus and malformative syndromes according to a phenotypic clustering graph. We now want to associated other centers in foetopathology to perform a statistical study of 1000 foetus with developmental anomalies (For you want to participate to this study, you can contact us at join@malformations.org).

Cognitive endophenotypes to genetically dissect Alzheimer disease. *S. Barral[1], J. H. Lee[1], R. Cheng[1], V. Santana[1], J. Williamson[1], R. Lantigua[1], M. Medrano[2], I. Jimenez[3], E. Rogaeva[4], Y. Stern[1], P. George-Hyslop[4], R. Mayeux[1]* 1) Taub Institute & Sergievsky Ctr,Columbia Univ,New York, NY 10032; 2) Univ Tecnol de Santiago, Santiago, DR; 3) Department of Internal Medicine, Univ of Puerto, San Juan, PR; 4) Ctr for Research in Neurodegenerative Diseases, Univ of Toronto, Toronto, Canada.

Alzheimer Disease (AD) diagnosis relies on the assessment of memory performance and other cognitive functions. We and others showed that memory, a strong AD predictor, is highly heritable, and therefore may be used as endophenotype to genetically dissect AD. We propose that there might be distinct pathways involving distinct genetic factors: 1) those associated with early memory decline that eventually lead to AD; 2) those associated with memory decline, but do not lead to AD; 3) those associated with AD without significant cognitive decline. We examined 3 regions: two of them, 3q28 and 5p15, were previously reported in our genome-scans as strong associated with AD. The third region, 2q24, represents a more modest AD signal. We studied verbal memory (total recall, delayed recall and recognition) in 1068 subjects from 210 Hispanic families. We performed 2-point variance component analysis adjusting for age, sex and education. We also created composite cognitive index (CCI) -- a weighted combination of total recall, delayed recognition, and education which predicts individuals AD risk -- to further investigate 2q24. LODs of 3.1 and 1.9 were observed for AD at 3q28 and 5p15, respectively. A modest LOD of 0.53 was found in 2q24. For total recall, delayed recall and recognition, LODs were 2.2, 1.7 and 2.4 for 3q28; 1.3, 0.9 and 7.9 for 5p15. LODs in 2q24 region were <1. However, we found a LOD of 1.45 for CCI, which increases to 2.43 when restricted to unaffecteds. The results suggest that paths may differ at these 3 loci. Results in 5p15 and 2q24 imply that genetic factors may influence memory and CCI directly but not AD, since the results became stronger after removing AD subjects. 3q28 might harbor AD genes that are not associated with significant memory decline. Here we have shown that memory and related traits can be used to dissect AD.

Precise identification of a supernumerary chromosome by high density microarray. *I. GADI[1], M. HORNER[2], D. DAY-SALVATORE[2], J. TEPPERBERG[1], V. JASWANEY[1], P. PAPENHAUSEN[1]* 1) CYTOGENETICS, LABORATORY CORPORATION OF AMERICA, RTP, NC; 2) INSTITUTE FOR GENETIC MEDICIANE, ST. PETERS'S UNIVERSITY HOSPITAL, 254 EASTON AVENUE,NJ 08903-0591.

An eight year old adopted female with global developmental delay, mental retardation, dysmorphia and hyperactivity was referred for whole chromosome SNP microarray analysis. A previous cytogenetic and FISH analysis had revealed a supernumerary chromosome derived from chromosome 9 detected through whole chromosome paint probes. However, additional FISH for the pericentromeric region of chromosome 9 was negative. A high resolution whole genome microarray (Affymetrix Inc.) based analysis of 1.8 million SNP/copy number probes confirmed a gain of the chromosome 9 short arm, although the three copy dosage did not extend into the centromeric region of 9p. The SNP array also revealed a significant gain of the chromosome 13 proximal long arm. A 36.2 Mb gain of 9p21.3-->9pter included the linear base pair position extending from 263651 to 20,502,190 Mb was evident from the SNP array results. A chromosome 13 gain of 3.273 Mb included the linear base pair position 17,943,628-->21,216,442 of 13q11 to 13q12.11. These results indicate that the reported supernumerary chromosome is composed of 9p and a smaller, apparent centromeric portion of proximal 13q. The chromosome microarray and FISH results are consistent with a supernumerary derivative chromosome 13 [der(13)t(9;13)(p11;q12)] which has most likely resulted from a 3:1 meiotic segregation of a balanced parental translocation involving chromosomes 9 and 13. Unfortunately biological parents of this adopted child were not available for additional studies. High-resolution SNP microarray can be utilized for rapid and precise resolution of marker chromosome composition that can accurately define genomic imbalance necessary for genotype-phenotype correlation.

Polymorphisms of iron-related genes and childhood leukemia risk. *C. Davis, T. Do, M. T. Dorak* Genomic Immunoepidemiology, HUMIGEN LLC, the Institute for Genetic Immunology, 2439 Kuser Road, Hamilton, NJ 08690.

Hemochromatosis gene (HFE) variants that increase body iron levels also increase the risk for childhood acute lymphoblastic leukemia (ALL). We extended the original HFE association study in 114 cases with childhood ALL and 414 newborn controls from Wales (UK) to 20 SNPs in iron-related genes (IRG): HFE2 (hemojuvelin), HFE4 (ferroportin), TF (transferrin), TFRC (transferrin receptor), HAMP (hepcidin), homolog genes HEPH (hephaestin) and CP (ceruloplasmin), HMOX1 (heme oxygenase1) and BMP2 (bone morphogenetic protein 2) as well as 13 SNPs in HFE and its flanking regions. Univariate analysis showed a strong protective association with HFE flanking region SNP rs807212 (OR=0.32; P<0.0001 in males) which accounted for the original male-specific C282Y association. There were other protective associations in males (TF rs1049296 and rs4481157), in females (HMOX1 rs2071748) and with no sex-specificity (HFE2 rs4970862) with marginal statistical significance. While univariate associations were weak, their additive effect (P for gene-dosage effect <0.0001 in boys) and interactions were strong. HAMP and HEPH/CP interacted with TFRC with sex effect, and HFE2 interacted with BMP2 and HFE4. BMP2 and HFE2 are both involved in an iron sensing pathway and statistical interactions observed corresponded to biologic interactions among these molecules and HFE. The combination of HFE2 rs4970862, HFE4 rs2304704 and BMP2 rs235756 conferred risk (OR=3.7; P=0.02) in girls, but the same association was non-significant in boys (OR=2.4, P=0.15). We previously reported the interactions between HFE and TFRC increasing birth weight in males which would confer slight protection from genotoxic effects of excess iron. Overall, iron-related genes modify childhood leukemia risk possibly due to their effect on placental iron transport. Our interpretation is that greater iron transport to the fetus would increase the risk for leukemia in girls, whereas boys would be less affected owing to their ability to increase cell proliferation rate to reduce excess iron. Boys would therefore only be at risk at extreme iron excess which would also lead to excessive birth weight.

Acute Intermittent Porphyria: Development of AAV2/8 Gene Therapy. *L. Gan*[*1], *M. Yasuda*[*1], *D. F. Bishop*[1], *R. J. Ziegler*[2], *S. H. Cheng*[2], *R. J. Desnick*[1] 1) Genetics and Genomic Sciences, Mount Sinai Sch Medicine, New York, NY; 2) Genzyme Corporation, Framingham, MA.

Acute Intermittent Porphyria (AIP) is an autosomal dominant inborn error of heme biosynthesis due to the half-normal activity of hydroxymethylbilane synthase (HMBS). The most common hepatic porphyria is manifested by life-threatening, acute neurological attacks precipitated by various drugs, fasting, alcohol, and hormonal changes. Current therapy for acute attacks involves intravenous infusion of hematin, which can be venotoxic and is short-lived. Thus, development of a preventative therapy is desirable, especially for patients with frequent attacks. To design an adeno-associated viral (AAV) vector with optimal transgene expression, four unique combinations of liver-specific enhancers and promoters were evaluated for hepatic transgene expression by transient transfection of HepG2 cells and hydrodynamic delivery in mice. The 1-microglobulin enhancer/1-antityrpsin promoter combination achieved the highest transgene expression *in vitro* and *in vivo* (*Yasuda et al., J Gene Med 9:806, 2007*). These regulatory elements were used to generate a recombinant AAV8-based serotype vector encoding murine HMBS (rAAV2/8-HMBS), and AIP mice (*Lindberg et al., Nat Genet 12:195, 1996*) were used to assess the efficacy of AAV-mediated therapy. Intraperitoneal injection of rAAV2/8-HMBS showed a time- and dose-dependent increase of HMBS, most marked in the liver. Notably, administration of 7.6×10^{11} particles - the highest dosage tested - achieved a 1.5-2 fold increase of hepatic HMBS over wildtype that was sustained for 8 weeks. Treated mice were resistant to the characteristic accumulation of porphyrin precursors when induced by serial phenobarbitol injections, indicating that the expressed enzyme was functional *in vivo*. These studies demonstrated that AAV-mediated gene therapy can correct the biochemical defect in AIP mice, and thus, may be a promising preventative therapy for patients with recurrent acute attacks. Further studies are currently underway to evaluate the safety and long-term efficacy of AAV-mediated gene therapy for AIP. (*equal authors).

Common variants in *STK39* are associated with blood pressure levels. *Y. Chang[1], Y. Wang[1], J. O'Connell[1], P. McArdle[1], J. Wade[2], S. Dorff[1], S. Shah[3], X. Shi[1], L. Pan[4], E. Rampersaud[1], H. Shen[1], J. Kim[5], A. Subramanya[2], N. Steinle[1], P. Welling[2], C. Ober[4], A. Weder[6], A. Chakravarti[7], B. Mitchell[1], A. Shuldiner[1]* 1) Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD; 2) Department of Physiology, University of Maryland School of Medicine, Baltimore, MD; 3) Section of Cardiology, Department of Medicine, University of Chicago, Chicago, IL; 4) Department of Human Genetics, University of Chicago, Chicago, IL; 5) Georgetown University School of Medicine, Washington, DC; 6) Department of Internal Medicine, University of Michigan School of Medicine, Ann Arbor, MI; 7) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Hypertension places a major burden on individual and public health, but the genetic basis of this complex disorder is poorly understood. We conducted a genome-wide association study of systolic and diastolic blood pressure (SBP/DBP) in Amish subjects and found strong association signals with common variants in a serine/threonine kinase, *STK39*. We confirmed this association in an independent Amish and 4 non-Amish Caucasian samples including the Diabetes Genetics Initiative, Framingham Heart Study, GenNet, and Hutterites (combined N=7,125, $P<10^{-6}$). The higher BP-associated alleles have frequencies > 0.09 and were associated with increases of 3.3 and 1.3 mmHg in SBP/DBP, respectively, in Amish subjects and with smaller but consistent effects across the non-Amish studies. *In vitro*, STK39 is known to interact with WNK kinases and cation-chloride cotransporters, mutations in which cause monogenic forms of BP dysregulation. We demonstrate that *in vivo*, *STK39* is expressed in the distal nephron, where it may interact with these proteins. While none of the associated SNPs alter protein structure, we identified and experimentally confirmed a conserved intronic element with allele-specific *in vitro* transcription activity as a functional candidate for this association. Hence variants in *STK39* may influence BP by increasing STK39 expression and altering renal Na^+ excretion, thus unifying rare and common BP-regulating alleles in the same physiologic pathway.

Factors affecting the risk of early menopause in carriers of *FMR1* premutations. *A. Murray[1], C. E. Bennett[1], P. A. Jacobs[2], J. N. Macpherson[2]* 1) Peninsula Medical School, University of Exeter, Exeter, United Kingdom, EX1 2LU; 2) Wessex Regional Genetics, Salisbury District Hospital, Salisbury, Wilts, UK SP2 8BJ.

The *FMR1* gene contains a polymorphic CGG repeat in exon 1 which has been associated with three phenotypes; Fragile X Syndrome (FXS), Fragile X Tremor and Ataxia Syndrome (FXTAS) and Premature Ovarian Failure (POF). FXS is caused by inactivation of *FMR1*, usually by methylation of the gene as a result of expansion of the CGG to over 200 copies. FXTAS and POF are both associated with unmethylated, premutation sized repeats and are thought to be caused by an RNA gain-of-function mechanism. We have investigated the role of the CGG repeat in ovarian failure in over 500 women ascertained because of ovarian failure and nearly 400 women from fragile X families. Contrary to published data and in a larger study population, we do not find an association with large normal or intermediate sized repeats (35-55 CGG) and POF, in 351 cases compared to 1564 controls (p=0.55). In premutation carriers POF was more likely in women who had a repeat of between 80 and 100 CGGs, no AGG interruptions, and a FRAXE GCC repeat allele below the population mean.

Endometrial cancer and somatic G>T *KRAS* transversion in patients with constitutional *MUTYH* biallelic mutations. *M. Genuardi[1], B. Ciambotti[1], P. Bet[2], B. Gatteschi[3], V. Gismondi[2], B. Toschi[1], L. Varesco[2], R. Tricarico[1]* 1) Dept. Clinical Pathophysiology, Medical Genetics, Univ Florence, Florence, Italy; 2) National Cancer Institute, Hereditary Tumour Unit, Genoa, Italy; 3) National Cancer Institute, Pathology Unit, Genoa, Italy.

MUTYH-associated polyposis (MAP) is an autosomal recessive condition predisposing to colorectal cancer, caused by inherited defects in the base excision repair gene *MUTYH*. Colorectal tumours from biallelic *MUTYH* mutation carriers display an excess of somatic G>T mutations in the *APC* and *KRAS* genes due to defective BER function. To date, few extracolonic manifestations have been observed in MAP patients, and the clinical spectrum of this condition is not yet fully established. Recently, one patient with a diagnosis of endometrial cancer and biallelic *MUTYH* germline mutations has been described. However, it is not yet clear if *MUTYH* mutations increase the risk of endometrial tumours. We here report on two unrelated MAP patients with biallelic *MUTYH* germline mutations who developed endometrial carcinoma. The endometrial tumours were evaluated for *PTEN*, *PIK3CA*, *KRAS*, *BRAF* and *CTNNB1* mutations. A G>T transversion at codon 12 of the *KRAS* gene was observed in one tumour. A single 1bp frameshift deletion of *PTEN* was observed in the same sample. Overall, these findings provide additional evidence for the inclusion of endometrial carcinoma among the phenotypic manifestations of MAP. In addition, they indicate that MAP should be considered as a differential diagnosis with Lynch syndrome for patients with colorectal and endometrial tumours.

Participants' attitudes towards Biobank Japan. *K. Muto[1], C. Chiungfang[1], S. Suzuki[2], I. Kobayashi[2], Y. Nakamura[1]*
1) Dept Public Policy, IMS, University of Tokyo, Tokyo, Japan; 2) Shonan Kamakura Hospital, Kanagawa, Japan.

[Purpose and Method] Biobank Japan is the largest sample bank donated by 200,000 Japanese patients with various diseases. Paticipants are asked to donate serums and clinical information once a year since 2003 other than DNA. To evaluate our quality of consent process and exlore participants' motivation to keep participating, we've been conducting a questionnaire survey since 2007.[Subjects] Patients of one hospital in the suburbs of Tokyo were asked to respond our questionnaires at their regular visits for donation. [Results] 459 participants responded (M:F=1:0.73, RR=70.). 80% of them responded that they would keep participating and 65% didn't feel any burden for donation. However, 39% had already fogotten what they were informed when they gave consent to participate.[Discussions] The initial consent process was not enough to keep participants remember the purpose of the research project and why they were asked to donate. We need to make efforts to seek better communication between participants and scientists.

A novel approach for obtaining confidence sets of SNPs regulating quantitative phenotypes. *C. Papachristou*[1], *S. Lin*[2] 1) Math/Phys/Stat, University of the Sciences in Philadelphia, Philadelphia, PA; 2) Statistics, The Ohio State University, Columbus, OH.

As the genetic maps become highly dense, the desire to sufficiently localize putative disease loci has become an achievable goal. This has prompted an increased interest in methods for constructing confidence intervals for the location of trait contributing genes. Such intervals are very important since, by reducing the number of candidate genes, they can help us design cost-effective and time-efficient follow-up studies. We introduce a new approach that can be used in whole genome scans to obtain a confidence set of quantitative trait loci (QTLs) contributing at least a predetermined percentage *h* to the overall genetic variation of a quantitative phenotype. The method is developed in the framework of the generalized linear mixed models and can accommodate families of arbitrary size and structure. Specifically, we assume the availability of a dense SNP map consisting of *S* markers and for each SNP *s, s=1,..., S*, we test the following hypotheses: $H_{0s}: {}^2_{G_s} h^2_{G_T}$ *vs.* $H_{0s}: {}^2_{G_s} h^2_{G_T}$, where $^2_{G_s}$ is the genetic variance attributed to SNP s, $^2_{G_T}$ is the total genetic variance of the quantitative phenotype, and *h* is a number between zero and one chosen in advance. Obviously, the set of markers for which the above null hypothesis is not rejected at level constitutes an *(1-)×100%* confidence set of loci contributing at least *h×100%* percent of the total genetic variance of the phenotype. Implementation of the method needs knowledge of the total genetic variance of the trait which can be readily estimated, usually with good accuracy, from the data themselves. Our simulation results under various genetic models and different levels of relevant factors, such as family structure and size, confirm that our method provides confidence sets that maintain the nominal coverage. Furthermore, with just 250 nuclear families with two offspring, our method was able to place the causative SNP in a set of at most 3 SNPs, even when the QTL contributed as little as 10% to the total phenotypic genetic variance, while at the same time it held the false positive rate below acceptable levels.

Abnormal karyotype acute myeloid leukemia (AML) occurring after normal karyotype AML represents therapy-induced secondary disease: an array CGH analysis. *S. Sait[1], G. Deeb[2], D. Gaile[3], L. Sheperd[3], S. Lui[3], P. Starostik[2], L. A. Ford[4], M. Wetzler[4], J. Conroy[5], N. Nowak[5], E. S. Wang[4]* 1) Clinical Cytogenetics Lab; 2) Department of Pathology and Laboratory Medicine; 3) Department of Biostatistics; 4) Leukemia Service, Department of Medicine; 5) Microarray Facility, Department of Cancer Prevention and Control, Roswell Park Cancer Institute, Buffalo,NY.

Although karyotype instability (defined as the acquisition of further aberrations in addition to those present at diagnosis) has been reported to occur in up 10-30% AML patients with normal primary diagnostic karyotype, the etiology and clinical significance of these abnormalities is uncertain. While possible that cryptic chromosomal aberrations were present at diagnosis but not detected by standard cytogenetic methods due to dilutional effects; alternatively, these abnormal karyotype AMLs may represent secondary leukemias resulting from intensive chemotherapy regimens. We examined 26 de novo normal karyotype (NK) AML patients at diagnosis found to have abnormal karyotype (AK) AML at relapse/disease persistence. Ten cases were FAB-M2, seven were FAB-M1, six FAB-M4, two FAB-M5a, and one FAB-M0. Median age was 64 years; gender was evenly split. Chromosomal abnormalities included unbalanced and balanced structural rearrangements, complex karyotypes, and numerical changes. Rearrangements did not include commonly reported abnormalities, except for one patient with trisomy 8. Aberrations commonly associated with secondary AML i.e. -5/5q-, -7/7q- and 11q23 abnormalities were observed in two patients with -7/7q-. High-resolution array-based comparative genomic hybridization (aCGH) revealed no copy number aberrations in 11/12 NK/AK diagnostic patient samples examined but confirmed the presence of multiple abnormalities in 2/2 NK/AK relapsed patient samples, consistent with conventional cytogenetic results. Our data suggest that the majority of cases of karyotypically abnormal AML following a diagnosis of normal karyotype AML represent secondary leukemic disease resulting from therapy-induced DNA damage rather than clonal dilutional effects of the original AML clone.

Risk for Autism is Increased With Advanced Parental Age and Education in an Iranian Population Sample. *R. Sasanfar[1,2,4], S. Haddad[1], A. Tolouei[3], M. Ghadami[4], S. L. Santangelo[1,2,5]* 1) Psychiatric and Neurodevelopmental Genetics Unit, Center for Human Genetic Research, Massachusetts General Hosp, Boston, MA, USA; 2) Dept. Psychiatry, Harvard Medical School, Boston, MA, USA; 3) Diagnosis and Prevention, Special Education Organization, Tehran, Iran; 4) Ministry of Education, Special Education Organization, Tehran, Iran; 5) Dept. Epidemiology, Harvard School of Public Health, Boston, MA, USA.

The etiology of idiopathic autism is still unclear and despite its strong heritability, few susceptibility genes have been identified. Evidence from several epidemiological studies has implicated parental age as a risk factor for autism. Recently implemented population screening for autism in Iran allowed for a large-scale epidemiological study to investigate the effect of parental age on risk for autism spectrum disorders (ASD) in an Iranian population sample consisting of 179 ASD cases and 549,354 cohort comparison children, aged 5-12. ASD diagnoses were made by DSM-IV criteria and standard diagnostic instruments. Analyses used logistic regression, adjusting for maternal age, parental education, birth order, consanguinity, and sex. We found a ~2-fold increased risk for ASD with increasing paternal age over 36 years. Compared with fathers in the age range 26-30, the odds ratio for fathers aged 36-40 was 1.99 (95% CI: 1.24, 3.21) while the OR for fathers > 40 years was 1.83 (95% CI: 1.02, 3.30). Maternal age > 26 years showed a more striking 4-fold increased risk for autism in a matched case-control analysis (OR: 4.1, 95% CI: 1.35, 12.93). Risk for ASD was also increased for a combination of higher parental age and education. Compared to young, uneducated parents, older parents with a college degree or graduate school had a ~5-fold risk of having a child with ASD (95% CI: 2.29, 11.15), with a clear dose-response relationship. Results from this study may be explained by an increased likelihood of DNA damage and/or improperly imprinted genes being transmitted by older parents. However, we cannot rule out the possibility that the apparent increase in risk with higher education may be due to greater health-care seeking behaviors in more educated parents.

A 15 Year Review of A Pediatric Down Syndrome (DS) Clinic. *M. Carlin, J. Spahis* UT Southwestern Medical School/Children's Medical Center, Dallas, Texas.

In 1993, the Center initiated a weekly clinic for pediatric patients with DS from birth to 18 yrs.. There have been 1923 new patients seen during 2523 visits through March, 2008; 815 patients were <12 mos. at first visit. A multidisciplinary team of professionals from genetics, nursing, PT, speech, social work and a parent from the local support group provide care as recommended in *Preventative Health Care for Children with Genetic Conditions*, Wilson, GN & Cooley, WC: 2nd ed., Cambridge University Press, 2006. Data have been collected from families and health records and entered into a Microsoft Access 2002 database. Ethnic background is: Caucasian 44%, Hispanic 44%, African 8%, Asian 3%, Other 1%. Karyotypes indicate 96% with non-disjunction trisomy 21, 3% translocations and 1% mosaicism. Common findings noted during the first year include: neonatal jaundice in 328(40%), thrombocytopenia 17(2%), congenital heart defect(s) 440(54%), GE reflux 276(34%), GI anomalies 118(14%) and congenital hypothyroidism 19(2%). Initial c-spine screens were obtained on 682 at 3 yrs. of age. Of those, 65(10%) showed instability. Other important findings across all ages are: recurrent respiratory infections 711(37%), PE tubes 684(36%), strabismus 385(20%), constipation 251(13%) and leukemia 9(<1%). Periodic screening detected acquired hypothyroidism in 82 patients.

Clinic impact is reflected in the improved preventative management for patients with DS in the community. Fewer children required thyroid and c-spine screening in 2007 (35% thyroid; 16% c-spine) than in 1993 (43% thyroid; 25% c-spine). A similar drop occurred in referrals for early intervention (10% in 1993; 4% in 2007). Interestingly, of the 35 patients with c-spine instability who were re-studied 1 yr. later, 22(63%) had normal films. Additionally, parents have expressed appreciation for advice and support from other parents during clinic visits.

Common variants in MTNR1B (melatonin receptor 1B) influence fasting glucose and type 2 diabetes risk. *C. Langenberg[1], I. Prokopenko[2,3], J. Florez[4,5,6], R. Saxena[4,7], G. Thorleifsson[8], N. Soranzo[9,10] for MAGIC* 1) MRC Epidemiology Unit, Cambridge, UK; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, UK; 3) Wellcome Trust Centre for Human Genetics, Oxford, UK; 4) Broad Institute of Harvard and MIT, Cambridge, MA; 5) Department of Medicine, Harvard Medical School, Boston, MA; 6) Center for Human Genetic Research and Diabetes Unit, Massachusetts General Hospital, Boston, MA; 7) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 8) deCODE genetics, Reykjavík, Iceland; 9) Wellcome Trust Sanger Institute, Hinxton, UK; 10) Twin Research and Genetic Epidemiology Department, King's College London, London, UK.

Fasting glucose (FG) levels usually are tightly regulated within a narrow physiologic range, and disruption of normal glucose homeostasis and elevation of FG are hallmarks of insulin resistance and type 2 diabetes (T2D). To identify novel loci that impact on FG we established MAGIC (Meta-Analyses of Glucose and Insulin-related traits Consortium), a collaborative effort of 10 individual studies represented by four consortia: ENGAGE (deCODE, NFBC66, NTR/NESDA, Rotterdam Study), GEM (CoLaus, TwinsUK), DFS (DGI, FUSION, SardiNIA) and the Framingham Heart Study. We initially exchanged the identities of 10-20 SNPs most prominently associated with FG from GWA scans in each study. All four groups (n=6,828-12,390) independently identified strong evidence for association at MTNR1B (melatonin receptor 1B), confirmed by meta-analysis of the 1Mb region flanking the gene (n=36,610; 381 SNPs). The risk allele of the SNP most strongly related to higher FG levels (per allele increase in FG 0.07 mmol/L [95% CI: 0.06-0.08]; $P=1.1x10^{-41}$) also showed evidence of association with HOMA-B ($P=1.0 \times 10^{-15}$), as well as an increased risk of T2D (per allele odds ratio = 1.12 [95% CI: 1.07-1.18]; $P=5.2 \times 10^{-6}$) in a meta-analysis of six case-control studies totalling 7,625 cases and 45,419 controls. In addition, we confirm the previously reported associations of variants at the G6PC2 ($P=7.1 \times 10^{-49}$) and GCK ($P=4.8 \times 10^{-20}$) loci and FG levels. We conclude that MTNR1B is a novel candidate gene involved in FG regulation and T2D risk.

Investigation of rare and common variants in resequencing data from 313 patients with dilated cardiomyopathy.

R. E. Hershberger[1], E. Rampersaud[2], K. Hamilton[2], S. Khuri[3], D. Li[1], J. Cowan[1], A. Morales[1], E. R. Martin[2] 1) Cardiovascular Division, University of Miami; 2) Miami Institute for Human Genomics, University of Miami; 3) Center for Computational Science, University of Miami.

Dilated cardiomyopathy (DCM) is a myocardial disease characterized by left ventricular enlargement and systolic dysfunction (ejection fraction less than 50%), and is a common cause of heart failure. Although mutations, primarily nonsynonymous missense or short indels, found in >20 autosomal and two X-linked genes have been shown to cause familial DCM (FDC), this variation explains only ~25-30% of genetic cause. Therefore, in an effort to identify additional causative variations, we undertook a comprehensive examination of resequencing data provided by the National Heart Lung and Blood Institute (NHLBI) from six known FDC genes (MYH7, TNNT2, SCN5A, CSRP3, LBD3, and TCAP) in 313 carefully phenotyped DCM patients and 253 controls. In total, 524 variation sites were examined, 252 of which fell in the 5UTR or 3UTR or resulted in nonsynonymous (NS) or synonymous nucleotide changes. Of highest interest were 36 NS changes that were absent in all controls. Since these alterations accounted for only a small fraction of the total genetic variability we then performed association analyses of all sites using a Fishers exact allelic test. After accounting for deviations from Hardy Weinberg Equilibrium and linkage disequilibrium, we identified 12 independent sites across all genes that were associated ($P<0.05$) with DCM. Removal of the 36 individuals with NS changes did not alter the significance of these associations, suggesting the presence of additional variation not captured by these rare variants. Furthermore, we observed a larger number of multiple hits across different genes in DCM cases compared to controls. This analysis suggests that common susceptibility variants alone or in combination may contribute to additional risk. This investigation highlights the importance of using a comprehensive approach to analyze extensive resequencing data sets, even in diseases that have previously been categorized as Mendelian.

The Effect of Background Selection on Patterns of Human Genetic Variation. *R. Hernandez, M. Przeworski* Human Genetics, University of Chicago, Chicago, IL.

Recent studies have demonstrated that the human genome is rife with deleterious mutations, arising in both coding as well as conserved non-coding regions. However, the possible effects of such a concert of deleterious mutations on flanking neutral variation has received little attention in human population genetics, despite background selection (BGS) having been described 15 years ago. To examine the possible effects of BGS on the human genome, we used detailed forward simulations with demographic, selective, and recombination parameters inferred from human data. We first investigated the effect of deleterious non-synonymous mutations on patterns of synonymous variation within the same gene. We found that while inference of selection at non-synonymous sites remains largely unbiased, the frequency distribution of neutral synonymous mutations can be significantly impacted by BGS in a non-stationary population. We extended our simulations to incorporate a genomic distribution of functional elements subject to deleterious mutations to characterize the spatial scale that BGS can affect. Observed patterns of variation near functional elements from large-scale human resequencing projects were then contrasted to the expected pattern of BGS to quantify the evidence for BGS as a driving force in the evolution of the human genome.

Genetic associations in childhood leukemia and interactions with sex. *M. T. Dorak, E. Ucisik-Akkaya, C. Davis, B. Morrison, T. Do* Genomic Immunoepidemiology, HUMIGEN LLC, Hamilton, NJ, 2439 Kuser Road, Hamilton, NJ 08690.

To gain further insight into previously reported associations with HLA genes, we examined the non-HLA genes of the HLA complex and a number of other candidate genes involved in iron homeostasis, immune surveillance and genome surveillance using a genic approach. The sample consisted of 114 cases with childhood acute lymphoblastic leukemia (ALL) and 414 newborn controls from Wales (UK). Most HLA complex associations were sex-specific (HSPA1B in males); SKIV2L, HLA-C and -DRA in females (similar to their associations in autoimmune diseases). Retinoic acid receptor gene (RXRB) showed an association which appeared to account for the HLA-DPB1 association previously reported. The DRB4 association originally found in the same sample remained the strongest risk marker for males. The most striking finding was a heterozygote advantage observed in males at three extended HLA complex loci (HFE rs807212, BAT3 rs2077102 and DRB ancestral lineages). A strong additive effect of these markers was noted ($P < 0.001$) and showed remarkable protection in newborn boys heterozygous at all three markers (OR = 0.05, 95% CI = 0.01 to 0.43; $P = 0.007$). SNPs at IRF4, TP53, several iron-related genes (TF, HFE2, HMOX1) and an NKG2D haplotype known to correlate with lower natural cytotoxic activity also showed associations and biologically plausible interactions. The African HapMap sample was monomorphic for the protective HSPA1B allele G. Associations shown to be independent resulted in a genome-wide additive susceptibility model which was highly significant ($P < 0.0001$). Some markers associated with risk in males or protection in females also showed decreased frequency in newborn males (HLA-DRB lineages, NKG2D and HMOX1). This finding provided a genetic basis for the link between male-specific prenatal selection and childhood ALL susceptibility suspected from the miscarriage history and leukemia risk connection (stronger in males). Further studies in the HLA complex which encodes more than 200 expressed non-HLA genes are justified given the genetic associations, heterozygote advantage and possible involvement in prenatal selection, all with sex effect, found in the present study.

Application of the Bayesian Regression with Singular Value Decomposition Method in Large-Scale Candidate Gene Association Studies for Insulin Resistance. *S. Kwon[1], X. Guo[1], M. o. Goodarzi[1], Y.-D. I. Chen[1], B. Fang[1], S. Cheng[2], V. Brophy[2], J. Li[2], L. Steiner[2], A. Xiang[3], K. D. Taylor[1], T. A. Buchanan[3], L. J. Raffel[1], J. I. Rotter[1]* 1) Medical Genetics Inst, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Roche Molecular Systems, Pleasanton, CA; 3) USC, Los Angeles, CA.

Genetic association studies have been widely used to identify genes involved in a disease pathophysiology. With the increasing number of reported positive associations, it is an important and challenging task to sort through the signals and identify the genes that confer the highest risk for disease development. We applied the Bayesian Regression with Singular Value Decomposition (BRSVD) method for large-scale genetic association studies when sample size (n) is much smaller than the number of markers (p). Massive dimension reduction from p to n can be achieved by applying SVD to the design matrix. The posterior densities of all parameters in the model were driven with conjugate priors. Model fitting can be accomplished via Markov chain Monte Carlo with Gibbs sampler, which can be constructed based on posterior densities. Test procedures based on permutation and generalized likelihood ratio are incorporated to select significant genes. We applied our BRSVD method to candidate gene data generated in a Hispanic American (HA) family cohort ascertained through probands with hypertension. A total of 227 SNPs from 103 candidate genes have been genotyped. The BRSVD method was used to assess all the genes simultaneously, using 103 offspring selected from the family cohort (one from each family with complete phenotype and genotype data) with the goal of identifying genes important for insulin resistance (IR), as measured directly by euglycemic clamp. In addition to age and BMI, 5 genes (CD14, GPRK2L, MMP7, CAPN10, and CD36) were found to contribute to IR significantly ($p<0.05$), with CAPN10 ranked at the top. This is a provocative finding given that CAPN10 was the first gene for T2DM identified by positional cloning and was initially discovered in a HA cohort. We propose that the BRSVD method will improve gene identification in large scale genotyping studies.

Novel Genetic Variants of TCF7L2 identified by direct sequencing in Mexican Mestizos and Amerindians. *L. del Bosque-Plata, A. C. Hernandez-Mondragon, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Intronic variants of the transcription factor 7-like 2 gene (TCF7L2) has been associated with type 2 diabetes (T2D). This association has been consistently replicated among diverse populations with different genetic backgrounds including Mexican population. These variants do not explain the original linkage signal, raising the possibility that other variants in the same region may predispose to T2D. Based on these observations showed the importance of direct sequencing this gene, especially if the replication cohort is of different ethnic group compared to the original one. Most of the Mexican population is considered Mestizo with a particular genomic ancestry that is the result of admixture between Amerindians with Spaniards and a lesser amount with Africans population. About 5% of Mexican population are Amerindian groups. We looked for new TCF7L2 variants by direct sequencing of all exons and intron-exon junctions in three Mexican Amerindian groups: 30 Zapotecan, 45 Mazatecan and 30 Mexican Mestizos. We have preliminary found four novel TCF7L2 variants in the Amerindian population. These were found in exon or intron regions: exon 17: Pro-His, Pro-Thr; intron 13: del CC, ins Pro490His, Pro502Thr, DelCC +209392, InsTCTCTC +209397. Some of these variants were localized in transcriptional binding sites. A second phase of this study is planned to look for these novel variants in Mexican population Mestizos by case-control association design. Identification of novel variants in TCF7L2 will contribuye to our knowledge of the patogénesis of T2D.

Telomere length in brain and psychiatric disorders. *D. Zhang, L. Cheng, C. Liu* Department of Psychiatry, University of Chicago, Chicago, IL.

Telomeres consist of a variable number of repeats of the sequence TTAGGG at the ends of chromosomes, involve in preventing from chromosome fusion and maintaining genome stability. Telomeres decline with cell division. Telomere shortening has been recently observed in leucocytes from psychological stress and psychiatric disorders such as schizophrenia (SZ), bipolar disorders (BD) and major depression (MD). We aim to test whether telomere length is altered in brain of psychiatric patients including MD, BD and SZ. Mean telomere length (mTL) varies greatly in humans with the same age. Linkage studies have suggested that several regions contribute to mTL. We also carried out a genome-wide mapping of mTL as a quantitative trait. We measured mTL in 155 Caucasian cerebellum samples from Stanley Medical Research Institute (SMRI) by real time PCR. These samples include 46 SZ, 46 BP, 15 MD and 48 healthy controls. No difference of mTL was observed comparing SZ (or BD or MD or all cases) and controls. Affymetrix Genome-Wide Human SNP Array 5.0 was employed for genotyping. 240576 markers with high quality were included in subsequent mapping analysis. SNP rs605863 showed the most significance with p value of 8.87E-06. No significance withstood multiple test corrections.

Expression profiling study on human monocytes identified novel MicroRNAs:miR-126, miR-151 and miR-152 for osteoporosis. *L. G. Sun[1], X. D. Chen[1], R. R. Recker[1], H. W. Deng[2], P. Xiao[1]* 1) Osteoporosis Research Center, Creighton University Medical Center, Omaha, NE,68131; 2) Department of Orthopedic Surgery and Basic Medical Sciences, University of Missouri-Kansas City, Kansas City, MO, USA, 64108.

MicroRNAs (miRNAs) are short noncoding RNA molecules that regulate gene expression by targeting mRNAs and causing mRNA cleavage or translation blockage. Recently, miRNAs have been implicated important in the etiology of various diseases. Osteoporosis is characterized by low bone mineral density (BMD) mainly resulting from imbalanced osteoclastogenesis and osteoblastogenesis. Circulating monocytes actively participate in osteoclastogenesis by serving as osteoclast precursors and producing factors important for the development and function of osteoclasts. There may be important miRNA-regulating mechanisms in circulating monocytes for the etiology of osteoporosis. In this study, we recruited 20 unrelated postmenopausal Caucasian females aged 57-68, 10 with high BMD (spine or hip Z-score > 0.84) and 10 with low BMD (spine or hip Z-score < -0.84). Total RNA (including miRNAs) from circulating monocytes for each subject was extracted and reverse-transcribed. miRNA profiling for each sample was performed using the ABI TaqMan Low Density Array, including 365 miRNA probes. miRNA expression levels were evaluated by comparative Ct method (Ct) using RNU48 as the endogenous control. Differentially expressed miRNAs were determined by t-test. We identified three down-regulated miRNAs, miR-126 (p=0.023), miR-151 (p=0.015) and miR-152 (p=0.035), in the low BMD group vs. the high BMD group. Another study showed that miR-126 affected hematopoietic stem cell (HSC) differentiation by regulating the expression of Hoxa9 gene, which is important in myeloid and T-cell differentiation as well as HSC function, suggesting that miR-126 may function in osteoclast differentiation. However, no previous study has identified the function of miR-151 and miR-152. This is the first in vivo miRNA expression study on human monocytes for osteoporosis. Our results suggest that miR-126, miR-151, and miR-152 may be involved in osteoclastogenesis and thus the etiology of osteoporosis.

Genomewide association study of schizophrenia in European ancestry and African American samples. *J. Shi[1], D. F. Levinson[1], A. R. Sanders[2], J. Duan[2], F. Dudbridge[3], I. Pe'er[4], P. Holmans[5], S. L. Bray[3], S. Gusev[4], B. J. Mowry[6], R. Freedman[7], A. Olincey[7], F. Amin[8], C. R. Cloninger[9], J. M. Silverman[10], N. G. Buccola[11], W. F. Byerley[12], D. W. Black[13], P. V. Gejman[2]* 1) Dept Psychiatry/Behavior Sci, Stanford Univ, Stanford, CA; 2) Dept Psychiatry, Evanston Northwestern Healthcare Research Inst, Evanston, IL; 3) MRC Biostatistics Unit, Cambridge, UK; 4) Dept Computer Sci, Columbia Univ, New York, NY; 5) Dept Psychol Med, Cardiff Univ, Cardiff, UK; 6) Queensland Ctr Ment Hlth Research, Univ Queensland, Brisbane, Australia; 7) Dept Psychiatry, Univ Colorado, Denver, CO; 8) Dept Psychiatry, Emory Univ, Atlanta, GA; 9) Dept Psychiatry, Washington Univ, St. Louis, MO; 10) Dept Psychiatry, Mt. Sinai SOM, New York, NY; 11) School of Nursing, LSUHSC, New Orleans, LA; 12) Dept Psychiatry, UCSF, San Francisco, CA; 13) Dept Psychiatry, Univ Iowa, Iowa City, IW.

We are reporting a genomewide association study of schizophrenia (SZ) on ~ 5,700 European-ancestry (EA) and 2,400 African-American (AA) cases and controls from the Molecular Genetics of Schizophrenia collaboration. Cases were recruited by 10 centers under a common protocol. Samples were genotyped with the Affymetrix 6.0 array, with extensive QC filtering. To control for population substructure, principal component scores were computed, outliers excluded, and ten scores included as covariates in logistic regression analyses (trend tests). Preliminary analyses include half of the EA dataset (1351/1378 cases/controls post-QC) and 95% of the AA dataset (1199/954 cases/controls), genotyped by the GAIN program. Post-QC genomic control lambdas were ~1.03 (AA) and ~1.07 (EA, EA+AA). The strongest signals were in the FAM69A/RPL5/EVI5 cluster (p=10-6, EA) and in MAD1L1 ($p=2x10^{-6}$, EA; and $7x10^{-8}$, EA+AA), C10orf59 ($4x10^{-6}$, AA) and ERBB4 ($4.5x10^{-6}$, AA). Evidence for association to FAM69A/RPL5/EVI5 has been reported in multiple sclerosis. ERBB4 is the receptor for the product of NRG1, a SZ candidate gene which also received support here ($p=3x10^{-5}$, AA). We will present analyses that include an additional ~ 2800 EA and 130 AA samples, imputation of all HapMap SNPs, and analyses of copy number variants.

A flexible and accurate genotype imputation method for the next generation of genome-wide association studies.

B. N. Howie[1], P. Donnelly[1,2], J. Marchini[1] 1) Dept Statistics, Univ Oxford, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, Univ Oxford, Oxford, United Kingdom.

The past couple years have seen a flurry of novel disease associations arising from genome-wide scans, and these successes have been facilitated by the rise of genotype imputation methods. To date, most genome-wide imputation analyses have used HapMap as a reference. This strategy has proven fruitful, but imputation based on a (relatively) small number of haplotypes is inherently limited in the sorts of patterns it can capture; these limitations disproportionately affect rare SNPs, which are an important source of power in imputation analyses. In the near future, publicly available datasets (such as the Wellcome Trust Case Control Consortium controls and samples from the 1,000 Genomes Project) will serve as rich reference panels that can be used to increase power in association studies. These new opportunities also present new challenges for imputation, however, such as the computational and modeling difficulties posed by much larger samples of possibly unphased and incomplete genotypes. Building on the established method IMPUTE, we describe a new method (IMPUTE++) for genotype imputation whose main innovations are to model such data efficiently and to seamlessly integrate new reference panels with existing ones. We illustrate our method by performing a cross-validation experiment using the WTCCC 1958 Birth Cohort samples with genotypes from the Affymetrix 500K and Illumina 550K SNP chips, where 1000 of the samples are used as an expanded reference panel to impute genotypes in the remaining 500. We show that applying IMPUTE++ to this expanded reference panel yields substantially more accurate results than leading methods can attain based on HapMap alone: our approach often cuts error rates by a factor of 1.5-2.0, across rare (MAF < 5%) and common SNPs alike. We also apply simpler methods based on multi-marker tags to the expanded reference panel dataset and obtain error rates more than 2X ours. Our approach is quite general, and provides a robust foundation for analyzing new datasets (e.g., the 1,000 Genomes Project) and conducting meta-analyses to boost power even further.

Macrocephalic sperm head syndrome: about four familial North African cases. *T. Rebai[1], R. Frikha[1], R. Louati[1], L. Lamine[2], N. Abdelmoula[1]* 1) Histology, Medical University , Sfax, Tunisia; 2) Private Sector of gynecology, Sfax, Tunisia.

Men presenting with teratozoospermia associated with large heads and multiple-flagella spermatozoa are now considered to have the macrocephalic sperm head syndrome, also known as meiotic division deficiency witch accounts for <1% of male infertility. Analysis of the sperm chromosomal content using FISH demonstrated a relationship between the aneuploidy and polyploidy rate and the rate of large-headed multiple-tailed spermatozoa. Recently, a common region of homozygosity harboring the aurora kinase C gene (AURKC) with a recurrent single nucleotide deletion in the AURKC coding sequence has been reported in macrocephalic sperm head syndrome. In the present study, we report on genetic analysis in four infertile North African men having macrocephalic sperm head syndrome (two brothers from a first Libyan family (F1) and two other brothers from a second Libyan family (F2)). In the first family, the patients were born from first degree cousins but in the second, the brothers were born from non consanguineous parents. The F1 brothers (45 and 42 years old men) had 18 and 2 years history of infertility, normal blood lymphocyte karyotype and 100% of large heads and multiple-flagella spermatozoa in semen investigations. They had familial history of a sister with mental retardation children and a brother who failed to conceive because multiple pregnancy losses. The F2 brothers (43 and 38 years old men) had 12 and 5 years history of infertility, normal blood lymphocyte karyotype, severe OAT and large heads and multiple-flagella spermatozoa in semen. For the first brother, two ICSI attempts had been done without results: failure of fecundation for the first attempt and failure of pregnancy in the second. Molecular investigation mainly by sequencing the AURKC gene is performed in our cases. Results will be discussed in the light of literature.

***TRIM32* in limb girdle muscular dystrophy type 2H/sarcotubular myopathy.** *P. L. Miller, H. Ding, Y. Heng, A. Kania, X. Wu, A. Funk, C. Hirst, S. Krawitz, M. DelBigio, K. Wrogemann* University of Manitoba, Winnipeg, Manitoba, Canada.

Limb Girdle Muscular Dystrophy Type 2H is a relatively mild form of muscular dystrophy that occurs commonly in the Hutterite population. A homozygous point mutation (D487N) in TRIM32 was found in all patients. A congenital non progressive sarcotubular myopathy (STM) was also described in Hutterites and in two German patients with the same mutation, indicating they represent just one disease. Re-evaluating the pathology of past biopsies from 12/14 LGMD2H patients shows varying degrees of vacuolation in scattered fibres, in agreement with the genetic findings. A different mutation (P130S) leads to one form of Bardet-Biedl Syndrome (BBS). A knockout mouse model shows signs of muscular dystrophy and vacuolation characteristic of LGMD2H/STM and thus confirms that the correct gene has been identified. Additional mutations in LGMD patients have recently been found by others, and all map to one of the six NHL domains. Elevated levels of wt Trim32 in skin carcinogenesis and the observation that mutated TRIM32 leads to muscular dystrophy suggested that TRIM32 exerts anti-apoptotic activity (Albor et al., J. Biol. Chem. 281: 25850-66, 2006). Semi-transformed human myoblasts show greater susceptibility to staurosporine induced apoptosis. This should not necessarily indicate that increased apoptosis underlies the pathogenesis of LGMD2H/STM. It could just be a result of the disease process. The gene is highly expressed in regenerating skeletal muscle. When myoblasts are cultured under conditions of differentiation those from LGMD2H patients show reduced levels of myosin heavy chain and caveolin, indicative of a possible impairment in the differentiation process. TRIM32 is an E-3 ubiquitin ligase. Monoclonal Abs have been developed and detect TRIM32 in most tissues with highest expression in brain and testis, while tissues from knock-out mice show no signal. Skeletal muscle biopsies from LGMD2H patients show reduced levels of TRIM32, which is also seen in myoblasts and fibroblasts from 2H patients. The precise roles of TRIM32 mutations in the pathogenesis of LGMD2H remain to be elucidated.

A Delphi-based Consensus Clinical Practice Protocol for Very Long Chain Acyl-CoA Dehydrogenase (VLCAD)Deficiency. *G. L. Arnold[1], D. Matern[2], J. VanHove[3], D. Freedenberg[4], N. Longo[5], B. Burton[6], C. Garganta[7], C. Ficicioglu[8], S. Cederaum[9], C. Harding[10], R. Boles[11], A. Feigenbaum[12], P. Chakraborty[13], A. Strauss[14]* 1) U Roch SOMD, Rochester, NY; 2) Mayo Clinic COM, Rochester, MN; 3) U Colo HSC, Denver, CO; 4) Vanderbilt U SOM, Nashville TN; 5) U Utah SOM, Salt Lake, UT; 6) Northwestern U Feinberg SOM, Chicago, IL; 7) Tufts NEMC, Boston, MA; 8) U Penn SOM, Philadelphia, PA; 9) UCLA SOM, Los Angeles, CA; 10) Oregon HSU, Portland, OR; 11) USC SOM, Los Angeles, CA; 12) Hosp Sick Child, Toronto, ON; 13) Child Hosp E Ontario, Ottawa, ON; 14) U Cinn SOM, Cincinnati, OH.

VLCAD deficiency is diagnosed by newborn screening with relatively high frequency (1:31,500 births). Although most newborns appear well, it is important to determine which infants are at risk for the severe cardiomyopathy phenotype vs. the milder phenotypes of fasting intolerance or later onset myopathy. Evidence based guidelines for diagnosis and management of screen positive infants are lacking. After a review and grading of the literature (per the Oxford Centre for Evidence Based Guidelines), 14 metabolic experts developed consensus based clinical practice guidelines for VLCAD screen positive infants using the traditional Delphi consensus method.

Recommendations were considered for the initial evaluation of the screen positive infant, diagnostic testing, and management. Plasma acylcarnitine (AC) analysis was recommended as a follow-up test; because of false-negative AC studies a second diagostic method (DNA, enzyme asay or fatty acid oxidation probe) was recommended to verify normal AC. At present there are insufficient data to predict severity of phenotype from biochemical assays alone, however preliminary data suggest genotype or residual enzyme activity may help guide management. Age and phenotype-specific recommendation for dietary treatment (long chain fat restriction and medium chain triglyceride supplementation) were considered, as were recommendations for management of fasting during intercurrent illnesses. Carnitine remains controversial, although a slender consensus recommended supplementation if plasma carnitine is deficient.

Prediction of Antidepressant Drug Response in Geriatric Depression. *J. Sarginson, L. Lazzeroni, H. S. Ryan, A. F. Schatzberg, G. M. Murphy* Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA.

Background: Polymorphisms that can help predict medication treatment outcomes in geriatric major depression would be of great clinical value. Because the clinical efficacy of antidepressant agents depends on their concentrations in the brain, we focused on the MDR1 gene, which encodes the blood brain barrier transporter p-glycoprotein. P-glycoprotein affects the concentrations of some antidepressants such as paroxetine, but not others such as mirtazapine. Methods: We performed a multicenter pharmacogenetic study of 246 cognitively intact patients 65 years of age and older with major depression who were treated with either paroxetine or mirtazapine. Medications were administered in a double blind design over an 8-week acute phase with a 16-week extension phase. Mood, cognition, and medication side effects were quantified throughout the study. All individuals were genotyped for 15 SNPs spread across the MDR1 gene region. Statistical analyses were performed using mixed model regression on Hamilton Depression Scale 21 item (HamD-21) scores, and Kaplan-Meier survival analysis, using time to a HamD-21 score of 10 or less as a criterion for remission from depression. Results: Of the 15 MDR1 variants, only rs2032583 was a significant predictor of time to remission. Two other SNPs, rs2032582 and rs1045642, which are the most frequently genotyped MDR1 variants and have been associated with response to cardiac and chemotherapeutic medications, had no effect on antidepressant outcomes for either drug. Conclusion: These results indicate that MDR1 variation may affect treatment outcomes for geriatric patients given p-glycoprotein substrates such as paroxetine. This finding partially supports a previous finding in younger depressed patients (Uhr et al., Neuron: 57:203, 2008). We did not confirm a second association between rs2032582 and response to paroxetine in a Japanese cohort of depressed patients. Nevertheless, our results support further testing of MDR1 as a pharmacogenetic predictor in patients treated with p-glycoprotein substrate antidepressants. Support: NARSAD, Organon Inc., Department of Veterans Affairs, The Nancy Pritzker Network, and the NIMH.

Werner mesomelia with Hirschsprung disease in an affected father and son. *S. Ramanathan[1], Y. Ibrahim[2], C. Gurnett[3], R. D. Clark[1]* 1) Peds Genetics, Loma Linda Univ Hlth Care, Loma Linda, CA; 2) NICU Dept, Loma Linda Univ Hlth Care, Loma Linda, CA; 3) Dept Neurology, Univ of Washington School of Med, St Louis, MO.

We report a father and son with Werner mesomelic dysplasia and Hirschsprung disease. Fetal anomalies in the son noted on ultrasound at 20 weeks gestation were preaxial polydactyly of hands and a single bone in the lower legs. At 24 weeks, a double outlet right ventricle (DORV) was detected. The baby was born at 37 weeks by C-section to a 35-year-old G1 mother. He had bilateral preaxial synpolydactyly of hands and feet with 7 digits on each extremity, bilateral triphalangeal thumbs, short lower legs, talipes and a grade II systolic murmur. X-rays showed synpolydactyly with 7 digits of hands and feet, triphalangeal thumbs, radial deviation of hands, absent tibiae and talipes. Other anomalies were Hirschsprung disease and DORV. The babys father had below the knee amputations for absent tibiae. He also had asymmetric thumbs, preaxial polydactyly of feet, cardiac murmur and Hirschsprung disease. Werner mesomelia is a rare disorder characterized by absent or hypoplastic tibiae and preaxial polysyndactyly of the extremities. Only 2 cases of Werner mesomelia with Hirschsprung have been reported. To our knowledge, this is the first report of a familial case of Werner mesomelia with Hirschsprung disease. ZRS is a highly conserved domain 1 Mb upstream of Sonic Hedgehog (*SHH*) and regulates *SHH*. Mutations in ZRS have been reported in isolated preaxial polydactyly (Lettice *et al*., 2002), preaxial polydactyly and triphalangeal thumbs (Gurnett *et al*., 2007), and in Werner mesomelic dysplasia without Hirschsprung disease (Wieczoreg *et al*., ESHG abstract, 2008). ZRS studies in our family are in progress. Further studies are needed to determine if the severity of the Werner mesomelia phenotype and the presence of Hirschsprung disease are associated with specific mutations in ZRS. As the Hedgehog signaling pathway is critical in developmental patterning during embryogenesis, ZRS may play a role in the etiology of Hirschsprung disease and congenital heart disease even in the absence of recognized limb anomalies.

Addition of CYP450 2C9*8 and CYP450 4F2 to a dosing algorithm for Warfarin dosing. *P. Hujsak[1], P. Wang[2], A. Smith[3], A. Wu[3]* 1) AutoGenomics, Inc, Carlsbad; 2) Cornell University,Chemistry Laboratory, Methodist Hospital, Houston; 3) Clinical Chemistry Laboratory, San Francisco General Hospital, San Francisco.

The anticoagulant warfarin with its patient dependent narrow individual therapeutic range makes it difficult for a physician to prescribe a maintenance dose without repeated follow up INR testing. Patients sensitive to warfarin are at high risk of serious bleeding events. It has been shown that genetic variations in the CYP450 2C9 (*2, *3, *5, *6, *8, *11, *12 and *14) enzyme in the liver affect the rate of metabolism and clearance of warfarin. Warfarin inhibits the target vitamin K epoxide reductase complex-1 (VKORC1) enzyme activity.VKORC1 genetic variations at the 3673 (G:A), and the 7566 (C>T) positions implicated in warfarin dosing.The CYP4504F2 (V433M) enzyme has also been linked to Warfarin dosing. We retrospectively genotyped 71 patients on warfarin on an INFINITI automated platform, and compared the genotypes against the actual dose used to maintain a stable INR. The group is also highly diverse (36% Caucasian, 33% African American, 17% Asian, 10 Hispanic, 2% other). We used this data to create an algorithm based on age, gender, height, weight, inhibitors, ethnicity, and smoking. The algorithm we developed uses results of *2, *3, *8 for 2C9 and 3673 and 7566 VKORC1 and CYP4F2. The algorithm is: Log dose=1.1931-0.0008972(Age)-0.1389(asian)-0.09422(black)-0.06092(*2)-0.1846(*3)-0.1233(*8)+0.01019(4F2)+0.1102(gender)-0.09022(Hispanic)-0.001234(height)-0.01173(inhibitor)+0.05277(other)-0.04342(smoking)-0.1516(3673)-0.04646(7566)+0.0009239(weight) (2,*3 and *8 are still number of alleles, while VKORC13673=3 for AA, 2 for AG and 1 for GG,VKORC1 7566=3 for TT, 2 for TC and 1 for CC, 4F2=3 for TT, 2 for TC and 1 for CC) The regression coefficient improved slightly to r2=0.59with the additions of CYP 2C9 *8 and CYP 4F2 relative to to 2C9*2 and *3 and VKORC1 3673, 7566. There were 38.4% heterozygous samples of 4F2. The CYP2C9 *8 SNP was present 5.6% of this sample set. It is more prevalent in the African American population than *2. With continuing testing of a mixed population, more CYP SNPs will be uncovered that affect the dosing algorithm.

***IL18* locus is associated with susceptibility to esophageal disease in an Irish Population.** *M. Babar[1], G. Turner[1], A. W. Ryan[1], P. J. Murphy[1], A. E. Hughes[2], C. C. Patterson[2], L. A. Anderson[2], R. G. Watson[2], B. T. Johnston[2], J. McGuigan[2], H. Comber[2], L. J. Murray[2], J. V. Reynolds[1], R. McManus[1], FINBAR CONSORTIUM* 1) Trinity College Dublin & St. James' Hospital, Dublin, Dublin, Ireland; 2) Department of Medical Genetics, Queen's University Belfast, Royal Group of Hospitals, Belfast, Ireland.

Esophageal Adenocarcinoma (EAC) is multifactorial and the genetic background may be a crucial etiologic factor. Interleukin-18 is a multifunctional cytokine implicated in anti-tumour immunity. Encoded on chromosome 11q22.2_q22.3, variation in the *IL18* gene promoter has been associated with esophageal squamous cell carcinoma in the Chinese population. These promoter polymorphisms have been reported to alter *IL18* expression and have been linked to nasopharyngeal and ovarian cancers. **Methods** We analysed two *IL18* promoter polymorphisms, -137 G/C and -607 C/A, (rs187238 and rs1946518) in *IL18* gene on 11q22.2_q22.3. Each SNP was genotyped in 1708 individuals (EAC, n=192, Barretts, n=201, Reflux esophagitis, n=205, Controls,n=1110). We investigated the relationship between these SNPs and their haplotypes with the risk of esophageal disease. **Results** The data from all loci were in Hardy-Weinberg Equilibrium in all populations. The genotype frequencies of the *IL18* promoter polymorphism -607 C/A were significantly different between controls and Barretts (p=0.04) and marginally different between controls and EAC (p=0.07). The CC genotype was significantly associated with an increased risk of Barretts esophagus (p=0.012, OR=1.456) and slightly increased risk of EAC (p=0.06, OR=1.02). Although no significant association was observed between the disease groups at the -137 G/C locus, the -137C/-607C haplotype was associated with significantly increased risk of Barretts esophagus (p=0.032) with haplotype frequencies 0.596 in controls and 0.605 in Barretts. **Conclusion** These data shows a suggestive association of the Barretts population with the *IL18* -607 C/A promoter polymorphism. Higher *IL18* expression caused by the -607C allele might contribute to an inherited susceptibility to Barretts esophagus and possibly EAC.

Whole Genome Analysis of DNA Methylation Abnormalities in Breast Cancer. *A. H. O'Donnell[1,2], J. R. Edwards[3], C. Lee[5], H. Peckham[5], F. Haghighi[4], T. H. Bestor[1]* 1) Genetics and Development; 2) MD/PhD Program; 3) Columbia Genome Center; 4) Psychiatry, Columbia University, New York, NY; 5) Applied Biosystems, Foster City, CA, USA.

The nature of the DNA methylation abnormalities known to occur in cancer cell genomes remains controversial, in large part because of the lack of a method for analyzing the methylation patterns of the entire genome including repetitive elements in a rapid, cost-effective, unbiased manner. We have developed new methods for the fractionation of DNA according to methylation status and have employed ultra-high throughput DNA sequencing using the Applied Biosystems SOLiD platform to allow efficient whole-genome methylation profiling. A new computational pipeline to organize the flood of sequence data generated during this study has been implemented. We have assessed methylation status of nearly the entire genome in two breast cancers and adjacent normal breast tissues and the breast cancer cell line MCF-7 to create the largest methylation databases to date. We have found that the default program of DNA methylation is driven by local CpG density. However, CpG-dense promoters are shielded from methylation by histone H3K4 di- and tri-methylation marks. Young repetitive elements have higher methylation levels than predicted by CpG density, suggesting that there may be a mechanism that targets methylation of this class of sequences. From our analysis, we have detected a vast number of methylation changes between normal and tumor samples across the genome including in promoters, repetitive elements and other genomic regions, and are now examining the role these changes may play in breast cancer. Interestingly, promoter hypermethylation is not selectively present at tumor suppressor genes, but can also be seen at proto-oncogene promoters, supporting a role for DNA methylation in a hypermethylation/demethylation suicide pathway that kills cells that have lost mechanisms of growth control.

An association study of *CNR1* polymorphisms in schizophrenia with or without cannabis use. *K. Prasad, J. Wood, M. Talkowski, K. Chowdari, V. Nimgaonkar* Dept Psychiatry, Univ Pittsburgh Sch Med, Pittsburgh, PA.

Background: Cannabis use is associated with increased risk of psychosis or schizophrenia (SZ). Variations in endogenous cannabinoid system are observed in SZ independent of cannabis use. This suggests that pathology in the endocannabinoid system could predispose to both SZ and cannabis abuse. However, association of the gene encoding cannabis receptor 1 (*CNR1*) variations with SZ in the context of cannabis use has not been adequately examined. We comprehensively examined the association of *CNR1* polymorphisms with SZ with and without cannabis abuse/dependence. **Methods**: Consenting SZ patients (n=527) and healthy subjects (n=477) were administered the Diagnostic Interview for Genetic Studies (DIGS) and a consensus diagnosis was made. We selected 17 tag SNPs from HapMap based on a high correlation threshold (r^2<0.9). SNPs were genotyped using the Illumina Golden Gate platform (ABI Biosystems, Inc). We examined the association of tag SNPs with SZ, and then between those with history of cannabis abuse/dependence compared to those without. **Results**: SNPs rs806370 (p=0.048) and rs806365 (p=0.071) showed nominal associations with SZ but did not survive corrections for multiple tests. When patients with (n=121) or without (n=335) cannabis abuse/dependence were compared, rs1049353 (synonymous coding; ^{2}=9.2, p=0.024) and rs806369 (intronic; ^{2}=7.2, p=0.072) were significantly associated with SZ patients with cannabis abuse/dependence after correcting for effective number of tests (9.73). The odds ratio was 1.65 and 1.62, respectively. **Discussion**: These observations lend initial clues to the possibility that variations in *CNR1* may be associated with a subset of SZ patients who are abusing or dependent on cannabis. A small sample size did not allow us to reliably examine the onset of cannabis use relative to the onset of SZ. To our knowledge, this study utilizes one of the largest systematically characterized samples. We are, now, examining similar associations among bipolar disorder patients, and investigating the impact of these SNPs on in vivo neurobiological variables among first episode antipsychotic naïve SZ patients relative to matched healthy controls.

Y chromosome microsatellite haplotypes in the Hutterite founders. *M. Caliskan[1], I. Pichler[2], C. Platzer[2], P. P. Pramstaller[2], C. Ober[1]* 1) Human Genetics, U of Chicago, USA; 2) Institute of Genetic Medicine, European Academy, Bolzano, Italy.

The current population of >12,000 Schmiedeleut Hutterites are descendants of 38 male founders who were born between 1700 and 1830 in Europe. Only 12 of these founders, each with a unique surname, have living male descendants related through male-only lineages. DNA samples were available in our laboratory for 75 male descendants of 11 of the 12 founders, accounting for 673 independent paternal meioses. We genotyped 9 microsatellite loci, which included a mean of 6.8 (range 2-23) males per lineage to evaluate potential relationships between the founders. Fourteen different haplotypes were identified, with an average of 3.5 (range 1-8) pairwise differences between haplotypes. All descendants within each of 9 lineages had identical Y haplotypes. Descendents of two of these lineages, 2 and 10, had the same haplotype despite different surnames, suggesting possible relatedness between the founders of these two lineages. Descendants of two lineages, 6 and 11, each carried three distinct haplotypes. Within each of these lineages the haplotypes differed from the ancestral haplotype by one repeat size at two loci. Additional male descendants in lineages 6 and 11 were then genotyped for the discrepant microsatellites, confirming the presence of three Y haplotypes each in lineages 6 and 11. The one mutation arose at each of four loci: DYS388, DYS389II, DYS390, DYS393. Three mutations were gains of one repeat; it was not possible to determine if the fourth mutation was a gain or loss of one repeat. The ancestral haplotypes in these two lineages are identical at four microsatellite loci; the alleles at the other five loci differ by one repeat size. The average mutation rate at these 9 loci was 0.00066 (95% CI 0.00015-0.0013), similar to other estimates. These data suggest that the founders of lineages 2 and 10 may have been related through paternal lines and that surnames do not strictly correspond to unique Y chromosomes. Moreover, certain ancestral haplotypes (i.e., those in lineages 6 and 11) may be more prone to mutation. Supported by NIH grants HD21244 and HL085197.

A new model of Down Syndrome: human BAC transgenic for PCP4. *Y. Khvorostova[1,6], G. Barlow[1], D. L. Dickstein[2], D. Segal[2], P. R. Hof[2], L. S. Crnic[3], D. Patterson[4], T. Town[1], Z. Galdzicki[5], J. R. Korenberg[6]* 1) Cedars-Sinai Medical Ctr., Los Angeles, CA 90048; 2) Mount Sinai School of Med., New York, NY; 3) Univ. of Colorado School of Med., Denver, CO; 4) Eleanor Roosevelt Inst., Denver, CO; 5) Uniformed Services Univ. of the Health Sciences, Bethesda, MD; 6) The Brain Institute Univ. of Utah, Salt Lake City, UT.

Down syndrome (DS) or trisomy 21 is a common genetic disorder, and mental retardation based on memory and learning defects remains the hallmark of DS. These cognitive functions are dependent on hippocampus (HC) and prefrontal cortex (PFC) function, and are mediated in part by the effects of chromosome 21 genes expressed in these regions acting on neuronal structure and function. The HSA 21 gene, PCP4, encodes the protein PEP-19 and is expressed in PFC and HC and binds calmodulin. This results in diminished activity of downstream enzymes such as calmodulin kinase II, and may thereby influence learning and memory. Here, we present a new PCP4 DS mouse model. We have used a human BAC transgenesis strategy to assess the consequences of a single gene to the pathogenesis of DS. Using real-time RT-qPCR, we show that the human transgene is overexpressed in brains of transgenic mice. IHC and IF analysis showed a similar distribution of PEP-19 expression in wild type and transgenic mice. Basic behavioral testing of PCP4 mice revealed, in females, slight hyperactivity, decreased avoidance of open spaces, and shifted reaction to auditory stimuli - the phenotypes also seen in Ts65Dn mice carrying partial trisomy only for a subset of mouse genes homologous to HSA21. We applied Sholl analysis to dendrites from the pyramidal neurons of layer II/III from PFC and found that in PCP4 mice, the distal apical dendritic arbor has significantly more branches and intersections. Moreover, whereas wild type littermates loose dendritic length and complexity with age (5-6 months vs. 24-26 months), older PCP4 transgenic mice keep essentially the same structure of the dendritic tree from 6 to 26 months. This is the first evidence of any single DS gene, here PEP-19, altering both dendritic structure and behavior in vivo.

Meta-analysis of genome wide association studies with human height in European-originated monozygotic female twins and Northern Finland birth cohort. *J. A. Kettunen[1,2], I. Lindqvist[1], S. Ripatti[1,3], T. D. Spector[4], N. G. Martin[5], M. R. Järvelin[6,7], L. Peltonen[1,2], M. Perola[1], behalf of GenomEUtwin-project* 1) Department of Human Genetics, Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 3) Karolinska Institutet, Department of Medical Epidemiology and Biostatistics, Stockholm, Sweden; 4) Twin Research and Genetic Epidemiology Unit, King's College London, London, UK; 5) Genetic Epidemiology Laboratory, Queensland Institute of Medical Research, Brisbane, Australia; 6) Department of Epidemiology and Public Health, Imperial College, London, UK; 7) Department of Public Health Science and General Practice, Oulu University Hospital and University of Oulu, Finland.

In this study we report a genome wide association meta-analysis to human height. Our study aimed for reduced environmental variance in two ways: firstly by using the mean of each MZ twin pair as a phenotype and secondly genotyping a sample of individuals from an isolated area in Finland, born in the same year (1966). The sample sets comprised of 1631 European monozygotic female twin pairs from the GenomEUtwin consortium and 4734 individuals (2270 males, 2464 females) from Northern Finland Birth Cohort (NFBC) genotyped with Illumina 300 and 370 chips respectively. In the combined sample best association we observed was in the chromosome 13q14 region (p = 1.92*10-7) underlying the same area which was identified in the previously reported (Weedon, Lettre) genome wide association scans. Most of the lately reported GWA loci were replicated in our study. We performed sex specific analysis and found some interesting regions exemplified by female specific association in chromosome 5q33 region (p = 1.39*10-7). We identified some novel regions and the replication study is underway. We also tested for genes that might be responsible for increasing variance in human height. This was performed in the MZ scan and was aiming to find loci responsible for genotype-environment interaction or imprinting/gene silencing. The most significant finding for variance in stature (p = 1.22 * 10-5) was identified on 6q14 region.

Public Attitudes and Knowledge and the Integration of Genomic Medicine into Primary Care. *C. A. Christianson[1], K. P. Powell[1], S. E. Hahn[2], D. Bartz[1], T. Roxbury[1], S. Blanton[2], M. Pericak-Vance[2], V. C. Henrich[1]* 1) The University of North Carolina at Greensboro, NC; 2) The University of Miami, FL.

Integration of genomic medicine into primary care will depend in part on the publics acceptance & utilization of these services. Factors that influence the publics uptake of genetic technology include moral codes, perceived use, confidence in regulatory agencies & genetics knowledge. The purpose of this study was to assess the attitudes about genomic medicine & genetics knowledge of patients seen in three primary care practices in North Carolina & compare these to the results of a community telephone survey (N=1136). The survey was given to patients at each practice during a 3 month period. The survey included 15 attitude questions regarding genetic tests, concerns about privacy & genetic discrimination & the anticipated uses & benefits of genetic tests. There were 16 knowledge questions about family history, inheritance, screening, genetic testing, & existing privacy/discrimination laws. Most respondents (N=1183) were female (65%), Caucasian (81%) & the mean age was 57. The majority were not morally concerned about genetic testing. They were more worried about the potential loss of privacy than genetic discrimination (61% vs. 53%). They thought health insurers were more likely to use genetic information than employers (54% vs. 27%) & 69% thought the government would protect them from discrimination. Similar trends were seen on the community survey. The mean knowledge score on the patient survey (8.96, sd = 2.4) was less than on the community survey (9.44, sd = 2.1). A factor analysis identified groups of questions that measured knowledge in 5 areas. Patients knew that diseases run in families & they over estimated the utility of genetic tests. Education & experience with genetic diseases & tests were associated with higher mean knowledge scores ($p < .001$). Respondents generally approved of genetic tests, believed that genetics will positively affect healthcare & understood there is a connection between genetics & disease. These data suggest the public will support the integration of genomic medicine into primary care if their concerns about discrimination are addressed.

Homologous Recombination conserves DNA sequence integrity throughout the cell cycle in embryonic stem cells.
L. Serrano, L. Liang, Y. Chang, L. Deng, C. Maulion, S. C. Nguyen, J. Tischfield Genetics, Rutgers University, Piscataway, NJ.

The maintenance of genomic integrity is crucial to embryonic stem cells (ESCs) considering the potential for propagating undesirable mutations to the resulting somatic and germ cell lineages. Indeed, we previously reported that mouse ESCs exhibit a significantly lower mutation frequency compared to differentiated cells. This could be due to more effective elimination of genetically damaged cells via apoptosis, or especially robust, sequence-conserving DNA damage repair mechanisms such as homologous recombination (HR). We used fluorescence microscopy and 3D quantitative image analysis to compare mouse ES and differentiated cells, with regard to HR-mediated repair of spontaneous and x-ray-induced double strand breaks (DSBs). Microscopic analysis of repair foci and functional assay of nuclear extracts both indicate that HR is greater in mouse ESCs compared to fibroblasts. Strikingly, HR is not exclusively associated with post-replicative chromatin and appears to repair induced or spontaneous DNA damage throughout the ESC cell cycle, including in G1 synchronized cells. This is dramatically different from what we observe in primary fibroblasts, and from what has been reported in other adult mammalian cell types, where HR is essentially confined to S-phase. This result suggests that alternative templates, such as homologous chromosomes, are more frequently used to repair DSBs in ESCs, which can result in a crossover and potentially lead to loss of heterozygosity (LOH). However, our data indicate that much of the HR occurs before DNA replication. In this way ESCs would maintain a low mutation frequency through an error-free DNA repair pathway (HR), which would alter linkage relationships compared with parental cells but does not lead to LOH. Relatively frequent HR utilizing homolog chromosome sequences preserves genome integrity in ESCs and has distinctive and important genetic consequences to subsequent somatic and germ cell lineages.

Balanced t(12:17) translocation upstream of SOX9 resulting in 46,XX testicular DSD. *O. M. Refai[1], A. Friedman[1], L. Terry[2], T. Jewett[2], H. Otsrer[1]* 1) NYU School of Medicine, New York, NY; 2) Wake Forest School of Medicine, Winston Salem, NC.

Individuals with rare cytogenetic variants have contributed to our understanding of the genetics of sex development and its disorders. Study of such individuals has demonstrated the dose-dependency of SOX9 in gonadal development. Here, we report a case of a balanced chromosome 12;17 translocation 46,XX,t(12;17)(q14.3;q24.3) resulting in 46,XX testicular DSD in one of monozygotic twins concordant for genotype and phenotype. The translocated chromosomes were isolated via human-hamster somatic cell hybridization and screened using microsatellite genotyping. A pair of cell lines containing both the normal chromosome 12 as well as the 12;17 translocation were analyzed on Affymetrix 500K SNP arrays. The data were analyzed for copy number and loss of heterozygosity to localize the breakpoints on both chromosomes. The chromosome 12 breakpoint occurred at 64.4-64.6 Mb, i.e. within intron 2 of the HMGA2 gene. The chromosome 17 breakpoint occurred at 66.4-67.1 Mb, at least 400 kb upstream of SOX9, and near the well-characterized promoters 300 kb upstream of the first exon of this gene. Thus, the t(12;17) translocation disrupted the HMGA2 gene, potentially causing it to up-regulate the testis-determining SOX9 gene during gonadal development and the phenotype of 46,XX testicular DSD.

A Common Genomic Copy Number Variant Locus Is Associated with Colorectal Cancer Risk and Poor Survival.

R. Abdel-Rahman[1], G. Zogopolous[3,4], S. Farrington[2], A. Gropper[3,4], K. Ha[3,4], K. hyeja[5], S. Moore[3,4], G. Bader[5], R. gryfe[3,4], B. Zanke[6], A. Montpetit[7], P. Laflamme[7], J. Hurley[8], T. Chiang[7], A. Tenesa[2], D. Farhat[2], T. Hudson[7], M. Dunlop[2], G. Steve[3,4], H. Campbell[1,2] 1) Public Health, Univ Edinburgh, Edinburgh, United Kingdom; 2) Institute of genetics and molecular medicine; 3) Samuel Lunenfeld Research Institute; 4) Fred Litwin Centre for Cancer Genetics; 5) University of Toronto; 6) Cancer care Ontario; 7) Ontario Institute for Cancer Research; 8) biotrove inc.

Background: Genomic copy number gains and deletions are increasingly recognized as underlying disease susceptibility. Methods: Independent genome-wide association studies were conducted concurrently in Canada and Scotland to investigate the role of copy number variation (CNV) in colorectal cancer. 1257 cases and 1336 controls from Canada and 1012 cases and 1012 controls from Scotland were assayed for CNVs across 500K and 550K genomic markers respectively. Results: Genomic copy number gain at one locus was found to be associated with increased risk of colorectal cancer (minimum p value $1.1x10^{-}9$ in the Canadian study and $p=1.9 \times 10^{-}11$ in the Scottish study). These observations were verified using quantitative PCR in an independent series of 304 cases and 354 controls. In this series, the locus copy number gain was detected in 13.9% cases versus 3.5% controls ($p=1.46x10^{-}5$; O.R.=3.95) and was associated with reduction in overall cancer survival (multivariate Cox proportional hazard ratio = 1.7 [95% CI 1.3 - 2.2], $p=6x\ 10^{-}5$). Five-year survival was 57% in carriers of this copy number gain, compared to 71% in non-carriers. Conclusions: We report the first association of a common copy number change with increased cancer risk in individuals without a familial cancer syndrome. Copy number gain at the identified locus is associated with the risk factor for colorectal cancer, and an independent prognostic predictor of worse survival. The identified locus is located near gene that provides a plausible candidate that might mediate risk and survival effects. These findings have clinical relevance and implications for predicting risk within populations.

Weighted Genome-Wide Association Study of Bipolar Disorder. *M. B. McQueen[1], P. Sklar[2], J. W. Smoller[2], J. Fan[2], I. Ionita-Laza[3], V. L. Nimgaonkar[4], S. V. Faraone[5], S. M. Purcell[2], B. Devlin[6], N. M. Laird[3]* 1) Inst Behavioral Genetics, Univ Colorado, Boulder, CO; 2) Center for Human Genetic Research, Mass General, Boston, MA; 3) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 4) Departments of Psychiatry and Human Genetics, University of Pittsburgh, Pittsburgh, PA; 5) Department of Psychiatry and Behavioral Sciences, Upstate Medical University, State University of New York, Syracuse, NY; 6) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA.

We recently conducted two large-scale gene-mapping efforts targeting bipolar disorder. The first was a combined analysis of eleven linkage studies including over 1000 families (McQueen et al, Am J Hum Genet 2005). The second was a genome-wide association study (GWAS) obtained through the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) involving 955 bipolar I cases and 1498 controls (Sklar et al, Mol Psychiatry 2008). In an effort to combine evidence across both strategies, we adopted the weighted hypothesis testing approach as implemented by Roeder et al (Am J Hum Genet, 2005). In particular, we used the genome-wide linkage statistics (Z-scores) from the combined linkage scan to weight the GWAS p-values. In this way, association signals arising from prior linkage regions are "up-weighted" while signals from other regions are "down-weighted". By adopting this approach, the same SNP identified in the Sklar et al study (rs4939921; chromosome 18) was the most significant signal, even though chromosome 18 displayed only modest linkage evidence in the combined analysis. Furthermore, as expected, SNPs with modest statistical significance residing in the chromosomes 6q, 8q and 9p linkage regions achieved much stronger statistical evidence by incorporating the prior linkage information. Therefore, while there is some overlap with respect to the "top" association signals using both the weighted and unweighted GWAS, there are a considerable number of SNPs identified using the weighted approach that warrant follow-up.

Optimization of the NimbleGen array Comparative Genomic Hybridization Protocol. *M. Ikeda, S. T. Warren*
Human Genetics, Emory Univ, Atlanta, GA.

To improve identification of genomic deletions or duplications, we sought to modify the current protocol for NimbleGen high-density array Comparative Genomic Hybridization. Hypothesizing that more stringent hybridization and wash conditions would increase our ability to detect copy number changes, we investigated three different labeling protocols and two different hybridization and wash systems. We tested labeling protocols using Cy3/Cy5-end labeled randomers (NimbleGen strategy), Cy3/Cy5-labeled nucleotides, or amine-modified nucleotides (AM) to which Cy3/Cy5 could be conjugated. While NimbleGen recommends the Maui hybridization system and manual washes, we also tested the Tecan HS4800Pro which allows greater user control of hybridization conditions. Using a sample with a validated deletion, we tested various strategies. Following the NimbleGen protocol, for this sample, the average log2 for deletions was -0.51 and 0.66 for duplications. We first increased hyb temp from 42C to 52C, which decreased the average log2 by 56% for deletions and 50% for duplications. Substituting AM nucleotides, the average log2 for deletions increased by 2% while duplications decreased by 15%. By increasing the temp and changing the label, the average log2 values increased deletions by 49% and decreased duplications by 22%. With the Tecan station, we used more washes at higher temps, and tested hybridization at 42C and 52C with increased agitation. These factors increased discrimination for the NimbleGen labeling strategy at both the original and increased hyb temp. At 42C, the average log2 increased for deletions by 35% and for duplications by 45% and, at 52C, 124% and 1% respectively. Finally, we explored alternative labels at 52C. While the Cy3 or Cy5-labeled nucleotides decreased the average log2 for deletions by 53% and duplications by 5%, the AM nucleotides increased the average log2 for deletions by 193% and 22% for duplications. By using AM-based labeling, increasing hybridization temp and increasing stringency of the washes, we have demonstrated a substantial increase in the average log2 values for deletion and duplications on NimbleGen arrays. These protocol changes allow greater certainty in the identification of copy number variant loci.

A Polymorphism in *SLC34A2*, a strong positional and biological gene for osteoporosis, is associated with bone mineral density in three independent populations. *J. Liu[1], N. Hoppman-Chaney[2], P. Giampietro[3], C. McCarty[3], B. Mukesh[3], L. Ivacic[3], N. Ghebranious[3], E. A. Streeten[1], D. McBride[1], A. R. Shuldiner[1], B. D. Mitchell[1]* 1) Dept Human Genetics, Univ Maryland, Baltimore, MD; 2) Clinical Molecular Genetics, Mayo Clinic, Rochester, MN; 3) Dept Med Genetics, Marshfield Clinic, Marshfield, WI.

Low bone mineral density (BMD) is a major risk for osteoporosis and is highly heritable. In a previous linkage study carried out in Mexican Americans, strong evidence was obtained for a QTL influencing forearm BMD to a region harboring over 30 known genes on chromosome 4p near D4S2639 (LOD= 4.3). To identify gene(s) on 4p accounting for this linkage, we genotyped 1506 SNPs in or near every gene within the 2-LOD support interval. We observed that 6 SNPs from four genes (*KCNIP4*, *SLC34A2*, *LDB2* and *STIM2*) were strongly associated with forearm BMD ($p<0.001$). Of these, one SNP, rs2240997 (MAF=0.26), in *SLC34A2* showed the strongest association with both forearm ($p=0.0003$) and hip BMD ($p=0.000035$). The at-risk allele was associated with an estimated 0.27 unit decrease in Z score of hip BMD and accounted for 3% of variance in this trait. These six SNPs were genotyped in an independent population comprising postmenopausal Caucasian women without osteoporosis or osteopenia (n=293). Rs2240997 (MAF=0.14) was strongly associated with decreased Z score of BMD ($p=0.006$) in this replication set with the risk allele associated with a 0.23 unit decrease in BMD Z score, consistent with our original finding in Mexicans Americans. As a second replication, rs2240997 was associated with spine BMD in a recent published BMD genome-wide association study of Icelanders (n=5861; $p=0.027$) (Stefansson et al, N Engl J Med; 2008; 358). In summary, we have identified a genetic variant in *SLC34A2* that influences BMD in Mexican Americans and observed this association to be replicated in two independent Caucasian populations. SLC34A2 is a sodium-phosphate transport protein expressed mainly in the intestine, which may be involved in regulation of bone metabolism by affecting phosphate absorption, making it an excellent biological candidate gene for BMD and osteoporosis.

SNPs in *FTO* and *GNB3* are associated with obesity in Mexicans. *D. Velazquez[1,2], I. Silva-Zolezzi[1], A. Contreras[1], J. S. Hernandez[1], C. Diaz[1], R. Gutierrez[1], K. Carrillo[1], R. Reynoso[2], M. F. Herrera[2], E. Garcia-G[2], G. Jimenez-Sanchez[1]*
1) National Institute of Genomic Medicine, Mexico; 2) National Institute of Medical Sciences, Salvador Zubiran, Mexico.

Obesity is a worldwide epidemic. In Mexico, approximately one fourth of the population is obese (BMI 30 kg/m2). We designed a case-control study in Mexicans by their BMI (30 and 27 kg/m2 respectively). A total of 138 cases and 92 non-obese controls were included (mean BMISD in cases=26.74.3 kg/m2 and in controls=46.810 kg/m2, p<0.0001). About 50% of cases reported to have a first-degree obese relative and/or to have obesity since childhood. We compared these groups with 1288 individuals obtained from the general population (from 8 different states of Mexico). We genotyped the following 23 SNPs in 14 genes by TaqMan (ABI, USA): *ADIPOQ* (rs1501299, rs2241766, rs822396), *LEPR* (rs1137100, rs1137101, rs8179183, rs13306526), *LEP* (rs17151919), *GNB3* (rs5443), *MC3R* (C_27859133), *MC4R* (rs13447335, rs13447324, rs13447332), *NR3C1* (rs6195, rs33391, 6192), *AGRP* (rs5030980), *ADRB3* (rs4994), *ADRB2* (rs1042714), *PPARG2* (rs1801282), *POMC87* (rs1042571), *POMC158* (rs2071345) and *FTO* (rs8050136). To test for association we used traditional Chi square analysis and Cochran-Armitages trend test. Our results showed association for rs5443 in *GNB3* (OR=1.7 95% CI=[1.2-2.6], p=0.007) and for rs8050136 in *FTO* (OR=2.1 95% CI=[1.3-3.4], p=0.002). Observed MAF in cases for selected SNPs were closer to those in control population particularly in the case of *GNB3*. In addition, we observed that females were predominantly more obese than males (p=0.0001), and both, fat percentage and waist & hip ratio were significantly different between the groups (p<0.0001). We found evidence that variants in *GNB3* and *FTO* are moderately associated to obesity in Mexican Mestizos. To increase statistical power in our study we are increasing sample size and will further analyze population stratification in our sample.

Phagocytosis is altered in cell cultures from patients with choroideremia. *A. K. Thiagarajasubramanian[1], N. Strunnikova[1], Y. Sergeev[1], N. Gordiyenko[1], C. Silvin[2], R. Fariss[3], I. M. MacDonald[1]* 1) OGFVB/ NEI/NIH, Bethesda, MD; 2) NHGRI/NIH, Bethesda, MD; 3) OSD/NEI/NIH, Bethesda, MD.

Choroideremia (CHM) is an X-linked form of retinal degeneration characterized by slowly progressive atrophy of the retinal pigment epithelium (RPE), photoreceptors, and choroid. The disorder is caused by loss-of-function mutations in the Rab Escort Protein 1 gene (*REP1*), which is a key regulator of vesicular trafficking, phagosome fusion and maturation. CHM is thought to specifically affect the eye as, in other tissues in the body, a second Escort Protein (REP-2) may compensate for the functional absence of REP-1. To test the potential systemic effect of REP1 mutations, we performed experiments on skin fibroblasts and monocytes from CHM patients. All patients had mutations in *REP1* and lacked the protein product as determined by immunoblot analysis with anti-REP-1 antibody. Phagocytosis in fibroblasts was induced with collagen-coated FluroSpheres (Invitrogen, Carlsbad, CA). Similar experiments were undertaken in fibroblasts and monocytes with *E. coli* conjugated with a pH dependent dye (pHrodo). Phagocytosis was tracked using fluorescence-activated cell sorting (FACS) and live cell imaging analysis. Skin fibroblasts from 3 CHM patients and age-matched controls, and monocytes (CD14 positive fraction) from 6 CHM patients and controls were compared for differences in phagocytosis. In the fibroblasts from CHM patients, the rate and quantity of *E. coli* pHrodo uptake was decreased compared to the controls. The same effect was seen in fibroblasts from CHM patients fed with collagen microspheres. In the monocytes from CHM patients, *E. coli* pHrodo uptake was significantly increased in comparison to the controls. These novel findings from the study of monocytes and fibroblasts suggest a systemic dysregulation of phagocytosis in CHM patients. These observations may lead to new approaches to the study and potential treatment of this unique disorder.

Expression microarray platform performance and content analysis in mouse model of mitochondrial disease therapy. *E. F. Rappaport[1], Z. Zhang[1], M. J. Falk[2], D. L. Gasser[3]* 1) Biomedical Informatics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Genetics, University of Pennsylvania School of Medicine.

As more options for microarray platform emerge, questions arise concerning array content and design to best maximize experimental data analysis. Prior cross-platform studies have tended to provide a more global comparison of array performance. Our goal was to compare the functional consequences of differences in array data between platforms utilizing samples for a discrete animal model in which we had already established a foundation of biological knowledge. Liver RNA was isolated from four liver-conditional Pdss2 knockout mice aged 140 to 169 days (B6. Alb/cre,Pdss2loxP/loxP), two of whom were treated with the antioxidant Probucol since birth and the other two of whom were untreated. Targets from these samples were prepared and hybridized to Affymetrix Mouse Genome 430_2 (a 3 focused array), Affymetrix Mouse Exon 1.0 ST, and Illumina Mouse Whole Genome WG-6 arrays. Significant inter-platform correlation was seen in differential gene expression between treated and untreated groups, and all three platforms identified Biosynthesis of Steroids as the most altered KEGG pathway. However, the three platforms differed in terms of content, annotation, and software support. The exon array had superior representation by covering more than 98% of KEGG genes, but biased results in favor of bigger genes. The 3-focused array had superior software and well-established analysis methods, but some outdated content and less extensive coverage than the other two platforms. The Illumina platform demonstrated high technical repeatability, up-to-date content, and less-ambiguous annotation, but software and analytic methods were not as extensive as for the 3-focused arrays. These results indicate that similar data and conclusions can be generated with any of these expression array platforms, but the specific goals of the investigator might determine which one is best suited to a given study.

Markers for sex-specific prenatal selection. *E. Ucisik-Akkaya, C. Davis, B. Morrison, T. Do, M. T. Dorak* Genomic Immunoepidemiology, HUMIGEN LLC, the Institute for Genetic Immunology, 2439 Kuser Road, Hamilton, NJ 08690.

There are no established genetic markers mediating prenatal selection. Most studies are designed to find clues focused on couples experiencing recurrent miscarriages, but such events represent only a fraction of total prenatal loss. Based on the strikingly high male-to-female ratio at the time of fertilization, which diminishes by birth, we postulated that prenatal selection is sex-specific and strongly acts against males. To test this hypothesis, we examined candidate genes in male and female newborns (n=389). We first considered the HLA complex to replicate previously reported findings. We identified a haplotype (HSPA1B rs1061581- HLA-DRA rs7192- HLA-DQA1 rs1142316) whose major alleles characterize the ancestral HLA-DRB4 lineage (HLA-DR4, DR7 and DR9), while the minor alleles represent the HLA-DRB3 lineage (DR3, DR11/12 and DR13/14). Similar to our previous finding by HLA-DRB1 typing, males had a deficit for homozygosity for the SNP haplotypes corresponding to the ancestral lineages (6.7% vs 16.4%; $P = 0.007$). These SNPs can replace HLA typing in replication studies. In KLRK1 (chromosome 12) encoding the natural killer receptor NKG2D, multiple SNPs showed reduced heterozygosity rates in males compared with females ($P < 0.05$). Hardy-Weinberg equilibrium was violated in boys but not in girls. Wrights fixation index suggested the loss of up to 18.4% of males during the prenatal period. Given the eminent role played by NK cells and in particular the NKG2D receptor in feto-maternal interactions, this finding is biologically plausible. In contrast to other reports, we did not find any evidence for the involvement of TP53 rs1042522 (R72P) in prenatal selection. Heme oxygenase 1 activity is implicated in fetal protection and we found evidence for decreased minor allele homozygosity at HMOX1 SNP rs2071748 in males (13.8 vs 22.6%; $P = 0.04$). Overall, these findings suggested that male-female differential in genotype frequencies at loci relevant to fetal survival may be sought to discover markers for prenatal selection.

Promoter polymorphisms of the *CSF2* gene are associated with its transcription. *JQ. He, J. Yuan, P. Paré, A. Sandford* James Hogg iCAPTURE Centre for Cardiovascular and Pulmonary Research, St. Pauls Hospital, University of British Columbia, Vancouver, BC, Canada.

Background: We previously reported an association of the A allele of a single nucleotide polymorphism (SNP) of *CSF2*_545A/G (-1440A/G, rs2069616) with atopic asthma in at-risk children at 1 year of age. A later report showed that the mutant allele (C allele) of another SNP, *CSF2*_-677A/C (rs1469149), in complete linkage disequilibrium (LD) with the -1440A/G SNP, was associated with lower frequency and severity of childhood allergic dermatitis. We hypothesized that promoter polymorphisms of *CSF2* are associated with its transcription. Methods: A third SNP (*CSF2*-1916T/C, rs2069614), in complete LD with the two abovementioned SNPs, was identified from the SeattleSNP database. Two constructs containing the wild-type haplotype of these 3 SNPs (-1916T/-1440A/-677A) and the mutant-type haplotype (-1916C/-1440G/-677C) were obtained from PCR amplifying samples homozygous for either the wild-type or mutant-type at all three SNPs. The effect of these SNPs on gene expression was evaluated by the transient expression of a luciferase reporter gene using the pulmonary epithelial cell line A549. Results: The transcriptional activity of the mutant-type *CSF2* haplotype (CGC) was significantly decreased compared with the wild-type *CSF2* haplotype (TAA) (14% decrease, $p = 0.0002$). Stimulation by TNF increased the transcriptional activities by 1.6 fold. However, the fold increases of transcriptional activities after TNF stimulation were not significantly different in cells with the wild-type vs. mutant-type haplotype. Conclusion: Consistent with the previous association study that the mutant-type of *CSF2* genotypes were associated with protection against allergic diseases, the mutant-haplotype was associated with less transcription in reporter gene assays. Supported by the Canadian Institutes of Health Research.

Feline Acute Intermittent Porphyria (AIP) Masquerading as Congenital Erythropoietic Porphyria: Biochemical & Molecular Studies of Three Unrelated Cats. *S. Clavero[1], D. F. Bishop[1], M. Haskins[2], U. Giger[2], R. J. Desnick[1]* 1) Genetics & Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Section of Medical Genetics, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA.

Acute Intermittent Porphyria (AIP) is an autosomal dominant inborn error of heme biosynthesis, due to the half-normal activity of hydroxymethylbilane synthase (HMBS). Humans with AIP can experience life-threatening acute neurologic attacks precipitated by various drugs, dieting and hormonal changes. No naturally occurring animal models exist. Three unrelated domestic shorthair or Siamese cats from three disparate locations in North America were referred for evaluation of congenital erythropoietic porphyria (CEP) due to reddish-colored urine and reddish-brown teeth (erythrodontia) that fluoresce under UV light. Although the clinical phenotype was consistent with recessively inherited CEP, inheritance appeared autosomal dominant and sequence analysis of the feline uroporphyrinogen III synthase gene identified no mutations. Analysis of urinary porphyrins and metabolites revealed marked elevations of PBG (2- to 7-fold), uroporphyrinogen I (25- to 101-fold) and III (42- to 149-fold), coproporphyrinogen I (3- to 12-fold) and III (3 to 6-fold), and normal to 8-fold elevated 5-aminolevulinic acid (ALA), suggesting an acute porphyria. Erythrocytes from all three cats had ~50% HMBS activity, consistent with AIP. Cloning and sequencing of the feline *HMBS* gene from these three cats revealed three different mutations: an in-frame three base deletion (c.842_844delGAG), reported in a human AIP family, a single thymidine insertion (c.189insT) and a missense mutation (R149W; R149X in human AIP). While these AIP cats phenotypically masquerade as CEP, they are actually AIP, with the more severe deletion and insertion mutations resulting in constitutively high ALA and PBG levels, indicating that they have a cronic acute attack syndrome. These cats are the first natural animal models for AIP and future studies of their neuropathology may provide insights into the neurotoxic metabolites causing human AIP. Support: NIH R01DK026824 & RR02512.

Next-Generation whole genome sequencing of a single human recapitulates population signatures of natural selection. *F. C. L. Hyland[1], Z. Zheng[1], S. McLaughlin[2], E. F. Tsung[2], H. Peckham[2], C. Lee[2], G. Costa[2], F. M. De La Vega[1], K. McKernan[2]* 1) Applied Biosystems, Foster City, CA; 2) Beverly, MA.

We sequenced the whole genome of an African Yoruba individual (in HapMap and 1000 Genomes Projects) by sequencing fragment and mate-pair libraries of various sizes with the Applied Biosystems SOLiD system. We detected over 2,000,000 SNPs; 81.4% are in dbSNP. SNPs are under-represented in exons (1.98%). 11% of exons contain at least one SNP. Of coding SNPs, 54% are silent, 45% are missense, and 0.6% are nonsense. We categorize the functions of genes using the Panther ontology, and we annotate the damaging potential of non-synonymous SNPs (nsSNPs) using PolyPhen. 20.5% of nsSNPs in this sample are predicted to be damaging, vs 33.2% in the PolyPhen database. We discovered that transcription factors, ligases, growth factors, receptors, and RNA helicases are the molecular functions most under-represented for damaging mutations. Further, we discovered that GPCR genes involved in Olfaction, and genes for Immunity and defense are the biological functions most highly over-represented for damaging mutations. Olfaction and Immunity have previously been observed to be under recent positive selection in human populations; we observe evidence of purifying selection and of directional selection in a single human sample. We performed gap alignments of reads looking for small InDels (11bp deletion to 4bp insertion), identifying 90,000 small InDels. The number of insertions and deletions is symmetrical; 1bp is the most common size. InDels are significantly underrepresented in exons. Most InDels in exons occur in the last exon, which contains the 3 UTR region; they are also overrepresented in the first exon, containing the 5 UTR - as expected, since an InDel in a translated region may cause a frameshift. Of 1290 exons which contain an InDel, 979 are the first or last exons (851 are the last exon). InDels are highly non-randomly distributed within genes: we expect to see 13 genes with 2 or more InDels, instead we see 184 ($p << 10\text{-}10$). These observations are consistent with a low rate of false positives, and provide evidence for strong purifying selection against InDels in translated exons.

Genome-wide linkage analysis of an autosomal recessive hypotrichosis identifies a novel P2RY5 mutation. *L. Petukhova[1], E. C. Sousa, Jr.[2], A. Martinez-Mir[1], A. Vitebsky[1], L. G. dos Santosc[3], L. Shapiro[4], C. Haynes[5], D. Gordon[6], Y. Shimomura[1], A. M. Christiano[1, 7]* 1) Department of Dermatology, Columbia University, New York, NY, USA; 2) Departmento de Clínica Geral (Clínica Cirúrgica I), Universidade Federal do Piauí, Teresina, Piauí, Brazil; 3) Departamento de Pathologia, Universidade Federal do Piauí, Teresina, Piauí, Brazil; 4) dDepartments of Biochemistry & Molecular Biophysics and Ophthalmology, Columbia University College of Physicians & Surgeons, New York, New York, USA; 5) Laboratory of Statistical Genetics, Rockefeller University, New York, NY, USA; 6) Department of Genetics, Rutgers University, Piscataway, NJ, USA; 7) Department of Genetics & Development, Columbia University College of Physicians & Surgeons, New York, New York, USA.

While there have been significant advances in understanding the genetic etiology of human hair loss over the previous decade, there remain a number of hereditary disorders for which a causative gene has yet to be identified. We studied a large, consanguineous Brazilian family that presented with sparse woolly hair at birth that progressed to severe hypotrichosis by the age of 5, in which 6 of the 14 offspring were affected. After exclusion of known candidate genes, a genome-wide scan was performed to identify the disease locus. Autozygosity mapping revealed a highly significant region of extended homozygosity (LOD score of 10.41) that contained a haplotype with a linkage LOD score of 3.28. Results of these two methods defined a 9 Mb region on chromosome 13q14.11-q14.2. The interval contains the P2RY5 gene, in which we recently identified pathogenic mutations in several families of Pakistani origin affected with autosomal recessive woolly and sparse hair. After the exclusion of several other candidate genes, we sequenced the P2RY5 gene and identified a homozygous mutation (C278Y) in all affected individuals in this family. Our findings show that mutations in P2RY5 display variable expressivity, underlying both hypotrichosis and woolly hair, and underscore the essential role of P2RY5 in the tissue integrity and the maintenance of the hair follicle.

Increase in Left Ventricular Mass in Glycogen Storage Disease IIIa. *S. M. Vertilus[1], S. Austin[2], K. Foster[1], K. Boyette[2], D. Bali[2], J. S. Li[1], P. Kishnani[2], S. Wechsler[1,2]* 1) Pediatric Cardiology, Duke University Medical Center, Durham, NC; 2) Medical Genetics, Duke University Medical Center, Durham, NC.

Background: Glycogen Storage Disease type IIIa (GSD IIIa) is caused by a deficiency in glycogen debranching enzyme resulting in an accumulation of glycogen in the liver, skeletal and cardiac muscle. Some patients (pts) with GSD IIIa develop an increase in left ventricular mass (LV mass) by echocardiography, but the rate of increase and clinical significance remain unknown. There are a few reports of sudden cardiac death and one reported case of heart, liver, and kidney transplant. To date, there is no systematic review of long term follow up to assess the extent and rate of progression. Methods: We evaluated a cohort of 12 pts with GSD IIIa, mean age 12.9 years (5 months - 39 yrs), over a mean time period of 4.8 yrs (1.1 - 9.1 yrs). GSD IIIa was confirmed by genetic and/or enzyme analysis in all pts. These pts had serial echos read by two investigators (SV, KF). Measurements reviewed included LV mass, shortening fraction (SF), and ejection fraction (EF). No alternate cause of increased LV mass was identified in any pt. Results: Eight of the 12 pts had an increase in LV mass from baseline to endpoint assessments. Four of these 8 pts had a substantial increase in mass over time. Three patients doubled their LV mass over time. Two pts had rapid increases in LV mass (40 gm/m2 and 24 gm/m2) over a short period (1 - 1.5 yrs.). The mean LV mass at baseline was 54.8g/m2 (30 - 103) and the mean LV mass at endpoint was 74.2g/m2 (43 - 129). For all 12 pts, the mean change in LV mass was 19 g/m2 (-13 - 75), from baseline to endpoint echos. SF and EF remained normal for all patients at all points examined (36 and 24 measurements respectively) over the entire period. No pt required cardiovascular medications. Conclusion: Pts with GSD IIIa develop an increase in LV mass, albeit not to the same extent as seen in patients with other types of GSDs, but with no diminution in SF or EF by echo. This suggests that serial echos with attention to left ventricular mass are necessary in the care of these pts.

DOES THE NEURAL RESTRICTIVE SILENCER FACTOR (NRSF) REGULATE THE EXPRESSION OF CHOLINE ACETYLTRANSFERASE (CHAT) IN CEREBRAL TISSUE OF ALZHEIMER'S DISEASE PATIENTS? *R. E. Gonzalez-Castañeda[1,2,4], V. Sánchez-González[2,4], V. Loera-Castañeda[5], G. Vázquez-Camacho[3], M. Macías-Islas[3], A. Barba-González[4], G. Gabriel Ortiz[2,4]* 1) Neurociencias, Universidad de Guadalajara, Mexico; 2) Laboratorio de Desarrollo-Envejecimiento; Enfermedades Neurodegenerativas, CIBO, IMSS,; 3) Depto. de Anatomía Patológica y Depto. de Neurología, UMAE-HE, CMNO, IMSS, México; 4) Depto. de Ciencias Básicas Médicas, Instituto Tecnológico y de Estudios Superiores de Monterrey, Guadalajara, México; 5) Centro Universitario de Investigación Integral Regional, Unidad Durango.

Alzheimer's disease (AD) is a particular form of progressive dementia associated with distinct neuropathologic changes. Likewise, the most consistent biochemical changes is a decrease in choline acetyltransferase (CHAT) enzyme activity in the target areas of basal forebrain cholinergic neurons. Previous reports showed that the syntheses of the cholinergic neuron-essencial molecules involved in cholinergic neurotransmission are elaborately controlled by DNA regulatory elements like the neural restrictive silencer factor (NRFS). Objective. To evaluate ChAT and NRSF genetic and protein expression cerebral tissues of AD patients. Methods. Frontal, temporal, entorhinal and parietal cortices were obtained from four autopsied patients with Alzheimer's, and patients with no clinical history or pathological findings suggestive of neurological diseases. The cerebral tissue was processed by the guanidine isothiocyanate method for RNA extraction. ChAT and NRSF expression was determined by reverse transcription-polymerase chain reaction (RT-PCR) and Western blotting. Results. CHAT expression in the control and AD group is greater in the frontal and entorhinal cortices and smaller in the temporal and parietal regions. Nevertheless, the expression is greater in the control than in the AD group. Despite the CHAT variations in the control group, the levels of ChAT protein remain constant; whereas in the AD group the expression presents a peak in the entorhinal cortex and a remarkable diminution in the frontal region ($p>0.05$, W test). The regional analysis of the NRSF gene is greater in the AD group ($p>0,05$, W test).

Joint effects of circadian genes and serum androgens on prostate cancer risk in the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial. *L. W. Chu[1], Q. Li[1], K. Yu[1], Y. Zhu[2], W.-Y. Huang[1], J. M. Weiss[1], P. S. Rosenberg[1], I. Menashe[1], S. Quraishi[1], A. P. Chokkalingam[3], R. B. Hayes[1], S. J. Chanock[1], A. W. Hsing[1]* 1) NCI, NIH, Bethesda, MD; 2) Yale University, New Haven, CT; 3) University of California, Berkeley, CA.

Circadian rhythms are controlled endogenously by 9 circadian genes and can influence androgen biosynthesis, which is important for prostate development. Using data from a case-control study nested in the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial used for the NCI Cancer Genetic Markers of Susceptibility Project (283 non-aggressive and 236 aggressive incident cases, and 563 controls), we examined the joint effects of circadian genes (represented by 155 SNPs) and serum androgens (categorized by quartiles, Q1-4) on prostate cancer risk. Polytomous regression analysis and likelihood ratio tests (LRT) showed significant interactions between androgens and 40 SNPs in 9 circadian genes(p_{LRT}<0.05). For example, for non-aggressive cases, the *CSNK1E* rs135757 A allele was not associated with prostate cancer risk relative to the GG genotype among men with Q1 levels of 3-androstanediol glucuronide (3-diol G; a surrogate marker for tissue androgen). However, among men with Q2 and Q3 levels of 3-diol G, the GA genotype conferred 1.5- and 1.7-fold increased risks, respectively (95% CI, 0.9-2.5 and 1.0-2.8, respectively), and the AA genotype conferred 3-fold increased risks (95% CI, 1.3-6.6 and 1.3-6.9, respectively; $p_{interaction}$=*0.003*); results for Q4 are less stable due to small numbers. After adjusting for all SNPs tested within the same gene by bootstrapping, significant interactions remained between androgens and 6 SNPs in 4 circadian genes, including that between 3-diol G and *CSNK1E* rs135757 (p_{LRT}=*0.03*). The truncated product method (TPM) for assessing pathway effects further showed significant interactions between the circadian pathway (including all SNPs from the 9 genes) and 3-diol G (p_{TPM}=*0.048*) and total testosterone (p_{TPM}=*0.03*). These results suggest that genes in the circadian pathway may interact with androgens to modulate prostate cancer risk.

Targeted genomic sequencing at an association locus. *A. Kapoor[1], D. Arking[1], A. OConnor[1], M. Sosa[1], N. Hansen[2], M. Ross[3], D. Bentley[3], J. Mullikin[2], A. Pfeufer[4], N. I. S. C. Comparative Sequencing Program[2], A. Chakravarti[1]* 1) IGM, JHU, Baltimore, MD; 2) NHGRI, NIH, Bethesda, MD; 3) Illumina, Little Chesterford, UK; 4) TU Munich, Germany.

Genome-wide association studies typically reveal a 15-150 kb locus with common variants that confer disease-susceptibility. There are yet no validated methods for identifying susceptibility variants directly, however, DNA sequencing to reveal all extant variation of target locus is a necessary first step. We describe a method to recover and sequence the entirety of 141 kb of NOS1AP locus associated with QT-interval. The target locus comprises of 5 region, exon 1 and 2, intron 1 and most of intron 2 of NOS1AP, and has 554 dbSNP/273 HapMap SNPs. DNA from target interval was recovered by long-range PCR and pooling of 16 overlapping amplicons. One amplicon showed differential allele-specific amplification that we mapped to a 1051 bp segment arising from sequence variation at a repeat motif on a haplotype marked by the A allele at rs4656349: we amplified this separately. We pooled all amplicons per sample from 8 CEU and 8 YRI HapMap samples and 48 samples from individuals with extreme QT-intervals. Direct sequencing of amplicon pool was performed using Solexa SBS Technology and paired-end reads of 25 nt were aligned to a reference sequence (NCBI36). Data were analyzed using ELAND and MPG software and we present the findings from CEU samples. The mean coverage depth in reads ranged between 269-555 (ELAND) and 304-792 (MPG) with variation largely from amplicon-to-amplicon differences and at an ELAND threshold of 6 (2 PhredQ30 bases or 3 Q20 bases) missed coverage of only 69-593 bp of the locus. MPG detected 535 known and 127 novel SNPs. There was 98.9% concordance of genotypes with HapMap, with all discrepancies at 11 positions due to genotyping errors from calls on complementary strands or call reversals and at 2 positions from deeper Solexa coverage. These results demonstrate the high specificity and sensitivity of this approach for obtaining full-coverage and a complete inventory of all genetic variation in a genomic region. Analyses of structural variation and additional samples is under completion.

A genome-wide survey of recent natural selection in African-origin samples. *T. Feng[1], H. Lyon[2], B. Tayo[3], S. J. Kang[1], C. Chiang[2], R. Cooper[3], J. Hirschhorn[2,4], X. Zhu[1]* 1) Dept. of Epi & Biostat, Case Western Reserve Univ., USA; 2) Div. of Genetics, Childrens Hospital Boston and Harvard Medical School, USA; 3) Preventive Medicine & Epi, Loyola Univ. Medical Center, USA; 4) Broad Institute of Harvard and MIT, Cambridge, MA.

The ability to detect recent natural selection in the human population would have profound implications for the study of human diseases. Here, we report a genome wide survey of recent selection by examining the long range haplotypes in two African-origin cohorts: 768 Nigerians and 703 African-Americans from Maywood, USA. All the DNA samples were genotyped with the Affymetrix 6.0 chip, with 857551 and 793950 SNPs passing quality control for Maywood and Nigerian samples, respectively. To reduce the computational burden, we partitioned chromosomes into blocks consisting of no more than 1500 SNPs, with each gene contained in one block. We inferred the haplotypes of each individual-with the software fastPhase. We next applied the software Sweep to detect selection signals across the genome. Similar to the previous reports in the literature, we observed widespread selection signals in the genome in both Maywood and Nigerian samples. Using the criteria that haplotype (consisting derived alleles) frequency 0.5, |iHs|2.5 and at least 3 SNPs in each core haplotype, we identified 2283 and 2072 regions that may show selection evidence in Nigerian and Maywood samples. There are 664 core haplotypes shared in the Maywood and Nigeria cohorts. Known selection evidence in genes such as CDH12, CD36 and Large is also confirmed in our dataset. Although the partially overlapping results may suggest many regions may be under population specific selection pressure due to the adaptation of environments, it may also indicate the challenge in separating true selection signals from noise using current statistical methods. Finally, the analysis in an African-American population could be confounded by admixture of chromosomes from different ancestral populations. We are testing this hypothesis by simulation of African-American chromosomes in genome regions where no selection evidence has been identified, as the null distribution.

Further Delineation of the Xp11.23-p11.22 Microduplication Syndrome. *P. Hurtado[1,2], S. Parkash[1], L. Dupuis[1], D. J. Stavropoulos[1,3], R. Mendoza-Londono[1]* 1) Div. Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, ON, Canada; 2) Inst de Genetica Humana, Pontificia Univ Javeriana, Bogota, Colombia; 3) Dept. Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, ON, Canada.

Pure duplications of segments of the X chromosome are rare events. Microduplications of chromosome X have been found in males with mental retardation and may involve known X-linked mental retardation genes as well as the *MECP2* gene. Females are less frequently affected possibly due to preferential inactivation of the duplicated X. We describe a 27-month-old girl who presented with status epilepticus, hypotonia, significant developmental delay and dysmorphic features including brachycephaly, triangular-shaped face with flat profile, small mouth with thin lips and small palpebral fissures. Her weight and length plotted along the 10th to 25th centile and her head circumference was on the 2nd centile. G-banding Karyotype revealed normal female complement 46,XX. Array comparative genomic hybridization (aCGH) revealed a *de-novo* duplication of ~4Mb of chromosome region Xp11.23-p11.22 involving 6 BAC clones. The duplication was confirmed by FISH with BAC clone RP11-576P23. Parental FISH analysis was normal. X inactivation studies are underway. This genomic region harbors over 20 genes. Our patient constitutes the 4th reported case of microduplication of Xp11.23-p11.22. The presence of seizures in her may be related to functional dysomy for one of the genes in this region. We present a detailed clinical comparison of the reported patients and further delineate the clinical phenotype for this newly recognized microduplication syndrome.

Specific Pur alpha-interacting proteins modulate the neuronal toxicity caused by fragile X premutation rCGG repeats. *W. Li, A. Qurashi, Y. Qin, L. Ray, P. Jin* Human Genetics, Emory University School of Medicine, Atlanta, GA.

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a neurodegenerative disorder in fragile X premutation carriers with FMR1 alleles containing 55-200 CGG repeats. Using a Drosophila model of FXTAS, we previously demonstrated that transcribed premutation repeats alone are sufficient to cause neurodegeneration, suggesting that rCGG repeat-binding proteins (RBPs) may be sequestered from their normal function by rCGG binding. Recently we identified Pur alpha and hnRNP A2/B1 as RBPs, which could modulate the rCGG-mediated neuronal toxicity. To further investigate the role of Pur alpha in rCGG-mediated neurodegeneration, we have taken a proteomic approach to identify the proteins that interact with Pur alpha. Around 100 proteins, including several known interactors such as Fmrp, were found to directly interact with Pur alpha in vitro. To evaluate the potential contribution of Pur alpha-interacting proteins to rCGG-mediated toxicity, we further tested their genetic interactions with rCGG repeats using our FXTAS transgenic fly models. Interestingly, only two proteins, Rm62 and Hts, could modulate the rCGG-mediated toxicity. These data suggest that specific pathway regulated by Pur alpha could contribute to rCGG-mediated toxicity.

Evolutionary analysis across the HRAS1 minisatellite locus and its functional implication. *C. Ouyang[1], G. X. Zhang[1], S. F. Ding[1], D. D. Smith[2], T. G. Krontiris[1]* 1) Division of Molecular Medicine, Beckman Research Institute of the City of Hope, Duarte, CA; 2) Division of Information Sciences, Beckman Research Institute of the City of Hope, Duarte, CA.

We investigated a 9-kb block of sequences in strong linkage disequilibrium on chromosome 11p15 encompassing the human HRAS1 oncogene and the downstream polymorphic minisatellite (VNTR) implicated in cancer predisposition. We resequenced 12 chimpanzees and 125 individuals across three major human populations (African, European, and Japanese), identified single nucleotide polymorphisms (SNPs), genotyped VNTR alleles, and constructed full SNP-VNTR haplotypes for evolutionary analysis. Phylogenetic analysis revealed that, despite a large number of minisatellite alleles, the common haplotypes could be clustered into two major clades arising since the divergence of the human and chimpanzee lineages. The four most commonly observed European minisatellite alleles and their derivatives marked the sub-clades. SNPs tagging such haplotype lineages showed significant association with expression levels of other genes, suggesting some novel functional property of the VNTR locus. Also, population genetic analysis suggested evolutionary selection further downstream from the HRAS1 gene and the minisatellite a region where no gene was annotated, but which demonstrated significant conservation across vertebrates.

Interstitial Cystitis is a genetically heterogeneous disorder. *S. Boyden[1,3], J. Dimitrakov[2], L. Kunkel[1,3]* 1) Dept Genomics, Children's Hosp, Boston, MA; 2) Dept Urology, Children's Hosp, Boston, MA; 3) Dept Genetics, Harvard Medical School, Boston, MA.

Interstitial Cystitis (IC) is a debilitating bladder disease characterized by chronic severe pelvic pain and extreme frequency and urgency of urination. Its etiology is unknown but there is a 17-fold increased relative risk to first degree relatives of affected patients. We ascertained a group of large kindreds from Bulgaria that show autosomal dominant inheritance of IC. Members of six of these families were genotyped using a 10,000 SNP microarray and parametric linkage analysis was used to map the locations in separate families of four distinct loci that each potentially harbor a mutation that causes IC. We provide the first evidence that IC is a genetic disease that can show Mendelian inheritance, and we demonstrate that it exhibits marked locus heterogeneity. The future identification of multiple IC genes may define a biological pathway essential for proper bladder function and lead to new avenues of IC research and targeted therapeutic strategies.

The Grancalcin gene on chromosome 2q22 is a novel positional candidate for pre-eclampsia susceptibility. *E. K. Moses[1], M. P. Johnson[1], L. F. Tømmerdal[2], C. E. East[3], T. D. Dyer[1], J. Blangero[1], R. Austgulen[2], S. P. Brennecke[3]* 1) Dept Genetics, Southwest Foundation for Biomedical Research, San Antonio, Texas; 2) Department of Cancer Research and Molecular Medicine, Faculty of Medicine, Norwegian University of Science and Technology (NTNU), Trondheim, Norway; 3) Department of Obstetrics & Gynaecology, University of Melbourne, Carlton, Australia.

We are currently dissecting a susceptibility locus for pre-eclampsia on chromosome 2q22 in Australian and New Zealand families. Our strategy involves SNPing across this region with known gene-centric SNPs combined with genome wide transcriptional profiling in decidua from pre-eclamptic and control pregnancies to prioritize genes for deep re-sequencing in our affected families. We initially genotyped 586 known SNPs from within 72 genes; 414 of these SNPs were polymorphic and our preliminary statistical analysis identified only 1 SNP (rs12693126) in the proximal promoter of the *ARL5A* gene showing significant evidence of association with pre-eclampsia. We have now re-sequenced 13 genes in 48 pre-eclamptic women from our families. A total of 423 polymorphisms (414 SNPs and 9 insertion/deletion variants) have been identified, including 42 of the 586 known SNPs that we had genotyped previously. Of the 372 newly identified SNPs, 192 have now been genotyped in the original set of 34 pre-eclamptic families (The 34 Family Cohort) plus an extension of this family cohort that incorporates an additional 40 pre-eclamptic families (The 74 Family Cohort). The *ARL5A* SNP (rs12693126) showing significant association in the 34 Family Cohort ($p = 1.1 \times 10^{-4}$) was not significant in the extended 74 Family Cohort (p > 10-2). The strongest association observed ($p = 1.33 \times 10^{-5}$ in the 74 Family Cohort) was for the rs17783344 SNP resulting in a non-synonymous amino acid change [S>A] in exon 3 of the GCA (Grancalcin) gene that has not previously been implicated in pre-eclampsia. We are currently performing a replication association study with the *ARL5A* and *GCA* SNPs in a large Norwegian case and control sample derived from the HUNT population study.

Autosomal recessive woolly hair with hypotrichosis caused by a novel homozygous mutation in the P2RY5 gene.
Y. Shimomura, M. Garzon, A. Christiano Dermatology, Columbia University, New York, NY.

During the last decade, several causative genes for hereditary hair diseases have been identified, which have disclosed the molecular mechanisms involved in the hair follicle morphogenesis and cycling. We and others have recently reported that mutations in the P2RY5 gene, encoding an orphan G protein-coupled receptor, underlie autosomal recessive woolly hair and/or hypotrichosis. Although these findings clearly reveal the involvement of P2RY5 mutations in hereditary hair diseases, the clinical manifestations of P2RY5 mutations have not completely been elucidated due to limited information to date. In this study, we ascertained a consanguineous family of Iranian origin with an affected girl showing sparse and hypopigmented scalp hair. She showed a woolly hair phenotype with normal hair density at birth, but has progressed with age to show hypotrichosis. Direct sequencing analysis resulted in the identification of a novel homozygous mutation (436G>A) in the P2RY5 gene of the patient, which results in a non-conservative amino acid change (G146R) at the protein level. Our findings extend the mutation spectrum of P2RY5 mutations, and further support a crucial role of P2Y5 in hair growth in humans.

Novel de novo genomic imbalances constitute a significant fraction in a cohort of 2333 consecutive clinical samples tested by whole-genome array CGH. *S. Aradhya, S. Warren, N. Flores, J. Hilburn, C. Ding, T. Bonaga, R. Busin, G. Richard* Clinical Microarray Services, GeneDx, Gaithersburg, MD 20877.

In 2333 consecutive clinical cases referred for whole-genome oligonucleotide array CGH testing, we identified 420 (~18%) positive cases and 158 (~6.8%) cases of variants of unknown clinical significance. Many of the positive cases involved rearrangements in regions of high genomic complexity featuring a rich concentration of segmental duplications. We found such rearrangements in 1q21, 2p15, 8p23.1, 9q34, 16p11, 16p13, and 17q21, and all of these loci were recently linked to disease-causing syndromes. As expected, both deletions and reciprocal duplications were identified at many of these loci, but not all rearrangements were pathogenic. Cases classified as variants of unknown clinical significance, in contrast, were generally not found in regions of high complexity, and sometimes involved only a few genes. However, many of these variants were likely causative of clinical phenotypes-a point emphasized by the finding that a significant number of them were de novo imbalances. Half of all cases classified as positive or variant of unknown clinical significance had parental testing data. De novo genomic imbalances accounted for 102 (43%) of these cases tested for inheritance. More than half (58%) of the de novo cases were genomic imbalances that were not described previously. Of the remaining (familial) cases, most were in the variants of unknown significance category. If the cases that did not have parental testing results were to also demonstrate a similar pattern of inheritance, the rate of de novo findings alone for all cases referred for array CGH testing could approach 10%. Our findings highlight the sensitivity of a whole-genome array CGH approach and demonstrate its power to discover genomic imbalances underlying novel clinical conditions.

***TGFBR2* Mutations Reduce Expression of Contractile Proteins in Aortic Smooth Muscle Cells and Predispose Individuals to Thoracic Aortic Aneurysms and Dissections.** *C. S. Kwartler[1], S. Inamoto[1], A. L. Lafont[1], Y. Y. Liang[2], v. Tran-Fadulu[1], M. Willing[3], A. Estrera[4], H. Safi[4], M. C. Hannibal[5], J. Carey[6], J. Wiktorowicz[7], F. Tan[1], X. H. Feng[2], H. Pannu[1], D. M. Milewicz[1]* 1) Department of Internal Medicine, University of Texas Medical School, Houston, TX; 2) Department of Surgery, Baylor College of Medicine, Houston, TX; 3) Department of Pediatrics, University of Iowa, Iowa City, IA; 4) Department of Cardiothoracic and Vascular Surgery, University of Texas Medical School, Houston, TX; 5) Department of Pediatrics, University of Washington School of Medicine, Seattle, WA; 6) Department of Pediatrics, University of Utah College of Medicine, Salt Lake City, UT; 7) Department of Biochemistry and Molecular Biology, University of Texas Medical Branch, Galveston, TX.

Mutations in the TGF- receptor type II gene (*TGFBR2*) cause thoracic aortic aneurysms and dissections (TAAD). Studies have suggested a gain of function for these mutations, with increased TGF- signaling resulting in vascular disease. We characterized the phenotype of smooth muscle cells (SMCs) with *TGFBR2* mutations, and our data suggest that *TGFBR2* mutations cause a loss of function resulting in defective SMC differentiation. Primary aortic SMCs from patients (n=4) showed a global decrease in SMC contractile proteins (ACTA2, MYH11, CNN1, SMTN; $p<0.001$) by quantitative PCR and showed no change in cytoskeletal protein expression when compared with control SMCs. Patient SMCs showed increased expression of S100A4, a marker of de-differentiated SMCs ($p<0.001$). Analysis of aortas from patients (n=3) confirmed decreased expression of SMC contractile proteins. Addition of TGF- increased the expression of SMC contractile proteins in control but not mutant SMCs. Fibroblasts from patients (n=8) failed to transform into myofibroblasts on TGF- stimulation. Finally, introduction of *TGFBR2* mutations into a mouse mesenchymal cell line (10T1/2 cells) disrupted expression of contractile proteins. These data suggest that *TGFBR2* mutations disrupt differentiation of SMCs and myofibroblasts. This is the first genetic defect identified to lead to defective SMC differentiation.

Genomewide copy number analysis in Cornelia de Lange Syndrome. *M. Deardorff[1], M. Kaur[1], M. Berman[1], L. Conlin[1], D. Clark[1], X. Gai[2], J. Perin[2], T. Shaikh[1], H. Hakonarson[1,3], L. Jackson[4], I. Krantz[1]* 1) Division of Genetics; 2) Bioformatics Department; 3) Center for Applied Genomics, Children's Hospital of Philadlephia, PA; 4) Drexel School of Medicine, Philadelphia, PA.

The Cornelia de Lange syndrome (CdLS) is a multisystem developmental disorder with facial dysmorphia, growth and cognitive retardation, gastrointestinal abnormalities and limb deficiencies. We have identified mutations in 65% of patients with CdLS. These mutations involve the genes *NIPBL*, *SMC1A* and *SMC3*, all of which are involved in sister chromatid cohesion, a process that regulates proper segregation of sister chromatids. We have yet to elucidate a cause of CdLS in 35% of patients and to facilitate identification of genes in CdLS we have used genome-wide CNV analysis. To date, 269 individuals submitted to our study for whom causative mutations had not been previously identified were analyzed using Illumina HapMap550K SNP arrays.

Analysis revealed 8932 potential variants ranging from 2bp to 20Mb with 5191 being 5 SNPs or less. Computational and manual curation prioritized potential causative variants that could contain candidate CdLS genes. We have identified a number of large chromosomal abnormalities in individuals with phenotypic overlap with CdLS, but who did not meet full clinical criteria. We also identified deletions in 5 patients that included *NIPBL* and were validated using MLPA. There were no deletions that included *SMC1A* and *SMC3*, consistent with previous findings of only missense mutations in these genes. We have identified CNVs involving several additional genes and are in the process of validating these abnormalities. We are currently using the same array platform to analyze an additional 250 unaffected parents, to facilitate the identification of de novo CNVs, and 150 mutation-positive patients, to quantify whether there is previously unappreciated aneuploidy in patients with CdLS. This work has provided potential leads for additional candidates for CdLS and is leading to increased insight of the molecular basis of this multisystem disorder and overlapping phenotypes.

Fragile X Mental Retardation Protein Interactomes in Drosophila and Mouse. *L. Lin, Y. Qin, L. Ray, P. Jin* Human Genetics, Emory University School of Medicine, Atlanta, GA.

Fragile X syndrome is caused by the functional loss of fragile X mental retardation protein (FMRP). FMRP is a selective RNA-binding protein that forms a messenger ribonucleoprotein (mRNP) complex associating with polyribosomes. FMRP, as an RNA-binding protein, has been implicated in mRNA transport and translational control. To further understand the biological functions of FMRP, we have taken a proteomic approach to identify the proteins that interact with FMRP. Both fly and mouse GST-Fmrp fusion proteins were used to capture the brain proteins directly interacting with Fmrp. Over one hundred distinct proteins were captured with either fly or mouse GST-Fmrp. Several known Fmrp interactors, such as FXR1, FXR2 and nucleolin, were captured. Importantly both fly and mouse orthologs of several novel proteins were also identified, including Nono, Heat shock protein 8 and GPI-anchored membrane protein 1. Some of them displayed the genetic interaction with Fmrp in our gain-of-function fly model as well, suggesting that they play a role in the pathways regulated by Fmrp. This systematic approach to identify the Fmrp-interacting proteins in both fly and mouse will facilitate our further understanding the biological roles of FMRP.

Clinical characterization of two siblings with microdeletion 15q13.2q13.3 identified through chromosomal microarray analysis. *J. Rousseau[1], S. Ben-Shachar[2], T. Sahoo[2], F. Dibazar[1], B. Moghaddam[1]* 1) Section of Genetics, Department of Pediatrics, UC Davis Medical Center, Sacramento, CA; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Microdeletion of 15q13.3 is a newly emerging syndrome of mental retardation, seizures, and subtle dysmorphic features. We report here two siblings who presented for genetics evaluations due to their personal and family history of mental retardation and were subsequently found to have a microdeletion of 15q13.3 through chromosomal microarray analysis (CMA). Both children have very subtle dysmorphic facial features and no congenital anomalies; therefore, we suggest that CMA is warranted even in the absence of such findings. Patient 1 is a 12-year-old female and patient 2 is her 9-year-old full sister. The sisters' biological mother is reported to have mild mental retardation and her biological father to have unknown psychiatric issues and probable cognitive impairment. Both patient 1 and patient 2 have been diagnosed with mild mental retardation. On physical examination, both are noted to be of average stature with normal weight and head circumference. Their subtle dysmorphic features include a narrow and elongated face with a pointed jaw, mild hypertelorism, a high arched palate, and elongated digits. Both are also noted to be hyperextensible and hypotonic. Patient 2 also has cupped ears, wide teeth with an overbite, and thoracic scoliosis. Characterization of the deleted region in both sisters defined its size to be ~1.6Mb. Parental studies are not possible due to the social situation. CHRNA7 is responsible for neuronal nicotinic cholinergic signal transmission mediation and has been associated with epilepsy and schizophrenia. Identifying deletions of this gene may affect medication choices in patients diagnosed with microdeletions of 15q13. Our two patients will undergo formal neurodevelopmental and psychiatric evaluations. We present these sisters as two patients who have a newly emerging syndrome associated with a microdeletion of 15q13 and to illustrate that such deletions may be identified in patients who have only very subtle dysmorphic features and developmental delay.

Estimating pleiotropy in pigmentation traits using admixed populations. *E. E. Quillen[1], S. Beleza[2], R. A. Kittles[3], R. W. Periera[4], J. Rocha[3], T. Frudakis[5], M. D. Shriver[1]* 1) Department of Anthropology, Pennsylvania State University, University Park, PA; 2) IPATIMUP, University of Porto; 3) Department of Medicine, University of Chicago; 4) Department of Genomics and Biotechnology, Catholic University of Brasilia; 5) DNAPrint Genomics, Inc., Sarasota, FL.

There are obvious correlations among pigmentation traits across populations. Individuals from West Africa tend to have darker skin, hair, and eyes relative to Northern Europeans. To determine if these correlations are due to population stratification or pleiotropy, this study examined two admixed populations, African Americans and Brazilians, for whom biogeographic ancestry (BGA) was calculated using MLE on 176 ancestry informative markers (AIMs) and for whom iris, skin, and hair pigmentation values were determined. Because these traits are correlated with BGA, as well as with one another, it is essential to remove this confounding effect before estimating the correlation among the phenotypes. For each population, the phenotype values were transformed using the regression equation for the phenotype and BGA for that population. The correlations between the transformed pigmentation values then yield a more accurate estimate of the degree of pleiotropy that is expected for each set of phenotypes in each population. In all cases, the correlations between phenotypes were reduced when the effect of their correlations with BGA were eliminated. Significant correlations remained in the African Americans for skin and iris color and in the Brazilians for skin and hair color. Genetic variation resulting in phenotypic variation in multiple pigmentation traits is expected since melanin production and distribution is essential to all three of these phenotypes. *KITLG* is an attractive candidate gene for a pleiotropic effect because it has been previously associated with both skin and hair color. These results suggest that while there is likely to be pleiotropy affecting pigmentation phenotypes, a substantial amount of variation may be due to genes affecting only one of the phenotypes. This appears to be the case for *TYRP1* which influences iris pigmentation in the African American sample but has no effect on skin or hair pigmentation.

Characterization of a Novel MeCP2 Isoform and its Role in Rett Syndrome. *P. J. Gianakopoulos, A. Mikhailov, B. Stachowiak, J. B. Vincent* Neurogenetics, Centre for Addiction and Mental Health, Toronto, Canada, Canada, M5T 1R8.

Rett syndrome (RTT) is a postnatal neurodevelopmental disorder that primarily affects females at a frequency of 1:10 000 births. Following a period of seemingly normal development of 6-18 months, a baby will rapidly regress, demonstrated by a loss of motor skills and communication; and autistic-like social behaviour, ultimately acquiring severe mental retardation. In 1999 it was discovered that mutations in MeCP2 were responsible for RTT. MeCP2 binds to methylated CpG dinucleotides and has been shown to be a regulator of transcription via its interaction with chromatin-modifying factors. In the known transcript of the Mecp2 gene, termed MeCP2_e2, all four exons are utilized. We recently identified a new variant of the MECP2 gene that is the result of alternative splicing, whereby the second exon is spliced out. There is strong evidence that this variant, termed MeCP2_e1, may be the etiologically relevant form in RTT. The main objective of this study is to delineate the relevant splice variant(s) of the Mecp2 gene that contributes to the neuropathology of Rett Syndrome. To undertake this stable clones of COS-7 cells were produced expressing either of the two splice variants of MeCP2 along with appropriate controls. Total RNA was extracted from 4 clones of each cell line and gene expression microarray was carried out as a service by the University Health Network Microarray Centre (Toronto, Canada) using Agilent rhesus monkey oligonucleotide arrays. Results indicated that MeCP2_e1 and MeCP2_e2 differentially regulated, by at least 2-fold, 71 and 115 genes, respectively, whereas 82 genes were targeted by both MeCP2 isoforms. Several neuronal-specific genes and histone gene family members were identified as genetic targets of one or both MeCP2 splice variants underscoring their function in neuronal modelling and chromatin remodeling. Understanding the differences between the two MeCP2 isoforms will have important implications, particularly for understanding the neurobiology of the disease, and for the development of future treatments for Rett.

Association of the Caucasian haplotype AH8.1 with AIDS-related Non-Hodgkin's Lymphoma. *B. Aissani[1], M. O. Kisani[2], S. Shrestha[1], J. Tang[2], L. P. Jacobson[3], E. Breen[4], O. Martinez-Maza[5], R. A. Kaslow[1,2]* 1) Epidemiology, UAB, Birmingham, AL; 2) Medicine, UAB, Birmingham, AL; 3) Epidemiology, Johns Hopkins University, Baltimore, MD; 4) Psychiatry, UCLA, CA; 5) Obstetrics-Gynecology, UCLA, CA.

OBJECTIVE: The genetic determinants of predisposition to Non-Hodgkins lymphoma (NHL) are poorly understood; however, a polymorphism in lymphotoxin alpha LTA (+252G) plus a polymorphism defining the high tumor necrosis factor (TNF)-producing allele (-308A) form the G-A haplotype that has been associated with NHL alone or in combination with HLA-B*08 or HLA-DRB1*03. Whether any of those gene variants is a true etiologic factor remains uncertain because they occur on the highly conserved Caucasian haplotype AH8.1. We aimed to determine whether any of these gene variants are also associated with susceptibility to AIDS-related NHL (AIDS NHL). METHODS. We typed 159 pairs of AIDS-NHL cases and matched controls selected from HIV-infected European American men in the Multicenter AIDS-Cohort Study for 63 SNPs across the LTA/TNF and the complement C2-C4B gene regions, and for 6 HLA class I and II genes. To account for confounding by the duration of HIV infection, we adjusted for CD4+ T-cell count at the time of diagnosis in the index cases. Logistic regression and haplotype trend regression models were used to assess the risk associated with extended HLA haplotypes. RESULTS. The G-A haplotype and alleles at 4 other SNPs in the C2-C4B region were associated with 1.5-3.0-fold increases of risk. Overall allele distributions at the HLA class I and HLA class II loci tested were not associated with AIDS-NHL. In multivariate analyses of haplotypes, only the G-A haplotype and a 4-SNP haplotype across the C2-C4B region were associated with NHL (OR=2.6, 95% CI: 1.4-4.7; OR=3.2, 95% CI: 1.5-6.9, respectively). These two haplotypes occur in combination with B*08 and DRB1*03 on the AH8.1. CONCLUSIONS. The haplotype AH8.1 confers an elevated risk for AIDS NHL as it does for non-AIDS NHL. The implication is that many variants in the numerous immune genes on the AH8.1 are as plausible etiologic determinants of AIDS NHL as the G-A haplotype.

Mapping copy-number variation in the ENCODE regions in different human populations using high resolution comparative genomic hybridization (HR-CGH). *F. Grubert[1], A. E. Urban[1,2], J. O. Korbel[3,4], D. Palejev[1], K. Kidd[1], M. Snyder[2], S. Weissman[1]* 1) Dept Genetics, Yale Sch Medicine, New Haven, CT; 2) Molecular, Cellular & Developmental Biology, Yale University, New Haven, CT; 3) Molecular Biophysics and Biochemistry Department, Yale University, New Haven, CT; 4) European Molecular Biology Laboratory, D-69117 Heidelberg, Germany.

Copy-Number Variation (CNV) and Copy-Number Polymorphisms (CNPs) are a pervasive architectural feature of the human genome and are expected to contribute significantly to phenotypic variation both in the healthy individual and in disease states. Array-CGH typically has a predictive resolution of about 50 kb. CNV below that horizon will be missed, as will be the actual breakpoint-sequence of the variant. For a complete catalog of human CNV a procedure that predicts CNV at sub-exon level is needed. In our study we use HR-CGH based on high-density oligonucleotide tiling microarrays [Urban, Korbel et al. PNAS 2006; Korbel, Urban et al. PNAS 2007]. Maskless Synthesis arrays with 385000 oligomers were constructed to represent the non-repetitive part of the 44 ENCODE regions corresponding to 1% of the entire human genome. This provides a tiling density of one 50mer every 38bp, resulting in an overlapping tiling path. The arrays are probed with fragmented full-complexity genomic DNA. The ratio of signal intensities from control and experimental channel are processed by our /BreakPtr/ algorithm, which predicts copy-number changes and breakpoints while screening out false-positive calls caused by cross-hybridization. Predictions are validated by PCR and direct sequencing of the resulting amplicons. Using this approach we have studied CNVs and CNPs, and their breakpoints, in 36 individuals of different ethnicities. Among those are 17 individuals from the HapMap panel (Caucasians, Asians, and Africans) and 19 from populations around the world (Surui, Nasioi, Masai, Mbuti, Sandawe, Yakut). We have detected, cataloged and verified numerous variations, both such that were previously known and novel variants, with the arrays allowing to detect CNV as small as 1 kb. This study adds information about the nature of CNV in different human populations.

High-resolution fluorescence in situ hybridization (FISH) using chemically synthesized oligonucleotide libraries.

P. Tsang[1], N. A. Yamada[1], R. Ach[1], L. Carr[1], N. Sampas[1], B. Peter[1], T. Dennis[2], M. Bittner[2], S. Laderman[1], L. Bruhn[1]
1) Agilent Technologies, Inc., Santa Clara, CA; 2) TGEN, Phoenix, AZ.

Fluorescence in situ hybridization (FISH) remains the preferred method for visualization of chromosomes in cytogenetics; however, developments in genomic measurements are unmasking variations that require visualization of smaller and more complex regions that challenge current FISH technology. To address the growing need to study such loci, we constructed high-complexity oligonucleotide libraries (>200 oligos per locus), consisting of chemically synthesized long oligonucleotides (166~194mers) of high fidelity (<0.4% error rate), to enable oligonucleotide-fluorescence in situ hybridization (oFISH) of complex sequences at high resolution. oFISH probes are generated by PCR amplification of the libraries, followed by fluorescent labeling. We designed our probes to defined regions of the reference genome sequence, while avoiding sequences that are repeat-rich or homologous to non-targeted areas, thereby improving specificity while eliminating the need for Cot-1 or other suppressive hybridization reagents. Routine work requires simple protocols that closely mimic current FISH procedures and is conducted using much smaller target sizes (<20 kb) than BAC-based FISH. We have successfully detected specific and robust metaphase and interphase staining at various loci on multiple chromosomes including one particularly repeat-rich region (53% repeat-masked). In addition, we achieved multi-color detection of regions flanking the centromere of the X-chromosome by creating p-arm probes in red and q-arm probes in green, positioned 624 kb and 384 kb away from the centromere, respectively. These centromere-flanking probes are free of repetitive sequences and may provide advantages over currently available centromeric probes that can cross-hybridize due to their repetitive nature. These results suggest that the resolution, specificity and flexibility afforded by oFISH meet the growing need to visualize microarray- and sequencing-based findings of fine scale structural variations and other variations throughout the genome.

Overlapping spectrum of mutations causing distal arthrogryposis type 1 and 2. *P. Kezele[1], A. E. Beck[1], M. J. McMillin[1], R. Toydemir[2], M. J. Bamshad[1]* 1) Dept Pediatrics, University of Washington, Seattle, WA; 2) Department of Human Genetics, University of Utah, Salt Lake City, UT.

The distal arthrogryposis (DA) syndromes are a group of 10 dominantly inherited disorders characterized by multiple congenital contractures such camptodactyly and clubfoot. DA syndromes are caused by mutations in at least seven different genes that encode components of the contractile apparatus of fast-twitch myofibers. We previously reported that distal arthrogryposis type 1 (DA1) is caused by mutations in *TPM2* whereas distal arthrogryposis type 2B or Sheldon-Hall syndrome (SHS) is caused by mutations in *MYH3*, *TNNI2*, or *TNNT3*. SHS has traditionally been distinguished from DA1 by the presence of contractures of the facial muscles and subtle differences in the pattern of limb contractures. However, making the distinction between the DA1 and SHS is often challenging. We screened a cohort of about 125 probands with either DA1 (n = ~50) or *MYH3*-negative SHS (n = ~75) with well-characterized phenotypes for mutations in *TNNI2*, *TNNT3*, and *TPM2*. Mutations were found in ~20% of probands, found more frequently in SHS than in DA1 and found more often in familial cases compared to sporadic cases. These results suggest that there are yet to be discovered genetic and/or environmental risk factors of DA1 and SHS. The phenotypic overlap between DA1 and SHS cases was substantial and frequently a diagnosis of SHS rather than DA1 was based on the presence of calcaneovalgus defects, deep nasolabial folds and a somewhat small mouthеach of which has also been reported at low frequency in DA1. Consistent with these observations, mutations in *TNNI2*, *TNNT3*, and *TPM2* were found in both probands with DA1 and probands with SHS. There was no consistent relationship between genotype and phenotype. Therefore, DA1 and SHS appear to represent the different tails of a distribution of phenotypic characteristics caused by mutations in *TNNI2*, *TNNT3*, and *TPM2*. Delineation of these syndromes as separate entities was critical to the process of gene discovery for DA disorders and yet further investigation now demonstrates that they share an overlapping genetic and phenotypic spectrum.

Vitamin D receptor: a versatile genetic modifier for Alzheimer and Parkinson disease. *K. Hara[1], L. Wang[1], G. Wang[1], G. Beecham[1], P. Gallins[1], P. Whitehead[1], M. Greg[1], M. Butler[1], K. Yu[1], E. Martin[1], J. Haines[2], J. Gilbert[1], J. Vance[1], M. Pericak-Vance[1]* 1) Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA.

By converging genomic evidence from published association and genome-wide linkage association, and expression studies, we identified the vitamin D receptor (*VDR*) gene as a strong candidate for late-onset Alzheimer disease (LOAD). *VDR* is a nuclear receptor for vitamin D, known to be a neuroprotective factor. We sought to thoroughly evaluated association in *VDR* using 492 cases with LOAD and 496 controls. First, we re-sequenced 96 chromosomes to catalogue all exonic and promoter SNPs(-6.0 kb) of *VDR*. The SNP panel used to evaluate the gene includes all HapMap phase II tagSNPs and all SNPs identified by re-sequencing. Analysis of the entire set of 68 *VDR* SNPs found association between 12 SNPs and AD risk. All the significant SNPs are located in the intron 1, 2, and the promoter region. The most significant associations were found at promoter SNP rs11568820 and rs7976091 ($P=9.0510^{-6}$, OR=1.69; $P=8.9410^{-5}$, OR=1.55, respectively). The two SNPs are in complete linkage disequilibrium with each other ($r^2=1$). We then conducted a family-based association analysis of the most interesting 19 SNPs and demonstrated significant allelic association for 6 SNPs among families with affected *APOE4* carriers (P=0.01 to 0.05). Given that the *VDR* gene expression was also associated with Parkinson disease (PD) risk, we evaluated association in *VDR* gene using a large PD family data set (N=3357). Strikingly, the same SNPs associated with AD risk were also associated with age-of-onset of PD, with the strongest association at rs4334089 (P=0.0008; P=0.0005 with AD risk). rs11568820 lies within a transcription factor binding site and rs4334089 resides in a conserved region with high regulatory potential. Preliminary luciferase reporter assay suggest that allelic differences at rs11568820 in the *VDR* promoter indeed affect transcriptional activity. Our data strongly indicate that *VDR* is a genetic modifier for two major neurodegerative diseases.

A framework for genomic risk counseling for common disease variants. *E. Levin, K. Kaplan, S. Kieran* Genetic Counseling Program, Navigenics, Redwood Shores, CA.

Genetic predisposition risk assessment has traditionally relied on tools like personal and family medical history, standard screening or diagnostic tests, and targeted monogenic genetic testing. While this approach is sufficient for certain well-defined hereditary conditions (e.g., cystic fibrosis, Lynch syndrome, Huntingtons Disease, etc.), genetic professionals have been limited in their ability to offer risk assessment for common, multifactorial conditions like diabetes, heart disease, and many cancers. With the discovery of single nucleotide polymorphism (SNP) associations with common diseases, new genomic tests are emerging that provide an additional, powerful tool that can be used as an adjunct to traditional risk assessment tools to inform about predisposition to common diseases. Genetic counselors and other clinical genetic professionals will be at the forefront of delivering this new service and will likely play a critical role in interpreting genomic test results and providing genomic risk counseling. However, one of the main challenges will be how to incorporate results from genome-wide assessments into traditional practice, as no guidelines currently exist. We propose a framework for providing genomic risk assessment. Core components include: discussing the benefits, risks, and limitations of genome-wide testing; explaining the effects associated with multiple, common SNPs versus rare, single gene mutations; assessing medical and family history for possibility of a highly penetrant gene mutation; evaluating patients health behaviors and lifestyle; explaining environmental contributions to disease risk; exploring patients personal experience with disease and motivations for pursuing genomic risk assessment; and reviewing strategies for disease prevention and early detection. Further, based on experience we explore common questions and reactions to genomic risk assessment to further outline the psychosocial considerations that need to be recognized and addressed. As this field evolves, this framework provides a basis for developing future professional practice guidelines.

Diagnositic testing for Smith-Lemli-Opitz syndrome by sequence analysis: a two tier approach. *S. F. Suchy, J. D. Higgs* GeneDx, Gaithersburg, MD.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive disorder of cholesterol biosynthesis due to mutations in the gene for 7-dehydrocholesterol reductase (DHCR7) that catalyzes the last step in cholesterol biosynthesis. Deficiency in DHCR7 results in global psychomotor retardation, failure to thrive, and multiple congenital malformations including dysmorphic facial features, microcephaly, cleft palate, syndactyly, polydactyly, and malformations of the brain, heart, gastrointestinal tract, genitalia and kidneys. Most patients have elevated 8-dehydrocholesterol (8-DHC) and 7-dehydrocholesterol (7-DHC) levels. One of the early indications of SLOS is a low maternal serum unconjugated estriol level, used as part of the test to screen for neural tube defects, Down syndrome and trisomy 18. *DHCR7* mutation testing, DHCR7 enzyme assay or the analysis of sterol biosynthesis in cultured cells are recommended methods to confirm the diagnosis of SLOS for family studies and in rare cases where levels of 7-DHC and 8-DHC are normal or in the range of heterozygotes. According to a large study of individuals with clinically and biochemically characterized SLOS, sequence analysis identified mutations in 96% of patients (Witsch-Baumgartner et al., 2000). As most *DHCR7* mutations occur in exons 6, 7, 8 and 9, we perform *DHCR7* sequence analysis by testing these exons first (Tier 1), followed by the rest of the exons (Tier 2). Of 64 probands referred to us for molecular testing for SLOS 36 patients had 2 or more mutations identified (56%). No patients in our cohort had only a single mutation identified. Of the patients with two mutations identified 30/36 had two mutations identified in Tier 1 exons, 4 patients had at least one mutation identified in Tier 1 and one in Tier 2 and one patient had two mutations identified in Tier 2. Overall, of 74 mutations identified, 66 mutations were found in Tier 1 exons (89%) and 8 in Tier 2 exons. The most common *DHCR7* mutation IVS8-1 G>C, was detected in 32/74 alleles (43%). These findings are consistent with previous report in a research setting (Witsch-Baumgartner et al., 2000) and confirm the value of a tiered approach in molecular testing for *DHCR7* mutations in a diagnostic laboratory.

Longitudinal genome-wide association of cardiovascular disease risk factors in The Bogalusa Heart Study. *E. Smith[1], M. Shaw[1], R. Salem[2], S. Srinivasan[3], W. Chen[3], E. J. Topol[1], N. J. Schork[1], G. S. Berenson[3], S. S. Murray[1]* 1) Scripps Genomic Medicine, Scripps Translational Science Institute, La Jolla, CA; 2) University of California, San Diego, CA; 3) Tulane University, New Orleans, LA.

Identifying the genes that contribute to CVD risk profiles will lead to direct insights not only into the mechanisms that the genes work through to cause CVD, but also insights into the clinical profiles that signal genetically-mediated susceptibility and early onset of disease. Previous genome-wide association (GWA) studies have found numerous associations with CVD and CVD risk factors in cross-sectional data. We are currently performing a GWA study on CVD risk factors using longitudinal data from >1200 individuals in the Bogalusa Heart Study (BHS), a long-term, epidemiologic program in a biracial community (35% African-American (AA) and 65% European-American (EA)). The BHS began in 1973 and 7 cross-sectional CVD risk factors screenings of children aged 5 to 17 years were conducted between 1973 and 1992. In addition, 8 cross-sectional screenings of young adults who had been previously examined as children have been conducted to date. We have genotyped these individuals at >650,000 SNPs and copy-number variable regions using Illuminas Human610-Quad and HumanCVDv2.0 genotyping BeadChips. In the Human610 BeadChip, we have observed a 99.95% call rate from 590,622 loci and 1234 samples, and >99.99% reproducibility in 34 replicate DNA samples. We have examined loci previously described in cross-sectional data in both EA and AA populations using mixed effect regression models with patterned covariance matrices, accounting for age and gender. In the EA population, many previously described associations were replicated, including 1p13.3, which was associated with LDL levels ($p = 8 \times 10\text{-}5$) as well as with changes in LDL over time ($p = 0.001$). We are currently analyzing all genome-wide SNP data and exploring analyses addressing interactions between specific markers and genetic background, copy number variations, and multi-trait models. Overall, our GWA study on longitudinal data provides insight into the genetic basis of how individuals develop disease over time, from childhood into adulthood.

Haplotype-based Linkage of *ZNF699* to Alcohol Dependence and Alcohol Response in *LaJolla* Population. *J. Liu[1], Z. Zhou[1], M. Schuckit[2], T. Smith[2], C. Hodgkinson[1], P. Shen[1], D. Goldman[1]* 1) Laboratory of Neurogenetics, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD; 2) Alcohol Research Center, VA San Diego Healthcare System, La Jolla, CA 92093-116A.

Development of tolerance is important in the progression to Alcohol Dependence (AD). Ethanol tolerance in Drosophila depends on two distinct molecular pathways: the octopamine pathway and a newly discovered cellular stress pathway within which functions hangover, a gene encoding a large nuclear zinc-finger protein. Human ZNF699 (Chr.19p13.2) is annotated in the NCBI database as a hangover ortholog. Recently, Riley et al associated ZNF699 to Alcohol Dependence in the Irish Affected Sib Pair Study, finding strong evidence for single marker association with AD, and a highly significant haplotypic association. To test the ZNF699 gene and human alcohol response and Alcohol Dependence we evaluated four SNPs that had individually shown significant association to Alcohol Dependence and two other SNPs located in the same haplotype block in LaJolla Alcohol Response dataset. We found no single marker association. But we did find that haplotype 211111 significantly associated with Alcohol Dependence (p=0.0004), with a frequency of 0.19 in cases and 0.02 in controls. The copy number of haplotype 211111 was significantly associated with alcohol abuse (p=0.0018) , but show no correlation between haplotype 211111 and level of response (Zpeakmin) and MaxDrink across four time points in LaJolla population. Our results implicate ZNF699 in alcohol response, but these findings need to be amplified in a larger sample for confirmation.

Obsessive Compulsive Disorder Collaborative Genetics Study (OCGS) candidate gene analysis: Association of *SLC6A4* variants with OCD in a large multi-center US family study. *E. Voyiaziakis on behalf of the OCD Collaborative Genetics Study (Brown U, Columbia U, Harvard U, JHU, NIMH & UCLA)* USC, Keck School of Med., Psychiatry & Behavioral Science, Los Angeles, CA.

Studies that have investigated a genetic association between *SLC6A4* and OCD have been equivocal. To resolve ambiguity in association findings, we genotyped the *OCGS* sample of 1241 persons from 278 pedigrees for 13 SNPs (ABI SNPlex), the LPR indel and molecular haplotypes of the LPR (*MSP1* endonuclease digest), two VNTR polymorphisms in introns 2 (Int2) and 7 (Int7), and a 381-base pair deletion 3 to the LPR. These data were then analyzed using FBAT with additive, dominant and genotypic models, using both OCD and sex-stratified OCD as the phenotype.

2-point FBAT analysis using a genotypic model detected nominal association with **Int2** (p= 0.0089) and **Int7** (p= 0.0187; negatively associated). All haplotypes including these polymorphisms gave significant corrected whole marker minimal p-values 0.05: **rs140700:Int7:rs4583306**, p= 0.0290; **Int7:rs4583306:rs7224199**, p= 0.0345; and **Int2:rs140700:Int7**, p= 0.0483. A sex analysis using FBAT revealed sexual dimorphism not stipulated previously. 2-point analysis showed strong association in females with **Int2** (p= 0.00018), significant after correction for LD, multiple marker- and model testing (p_{Adj}= 0.0069). The most significant haplotypes in females included: **rs140700:Int7:rs4583306**, p= 0.0133, and **Int7:rs4583306:rs7224199**, p= 0.0193.

We tested several hypotheses regarding the LPR indel. We did not observe over-transmission of the $\mathbf{L_A}$ allele as reported by Hu et al (2006). Likewise, we argue against the rare **425V** variant causing OCD, i.e., the OCD plus syndrome (Ozaki et al, 2003), as this variant did not segregate with OCD. In conclusion, we confirmed association at the *SLC6A4* locus with OCD by 2-point and haplotype analysis. However, current hypotheses regarding involvement of specific variants in conferring risk for OCD must be refined to accommodate the divergent data, including possibly differential gender risk.

Power of deep all-exon resequencing for discovery of human trait genes. *G. Kryukov[1], A. Shpunt[1,2], J. Stamatoyannopoulos[3], S. Sunyaev[1]* 1) Division of Genetics, Brigham & Womens Hospital and Harvard Medical Sch, Boston, MA; 2) Department of Physics, Massachusetts Institute of Technology, 77 Massachusetts Ave, Cambridge, MA 02139; 3) Department of Genome Sciences, University of Washington, 1705 NE Pacific Street, Seattle, WA 98195.

Availability of large genotyping microarrays propelled Genome-Wide Association Studies as a major tool for genetic analysis of complex diseases. Development of low cost sequencing technology is a widely anticipated next technological breakthrough, which is paralleled by the initiatives to phenotype hundreds of thousands of individuals. We investigate the potential of these two technological advances to enable fundamentally new ways for identification of genes underlying human complex phenotypes. While knowledge of all variants segregating in the population and identified by sequencing would seem to increase the power of genetic analysis, this prospect faces daunting statistical challenges, since an expanding pool of variants requires more stringent multiple testing correction whereas the power to detect association with low-frequency variants is reduced. Thus, we analyzed the potential of the unbiased gene discovery strategy that combines multiple rare variants from the same gene and treats genes rather than individual alleles as the unit for the association test. Our study was based on a population genetic model inferred from the deepest systematic re-sequencing dataset to date. The model incorporates incoming mutations, demographic history of the human population and natural selection. We demonstrate that the model is able to accurately recapitulate a large experimental dataset. We use this model to simulate genetic variation in larger population cohorts. We further simulate sequencing of samples from phenotypic extremes to evaluate power of unbiased discovery of genes underlying the phenotype. Our results suggest that genome-wide analysis of rare coding variation in individuals at phenotypic extremes will provide a powerful tool for discovery of new gene-phenotype associations. However, these studies would require sequencing of very large population panels exceeding 10,000 individuals.

Summary After-Segmentation Algorithm (SASA) for the analysis of copy-number variation. *C. Rangel-Escareño, V. Espinosa-Mateos, A. Hidalgo-Miranda, L. Uribe-Figueroa, R. Goya-Ogarrio, S. March, G. Jimenez-Sanchez*
National Institute of Genomic Medicine, Mexico.

High-density oligonucleotide arrays such as Affymetrix 500K and SNP6.0 allow the analysis of copy number variation (CNV) with an unprecedented resolution. This represents an opportunity for the detection of specific genes related with human diseases but nevertheless a considerable bioinformatic challenge. This task has been particularly difficult given the large amount of data generated. Current tools for this analysis include GISTIC (Rameen Beroukhim et al. 2007) and Partek (www.partek.com/). We present a new algorithm (SASA) implemented in R for detecting common altered regions and producing a graphic summary of the results after initial processing with aroma.affymetrix R-package available in Bioconductor (Henrik Bengtsson 2008). SASA searches for the critical regions throughout samples data and generates a list of regions and their corresponding frequencies based on a threshold. The highest frequency corresponding to the most common region. In addition, it graphs the frequencies and amplitude of such aberrations. To test the application of SASA we analyzed Affymetrix 500k and SNP6.0 array data from 3 normal and 15 cancer cell lines. Data were pre-processed using three different normalization algorithms and two different segmentation algorithms to also assess performance of different combinations of normalization and segmentation algorithms. Results included known regions with CNVs, including a wide amplification of chromosome 5p15 in HeLa and other 7 cell lines including the C33A for uterine cervix, the colon COLO205, and breast HS578T. 72% of the cell lines showed amplification in chromosome 2p11.2 and 44% of them coincide in amplification in 2p24.3 including HCT15 and COLO205. The SASA algorithm detects critical regions and aberration amplitudes in a timely manner facilitating analysis of CNVs.

A Recurrent Point Mutation and a Founder Copy Number Variant in SEPT9 Explain a Large Fraction of Hereditary Neuralgic Amyotrophy. *M. C. Hannibal[1], M. L. Landsverk[1], E. K. Ruzzo[1], H. C. Mefford[2,3], K. Buysse[4], J. G. Buchan[1], S. M. Seanez[1], D. M. Knutzen[1], L. R. Miller[1], J. R. Adkins[1], E. E. Eichler[3], P. F. Chance[1]* 1) Dept. of Pediatrics; 2) Dept. of Internal Medicine; 3) Dept. of Genome Sciences, University of Washington, Seattle, WA; 4) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Hereditary neuralgic amyotrophy (HNA) is an autosomal dominant syndrome that features painful episodic motor and sensory attacks and, in most cases, characteristic facial features. Relative hypotelorism is common, and occasional cleft palate is seen in individuals with HNA. The focal, recurrent peripheral neuropathy primarily affects the brachial plexus, but other nerves may be involved. Previously, we identified HNA point mutations in the SEPT9 gene encoding septin-9. Here, we report the characterization of HNA-causative mutations by sequence analysis and detection of copy number variants in the region of SEPT9. We identified exonic point mutations in 22% (11/49) of our HNA pedigrees. Interestingly, 9/11 have a recurrent NM_006640.4:c.262C>T mutation at a hypermutable base in a CpG island. Two HNA pedigrees have a NM_006640.4:c.278C>T mutation. Another 24% of our HNA pedigrees have a shared founder haplotype that was identified among North American pedigrees of European descent. We have now identified an intragenic genomic duplication of approximately 38 kilobases in these pedigrees. We find several other pedigrees have heterogeneous copy number variants within this region. SEPT9 transcription and translation is complex. Alternative promoter and 5 exon usage leads to multiple SEPT9 transcript variants encoding at least five unique protein isoforms. The founder genomic duplication results in SEPT9 transcripts that contain an in-frame, tandem duplication of the 645 bp exon containing the HNA point mutations. Immunoblotting demonstrates that this duplication results in expression of several SEPT9 protein isoforms of increased molecular weight. The duplicated 645 bp exon encodes most of the N-terminal proline-rich domain of the SEPT9, suggesting that it is important for SEPT9 function in morphogenesis and peripheral nerve maintenance.

Variants in the Human Trehalase Gene (TREH) Determine Trehalase Activity and are Associated with Type 2 Diabetes. *Y. Muller, R. Hanson, G. Nishimoto, J. Loebel, S. Kobes, J. Goswami, W. Knowler, C. Bogardus, L. Baier*
Epidemiology & Clinical Res, NIDDK/NIH, Phoenix, AZ.

The disaccharide trehalose, found primarily in insects and mushrooms, is hydrolyzed into 2 molecules of glucose by the enzyme trehalase. Deficiency of trehalase activity leads to trehalose intolerance which occurs in 15% of Greenland Eskimos. We have identified linkage to plasma/serum trehalase activity (LOD=7.0) in 570 non-diabetic Pima Indians at the trehalase locus TREH on Chr11q23. This same region was previously linked to body mass index (BMI; LOD=3.6) and type 2 diabetes (T2D; LOD=1.7) in 1037 Pima Indians. To identify the genetic variant(s) that control TREH activity, the coding and promoter regions of TREH were sequenced in 39 Pima Indians, and 26 SNPs were genotyped in the 570 subjects who had measures of trehalase activity. Enzyme activity was highly associated with rs2276064 (Arg486Trp), rs10892251 (intron1), rs745663 (intron 13), and a novel SNP (intron 11) ($p=10^{-12}$ to 10^{-16}, adjusted for age, sex and family membership). Combinations of these SNPs explained 73-78% of the linkage signal ($p<0.0001$). To assess the potential role of these SNPs in BMI and T2D, all 26 SNPs were genotyped in the 1037 subjects that gave rise to prior BMI and T2D linkage peaks. Multiple SNPs were associated with T2D in these 1037 subjects ($p<0.0001$ adjusted for age, sex and family membership) and the association with T2D was replicated in a population-based sample of 3501 full-heritage Pima Indians (adjusted $p<0.0002$). Although we were unable to demonstrate that plasma/serum trehalase activity alone predicted onset of T2D, when haplotypes of rs2276064 (Arg486Trp) and rs10892251 were ordered according to their association with trehalase activity, there was a nominal association such that those haplotypes associated with the lowest trehalase activity were associated with the lowest prevalence of T2D ($P_{trend}=0.03$, adjusted for age, sex and family membership). These results indicate that SNPs within TREH strongly influence trehalase activity, and specific haplotypes of TREH are associated with both low levels of activity and risk of T2D.

Genetic Variants of *EGF* and *PPAR* are associated with neuroendocrine tumor risk and overall survival. *C. Liu*[1], *MH. Kulke*[2], *DC. Christiani*[1] 1) Dept Environmental Health, HSPH, Boston, MA; 2) Dana-Farber Cancer Institute, Boston, MA.

The molecular mechanisms of neuroendocrine tumor growth remain largely unknown. Lack of prognostic and predictive markers with high sensitivity has hindered the development of molecular targeted therapeutics and screening procedures. Common alleles of genes in several biological pathways, such as cell growth, cell signaling, hormones, and metastasis, may influence the outcomes of treatment and the risk of developing cancer. To identify susceptible genes for therapeutic effects of neuroendocrine tumor treatments, we conducted a large-scale evaluation of single nucleotide polymorphisms (SNPs) in association with overall survival and risk of neuroendocrine tumor among 274 cases and 329 age- and gender-matched controls. A total of 150 SNPs from 58 candidate genes were genotyped. The candidate genes were selected in the pathways of cell growth, cell signaling, hormones, and metastasis. The genotyped SNPs include missense, exonic, and SNPs in the promoter and UTR regions with minor allele frequency 0.05. To test the associations between genetic variants and overall survival, we used Cox proportional hazard model adjusting for age, gender, and grade of malignancy. 17 SNPs were found to be associated with overall survival of neuroendocrine tumor at p-value<0.05. Among them, a SNP on 5 UTR of *EGF* (epidermal growth factor) gene achieves global significance level. Adjusted hazard ratios (HR) and 95% confidence intervals (CI), are 2.3 (1.5-3.7), 2.2 (1.1-4.4), and 3.5 (1.8-6.9) for additive, dominant, and recessive genetic effect models, respectively. Using these 17 SNPs, we performed multiple logistic regression models adjusting for age and gender to test association with risk of neuroendocrine tumor. A SNP on the promoter region of *PPAR* (Peroxisome Proliferator Activated Receptor Gamma) was found to be associated with an increased risk (odds ratio:1.5; 95%CI:1.1-1.9)and the adjusted HR of overall survival is 1.7 (95%CI: 1.1-2.6). Replication of the SNPs on *EGF* and *PPAR* is on-going in an independent Caucasian population. In conclusion, we found the genetic variants of *EGF* and *PPAR* may be associated with neuroendocrine tumor risk and overall survival.

Pathogenesis of Loeys-Dietz Syndrome and Therapeutic Implications. *D. Loch, J. Chen, H. C. Dietz* Instit of Genet Med & HHMI, Johns Hopkins, Baltimore, MD.

Loeys-Dietz syndrome (LDS), caused by mutations in the type 1 or 2 subunits of the transforming growth factor-beta (TGF) receptor (Alk5 and TRII), shows aggressive arterial disease and frequent death in childhood, highlighting the need for the development of medical therapies through elucidation of disease pathogenesis. We find that aortic vascular smooth muscle cells (AoSMCs) from LDS patients show no defect in TGF signaling and that vascular specimens obtained at surgery consistently show nuclear accumulation of Smad2 that has been phosphorylated at the C-terminus (pSmad2; a mediator of the TGF signal) indicative of paradoxically enhanced TGF signaling. This is in keeping with the demonstrated role for TGF in aneurysm formation in Marfan syndrome and other disorders. TGF signaling is normally self-regulated by mechanisms that include induction of Smad7 and phophorylation of Smad2 at negative regulatory sites in the linker region that promote the clearance of activated receptors and signaling Smads, respectively. Despite clear evidence for increased TGF signaling *in vivo*, AoSMCs from LDS patients show low expression of Smad7 ($p<0.005$) and reduced linker phosphorylation of Smad2, suggesting that mutant receptors impair TGFs ability to induce autoregulatory programs. We also demonstrate a significant reduction ($p<0.005$) in expression of the TGF accessory receptor endoglin in LDS cells. TGF signaling normally induces endoglin, which in turn promotes utilization of Alk1 instead of Alk5 by TGF ligands, resulting in activation of the bone morphogenetic protein (BMP) cascade (pSmad1/5/8) and inhibition of the canonical TGF cascade (pSmad2/3). In keeping with failed induction of endoglin, LDS cells show reduced levels of pSmad1/5/8 ($p<0.01$). LDS AoSMCs show abnormally high levels of expression of selected vascular smooth muscle markers (smooth muscle actin and calponin), but fail to express terminal markers of VSMC differentiation such as smoothelin, suggesting that cells populating the aortic media may be myofibroblasts derived from pathologic endothelial-to-mesenchymal transition (EMT), a process normally inhibited by BMP signaling. We are currently testing TGF and EMT antagonists in recently created mouse models of LDS.

Genome-Wide Association Study Identifies Locus with Sex-Specific Genetic Effects on Serum YKL-40 levels in a Founder Population. *D. Loisel[1], Y. Sun[1], L. Pan[1], J. Elias[2], G. Chupp[2], C. Ober[1]* 1) Dept. of Human Genetics, University of Chicago, Chicago, IL; 2) School of Medicine, Yale University, New Haven, CT.

Asthma is a complex disease that shows striking sex differences in prevalence, age of onset, and severity. Serum levels of the chitinase-like protein YKL-40 are a biomarker for asthma, with elevated levels occurring in individuals with asthma and reduced lung function (Chupp et al. *NEJM* 2007; 357:2016). We conducted a genome-wide association study (GWAS) of serum YKL-40 levels in the Hutterites, a founder population of European descent, and identified the *CHI3L1* gene as a major locus for YKL-40 levels that also confers risk for asthma and reduced lung function in Caucasian populations (Ober et al. *NEJM* 2008; 358:1682). In the present study, we assessed the sex-specific genetic architecture of this highly-heritable biomarker for asthma and reduced lung function by testing for genotype-sex interactions on serum YKL-40 levels in the Hutterites, using the same GWAS data. 15 SNPs showed genotype-sex interactions at $P < 10^{-5}$. One SNP was located ~5kb downstream of a sex hormone receptor, making it an intriguing candidate locus for sex-specific effects in asthma and asthma-related phenotypes (genotype-sex interaction $P = 7.86 \times 10^{-6}$). We thus focused our study on this SNP and examined associations with an asthma-associated phenotype, bronchial hyperresponsiveness (BHR), in the Hutterites. The SNP showed a significant sex interaction with BHR ($P = 0.003$): males homozygous for the minor allele had the highest levels of serum YKL-40 levels and highest prevalence of BHR, while females homozygous for the minor allele had the lowest serum YKL-40 levels and lowest prevalence of BHR. The genotype association with BHR in males was significant ($P = 0.002$), although the association did not reach significance in females ($P > 0.10$). The results of this study highlight the value of examining genotype-by-sex interactions in the analysis of complex traits and diseases to identify novel genes. Supported by NIH grant HL085197.

LIMP-2 expression in fibroblast cell lines from subjects with Gaucher disease. *T. Samaddar, J. Vithayathil, N. Tayebi, E. Goldin, E. Sidransky, O. Goker-Alpan* MGB/NHGRI, NIH, Bethesda, MD.

Lysosomal integral membrane protein 2 (LIMP-2) is a specific chaperone responsible for trafficking glucocerebrosidase, the enzyme implicated in Gaucher disease, to the lysosome. In this study, LIMP-2 gene and protein expression were explored in 9 fibroblast cell lines from subjects with Gaucher disease using quantitative (real-time) PCR and Western blots. The mutations included N370S, L444P, D409H+, G325R, P415R and a recombinant allele The gene and protein expression varied between cell lines, even in the ones from subjects with the same genotype. In immunofluorescence studies, GC co-localized with the early endosomal marker EEA1, instead of the lysosomal markers. In these cell lines with trafficking defects, LIMP-2 distribution was altered and steady state protein levels were relatively decreased with respect to gene expression, suggesting over-utilization of LIMP-2 protein in an attempt to rescue mistrafficked GC. Incidentally, large endosomes were observed in the cell lines where GC was mistargeted to the endosome instead of lysosomes. In addition to its function as a membrane receptor for GC, LIMP-2 is also believed to regulate the post-endosomal compartment, and LIMP-2 overexpression in these fibroblast cell lines can lead to the formation of large endosomes. These results indicate that intracellular LIMP-2 regulation may differ depending on GC mutations and folding, and LIMP-2 could be a modifier molecule affecting the cellular and hence clinical phenotype in subjects with Gaucher disease.

Investigation of the P300 Evoked Response via Quantitative Trait Linkage Analysis in a Nepalese Population Genetic Isolate. *S. L. Santangelo[1,2], T. Sitnikova[1], J. Subedi[3], T. D. Dyer[4], S. Ojha[5], M. K. Nepal[5], P. Shrestha[6], S. Tamang[6], J. Blangero[4], J. VandeBerg[4], S. Williams-Blangero[4]* 1) Harvard Medical School, Psychiatric and Neurodevelopmental Genetics Unit, Center for Human Genetic Reasearch, Massachusetts General Hospital, Boston, MA, USA; 2) Harvard School of Public Health, Boston, MA, USA; 3) Miami University, Oxford, OH, USA; 4) Southwest Foundation for Biomedical Research, San Antonio, TX, USA; 5) Tribhuvan University Institute of Medicine, Kathmandu, Nepal; 6) Nepal Biomedical Research Center, Kathmandu, Nepal.

In an effort to map genes associated with schizophrenia, we have been measuring traits thought to be endophenotypes for schizophrenia in a population genetic isolate in Jiri, Nepal. Measured traits include P300, N100, N200 and P50 electrophysiological evoked potentials (ERPs), as well as a number of cognitive tests. The P300 ERP was recorded during an auditory "oddball" paradigm while participants identified infrequent target tones among standard tones by pressing buttons. P300 was measured at the Pz scalp location as the most positive peak between 280-600 msec after tone onset in 617 individuals in one large extended pedigree of over 2500 individuals in the Jirel population. P300 amplitude and latency were evaluated in a quantitative trait locus (QTL) genome-wide linkage analysis after estimating the heritability of each QTL. Although both were significant, the overall heritability of P300 latency (0.42; $p<0.0001$) was higher than that for amplitude (0.22; $p=0.0122$). QTL linkage analysis for P300 amplitude (transformed and adjusted for age, sex, age*sex, age^2*sex) yielded a peak LOD score of 1.58 on chromosome 21, and a LOD of 1.07 on chromosome 7. For P300 latency, there were peak LOD scores of 1.76 on chromosome 3, 1.43 on chromosome 13, 1.32 on chromosome 6, 1.28 on chromosome 20, and 1.17 on chromosome 11. In a genome-wide linkage scan, we did not find significant linkage for the P300 ERP as measured at Pz. As data collection is ongoing, we will continue to evaluate this and other QTLs in a larger sample from this Nepalese population isolate.

Increased non-right-handedness (NRH) and less hand lateralization in nonsyndromic cleft lip with or without cleft palate (CL/P). *K. Neiswanger[1], X. J. Wang[1], R. S. DeSensi[1], R. Martin[2], A. E. Czeizel[3], J. E. de Salamanca[4], M. L. Marazita[1]* 1) Univ Pittsburgh, Pittsburgh, PA; 2) Wash Univ, St. Louis, MO; 3) F Comm Ctl Hered Dis, Budapest, Hungary; 4) Hos Inf Univ Niño Jesús, Madrid, Spain.

Many individuals with nonsyndromic CL/P are NRH, which may reflect unusual brain lateralization. The Pittsburgh Oral Facial Cleft study assesses NRH as a phenotype that may increase the informativeness of CL/P families for gene mapping and identification. We analyzed age-appropriate items from a modified Edinburgh Handedness Inventory on 213 individuals with CL/P (115 male, 98 female), 452 relatives (196 male, 256 female), and 241 controls with no family history of clefts (87 male, 154 female) from Pittsburgh, St. Louis, Madrid, Hungary. We defined NRH at a laterality quotient score cutoff of 85, and degree of hand lateralization as follows: strongly lateralized subjects used only their right or left hand for every item on the inventory, while less lateralized subjects used both hands for at least one item. NRH was significantly increased in CL/P cases compared to unaffected relatives (58% vs 44% p=.001) and controls (58% vs 39% p=.0001). Almost half (45%) of CL/P subjects were less lateralized, compared to 34% of relatives (p=.006) and 25% of controls (p=.00001). Lateralization differences persisted in right-handers (RH)those who did not use their left hand alone to perform any task in the inventory. For RH, 43% of CL/P individuals were less lateralized, compared to 29% of relatives (p=.005) and 21% of controls (p=.00003). Relatives and controls differed significantly in their degree of lateralization (entire sample p=.02; RH p=.04). Overall, males showed more NRH (51% vs 42% p=.008) and less hand lateralization (p=.06) than females. Of the 129 subjects with unilateral CL/P, 89 had left-sided CL/P and 40 right-sided. The left-sided group had more NRH and less lateralization than the right (62% vs 50%; 45% vs 40%, respectively), but the differences were not significant. Our results confirm that NRH is elevated in CL/P individuals and further suggest that degree of lateralization, irrespective of hand preference, is lessened in CL/P families. NIH grants: R01-DE016148, R21-DE016930, P50-DE016215.

Allocation of YSTR Microvariant Alleles to Y-Chromosome Binary Haplogroups. *A. L. Pollock[1], K. Ritchie[1], P. A. Underhill[2], A. A. Lin[2], S. R. Woodward[1], U. A. Perego[1,3], N. M. Myres[1]* 1) Sorenson Molec Genealogy F, Salt Lake City, UT; 2) Department of Genetics, Stanford University School of Medicine, Stanford, California, USA; 3) Dip. di Genetica e Microbiologia, Università di Pavia, Italy.

Y-chromosome short tandem repeat (YSTR) loci are used extensively in studies of population substructure, temporality of population dynamics, and forensic identification. The occurrence of non-consensus YSTR alleles, such as unusually short alleles or partial insertion/deletion events (microvariants), have been used successfully as indicators of common ancestry among YSTR haplotypes, exposing further levels of phylogenetic substructure with restricted geographic distributions. However, the high variability of STR loci can potentially lead to false associations due to homoplasy (ie, recurrent mutation). Thus, YSTR haplotypes are best interpreted within the context of the binary marker defined Y-chromosome phylogeny. To identify YSTR microvariant alleles potentially useful for elucidating further phylogenetic substructure within binary haplogroups, we have assessed the haplogroup affiliation of microvariant alleles found at informative frequencies in public YSTR databases for the following YSTR loci: DYS385, DYS392, DYS441, DYS446, DYS447, DYS449 and DYS464. We report haplogroup affiliations for each variant allele and geographic origins of representative samples.

A genome-wide association study of gene expression in skin. *J. Ding[1], J. E. Gudjonsson[2], L. Liang[1], R. P. Nair[2], P. E. Stuart[2], J. J. Voorhees[2], J. T. Elder[2], G. R. Abecasis[1]* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Dermatology, University of Michigan, Ann Arbor, MI.

Gene transcript levels can serve as an intermediate phenotype that bridges genotypes and more complex organismal phenotypes. We carried out whole genome genotyping and gene expression analysis in a set of skin biopsies from 111 individuals (including a biopsy of normal skin from all 111 individuals, and a biopsy of affected skin from 54 individuals who had psoriasis). Altogether, we genotyped 450,652 single nucleotide polymorphisms (SNPs) and measured gene expression for 54,675 transcripts in each sample. Using whole genome association analysis, we identified 1,270 SNPs that are strongly associated with expression levels for one or more transcripts at $p < 10^{-8}$. Overall, 519 transcripts showed association at $p < 10^{-8}$ with at least one SNP and 1,244 showed association at $p < 10^{-5}$ with a SNP that mapped within 100 kb of the transcript. The results provide a genome-wide look at regulation of gene expression in skin and should aid interpretation of genetic association studies for many skin diseases. They also allow us to compare genetic regulation of gene-expression in skin to that in other tissues. Among the 1,562 SNP-transcript pairs that showed strong association at $p < 10^{-8}$ around 80% also showed association in an independent survey of gene expression in lymphoblastoid cell lines (Dixon *et al.*, *Nat.Genet.* **39**, 1202 (2007).). While the overlap in signal between tissues is much greater than expected by chance, our results emphasize the importance of studying how SNPs impact gene expression patterns in different tissues and cell lines.

The Autism Genome Project: Dissecting the genetic and genomic etiology of autism. *J. S. Sutcliffe for the Autism Genome Project* Vanderbilt Univ.

Autism is a neurodevelopmental disorder that affects approximately 1 in 150 individuals and is characterized by deficits in reciprocal social interaction, communication and patterns of repetitive behaviors and restricted interests. Twin and family studies indicate high heritability, but evidence supports a highly complex architecture for the underlying genetic etiology. The Autism Genome Project (AGP) was formed to facilitate gene identification by uniting investigators and family data. AGP Phase I involved genome-wide (GW) analysis of linkage and copy number variation (CNV) in >1100 multiplex families. Linkage analysis revealed promising loci on 11p and 15q, with gender and ancestry influencing signals at these and other loci. CNV analysis of 10k data showed a striking degree of CNV, with instances of both inherited and de novo CNV. AGP Phase II involves GW analysis for association and copy number using the Illumina 1M SNP array in a dataset to ultimately reach ~3000 families. We will present results from our analysis of >1000 AGP parent-child trios, alone and combined with data from >800 AGRE families genotyped for the 550k subset of markers (>1800 families total). *The AGP represents by far the largest genetic study undertaken for autism*. AGP genotyping sites sent 1M SNP data to the central Data Coordinating Center; raw data was distributed for CNV analysis, while genotype data was assessed for quality control (QC) and Hardy-Weinberg equilibrium (HWE) prior to analysis for association. In a preliminary CNV analysis of 370 families (1362 samples), multiple algorithms were utilized to infer CNV from intensity and genotype data, and 76,916 CNVs were called by at least two algorithms. Mean and median CNV sizes were 225kb and 32kb, respectively, and 57 CNVs were detected per proband on average. Family-based association analysis of 600 AGP families using 1M data alone, or combined with 800 AGRE families, does not reach GW-significance. Many genes identified by SNPs with $10^{-4} > P > 10^{-7}$ are related to neuronal development and guidance, similar to those identified by CNV. It seems possible then that risk for autism is due, in large part, to rare variation; this conclusion, however, awaits validation based on results from more samples.

Power for sequencing studies. *D. Hu, E. Ziv* Institute for Human Genetics, Comprehensive Cancer Center, Dept Medicine, Univ California San Francisco, San Francisco, CA.

Rare variants are increasingly being recognized as important determinants of complex traits. As the technology for identifying rare variants continues to improve, these studies will increasingly be used to discover the genes involved in complex traits. However, it remains unclear how such studies should optimally be designed. We analyzed the power for sequencing based case-control association studies. We used population attributable risk (PAR) of the cumulative effect of all variants identified. PAR is defined as the portion of the prevalence of a phenotype in the population that is due to all of the variants at the causative locus. We used population attributable risk because the relative risks associated with each variant are likely to vary from gene to gene and are too rare to be assessed independently. We defined power, as the probability of detecting a significant difference between the cumulative frequency of variants in cases and in controls. We used an alpha of 2.5×10^{-6}, adjusting for 20,000 genes tested. Our analyses demonstrate that, in general, for a particular PAR, genes with fewer variants are easier to be detected. We found that if the cumulative prevalence of functional variants in the population is 4%, we would have 80% power to detect a gene that has a PAR of 6.6% with a study that sequences 1000 cases and 1000 controls. In comparison, if the cumulative prevalence of functional variants in the population is 1%, we would have 80% power to detect a gene that has a PAR of 4.2% with the same sample size. Our results suggest that, in general, these studies will need large sample sizes, similar to the ones required for genome wide association studies.

Single Stem Cell Gene Expression Analysis on the SOLiD System. *K. Lao[1], F. Tang[2], C. Barbacioru[1], N. Xu[1], J. Gu[1], E. Nordman[1], M. Barker[1], R. Wicki[1], F. De La Vega[1], N. Straus[1], M. Surani[2]* 1) Molecular Cell Biology, Applied Biosystems, Foster City, CA; 2) Wellcome Trust/Cancer Research UK Gurdon Institute of Cancer and Developmental Biology, University of Cambridge, Tennis Court Road, Cambridge, CB2 1QN, UK.

Embryonic Stem Cells (ES cells) are a well-studied type of stem cells with pluripotency. Recently, it has been proved that undifferentiated ES cells are heterogeneous and are a mixture of stem cells at different status with differential marker gene expression. This raises importance of gene expression profiling analysis of small amount of pure population of stem cells, ideally of a single stem cell. To obtain gene expression information of a single stem cell on whole genome scale, we develop a deep sequencing assay of a single cell based on Applied Biosystems SOLiD System. This will permit us to get digital gene expression profiles of stem cells at single cell resolution and will enable us to understand the transcriptome landscape of all subpopulations of ES cells. The combination of next-generation sequencing using the SOLiD System and single cell cDNA technique will allow us to find all expressed transcripts in a stem cell, no matter whether it is from predicted/known genes or from unpredicted/novel genes. This will be of importance for stem cells because there are high chances that stem cells express some unique, novel transcripts. Because the SOLiD System provides a digital gene expression measurement, there should be no background noise and should cover a wider dynamic range of gene expression, which will make the expression profile more accurate. This is particularly interesting for stem cells because some of the key transcription factors are expressed at very low levels (below 20 copies per cell) in stem cells, which are very likely undetected using microarrays because of their significant level of noise.

Expression profiling study in human B cells identified novel miR-181b, miR-7 and miR-627 MicroRNAs underlying osteoporosis. *X. D. Chen[1], L. G. Sun[1], R. R. Recker[1], H. W. Deng[2], P. Xiao[1]* 1) Osteoporosis Research Center, Creighton University, Omaha, NE; 2) Department of Orthopedic Surgery and Basic Medical Sciences, University of Missouri-Kansas City, Kansas City, MO.

MicroRNAs (miRNAs) are short noncoding RNA molecules that regulate gene expression by targeting mRNAs and causing mRNA cleavage or translation blockage. Recently, miRNAs have been implicated important in the etiology of various diseases. Osteoporosis is characterized by low bone mineral density (BMD) mainly resulting from imbalanced osteoclastogenesis and osteoblastogenesis. B cells play important roles in osteoclastogenesis via expression of osteoclast-related factors, such as transforming growth factor beta (TGF) and osteoprotegerin (OPG). Our recent mRNA expression profile study on human B cells identified ER and MAPK3 gene network for postmenopausal osteoporosis. However, little is known about the role of miRNAs in human B cells for etiology of osteoporosis. In this study, we aimed to identify differentially expressed miRNAs in B cells between the low and high BMD groups. We recruited 20 unrelated postmenopausal Caucasian women aged 57-68, 10 with high BMD (spine or hip Z-score 0.84) and 10 with low BMD (spine or hip Z-score -0.84). For each subject, $CD19^+$ B cells were isolated from peripheral blood and total RNA (including miRNA) was extracted from the B cells. miRNA profiling for each sample was performed using TaqMan Low Density Array with 365 miRNAs. Expression level of each miRNA was determined with C_T by subtracting C_T of endogenous control RNU48. Differential miRNAs were selected by t-test for miRNAs expressed in all 20 samples and by Wilcoxon Rank Sum Test for miRNAs expressed in partial (20) samples. Three significant miRNAs, miR-181b, miR-7 and miR-627, were upregulated (p = 0.0479, 0.0337 and 0.0412, respectively) in the low vs. high BMD groups. It was reported that miR-7 inhibits epidermal growth factor receptor (EGFR), an important factor for osteogenesis. This is the first *in vivo* miRNA expression profile analysis in human B cells for osteoporosis. Our results suggested that miR-181b, miR-7 and miR-627 may be involved in osteoclastogenesis and etiology of osteoporosis.

Assessing the biological relevance of sequence variants in and around *DPYSL2*, a candidate schizophrenia (SZ) susceptibility gene on 8p21. *Y. Liu[1], D. M. McGaughey[1], L. Zhang[1], P. Chen[1], D. Avramopoulos[1], V. Lasseter[2], D. Fallin[3], J. McGrath[2], P. Wolyniec[2], G. Nestadt[2], K. Liang[4], A. Pulver[2], A. S. McCallion[1], D. Valle[1]* 1) Institute of Genetic Medicine; 2) Dept of Psychiatry, Johns Hopkins School of Medicine; 3) Dept of Epidemiology; 4) Dept of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Linkage and association studies from our group and others implicate *DPYSL2*, at 26.5Mb on 8p, as a candidate gene for SZ. We identified significant association with SNPs in intron2 (rs388047) in European Caucasian (CEU) probands and just 3 (rs12155555) of *DPYSL2* in Ashkenazi Jewish (AJ) probands. Expressed in both the CNS and PNS, *DPYSL2* (also known as *CRMP-2*) encodes a 62kDa cytosolic protein that regulates axonal growth. To identify additional variants in and around *DPYSL2*, we sequenced all exons (14), the proximal promoter and 8 cNCSs in and around *DPYSL2* in 48 CEU and 48 AJ SZ probands plus 48 AJ and 96 CEU controls. We found 2 missense and 2 synonymous coding variants whose frequency was similar in cases vs. controls. We also identified 3 SNPs (rs367948, rs400181, rs445678) in the promoter region and 2 SNPs (rs379266, rs11781865) in intron1 (all in cNCS), that were associated with SZ in the CEU sample only (p-values ranging 0.007-0.041). We assessed their biological relevance in cells (293 and primary E14.5 mouse cortical neurons) using a luciferase reporter and in zebrafish (ZF) larvae using Tol2 transposon-mediated transgenesis. For the promoter SNPs, we found 1.7-fold increase in expression with the risk alleles reaching statistical significance in primary E14.5 cortical neurons ($P < 0.0001$) but not 293 cells. In ZF, the intron1 cNCS directed tissue specific expression in the CNS and PNS. Expression in mosaic larvae was similar in the risk allele and the non-risk allele constructs. We conclude that non-coding variants in and around *DPYSL2* are associated with SZ possibly by regulating expression. We also identified an intronic enhancer in the region of the associated SNPs, but have not yet shown causality. Additional studies in cultured cells and ZF are in progress to further test the functional consequences of these variants.

Whole-Genome Genetic Difference in DNA Variation between Caucasians and Asians. *J. Li[1], T. B. Jin[2,3], Y. Z. Liu[1,2], C. Papasian[2], H. W. Deng[2,3,4]* 1) Info Med Person Health, Univ Missouri - Kansas City, Kansas City, MO 64108; 2) Orthopedic Surg/Basic Med Sci, Univ Missouri - Kansas City, Kansas City, MO 64108; 3) School of Life Science and Technology, Xi'an Jiaotong Univ, Xi'an, Shaanxi, 710049, PR China; 4) College of Life Sciences, Hunan Normal Univ, Changsha, Hunan, 410081, PR China.

Understanding differences of DNA variation across populations can provide insights and future research direction for studies on human diseases and human evolution. A powerful tool for this purpose is the high-throughput genotyping that becomes available recently. While studies on the ethnic differences of DNA variation have been performed, relative small sample sizes and ascertainment biases can compromise the reliability of the results. In this study, we targeted to provide a robust description of the similarity and dissimilarity of the genome-wide DNA variation across two ethnic groups, Caucasians and Asians. Our data contained dense single nucleotide polymorphisms (SNPs) based on Affymetrix GeneChip 500K Mapping array and consisted of almost 1700 study subjects. We started our study with the characterization of SNP sharing and SNP frequency distributions in the two ethnic groups. We then compared the genome-wide patterns of linkage disequilibrium (LD). We also studied haplotype sharing and the relationship between DNA variation and conservation scores in these two ethnic groups. Consistent with previous studies, we found that common SNPs in one population were often observed in the other ethnic group. However, the percentage of shared SNPs were higher, an indication of the effect of larger sample sizes in studying DNA variation. We also observed similar patterns of LD structure in these two ethnic groups. Our results enrich our understanding of the ethnic difference of DNA variation and potentially furnish more tools for future studies in human complex diseases.

SIX3 Mutation Studies Broaden Understanding of the Holoprosencephaly Clinical Spectrum. *B. D. Solomon, F. Lacbawan, B. Feldman, S. Domené, E. Roessler, M. Muenke* Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Holoprosencephaly (HPE) is the most common structural malformation of the human forebrain. SIX3, which encodes a transcription factor expressed in the developing forebrain and eyes, is one of the most the common HPE-causing genes. In this largest cohort of patients (n=800), mutation screening of ZIC2, SHH, SIX3, and TGIF was done by PCR amplification of all exons, dHPLC screening, and was then followed by bidirectional sequencing. Among these genes, mutations in SIX3 (4.7%) were the third most common. Here we report 56 HPE cases with 38 different mutations in SIX3 and correlate their clinical manifestations. An additional 72 cases ascertained elsewhere with SIX3 mutations, submicroscopic deletions, or chromosome 2p21 abnormalities, are also included. The F:M ratio in this combined set of patients is 1.5:1. There is intrafamilial clinical heterogeneity in the 23 families, with penetrance of 68%. There are 27 patients with alobar HPE, 22 with semilobar, 7 with lobar, and 5 with MIHF. The most common associated clinical findings, in decreasing frequency, are hypotelorism, microcephaly, cleft lip/palate, seizures, premaxillary agenesis, diabetes insipidus, single central incisor, and coloboma. The majority of the mutations confer functional loss of SIX3, as clearly demonstrated by our group using an in vivo zebrafish assay (Domené et al., 2008), but the degree of severity of brain anomalies does not appear to be solely dependent on the genotype. However, there is regional clustering of the mutations within the SIX domain (43%) and homeodomain (26%) affecting the repressor function of SIX3. The related x-ray diffraction data on aa133-aa263 of SIX3 may be used in our attempts of molecular modeling to further refine genotype-phenotype correlations. As the understanding of the range of factors that could be functionally important is still incomplete, we cannot exclude important interactions between SIX3 and other genetic or environmental factors.

Ontology finger prints to quantitatively characterize genes and diseases for genome wide association study. *L. Tsoi[1], M. Boehnke[2], W. Zheng[1]* 1) Department of Biostatistics, Bioinformatics & Epidemiology, Medical University of South Carolina, Charleston, SC 29425-8350; 2) 2Department of Biostatistics, University of Michigan, Ann Arbor, MI, 48109-2029.

Genome Wide Association Studies(GWAS) may identify multiple genes that are associated with a disease. Quantitatively assessing how these candidate genes relate to the disease of interest is important to narrow down the candidate genes to perform downstream experimental validation. However, there is no widely acceptable way to assess quantitatively how genes may relate to disease, given that most diseases are complex and involve variants in many genes individually or combined. We developed an approach to assess if a gene is relevant to a disease by using ontology fingerprint derived from PubMed Abstracts. The fingerprints are generated by GO terms that are enriched in the abstracts relevant to a gene or disease through hypergeometric test. Such fingerprints can be quantified by the level of significance from the test, and the importance of a gene to a disease for GWAS can be assessed by comparing ontology fingerprints of genes to disease through the summary score calculation. We used 10 KEGG pathways to validate by comparing the summary scores of the genes belong to each pathway with that of genes from irrelevant pathways.We obtained a .9 for the averaged AUC of the 10 ROC curves,indicating the approach can reveal the relevancy of gene to biological phenomenon.By ranking the genes generated from GWAS on loci that influence lipid concentrations and risk of coronary artery disease, we found that the summary scores of this gene list are significantly higher than that of the rest of human genes, with larger proportion of GWAS identified genes obtaining higher score. This indicates GWAS-identified genes indeed has a significant bias toward genes involved in lipid metabolism. Our approach indicated that highest ranking genes are LDLR, APOE, and APOC2 for LDL; LIPC and CETP for HDL; and LPL for Triglyceride.We also find LPL, APOC2, and APOE are genes with highest ranking in all the above three studies.Our results demonstrate that ontology fingerprints can be used to effectively prioritize genes for GWAS.

Complex Disease Epistasis in AD: an enhanced version of MDR for complex SNP interaction analysis. *D. A. Ross[1], D. Wolfson[1], A. Smolgovsky[1], J. Sninsky[1], YH. Li[1], A. Grupe[1], J. H. Moore[2]* 1) Computational Biol, Celera, Alameda, CA; 2) Dartmouth College, NH.

Recently reported genome-wide association studies are using hundreds of thousands of SNPs and 1000s of patients and controls; these experiments are providing new opportunities to explore the epistatic network of genes that effect phenotypes. We have revised the program MDR, multifactor-dimensional-reduction(we call it MyT-MDR)so that it can accommodate datasets with hundreds of thousands of SNPs and 1000s of patients. Normalized-mutual-information and other metrics were incorporated for model evaluation. A significant speed increase, 12X per unit node was achieved by code refactoring; the code runs on a Beowulf-Scyld parallel cluster. The improved speed allowed us to perform the initial analysis and repeated cross-validation (10 fold CV with 10 fold randomization) within 5 days using whole genome SNP data and thousands of individuals. Cross validation was key to achieving an accurate prediction of models which will replicate(Motsinger and Ritchie (2006). When using synthetic data-sets with heritability of .05 we can repeat cross-validated studies for the 300K SNPs and 2000 individuals to obtain 3 and 4 way interactions. We use a small set of randomizations of the phenotype with patients to obtain a distribution of the false discovery rate to help evaluate the models. To explore interaction analysis in real data-sets we used the AD dataset from TGEN (Reinman, E. et. al. (2007) Neuron 54:713); in which the initial univariate analysis identified a single marker system around GAB2. This dataset has approximately 1400 case/controls. The dataset was divided into a train-test discovery(75%) and validation(25%)data-sets. The discovery set was repeat-cross-validated 100 fold to identity SNPxSNP models that were evaluated for error in the testing partitions. Finally a small number of these models were evaluated in the further validation datasets. We present significant marker models which replicated through all datasets. Although the overall size of the initial dataset was small, larger sample sizes can be handled efficiently using MyT-MDR to identify SNPxSNP interactions.

Asperger syndrome: atypical phenotype trisomy 10q. *L. R. J. da Silva, N. Sobreira, D. Brunoni, C. Borovik, A. Perez*
Morfology, UNIFESP, São Paulo, São Paulo, Brazil.

Asperger syndrome (AS) is a form of pervasive developmental disorder characterized by impairment in social interaction as well as a restricted pattern of behavior, interests, and activities. It is diagnosed almost exclusively in individuals with normal or high level of intelligence. The estimated male-to-female ratio is approximately 4:1. The pathophisiology of Asperger disorder is unknown but a susceptibility region was suggested, by Tentler et al. (2002), on 17p13 based on molecular characterization of two breakpoints. We describe a 16 years old male, only son of non consanguineous parents. To the birth he presented P=3400g, E=51cm, of scapular waist and criptorquidia at left side. He presented delayed milestones and abnormal behavior. His physical examination presents long face, long eyelashes, high and narrow palate, narrow and long thorax, long fingers (P>P97), increased distance between halux and 2º toe and overlapping of 3º on 2º and 4º toes, absence of plantar creases, cifoscoliosis, muscular hypotrophy and tall stature (P>97). He still presents infantile and effeminate behavior and increased interest for determined subjects. The echocardiogram evidenced diameter of aorta in the superior limit. The psicodiagnosis confirmed Asperger syndrome. Karyotype showed the presence of an additional segment in the short arm of chromosome 17, 46, XY, add(17p), and karyotype of the parents was normal. Using array CGH (GenoSensor, Abbott, Inc.) the additional segment was identified as 10q26-10q26.3 region. Distal trisomy 10q is a well know, but rare, syndrome. Typical features consist of psychomotor delay, a distinctive dysmorphic appearance, and growth retardation. This patient represents a rare case of pure distal trisomy 10q and does not presents the typical characteristics of this syndrome. On the other hand he presents tall stature and Asperger syndrome and candidates genes to Asperger syndrome were suggested at 17p13. So the comparation between the duplicated regions and the evaluation of the expression of genes in these regions of chromosome 10 and 17 may reveal candidate genes for these phenotypes.

Renal transplant in methylmalonic acidemia: a therapeutic option with or without renal failure. *P. de Lonlay[1], D. Rabier[2], G. Guest[3], Y. Aigrain[4], JF. Benoist[5], P. Niaudet[3], V. Valayannopoulos[1]* 1) Metabolic Dept, INSERM U393,Université Paris Descartes Hosp Necker-Enfants Malades, Paris , France; 2) Biochem Lab, Hosp Necker-Enfants Malades, Paris , France; 3) Ped Nephrology, Hosp Necker-Enfants Malades, Paris , France; 4) Ped Surgery, Hosp Necker-Enfants Malades, Paris , France; 5) Biochem Lab, Hosp Robert Debré, Paris , France.

Background: In methylmalonic acidemia (MMA), liver, kidney, or combined liver and kidney transplantation is a possible therapeutic option. Case Report: We report on a 5-year-old boy with MMA. The first symptoms occurred at 4 days of life, namely hyperammoniemic coma and ketoacidosis. After medical treatment his clinical course was uneventful until the 2nd year of life when he displayed several episodes of metabolic decompensation with vomiting and failure to thrive that required continuous enteral feeding. His neurological condition deteriorated (tremor, developmental arrest) while MMA levels remained high. We decided to propose renal transplantation for this patient despite normal renal function because liver transplantation was considered at high risk because of his impaired metabolic condition. Results: The procedure was uneventful and MMA levels in blood and urine fell rapidly to very low levels. Ten months after the transplant the patient is at home, started oral feeding and has normal somatic and cognitive developments and moderate protein restriction. No further metabolic decompensation occurred, except from a single and short episode of acute encephalopathy with low urine and plasma MMA levels, neither hyperammoniemia nor ketoacidosis, but elevated MMA levels in CSF. Conclusion: Although liver is the major site of methylmalonyl-CoA mutase activity, this case and similar ones suggest that the smaller mutase activity present in the transplanted kidney may be sufficient to ensure partial correction of the metabolic defect. However organ transplantation does not prevent neurological complications where the blood brain barrier by trapping toxic metabolites may play a major role.

Genome-wide Linkage Analysis of Colorectal Cancer in 302 Multiple-Case Families. *E. L. Goode[1], B. L. Fridley[1], W. Bamlet[1], D. Serie[1], R. W. Haile[2], D. C. Thomas[2], S. N. Thibodeau[1], N. M. Lindor[1], J. D. Potter[3] for the Colon CFR*
1) Mayo Clinic, Rochester, MN; 2) University of Southern California, Los Angeles, CA; 3) Fred Hutchinson Cancer Research Center, Seattle, WA.

Even accounting for known syndromes, colorectal cancer risk is associated with family history, and patterns of inheritance suggest other major susceptibility loci. We assessed linkage in 302 families of the Colon CFR, a multi-site NCI-supported consortium; families known to have FAP, MAP, or Lynch-related mutations were excluded. 1,882 individuals were successfully genotyped using the Affymetrix 10k 2.0 Array (5,453 SNPs with $r^2<0.1$) including 703 cases. Among 287 Caucasian families, peak Kong & Cox LOD scores (KCL) of 2.11 on chr 3 (128.8 cM), 1.60 on chr 23 (329.7 cM), and 1.40 on chr10 (308.7 cM) were observed. In addition, dominant lods (DL) of 7.27 on chr 2 (109.2 cM; 41% of families linked), 2.20 on chr 13 (41.1 cM; 26%), 1.53 on chr 15 (39.9 cM; 26%) were seen, assuming heterogeneity. Analysis of 30 families with loss of MLH1 expression yielded a KCL = 2.20 in the chr 3 *MLH1* region (97.5 cM; DL = 3.69, 94.8 cM) as well as a KCL = 2.42 on chr 19 (86.9 cM). Analysis of 18 families with MSH2 loss, including 17 with MSH6 loss, yielded a KCL = 5.07 in the *MSH2-MSH6* region (chr 2, 114.6 cM; DL = 10.3, 111.87 cM). 180 families were screened for MSI; the peak DLs for families with MSI-H (N=59), MSI-L (N=32), and MSS (N=89) tumors were 0.77 (*MLH1* region, chr 3, 94.81), 1.61 (chr 21, 55.8 cM), and 1.02 (chr 1, 205.8 cM), respectively. Among 219 families that did not have loss of MMR expression or MSI-H tumors, the genome-wide peak KCLs were 1.22 (chr 12, 182.6 cM), 1.17 (chr 3, 128.1 cM) and 1.00 (chr 5, 289.8 cM) with DLs of 1.58 (chr 4, 148.8), 1.38 (chr 2, 175.0), and 1.35 (chr 1, 195.7 cM), assuming heterogeneity. These results confirm linkage to *MLH1*, *MSH2*, and *MSH6* for families with protein loss and suggest novel regions for those with MMR proficiency. Among the latter group, minimal power and residual heterogeneity emphasize the need for analysis of newly-recruited families, combined analyses with other studies, and application of approaches to integrate linkage and association scans.

Detecting Inversions in the Human Genome from SNP data. *P. F. O'Reilly, C. J. Hoggart, L. J. Coin* Epidemiology & Public Health, Imperial Col London, London, United Kingdom.

The importance of structural variation in the human genome, in terms of its ubiquity and association with disease, has only recently been established. Since the first genome-wide map of structural variation by Redon et al (2006), intense efforts have focused on identifying Copy Number Variants (CNVs). The discovery of inversion polymorphisms has been relatively minimal, largely because of the particular challenge that their detection presents. However, recent evidence that inversions may be common in the genome, and examples suggesting a role in disease causation, call for the development of powerful methodology to identify them from large-scale SNP data. Here we present a statistical method, based on a Hidden Markov Model (HMM), designed to scan the genome for inversions using genotype data. The HMM is constructed to highlight loci where there exists a bipartition of individuals showing no, or little, between-group recombination. This captures the main discernible feature of inversions from genotype data: that recombinations between the inverted and non-inverted types are suppressed. Using an extensive forward-in-time simulator we find that our method has good power to detect even small inversions, and outperforms current alternatives. We apply our method to several large human datasets, building the most comprehensive genome-wide map of candidate inversions so far.

Mutations in the glucocerebrosidase gene confer a five fold increased risk of developing Parkinson disease: Results of an international multi-center collaborative study. *E. Sidransky, Multi-Center Collaborative Group Studying GBA Mutations in PD* MGB, NHGRI, NIH, Bethesda, MD.

Recent studies have demonstrated an increased frequency of mutations in the gene encoding glucocerebrosidase (GBA), the enzyme deficient in Gaucher disease, among different cohorts with parkinsonism. To better establish the frequency of GBA mutations in ethnically diverse subjects with Parkinson disease (PD), and to ascertain the relative risk of developing PD in GBA mutation carriers, we assembled an international multicenter collaborative group of investigators screening for mutations in this gene. As a first step, each group was provided with a uniform panel of DNA samples to determine which mutations could be detected by their center. Next, genotypes and phenotypic data on patients and matched controls were collected and assembled. The study included four centers from North America, two from South America, six from Europe, two from Israel and three from Asia, and included a total of 5749 patients (780 Ashkenazi Jews) and 4840 controls (399 Ashkenazi Jews). All participating centers demonstrated the ability to detect GBA mutations L444P and N370S. These two mutations were found in a total of 287 patients (5.0%), including 119 Ashkenazi Jews (15.3%) and 168 non Ashkenazim (3.4%), and 42 controls (0.87%), including 15 Ashkenazi Jews (3.8%) and 27 non Ashkenazim (0.61%). Screening for a total of 7 mutations in the Ashkenazi Jewish group increased the mutation frequency to 19.7% in patients versus 4.5% in controls. Among the non-Ashkenazi Jewish subjects, sequencing of all GBA exons was performed in a total of 1794 patients and 1446 controls, yielding a mutation frequency of 7.1% and 1.6% respectively, indicating that screens for only the L444P and N370S mutations in non-Ashkenazi cohorts may miss as many as 50% of mutant GBA alleles. Phenotypic data is being compared between heterozygous GBA mutation carriers and patients with wildtype GBA alleles. Our data demonstrate that the relative risk of developing PD in GBA mutation carriers from diverse ethnicities is increased approximately five-fold, rendering it one of the most significant PD risk factors indentified to date.

INCREASING THE EFFICIENCY OF GENOMEWIDE ASSOCIATION MAPPING VIA HIDDEN MARKOV MODELS. *H. Gao[1], H. Tang[1], C. D. Bustamante[2]* 1) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 2) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

With the rapid production of high dimensional genetic data, new difficulties have arisen in genome-wide association studies. A major one is the lack of effective and efficient statistical tools to resolve the loss-of-power problem caused by performing multiple statistical tests across millions of SNPs simultaneously. Here we present a novel method that serves as an effective measure for balancing power and type I error in genome-wide association studies. The approach uses hidden Markov model and its derivate Markov hidden Markov model to estimate the posterior probabilities of a markers being in an associated state, which naturally utilizes the correlation information among consecutive markers. We conducted extensive simulations based on the whole genome genotype data (500K SNPs) of 1000 Europeans from the GlaxoSmithKline project to calibrate the sensitivity and specificity of our method. We compared our method with many popular approaches for correcting multiple tests including Bonferroni correction, false discovery rate (FDR) control or positive false discovery rate (pFDR) control and Q-value control. Our simulation results suggested that at comparable low false positive rates 10^{-5}, our method is significantly more powerful than many other approaches, given moderate susceptibility of disease-predisposing variants.

Contractility of individual myofibers is altered in individuals with myosin mutations that cause Freeman-Sheldon syndrome. *A. E. Beck[1], M. J. McMillin[1], F. S. Korte[2], A. W. Ward[2], M. Regnier[2], M. J. Bamshad[1]* 1) Dept Pediatrics, University of Washington, Seattle, WA; 2) Dept Bioengineering, University of Washington, Seattle, WA.

The distal arthrogryposis (DA) syndromes are a group of ten dominantly inherited disorders characterized by multiple congenital contractures such as clubfoot and camptodactyly. DA syndromes are caused by mutations in at least seven different genes that encode components of the contractile apparatus of fast-twitch myofibers including troponin I, troponin T, tropomyosin, and several myosin heavy chains. *In vitro* contractility studies using recombinant mutant troponin and tropomyosin molecules suggest that DA syndromes are, in some cases, caused by increased myofiber contractility, although the mechanism by which contractility is altered is disputed. Mutations in *TNNI2* and *TPM2* explain only a small fraction of DA cases. The majority of mutations found to date to cause DA syndromes are located in *MYH3*, the gene that encodes embryonic myosin. Non-overlapping mutations in *MYH3* cause both the most common DA, Sheldon-Hall syndrome (SHS), and the most severe DA, Freeman-Sheldon syndrome (FSS). This observation suggests that *MYH3* mutations causing FSS have different functional consequences than those causing SHS. Myosin molecules are challenging to manipulate *in vitro* so we elected to explore the relationship between myosin mutations and muscle contractility by directly measuring the contractile properties of single chemically skinned muscle fibers sampled from affected muscles in individuals with FSS. Preliminary analysis suggests that maximal force normalized to fiber cross-sectional area was similar in case and control fibers, but the relationship between calcium concentration and contractile force differed between cases and controls. Understanding the mechanism by which myosin mutations affect myofiber contractility could provide a model to explore the mechanisms underlying more common contractures such as idiopathic clubfoot and facilitate the development of novel therapeutic approaches.

Clinical Genetics of Moebius Syndrome. *H. Gaspar[1], S. Chang[2], S. Scott[1], L. Edelmann[1], E. W. Jabs[1], . Moebius Syndrome Foundation[3]* 1) Mount Sinai School of Medicine, New York, NY; 2) Johns Hopkins University, Baltimore, MD; 3) Pilot Grove, MO.

Moebius syndrome is a rare, congenital disorder with partial or complete agenesis of the 6th and 7th cranial nerves (CNs), which control eye movements and facial expression. There is a broad spectrum of associated features such as limb malformation and mental retardation. This heterogeneous condition is usually sporadic, but can be inherited in a dominant or recessive manner. Hereditary Congenital Facial Paresis involves only the 7th CN and loci have been identified at 3q21-q22 and 10q21.3-q22.1. Our goal is to better define the diagnostic criteria and delineate the spectrum of features associated with Moebius syndrome by studying the largest reported cohort of 74 patients with a minimum criterion of 7th CN involvement. Clinical information was obtained from a questionnaire, medical records, and physical examinations on patients primarily referred by the Moebius Syndrome Foundation. Our data showed that 59 patients had the classic features of 6th and 7th CNs (80%) and 15 atypical patients had only 7th CN involvement (20%). We observed 3 dominant and 4 autosomal recessive families. Forty-seven patients (64%) had involvement of other CNs; 48 (65%) had muscular hypotonia; 37 (50%) had developmental delay in motor skills, 6 (8.1%) had mental retardation, 4 (5%) had seizures, 2 had autistic spectrum disorder, 3 (4.1%) had peripheral neuropathy, 47 (64%) had limb abnormalities, 7 (10%) had Poland sequence and 8 (11%) had cardiac defects. Moebius patients with both, 6th and 7th CN involvement showed a broader spectrum of features, particularly with neurological and cardiac findings, whereas familial cases were more common in patients with only 7th CN involvement. Karyotyping revealed an unbalanced de novo translocation chromosome t(10;15) in one patient and a familial balanced t(2;11) in another patient. By array CGH we did not find consistent aberrations in 20 complex cases, but we did identify specific aberrations in multiple patients involving regions of chromosomes 5, 7, 14 and 15. Other patients screened for candidate genes HOXB1, HOXB2, and KROX20 did not yield mutations.

Genotype/phenotype correlation in two Brazilian families harboring the Cys433Arg mutation in the MYOC gene. *J. P. C. Vasconcellos[1], R. Reis[2], C. Stefani[3], A. Tavares[4], C. A. Braghini[4], P. R. S. Cruz[4], D. B. O. Santos[4], S. R. E. Pião Jr.[4], V. P. Costa[1], A. V. Celestino[4], M. B. Melo[4]* 1) Dept. Ophthalmology, University of Campinas - UNICAMP, Campinas SP, Brazil; 2) Instituto da Visão, S. J. Rio Preto SP, Brazil; 3) Braojos Oftalmologia, S. J. Rio Preto SP, Brazil; 4) CBMEG, University of Campinas - UNICAMP, Campinas SP, Brazil.

Introduction: Primary open angle glaucoma (POAG) is characterized by progressive excavation of the optic disc with corresponding visual field loss. Mutations in the MYOC gene account for most cases of autosomal dominant juvenile open angle glaucoma (JOAG), an earlier and more severe form of POAG. In Brazilian JOAG patients, the most prevalent alteration associated with the disease is the Cys433Arg. Two JOAG Brazilian families harboring this mutation have been evaluated according to clinical parameters. Methods: A comprehensive ophthalmic examination was performed, including intraocular pressure (IOP) measurement, optic disc and corneal thickness evaluation. POAG was defined as untreated IOP over 21 mmHg, with characteristic optic nerve and visual field glaucomatous damage. Results: Twenty two out of 53 members of the families harbor the Cys433Arg mutation (9 developed glaucoma, 5 have high IOP and 8 are normal). Among the normal individuals with mutation, two members of the same family have more than 58 years of age. The mean IOP in right eyes (RE) was 16.203.60 and 27.5513.03 in the absence and presence of the mutation, respectively (P=0.002). In left eyes (LE) the mean IOP was 16.413.55 and 28.5814.37 in the absence and presence of the mutation, respectively (P=0.002). Cup to disk ratio in RE was 0.140.07 in eyes without mutation and 0.390.33 in eyes with mutation (P=0.003) and in LE it was 0.150.07 and 0.410.35 in the absence and presence of mutation, respectively (P=0.003). Corneal thickness did not differ in both groups. Conclusions: The Cys433Arg mutation in these two families is associated with high intraocular pressure, augmented cup to disk ratio and early onset glaucoma. The incomplete penetrance after 58 years of age in one of the families suggests the possible role of other genes modulating the disease phenotype.

Genome-wide Analysis of Gene-Gene Interaction in Alzheimer Disease. *S. D. Turner[1], E. R. Martin[2], G. W. Beecham[2], J. R. Gilbert[2], J. L. Haines[1], M. A. Pericak-Vance[2], M. D. Ritchie[1]* 1) Center for Human Genetics Research, Vanderbilt University, Nashville TN; 2) Miami Institute for Human Genomics, University of Miami, Miami, FL.

Genome-wide association studies (GWAS) have revolutionized complex disease studies by identifying individual genes that previously resisted identification. However, these genes rarely explain more than a few percent of the overall genetic risk. To more fully exploit the richness of these datasets and explore alternatives to single gene effects, we examined the feasibility of testing for gene-gene interactions using an Alzheimer Disease (AD) GWAS dataset of 492 AD cases and 496 cognitively normal controls. Single gene studies of this and other AD GWAS datasets confirmed that the only strong effect in AD is APOE. To identify novel interactions we removed APOE from the dataset and performed multifactor dimensionality reduction (MDR) analysis on the first half of the dataset. 13 two-locus models with a cross-validation consistency (CVC) of 9 or 10 were identified. Regression analysis of these 13 models in the second half of the dataset confirmed two strong interactions, one between rs12683393 (PRG-3 on chromosome 9) and rs3791426 (HDAC4 on chromosome 2) (OR=2.44, p=0.034) and another between rs6473522 (on chromosome 8) and rs11265191 (OR10J on chromosome 1) (OR=2.93, p=0.006). These interaction effect sizes are substantially larger than any single locus effect other than APOE. To test for interactions with APOE, we ran MDR on the full dataset (to increase power given APOEs strong main effect) and identified a model with high prediction accuracy (72.3%) that included APOE and rs2161082, an intronic SNP in SPAG16 on chromosome 2. These results suggest that gene-gene interaction effects in AD are substantially larger and perhaps more important than individual gene main effects. They also highlight the value of deeply exploring the richness of GWAS data.

Very-long-chain acyl-CoA dehydrogenase deficiency in two patients with normal newborn screening by tandem mass spectrometry. *C. Ficicioglu, C. R. Coughlin II, M. Yudkoff* Biochemical Genetics, Children's Hospital of Philadelphia, Philadelphia, PA.

Very-long-chain acyl-CoA dehydrogenase deficiency (VLCADD) is an autosomal recessive disorder of fatty acid oxidation (FAO). VLCADD may present with cardiomyopathy in the neonatal period, hypoglycemia in childhood, and rhabdomyolysis and myglobinuria in adulthood. VLCADD can be detected through newborn screening by measuring C14: 1 level with tandem mass spectrometry. Case 1:The first patient was a previously healthy nine-month old infant presented with severe hypoglycemia and dehydration after a one-day history of acute gastroenteritis. She developed hypoxic ischemic encephalopathy and liver failure, and died as a result of severe brain injury due to hypoglycemia. The extensive metabolic work up did not show any specific disease. Plasma acylcarnitine analysis showed elevations of multiple long-chain acylcarnitine species in a non-disease specific pattern. Newborn screening was within normal limits with a C14: 1 of 0.58 umol/L .The patients sibling was born three years later and newborn screening revealed an elevated C14: 1 level of 2.21 umol/L. Plasma acylcarnitine analysis performed on day two of life revealed C14 and C16 elevations that were consistent with diagnosis of VLCADD. Sequence analysis of the VLCAD gene revealed two novel mutations (1049G>T, 1700G>A). These mutations were later confirmed in the deceased patients fibroblast. Case 2: The second patient presented at 13 months of age as a result of hypoglycemia leading to an unresponsive state. Prior to this episode she was hospitalized twice for dehydration secondary to vomiting and diarrhea. Acylcarnitine analysis performed during her presenting illness revealed C14 and C16 elevations that were consistent with VLCADD. Sequence analysis of the VLCAD gene revealed two mutations (IVS7-8C>T, 1600G>A). Her newborn screen was within normal limits. Our cases show that newborn screening may not detect all cases of VLCADD. A diagnosis should be considered when clinical symptoms are consistent with a disorder of FAO even if newborn screening and acylcarnitine analysis are within normal limits.

I Gave at the Office: Privacy, Discrimination, and the Employer-Sponsored Biobank. *L. R. Eisenberg, J. M. Henriksen Hellyer, B. A. Koenig* Bioethics Research, Mayo Clinic, Rochester, MN.

Giving at the office used to refer to a donation to the United Way or the purchase of Girl Scout cookies. Giving at work may soon take on new dimensions as more research institutions develop biobanks stocked with DNA samples from healthy members of the population. It is inevitable that staff persons at research institutions will be asked to donate blood to employer-sponsored population-based biobanks. We explore the concerns that arise when an employer maintains a biobank that not only stores biological samples but also associates them with a wide range of health, lifestyle, and ancestral information. A critical issue in the maintenance of any biobank is privacy. Although samples are separated from identifying information such as name and social security number, its unclear whether complete anonymity is possible in the relatively small community of a research institution. Despite the recent passage of the Genetic Information Nondiscrimination Act, there is a widespread fear that employers will try to control costs in the future by limiting health coverage based upon an individuals genetic makeup. A recent study found that most adults would trust researchers to properly handle their genetic information but would not trust their employers with the same data. Which belief will prevail when employer and researcher are one in the same? How can an employer earn and keep the employees confidence while avoiding coercion stemming from the power differential inherent in their respective roles? Institutions committed to maintaining trust must apply intentional strategies when designing and implementing population-based biobanks. We examine such strategies, including the use of a deliberative democracy process, which involves employees in active, reasoned reflection about the risks and possibilities of biobanking in the design stages of the project, as well as continued input via consultation roles for the employee-participants as part of ongoing advisory groups. Biobanks may also utilize after-the-fact methods for improving privacy, such as the use of a charitable trust, or the double coding of samples with the help of a trusted intermediary.

Genome-Wide Association of Bipolar Disorder in European American and African American Individuals. *C. S. Bloss[1], E. N. Smith[1], C. Nievergelt[3], N. J. Schork[1,2], J. R. Kelsoe[3] for The Bipolar Genome Study (BiGS) Consortium* 1) Scripps Genomic Medicine, Scripps Translational Science Institute, La Jolla, CA; 2) Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA; 3) Department of Psychiatry, University of California, San Diego, La Jolla, CA.

Bipolar disorder (BD) is a debilitating neuropsychiatric illness characterized by alternating episodes of depression and mania. Family, twin, linkage, and candidate gene studies all suggest a strong genetic component in BD, although genome-wide association (GWA) studies, which to date have been limited to individuals of European Ancestry (EA), have generally failed to detect signals that have been replicated consistently. We performed two GWA studies, one in a sample of individuals of EA (n = 1,001 cases; 1,034 controls) and the second in a sample of individuals of African Ancestry (AA; n = 362 cases; n = 671 controls). Both studies utilized the Affymetrix 6.0 array. Analyses involved association using different methods to adjust for admixture, as well as exploration of the extent to which some single nucleotide polymorphisms (SNPs) demonstrate genetic background-dependent effects. Results revealed significant levels of admixture, particularly among individuals of AA, and highlight the need for analytic methods that account for this. Among individuals of EA, six SNPs in the Nck-associated protein 5 (NAP5) gene were nominally associated with BD (p-values all $< 1 \times 10^{-5}$), a gene known to be expressed in both fetal and adult human brain tissue. Among individuals of AA, three SNPs in the dyp-19-like protein 3 (DPY19L3) gene were nominally associated with BD (p-values all $< 1 \times 10^{-5}$), a gene with evidence of expression in several human tissues including brain. We also considered analyses exploring copy number variations and pathways implicated by the most strongly associated variations. Overall, our study is among the first to conduct GWA of BD in individuals of AA and suggests that genetic variations that contribute to BD may vary as a function of ancestry.

Sequence variation in the *IL4* gene and resistance to *Trypanosoma cruzi* infection in Bolivians. *L. E. A. Arnez[1], E. N. Venegas[1], C. Ober[2], E. E. Thompson[2]* 1) Laboratory DIANA of Histocompatibility and Immunogenetics, Cochabamba, Bolivia; 2) Department of Human Genetics, The University of Chicago, Chicago IL.

Th2 immunity plays a central role in response to intracellular pathogens, such as *Trypanosoma cruzi* (*T. cruzi*), which is endemic to Latin America. Variation in the gene encoding interleukin 4 (IL-4), a signature Th2 cytokine, has been associated with Th2-mediated diseases. A promoter polymorphism (-590C/T; rs2243250) affects gene expression and has been associated with susceptibility to Th2-mediated allergic and parasitic diseases. We hypothesized that variation in the *IL4* gene confers differential resistance to T. cruzi infection. The *IL4* gene was re-sequenced in DNA from 110 Bolivians to determine whether genetic variation at this locus contributes to *T. cruzi* infection status in exposed individuals. Standard sequencing techniques were used to detect single nucleotide polymorphisms (SNPs) in susceptible (*T. cruzi* positive cases) and resistant (exposed but *T. cruzi* negative controls) individuals from Bolivia. A total of 45 polymorphisms were identified in the *IL4* gene, 19 of which have not previously been reported, including a novel non-synonymous SNP. Two classes of haplotypes, referred to here as Clade A and Clade B, defined by alleles at a functional promoter SNP, -590C/T, were identified. Using the chimpanzee as an outgroup, we estimated that these haplotypes diverged approximately 40,000 years ago. Clade A haplotypes (with the derived -590T allele) were more common in the resistant group compared to the *T. cruzi* susceptible group (0.64 v. 0.49, respectively, $P = 0.033$). We also observed an excess of intermediate frequency variants in the resistant group (Tajimas D =1.78, $P = 0.01$) and the occurrence of all singletons in the susceptible group ($P = 0.0025$), suggesting that selection is favoring the maintenance of Clade A haplotypes in the Bolivian population. Our study of the *IL4* gene in Bolivians reveals many alleles that may be population-specific, and the possible involvement of a common haplotype conferring protection against *T. cruzi* infection. This work was supported by NIH grants R01 HL072414 to C.O. and T32 HL007605 to E.E.T.

Fine mapping on chromosome 10q22-23 implicates *Neuregulin 3* (*NRG3*) in Schizophrenia. *P. Chen[1], D. Avramopoulos[1,2], V. K. Lasseter[2], J. McGrath[2], M. D. Fallin[3,4], K.-Y. Liang[4], G. Nestadt[2], N. Feng[1], G. Steel[1], A. S. Cutting[1], P. Wolyniec[2], A. Pulver[2], D. Valle[1]* 1) Inst Genetic Medicine, Johns Hopkins Sch Medicine, Baltimore, MD; 2) Dept Psychiatry, Sch of Medicine; 3) Dept Epidemiology, Sch of Public Health; 4) Dept Biostatistics, Sch of Public Health.

Linkage studies have implicated 10q22-23 as a schizophrenia (SZ) susceptibility locus in Ashkenazi Jewish (AJ) (Fallin *et al*. Am J Hum Genet 73:601, 2003) and Han Chinese from Taiwan (Faraone *et al*. Am J Psychiatry 163:1760, 2006). To further explore our previous linkage signal in the AJ (NPL score: 4.27, empirical $p = 2x10^{-5}$), we performed a peakwide association fine mapping study using 1414 SNPs across ~12.5 Mb in 10q22-23 in 1515 AJ individuals, including 285 parent-child trios, 173 unrelated cases and 487 unrelated controls. We analyzed the binary diagnosis of SZ and 9 heritable quantitative traits derived from a principal components factor analysis of 73 items from our consensus diagnostic ratings and assessment interviews. Although there was no association with the diagnosis of SZ, we found strong evidence of association using the Delusion factor as the quantitative trait at 3 SNPs (rs10883866, rs10748842 and rs6584400) located in a 13 kb interval in intron 1 of *NRG3*. Our best *p* value from family-based association analysis was $7.26x10^{-7}$. We replicated this association in the collection of 173 unrelated AJ cases ($p = 1.55x10^{-2}$), with a combined *p* value of $2.30x10^{-7}$. With 10,000 permutations of each phenotype, we estimated the empirical study-wide significance across all 9 factors to be $p = 2.7x10^{-3}$. The 20 SNPs with the smallest *p* values in our factor analysis includes a total of 10 (50%) SNPs in *NRG3*, showing association with Delusion and 2 other factors (Scholastic and Disorganization) in different regions of the gene. We also identify 2 novel segregating microdeletions in *NRG3*. *NRG3* is primarily expressed in the central nervous system and is one of 3 paralogs of *NRG1*, a gene strongly implicated in SZ. These biological properties together with our linkage and association results strongly support a model in which multiple alleles of *NRG3* confer susceptibility for different clinical presentations of SZ.

***ATP8B1, ABCB11* and *ABCB4* gene mutation analysis in progressive familial intrahepatic cholestasis patients.** *J. Wang[1], IC. Lee[1,2], ES. Schmitt[1], S. Zhang[1], LC. Wong[1]* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Chung-Shan Medical University Taichung, Taiwan.

Background: Progressive familial intrahepatic cholestasis (PFIC) is a genetic heterogenous autosomal recessive disorder caused by the defects of bile acids and phospholipids transporters. PFIC is characterized by early-onset progressive cholestasis, and lead to hepatic fibrosis, cirrhosis, and end-stage liver failure before adulthood. There are three loci known to cause PFIC: PFIC1 (*ATP8B1*), PFIC2 (*ABCB11*) and PFIC3 (*ABCB4*). Both PFIC1 and PFIC2 are characterized by normal or near normal serum GGT, while PFIC3 has elevated GGT. PFIC2 results from the defects in canalicular bile salt excretion. PFIC3 is caused by the defects of transporting phospholipid to canalicular lumen. Results: Entire coding exons and adjacent flanking intronic regions of *ATP8B1*, *ABCB11*, and *ABCB4* genes were sequenced. In 360 patients suspected of PFIC, 54 mutations and variants were identified, 34 of them are novel findings. Table 1 summarizes the results of three PFIC gene tests.

PFIC type	Patients	Positives(%)	2 mutations	1 mutation	Mut & Var	Novel
PFIC1	127	14 (11)	8	6	17	11
PFIC2	143	31 (22)	21	10	29	18
PFIC3	90	8 (9)	4	4	8	5

*Conclusions: PFIC is a group of early onset liver disorders with similar clinical phenotypes. We present a spectrum of mutations in ATP8B1, ABCB11, and ABCB4 genes in PFIC patients, with genotype/ phenotype correlations. Mutation analysis is useful for identifying disease etiology and provides information relevant to counseling families.

Specific Sets of Genetic/Genomic Melanoma Changes with Differential Responses to Targeted Therapies. *M. Dalla Palma[1], K.SM Smalley[2], R. Letrero[1], KL. Nathanson[1,3]* 1) Department of Medicine; 2) The Wistar Institute, Philadelphia, PA; 3) Division of Medical Genetics , University of Pennsilvania, Philadelphia, PA.

Understanding the molecular genetics of melanoma provides the basis for the development of rational therapies. To evaluate mutations in oncogenes and tumor suppressor genes involved in melanoma transformation, 78 melanoma primary cell lines were screened for mutations in *BRAF*, *NRAS*, *PTEN*, *CDKN2A*, *TP53*, *CKIT*, and *CDK4*. The identified genetic changes in these cell lines allow us to divide them into groups with distinct genetic profiles. The vast majority (70%) contains *BRAF* mutations, but this large group can be further divided in clusters based on the mutational status of the other genes analyzed. We defined a *PTEN* mutant (32%) and a *PTEN* wild type (17%) group, among which the frequency of TP53 alterations is 24% and 38%, respectively. Another interesting group is represented by six (8%) melanoma harboring both CDK4 and BRAF mutations, all but one in absence of TP53 mutations. Among the melanoma cell lines without BRAF mutations, 12 (13%) carry an alteration in *NRAS*, all at codon 61 and 8 cell lines (10%) are *BRAF* and *NRAS* wild type. Of those, two (2.5%) have *KIT* mutations, two have co-overexpression of *KIT* and *CDK4*, one a *TP53* mutation and three a *CDKN2A* alteration. *CDKN2A* point mutations/deletions (65%) are distributed across the different groups and do not appear any specific sub-type of melanoma. We proved the existence of distinct genomic mutational profiles in melanoma which reflect tumor heterogeneity. Understanding these different mutational groups is essential for the selection of targeted melanoma therapies. Indeed, we have demonstrated that BRAF V600E mutated melanomas with *CDK4* mutation and cyclin D1 amplifications are resistant to *BRAF* inhibitors. Increased resistance to a BRAF-inhibitor was not seen in cell lines with a *CDK4* mutation alone, but was in a cell line with a *CDK4* mutation and *CCND1* amplification. Moreover, we have shown that the group of melanomas and cell lines co-overexpressing CDK4 and KIT are resistant to *BRAF* inhibitors but sensitive to imatinib both in vitro and in vivo using pharmacological studies.

Mitochondrial tRNA Serine Novel Mutation Causes Multi-Systemic Disease. *L. Wong[1], E. Pierce[2], W. Anninger[2], E. Place[3], J. Golden[4], M. Flak[3]* 1) Prof, Dept Molec/Human Gen,MDL, Baylor Col Med, Houston, TX; 2) Dept Ophthalmology, CHOP/UPENN, Philadelphia, PA; 3) Human Genetics, CHOP/UPENN, Philadelphia, PA; 4) Pathology, CHOP/UPENN, Philadelphia, PA.

A mitochondrial etiology should be considered in the face of progressive multi-systemic disease, regardless of initial presenting problems. We report here a 20-year-old Caucasian man with complications of an open neural tube defect involving hydrocephalus, Chiari malformation, bilateral lower-extremity paralysis, bowel/bladder incontinence, scoliosis, restrictive lung disease, osteopenia, and proximal femur/acetabulum deformities. However, a host of multi-system manifestations developed that were not readily attributable to myelomeningocele complications, including: cardiac, CNS, endocrine, ophthalmologic, muscular, and metabolic. Bardet-Biedl GeneChip analysis, common mtDNA point mutations and large deletion screening were negative. Muscle biopsy revealed mitochondrial proliferation, ragged red fibers, scattered COX-negative fibers, coarse granular SDH staining, irregular mitochondrial morphology with lipid deposits. Analyses for respiratory chain complexes and pyruvate dehydrogenase were in the normal range. Leukocyte coenzyme Q content was normal. Sequencing analysis of the whole mitochondrial genome in muscle identified an apparently homoplasmic, novel, 12264 C>T transition in the tRNA serine (AGY) gene. The 12264C is at the last base of the amino acid acceptor stem, crucial for recognition of precursor RNA processing. This mutation disrupts the G-C pair that may be important in the stabilization of tRNA structure and amino acylation. A 12207 G>A transition affecting the same G-C pairing was previously reported in a patient with clinical features of MERRF and MELAS (Wong et al, J Med Genet 2006;43:e46). Both tRNA serine patients had a high percentage of mutant heteroplasmy, mitochondrial proliferation, relative complex I-III deficiency, and hearing loss, whereas only our patient had cardiac involvement and lacked hepatic involvement. This case highlights the value of whole mitochondrial genome sequencing in the diagnostic evaluation of suspected mitochondrial disease.

Recent development of Goldsurfer2 for functional analysis of GWA studies. *F. Pettersson[1], A. P. Morris[1], M. R. Barnes[2], L. R. Cardon[3]* 1) Dept Bioinformatics, Wellcome Trust Centre, Oxford, United Kingdom; 2) Molecular Discovery Informatics, GlaxoSmithKline Pharmaceuticals, Harlow, Essex, UK; 3) Fred Hutchinson Cancer Research Center, Seattle, Washington, USA.

Large-scale systematic genome-wide association (GWA) studies driven by the development of high-throughput genotyping technology seems to have fulfilled its promise for hypothesis generation by identifying a substantial number of highly significantly associated genetic variants for various disorders and phenotypes. In order for the initially promising results to help us increase our understanding of the underlying biological mechanism, in-depth functional characterization needs to be performed. This is likely to involve generation of new large scale dataset from for example resequencing and measuring of gene expression. The Goldsurfer2 (Gs2) software is based around a user-friendly GUI and was developed to be used in GWA studies for data pre-treatment, association testing, together with evaluation, visualization and interpretation of results [1]. The new version of Gs2 has added functionality to handle and analyse sequences, systems biology data such as gene expression and proteomic profiles, and to access functional information from sources such as GO, KEGG and UCSC. A strong emphasis in the recent development is adding support for investigating the link between genetic variants and gene expression (eQTL analysis). Functions for this include a new method for on the fly imputation of genotypes, used in investigating cis effects for nongenotyped variants in candidates. Another new feature identifies variants in microarray probes. With many GWA studies publicly available, it's attractive to combine these for increased statistical power. This can be done in Gs2 even for combining genotypes from different platforms with imputation being instrumental and reference data accessed from a newly designed database. Goldsurfer2 is implemented in Java and is available for Mac OSX, Linux and Windows. [1]Pettersson, F., Morris, A.P.; Barnes, M.R. and Cardon, L.R. Goldsurfer2 (Gs2): A comprehensive tool for the analysis and visualization of genome wide association studies. BMC bioinformatics 2008; 9 (138).

Searching for independent association signals in genome-wide association studies: evidence for a second signal with HDL cholesterol level at the *LIPC* locus. *T. M. Teslovich[1], C. J. Willer[1], L. J. Scott[1], A. U. Jackson[1], L. L. Bonnycastle[2], H. M. Stringham[1], P. S. Chines[2], M. G. Rees[2], T. T. Valle[3], R. N. Bergman[4], J. Tuomilehto[3], F. S. Collins[2], K. L. Mohlke[5], M. Boehnke[1]* 1) U Mich, Ann Arbor, MI; 2) NHGRI, Bethesda, MD; 3) National Public Health Institute, Helsinki, Finland; 4) USC, Los Angeles, CA; 5) UNC, Chapel Hill, NC.

To understand better the allelic architecture of complex traits, we are seeking to identify trait loci at which multiple independent causal variants may be present. For each locus, this will further our understanding of the genetic basis of the trait and may allow better prediction of personalized risk and drug therapies. This knowledge may inform future studies that seek to identify alleles involved in common diseases as the identification of multiple independent signals may provide stronger evidence of true association.

We are examining loci that showed association with lipid levels in a meta-analysis of genome-wide scans performed by the FUSION Study, the SardiNIA Study of Aging, and the Diabetes Genetics Initiative. After follow-up in additional samples, the analysis identified genome-wide significant associations with 18 loci, including one between serum HDL cholesterol levels and SNPs rs261332 (p=2.3x10^{-15}) and rs4775041 (p=3.2x10^{-20}) near LIPC on chr 15. rs261332 is in high LD with promoter polymorphisms that have been associated with HDL. rs4775041 is located ~50kb upstream of LIPC and is not in LD with previously associated variants.

To determine whether rs261332 and rs4775041 represent independent signals, we simultaneously tested both SNPs for association with HDL in 3,738 FUSION samples using linear regression. Neither signal is attenuated in the joint analysis (FUSION p-values: rs261332 unadj 1.2x10^{-7}, adj 3.0x10^{-8}; rs4775041 unadj 1.4x10^{-8}, adj 3.6x10^{-9}). These results suggest that rs4775041 represents an independent association signal at the LIPC locus.

We are currently investigating the remaining loci with preliminary evidence for multiple association signals that may act independently to increase disease risk.

Pseudo Myosin Light Chain Kinase (MLCK) Gene Transcribes in Cancerous Tissues and Cells. *Y. Han[1,2], J. Garcia[2], P. de Lanerolle[1]* 1) Dept Physiology & Biophysics, Univ Illinois, Chicago, Chicago, IL; 2) Dept Medicine, Univ Chicago, Chicago, IL.

Pseudogenes have been defined as nonfunctional genomic sequences that are originally derived from paralogous functional genes. Although biological importance of pseudogenes is not clear, pseudogenes have been widely used as evolution fossils. During the evolution to high primates, a functional MLCK gene was partially duplicated, making a pseudo MLCK gene in humans, chimpanzees, and gorillas. Because MLCK is of critical importance in regulating cytoskeletal dynamics by increasing myosin-actin crossbridge, we investigated the structure and expression of pseudo MLCK gene in humans. A functional MLCK gene, namely MYLK, locates on chromosome 3q21 spanning over 270 kb and contains at least 33 exons that encode 3 proteins: non-muscle MLCK (nmMLCK, 220 kDa), smooth muscle MLCK (smMLCK, 130 kDa) and Telokin (20 kDa). The nmMLCK translates from exon 1 to exon 33 while the smMLCK translates from exon 17 to exon 33. A pseudo MLCK gene, in contrast, locates on chromosome 3p12 and contains only 5 exons which correspond to exons 13-17 of the functional gene. Interestingly, the pseudo gene has a functional promoter for smMLCK at the intron between exons 16-17 and possibly transcribes a part of smMLCK gene. To investigate this possibility, we performed reverse transcriptase PCR (RT-PCR) and Northern blot analyses using RNAs purified from various human tissues with/without cancers. In humans with no diseases, none of tissues or cultured cells expresses the pseudo MLCK. However, it does express mRNA in all of cancerous tissues and cell lines that we have examined so far. These data strongly suggest that the pseudo MLCK gene selectively expresses in the development of cancer. While the functional importance of the pseudo gene expression is to be investigated, this is, to our best knowledge, the first discovery associating a pseudogene expression with a human disease. These data could lead to novel insights into the pathological importance of pseudogenes in the development of human diseases.

Additional Support for the Association of *SLITRK1* var321 and Tourette syndrome. *B. J. O'Roak[1], T. M. Morgan[2], E. Saus[3], P. Alonso[4], M. Gratacòs[3], X. Estivill[3,5], Y. Kohn[6], M. W. State[1]* 1) Dept of Genetics, Program on Neurogenetics, Child Study Ctr, Yale Univ, New Haven, CT; 2) Dept of Human Genetics, WashU, St. Louis, MO; 3) CIBERESP, Genes and Disease Program, CRG, Barcelona, ES; 4) OCD Clinical and Research Unit, Psychiatry Dept, Hospt Universitari de Bellvitge, L'Hospitalet de Llobregat, Barcelona, ES; 5) Experimental and Health Sciences Dept, Pompeu Fabra Univ, Barcelona, ES; 6) Child and Adolescent Psychiatry Unit, Hadassah Hebrew UMC, Jerusalem, IL.

We have identified *SLITRK1* as a candidate for Tourette syndrome (TS) based on the mapping of a *de novo* chr13 inversion; the identification of a frame-shift mutation in the gene in a family with TS and related disorders; and a rare 3 UTR variant (var321) in a miRNA binding domain that was found in 2/174 cases and 0/2148 controls (P=0.0056). The var321 alleles were hypothesized to be of independent origin, further supporting an association (P=0.000056). Subsequent to these initial findings, var321 has been identified at low frequency in affected and control samples (Wendland et al. 2006, Keen-Kim et al. 2006, Scharf et al. 2008). These studies, taken together, demonstrate an overrepresentation in affected individuals. However, two recent publications have proposed that var321 is an Ashkenazi (ASH) allele leading us to misinterpret our original findings. We have examined this hypothesis through extensive genomic characterization of individuals carrying var321 including our previously reported cases (F3/F4), a family with OCD (SP), a human variant panel (HVP) sample and an ASH control (AN). Detailed analysis of the region surrounding var321 supports at least 2 distinct haplotypes (maximal sharing 18kb). Genome-wide SNP data were compared with 1117 White Non-Jewish and 758 Jewish samples using multidimensional scaling analysis. Cases F3, F4 and SP cluster with the Non-Jewish group; HVP and AN cluster with the Jewish group. Finally, Y chromosome and mitochondrial DNA was evaluated in cases F3 and F4 and no ASH-related haplotypes were identified. These data argue strongly against var321 being an ASH variant and support our initial conclusion of an association with TS spectrum disorders.

***NF1* microduplication in a male with atypical café au lait spots.** *M. E. Walker[1], H. M. Saal[1], F. M. Mikhail[2], L. Messiaen[2]* 1) Div Human Genetics, Cincinnati Children's Hospital Med Ctr, Cincinnati, OH; 2) Dept Genetics, Univ Alabama, Birmingham, AL.

Mutations in the *NF1* gene can be identified in ~95% of non-founder patients with neurofibromatosis 1 (NF1) when a full cascade of techniques is applied. Approximately 5% of patients have a 1.4 Mb microdeletion involving *NF1* and typically present with a more severe phenotype. Duplication of the *NF1* gene is apparently rare. We report a *de novo* 1.4 Mb microduplication of *NF1* and flanking genes in a biracial male who presented at age 11 yrs with a prior diagnosis of NF1 based on presence of 6 atypical café au lait spots and hyper-pigmented lesions measuring 0.5-6 cm. MRI at age 9 yrs showed mild distention of the optic nerve sheath suggestive of dural ectasia but no other stigmata of NF1. Clinical exam revealed no axillary/inguinal freckling or skin tumors. He has learning difficulties in several areas. His brother and both parents had normal *NF1* analyses. MLPA analysis of the *NF1* gene in his blood DNA revealed 3 copies of the 1.4 Mb region flanked by REPa and REPc. This duplication was confirmed by interphase FISH probes (RP5-1002G3 & RP5-926B9) that span both ends of the *NF1* gene, demonstrating 3 red/green fusion signals with 2 of these signals co-localizing. The duplication at 17q11.2 is in tandem: metaphase FISH showed an enhanced *NF1* signal on one chromosome 17. Importantly, no mutations were found in the coding regions of the 3 copies of *NF1*. Intragenic microsatellite analysis indicated the duplication was of maternal origin and is heterodisomic, implying a meiosis I error. The only other similar report is a kindred in which an *NF1* microduplication was stable over two generations and carriers were either unaffected or had features of mild MR, early onset baldness, and dental enamel hypoplasia. Our patient may be still too young to present with the latter features. The data do not allow determination of whether the learning problems can be attributed to the microduplication, since his brother without the duplication has mild DD/autism spectrum disorder of unknown cause. More patients must be identified to further understand phenotypes associated with NF1 microduplication.

Association studies of *LOXL1* gene polymorphisms in both high- and normal-pressure Primary Open Angle Glaucoma. *T. Rezaie[1], J. Aragon-Martin[1,2], V. Schmidt[1], L. Beveridge[1], R. Ritch[3], J. Liebmann[3], E. Ilitchev[3], A. Child[2], M. Sarfarazi[1]* 1) Molecular Ophthalmic Genetics Laboratory, University of Connecticut Health Center, Farmington, CT; 2) St. Georges University of London, London, UK; 3) New York Eye and Ear Infirmary, New York, NY.

Primary open angle glaucoma (POAG) is a hereditary optic neuropathy and a common cause of blindness worldwide. In part, POAG is caused by mutations in MYOC, OPTN and WDR36 genes. A recent genome wide study in the Icelandic population identified a significant association between exfoliation glaucoma and *LOXL1* (Lysyl Oxidase-Like 1) gene polymorphisms. Herein, we investigated genetic contribution of 3 coding variants of *LOXL1* in high-pressure POAG and normal-pressure glaucoma (NPG) subjects. All participating glaucoma and normal subjects were Caucasians and received a full ophthalmological examination. A total of 733 (156 POAG, 244 NPG and 333 normal) subjects were genotyped for 3 *LOXL1* variants of R141L (rs1048661), G153D (rs3825942) and S159A. Genotypic and allelic frequencies were tabulated and statistical tests evaluated between normal and glaucoma subjects. The observed R141L allele (G;T) frequencies were: POAG (199;113), NPG (323;165) and controls (464;196). The G153D allele (G;A) frequencies were: POAG (266;46), NPG (413;75) and controls (530;134). The S159A allele (T;G) frequencies were: POAG (311;1), NPG (480;8) and controls (172;8). The S159A was generally uninformative. No significant associations were observed for any of the 3 *LOXL1* coding variations. A marginal allelic (p=0.0363) but not genotypic association (p=0.0732) was observed for G153D in the NPG group. Likewise, when for R141L and G153D the 3 haplotype frequencies of GG, GA and TG (TA was not observed) were tabulated for POAG, NPG and control groups, no significant associations were detected. Our prior studies confirmed that there is a significant association between the *LOXL1* gene polymorphisms for both exfoliation syndrome and exfoliation glaucoma (Mol Vis 2008; 14:533-541). However, present study suggests that no such association exist between *LOXL1* variations with both high- and normal-pressure glaucoma. Supported by M01RR-06192.

Combining pedigree and high-density markers for genome-wide association studies. *D. Heckerman[1], C. Kadie[1], H. M. Kang[2]* 1) Microsoft Research, Redmond, CA; 2) Department of Computer Science and Engineering, University of California, San Diego, California 92093.

In genome-wide association mapping, family-based designs are known to be robust to confounding due to (e.g.) population structure. Unfortunately, these studies often suffer from lack of power because they ignore the relationships among families, which is often impossible to obtain. The recent availability of high-density genotype data not only improves the genomic coverage of disease loci, but also enables accurate estimation of genetic relatedness between individuals. Consequently, we propose an approach that combines pedigree and high-density markers for genome-wide association studies. The approach uses a linear mixed model for quantitative phenotypes or a generalized linear mixed model (GLMM) for binary phenotypes wherein the random effects are modeled by a directed acyclic graphical (DAG) model (equivalent to a multivariate-Gaussian) that combines pedigree and marker information. In particular, known relationships in the pedigree are translated to the graphical model in the usual way (e.g., Wright 1922) and the remaining relationships are inferred from the markers (e.g., via estimates of IBD or IBS coefficients). A variational approximation is used to estimate the parameters of the GLMM, yielding a novel approach that provides a conservative estimate of likelihood ratio statistics that is efficient to compute. Our investigations with simulated and real data including that from GAW14 demonstrate that the approach robustly corrects for inflated false positives due to population structure and has increased power over family-based designs.

Mitochondrial Genetics of Outcomes Attained after Traumatic Brain Injury. *Y. Conley, S. Alexander, S. Deslouches, D. Ren* University of Pittsburgh.

Traumatic brain injury (TBI) results in a cascade of events at the cellular level that have the potential to cause secondary injury. A better understanding of the mechanisms of secondary injury could result in improved intervention at a time when further injury can be avoided and long term outcomes following TBI optimized. The purpose of this study is to determine if the mitochondrial genome and mitochondrial function account for secondary injury and is associated with variation in long term outcomes. Outcomes are defined by Glasgow Outcome Scale (GOS) following severe TBI, defined as a Glasgow Coma Score (GCS) of 8 or below. To address this, cerebrospinal fluid (CSF) drained as standard of care from TBI victims for the five days following injury is evaluated for mtDNA integrity, mtDNA level and ATP level. A subset of our available subjects have been evaluated to date (n=111) for level of mtDNA; measured using qRT-PCR and normalized with simultaneous qRT-PCR for betaglobin; and level of ATP using a luciferase based assay. MtDNA and ATP level for the first five days post injury were not impacted by age, gender or GCS, which are well known potential confounders when assessing outcomes following TBI. While mtDNA level did not significantly change over the first five days after injury, ATP level approached significance (p=.0630). GOS at 3, 6, 12 and 24 months was not significantly associated with mtDNA level. This preliminary data potentially indicates that quality of mtDNA and not mtDNA quantity may be important during the acute period following TBI given that mtDNA quantity does not change considerably during the acute period, however it appears that ATP production does. This is the first study to investigate mtDNA quantity during the acute period following TBI and long term functional outcomes and from this data it does not appear that mtDNA quantity plays a role in long term functional outcomes after TBI.

A comprehensive gene network based on genetic correlations among gene expression levels. *H. H. H. Göring, E. I. Drigalenko, J. E. Curran, T. D. Dyer, J. C. Charlesworth, M. P. Johnson, S. E. Cole, E. K. Moses, J. Blangero* Dept. of Genetics, Southwest Foundation of Biomedical Research, San Antonio, TX.

Differences in gene expression levels are thought to be important contributors to risk of complex disease. By now it is feasible, using commercial technologies, to quantify expression levels of the entire human transcriptome. Recently, multiple large-scale investigations have mapped the genetic determinants influencing the expression levels of individual transcripts. We have previously reported on genetic analyses of expression profiles in lymphocytes from 1,240 Mexican American participants in the San Antonio Family Heart Study. We, and others, have demonstrated the frequency and strength of proximal genetic effects (presumed to act in *cis*) on gene expression regulation. Conversely, distal genetic factors (presumed to act also in *trans*) were found less frequently and exhibit weaker effects. Given the scarcity of distal (*trans*) signals, it is difficult to build gene networks from such data. To overcome this challenge, we have computed (using ~40 computer processor years) all pairwise phenotypic, genetic, and environmental correlations among the 11,493 autosomal RefSeq transcripts that we detected and whose quantitative expression levels were significantly heritable at an FDR of 1%. Using bivariate variance components analysis, we obtained the genetic and environmental correlations for these >66 millions pairs of transcripts based on the pattern of covariation among relatives in our extended pedigree sample. Formal tests of our empirical genetic network yield evidence for intergenic relationships that is consistent with other classical sources of information (such as physical interaction data provided by 2-hybrid systems). We plan to make this resource freely available via the web, enabling researchers to rapidly build empirical gene networks by identifying those genes whose expression levels are significantly genetically correlated with that of a gene (or multiple genes) of interest. Genetically-correlated genes represent good candidates---chosen by an objective criterion---to act upstream, downstream or in parallel to the gene(s) of interest.

Genotype-by-sex interactions influence the regulation of human gene expression. *L. E. Bauman, J. C. Charlesworth, J. W. Kent, Jr., J. E. Curran, M. P. Johnson, S. E. Cole, T. D. Dyer, E. K. Moses, J. Blangero, H. H. H. Göring* Southwest Foundation for Biomedical Research, San Antonio, TX.

Men and women differ from one another biologically in many ways, including life span, risk of various diseases and response to drugs. To identify sub-cellular differences between males and females, we performed a comprehensive evaluation of the importance of sex effects on gene expression levels, including the detection of genotype-by-sex (GxS) interaction. Genome-wide expression profiles were previously generated on lymphocytes from 1,240 Mexican American participants in the San Antonio Family Heart Study (506 males and 734 females). The current investigation focused on 12086 autosomal RefSeq transcripts whose expression level was heritable at an FDR of 5%, used as the significance criterion throughout this study. Using a mixed model approach, we found that nearly 1/3 of all transcripts (3935) vary significantly in gene expression level between sexes, with 43% showing higher expression levels in females and 57% in men. Next, we assessed whether the genetic architecture underlying the expression of individual transcripts varies between the sexes by modeling additive polygenic GxS interaction, and found significant interaction for almost 10% of transcripts (1154). Interestingly, over 99% of these transcripts have higher genetic variance in females than in males. Finally, we considered whether particular locations in the genome differentially influence gene expression levels among males and females. Using a linkage-based GxS interaction model and focusing on those transcripts with significant evidence of proximal (and likely cis) genetic regulation, we discovered GxS interaction at the position of the structural locus for 57 genes. We are currently in the process of identifying the specific genetic variants responsible for the observed GxS interaction within these genes. Our results highlight the general importance of sex effects on transcription and the substantial role that GxS interactions play in the regulation of human gene expression.

Analysis of neuregulin 1 missense mutations in Costa Rican families. *A. Davelos Baines[1,4], C. Walss-Bass[1,2], A. Figueroa[1,5], R. Salazar[3], A. Dassori[2], J. Peters[2], I. Chavarria-Siles[2], H. Loria[4], J. Cardoza[4], M. Escamilla[1,2], H. Raventos[3]* 1) South Texas Medical Genetics Group, University of Texas Health Science Center San Antonio, Edinburg, TX; 2) Department of Psychiatry, University of Texas Health Science Center, San Antonio, TX; 3) Centro de Investigacion en Biologia Celular y Molecular, Universidad de Costa Rica, San Pedro, Costa Rica; 4) Department of Biology, The University of Texas - Pan American, Edinburg, TX; 5) Department of Computer Science, The University of Texas - Pan American, Edinburg, TX.

Background: A missense mutation (Val to Leu) in the transmembrane domain of the neuregulin 1 (NRG1) gene has been associated with schizophrenia in a population from the Central Valley of Costa Rica (CVCR). Missense mutations in exon 2 (rs3924999) and exon 12 (rs10503929) of NRG1 have been previously identified but had not been examined in this population. Methods: DNA genotyping and association studies were performed for 442 individuals with psychosis (243 of whom had a diagnosis of schizophrenia) and their relatives (1167 subjects total) from the CVCR. Transmission disequilibrium tests were performed using Family Based Association Tests (FBAT). Results: Association analysis revealed that the exon 12 missense mutation was significantly associated with psychosis ($p = 0.010$), and with schizophrenia ($p = 0.04$), but after correcting for multiple testing, only the association with psychosis remains significant. There was no association of the exon 2 missense mutation with either psychosis ($p = 0.38$) or schizophrenia ($p = 0.59$). Discussion: This study reveals significant association of a missense mutation in exon 12 of NRG1 with psychosis. Further investigation of functional differences among variants is required to identify the basis for this association.

Structural variation classification and detection based on paired-end read patterns of coverage. *C. Stewart, G. Marth* Biology, Boston College, Chestnut Hill, MA 02467.

The advent of next-generation sequencing technologies using paired-end reads allows for the detection of structural variations at unprecedented levels of efficiency and precision. Here we describe a classification scheme for 9 fundamental types of structural variants based on distinct patterns of paired-end read genome coverage. The SV types are: 1. deletion, 2. tandem duplication, 3. dispersed duplication, 4. VNTR, 5. novel insertion, 6. repeat insertion, 7. local translocation, 8. inter-chromosomal translocation, 9. inversion. Classification and measurement accuracy depends on the choice of technology as well as parameters such as the read length, depth of coverage, fragment length, and the dispersion of the fragment length distribution. Simulated sequence data is used to assess detection accuracy for each type of structural variant for typical choices of sequencing parameters. The algorithms performance is also assessed with human paired-end read data from the Illumina, AB, and 454 platforms. A given paired-end read alignment is quantified in terms of the genomic position of the leading read (p), the distance between the aligned ends of the fragment (LM), the orientation of the read pairs (o), as well as the confidence that each end is uniquely aligned. The number of reads overlapping a given base in the reference genome is the depth of coverage (d). Each of the 9 structural variant types has a distinct pattern in (p,LM,o,d) space which is used as a constraint in the classification algorithm. For example, deletion events are characterized by a cluster of fragments with exceptionally long LM spanning a region in the reference genome with low depth of coverage. A chromosomal translocation event is identified as a cluster of fragments with long LM spanning a region of normal depth of coverage adjacent to clusters of read pairs that span across regions on two chromosomes. The algorithm is implemented as a command-line tool publicly available at http://bioinformatics.bc.edu/marthlab/software/Spanner. A visualization tool is also under development as an aid for researchers to scan and assess evidence for candidate structural variant events.

Novel duplication in the PDHA1 gene in a family with 3 variably affected females with pyruvate dehydrogenase deficiency. *C. R. Coughlin[1], F. Y. Li[2], L. J. Wong[2], J. Ganesh[1]* 1) Biochemical Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Baylor College of Medicine.

Pyruvate dehydrogenase complex (PDHC) deficiency is a clinically heterogeneous disorder with symptoms ranging from asymptomatic carrier status, chronic neurological dysfunction of varying degree or fatal neonatal lactic acidosis. The majority of cases are due to mutations in the X - linked, E1 subunit gene (PDHA1). Insertions/deletion mutations especially in Exons 10 or 11 are common in females and missense mutations predominate in males. A 10 month old girl was referred for global delay, lactic acidosis, microcephaly, WPW syndrome and seizures. MRI of the brain revealed agenesis of the corpus callosum. Activities of PDHC and respiratory chain complexes were normal in skeletal muscle. As clinical features and biochemistry were suspicious for PDHC deficiency and the delivery of a sibling was imminent, molecular studies were undertaken. Sequencing of the E1 alpha subunit gene revealed a novel 26 nucleotide duplication within exon 10 (c.900-3_c.922dup). The duplication creates a frameshift and premature termination codon which is predicted to be deleterious. PDHC activity was subsequently confirmed to be low in skin fibroblasts. A female sibling was born shortly after the diagnosis was confirmed and presented with microcephaly, growth retardation, hypotonia and high blood lactate and pyruvate levels. Brain MRI done at 2 weeks of age revealed periventricular leukomalacia, but her overall clinical picture was milder than the proband. Molecular testing revealed the neonate had inherited the familial duplication. Ketogenic diet was started at 6 weeks of life and at the age of 7 months, she is thriving and gaining milestones. Parental testing revealed that the mother who has mild microcephaly and learning disability was heterozygous for the duplication. A novel mutation in PDHA1 variably affecting multiple generations within a family is described. This case underscores the value of molecular testing for PDHA1 mutations even if PDHC activity is normal in peripheral tissues especially in females. This data has significant impact on counseling and management of PDHC deficiency.

Characterization of gene expression in severe forms of dengue virus infection. *M. Yasunami[1], N. T. P. Lan[1], M. Kikuchi[1], V. T. Q. Huong[2], V. T. T. Ngu[2], H. N. Dao[2], D. Q. Ha[2], T. T. Thuy[3], H. M. Tuan[3], K. Morita[1], K. Hirayama[1]*
1) Inst Trop Med, Nagasaki Univ, Nagasaki, Japan; 2) Pasteur Institute in Ho Chi Minh City, Ho Chi Minh City, Vietnam; 3) Nhi Dong Hospital No.2, Ho Chi Minh City, Vietnam.

Dengue fever is caused by acute infection by dengue virus. Severe illness designated as dengue hemorrhagic fever (DHF) develops in small part of the patients, which is recognized by hemorrhagic tendency and plasma leakage from blood vessels in addition to general febrile symptoms. Among the patient with DHF, severe plasma loss causes hypovolemic shock (dengue shock syndrome, DSS) which requires further intensive medical care. Excessive host response known as cytokine storm has been reported to accompany to these severe cases, but pathogenesis of severe illness remains to be elucidated. For the better understanding of host determinants for disease severity, RNA expression profiling was conducted in the present study. Ten children aged from nine months to 14 years who admitted to Nhi Dong Hospital No.2 in Ho Chi Minh City, Vietnam in August and November, 2007 because of clinical symptoms meeting WHO criteria of DHF grade II (corresponding to DHF, 6 cases) or grade III (corresponding to DSS, 4 cases) were enrolled. In addition to routine hematological and virological examinations during hospitalization, paired blood samplings for RNA preparation were done on the day of onset of severe illness and several days later when the most symptoms disappeared. Ten pairs of RNA samples were then analyzed for the levels of 48,701 transcripts by Illumina Human-6 Expression Bead Array. Seven genes including complement component 2 (*C2*) were expressed more than two-fold and nine including genes for Protein S (*PROS*) and von Willebrand factor (*VWF*) exhibited less than half on the day of onset in comparison to the recovery phase in all ten pair comparisons. The results suggested the dysregulation in blood coagulation and complement system is common background for hemorrhagic manifestations. Further analyses of these data will provide certain insights for determinants of disease severity between DHF (grade II) and DSS (grade III).

Comprehensive mutational analysis of BRCA1/2 using direct sequencing and gene dosage analysis. *H. Park[1], M. Seong[1,2], S. Cho[1], D. Noh[3], W. Han[3], S. Kim[4], C. Park[1], S. Kim[1], S. Park[1]* 1) Department of Laboratory Medicine, Seoul National University Hospital & Clinical Research Institute, Seoul, Korea; 2) Department of Laboratory Medicine, National Cancer Center, Goyang, Korea; 3) Department of Surgery, Seoul National University Hospital, Seoul, Korea; 4) Department of Surgery, Seoul National University Bundang Hospital, Seongnam, Korea.

Purpose: The BRCA1 and BRCA2 genes are the strongest susceptibility genes of breast cancer worldwide. However, BRCA1/BRCA2 would be incompletely investigated due to their large size and genomic rearrangement occasionally involving them. Here we performed comprehensive mutational analysis for BRCA1/BRCA2 in 206 Koreans. Methods: We analyzed all exons and flanking regions of BRCA1/BRCA2 by direct sequencing and screened deletions or duplications involving BRCA1/BRCA2 by multiplex ligation-dependent probe amplification. We constructed haplotypes using several intragenic SNPs with minor allele frequency threshold of 5% to investigate founder effect of recurrent mutations and genotype-phenotype association. Results: In our series, thirty-eight patients (18.4%) including a double heterozygote had one or more BRCA1/BRCA2 mutations. Four additional patients carried distinct unclassified variants of possibly harmful effect. Any large deletion or duplication involving BRCA1/BRCA2 was not identified in our series. Haplotype analysis suggested that the most frequent mutation BRCA2:c.7708C>T might be originated from a common ancestor. We confirmed that this mutation was in a tight linkage with the specific haplotype using allele separation in some patients. BRCA1/BRCA2 mutations were more frequent in a group with family history, bilateral cancer, or multiple site cancer than group without the risk factor concerned or unknown risk group. In contrast, mutation frequency in early-onset cancer group was similar to unknown risk group. Conclusions: This is the first comprehensive mutation report using both direct sequencing and dosage analysis in the Korean population, and the first report showing possibility of a founder mutation in this population.

Detecting Essential Interactions in Genome-Wide Association Studies. *C. Wu[1], H. Zhang[4], X. Liu[2], Z. Ying[3], Y. Yang[4], J. Hoh[1]* 1) Epidemiology and Public Health, Yale University, New Haven, CT; 2) Department of Applied Mathematics, Yale University, New Haven, CT; 3) Department of Statistics, Columbia University, New York, NY; 4) Department of Statistics and Finance, University of Science and Technology of China.

Gene-gene interactions have become the next threshold in the analysis of the genome-wide association (GWA) data now that single-gene main effects are being found at an accelerating pace. A typical GWA dataset now produces ½ million to almost 2 million genetic markers. Many of these markers have some level of dependence on nearby markers owing to linkage disequilibrium (LD). As such, exhaustive testing of the astronomical number of interactions in this classic Np-hard problem is computationally infeasible for any GWA study. Statistical interactions are characterized into two distinct classes, the essential interactions and the removable interactions. Essential interactions (EIs) are invariant under any risk measures while removable interactions (RIs) are sensitive to the choice of the risk functions that measure the effects. In light of the need to reduce complexity in the GWA data, we propose a fast and reliable screening strategy based on the necessary and sufficient condition for an interaction to be essential. The likelihood ratio test and a resampling procedure are developed to evaluate statistical significance of the EIs. Simulation analyses show the proposed approach having sufficient statistical power with the false-positive error rates being small and tolerable. This approach has been applied to a real GWA datasets.

Preimplantation Microarray Analysis (PMA) is a Robust technique that allows for Aneuploidy Screening of all 24 chromosomes with a lower Misdiagnosis rate than FISH based methodologies. *B. Levy[1,2], O. Nahum[1], M. Kamani[2], K. Miller[2], J. Su[2], N. Treff[2], R. Scott, Jr.[2]* 1) Dept Pathology, Columbia University, New York, NY; 2) Reproductive Medicine Associates of New Jersey, Morristown, NJ.

The blend of whole-genome amplification & microarray technology may provide an attractive solution to the limitations of current preimplantation FISH-based aneuploidy screening strategies. We have previously validated the use of SNP oligonucleotide microarray analysis (SOMA) for the detection of aneuploidy in IVF blastomeres. In order to demonstrate the accuracy of SOMA, we compared the consistency of the results in embryos analyzed both by a 9 chromosome FISH panel & by SOMA. 8 arrested cleavage stage embryos were biopsied into individual cells, randomized into even groups & blindly assigned for further analysis by FISH (n=51) or SOMA (n=52). 6/8 embryos showed a consistent diagnosis for all cells analyzed (n=39) by SOMA. The remaining 2 embryos showed mosaicism that made biological sense (i.e. 46,XY; 45,XY,-13; 47,XY,+13). Every embryo analyzed by FISH showed mosaicism with little consistency in the diagnosis between cells derived from the same embryo. The robust nature of PMA was further validated by comparing the consistency of the results obtained from cells analyzed both by CGH and SOMA. DNA aliquots from 10 coded blastomeres were subjected to CGH and SOMA. The sex matched perfectly for all cells. The copy number for each chromosome was concordant in 97.5% of the 240 chromosomes analyzed. The FISH results of 4304 embryos were also compared to the SOMA results from 505 embryos. Using the SOMA data as a standard, misdiagnosis rates were calculated by contrasting the overall abnormality rate per embryo in embryos diagnosed by FISH vs SOMA. FISH (9 chromosome panel) had an overdiagnosis rate (dx as abnormal when embryo is actually normal) of 40% & an underdiagnosis rate (failure to identify abnormals in chromosomes not tested) of 12%. These studies indicate that PMA assays likely offer a superior means for aneuploidy screening in IVF embryos compared with FISH. They may also partially explain the failure of FISH PGD to produce meaningful improvements in clinical outcomes for IVF patients.

MESA-A Novel Method to Detect Copy Number Polymorphisms. *B. Zhang, J. Li, J. Andriesen, J. Hanson, L. Zhao*
Fred Hutchinson Cancer Research Center, Seattle, WA.

Copy number polymorphisms (CNP) have been discovered in the human genome, and associations have been seen between CNPs and complex phenotypes. The recent development of array technologies with probes specifically designed to detect CNP sites has further stimulated interest in discovering disease-associated CNP in the human genome. To enable these studies, detecting and cataloging CNP within the study population is critically important. Here we propose a new statistical method for detecting CNP sites using genome-wide SNP array data. The method utilizes moving windows throughout the genome to estimate CNP segments and their phenotypic associations. We term this method MESA (moving estimation of segmentation and associations). When MESA is applying to data from Affymetrix Genome-Wide Human SNP 5.0 and 6.0 arrays, it utilizes intensity signals from all probes, including all CN probes and the multiple probes for individual SNP alleles. The method computes the log ratios of probe intensity values over those from a reference population. Log ratios are then used for detecting segmentation and smoothing signals within each segment for every individual. To detect CNP sites in our study population, MESA repeats the segmentation process on the population-averaged signals from smoothed data. Gaussian mixture model is used to detect the presence of multiple modes in the log ratio values, the confirmation from which leads to the assignment of CNP sites. MESA was used on data generated from 3000 samples with the Affymetrix SNP Array 5.0. A total of 130 CNP sites were identified in this population. To indirectly validate these discoveries and hence the method, we compared our identified CNP sites with those discovered using other methods. Our findings overlapped with sites identified in other studies while also identifying several potentially novel CNP sites in our population. While our results remain preliminary, it suggests that MESA is robust and efficient for the detection of CNP sites. Due to its ability to utilize information from differing probe types, MESA is readily applicable to genomewide data generated by other arrays or other technology platforms.

Fabry Disease: 11 Novel -Galactosidase A Mutations. *R. Dobrovolny[1], D. Kwan[1], M. Rudelli[1], S. Garman[2], I. Nazarenko[1], M. Yasuda[1], R. J. Desnick[1]* 1) Department of Genetics & Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Department of Biochemistry and Molecular Biology, University of Massachusetts, Amherst, MA.

Fabry disease is an X-linked glycosphingolipidosis resulting from the deficiency of lysosomal exoglycosidase, -galactosidase A (-Gal A). To date, over 500 disease causing mutations have been reported. Most are family specific and only a few are more frequent (e.g. R122H, A143T, N215S, R227X). Incidence of the Fabry disease is about 1:40000 males but it was shown that many of the patients remain undiagnosed. We report 11 previously undescribed mutations in the -Gal A gene (GLA) causing the classic phenotype in unrelated families. These include six missense mutations (M1K, Y86D, W95L, G183V, L275F, L372R), four nonsense mutations (E7X, K82X, E103X, W287X) and one small deletion (c.883delT). Of the missense mutations, M1K occurred in the initiation codon and completely blocked the translation of active enzyme. Mutations Y86D, W95L and G183V occurred in highly conserved residues which were buried in the enzymes 3D structure of catalytic domain and were predicted to cause instable enzyme polypeptide. Change of leucine 372 for arginine in L372R mutation leads to steric clash in noncatalitic domain of the molecule and predicts instability of the enzyme structure. Though not highly conserved, in all plant and animal -galactosidases as well as in phylogeneticaly related -N-acetylgalactosaminidases this position was occupied by a small residue such as leucine, isoleucine or glycine. The dysfunction of the missence mutations was also confirmed by in vitro expression assays. These studies further define the molecular heterogeneity of the -Gal A mutations in Fabry disease and provide insight into -Gal A structure-function relationships.

EMINIM : An accurate, rapid, and memory efficient method for imputation of unobserved genotypes. *H. M. Kang[1], N. A. Zaitlen[2], B. Han[1], E. Eskin[3,4]* 1) Computer Sci Engineering, Univ California, San Diego, La Jolla, CA; 2) Bioinformatics Program, Univ California, San Diego, La Jolla, CA; 3) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA; 4) Department of Computer Science, University of California, Los Angeles, Los Angeles, CA.

The availability of comprehensive reference panel for genetic variation map such as HapMap enables us to increase the coverage of genome wide association studies by inferring unobserved genotypes from the genotypes collected through high-density genotyping arrays. We propose a novel imputation method EMINIM for accurate, rapid, and memory efficient genotype imputation. Our method learns the parameters in the hidden Markov model from the genotype data with an exact EM algorithm rather than using predefined parameters or simplfying the model. Our method is several times faster than previous method by reducing the time complexity from quadratic to linear time with respect to the number of states. Our method also consumes an order of magnitude less memory by maintaining the states only for observed genotypes. We applied our method to the imputation of genotypes in the inbred mouse strains, and achieved imputation error of 0.37% in high-confidence category, which is more ten times smaller than the previous studies. Our application of EMINIM to Wellcome Trust Case Control Consortium (WTCCC) dataset also shows significant improvement in the imputation accuracy as well as dramatic reduction both in the computational cost and the memory usage over the previous methods.

Deletion of Tumor Necrosis Factor-alpha delays neurodegeneration in Sandhoff mice. *H. Abou-Ouf[1], M. Melas[1], A. Fiebig[1], B. Trigatti[3], S. Igdoura[1,2]* 1) Biol Dept, McMaster Univ, Hamilton, ON, Canada; 2) Department of Pathology and Molecular Medicine, McMaster University, Hamilton, ON, Canada; 3) Department of Biochemistry and Biomedical Sciences, McMaster University, Hamilton, ON, Canada.

Neuro-inflammation is considered a prominent pathogenic feature in several neurodegenerative diseases. Tumor necrosis factor-alpha (TNF-) has been demonstrated as a key modulator of the CNS immune response. Elevated levels of TNF- have been detected in Alzheimers disease, Parkinsons disease, HIV-dementia, G_{M2} gangliosidosis and other neurodegenerative diseases. However, TNF- has dual, neurodegenerative and neuroprotective functions as well as differential region-specific effects. A variable net effect of TNF- on the pathogenic process may be attributed to the profile of microglial distribution and their inflammatory mediators and as such the overall impact of TNF- has been difficult to decipher. In our studies, the involvement of TNF- in the neurodegenerative process was evaluated using a mouse model of Sandhoff disease. Sandhoff disease is a lysosomal storage disorder caused by deficiency in hexosaminidase B (hexb). We generated a double knockout of TNF- and hexb and compared the resulting phenotype with single knockout mice. Our behavioral analysis revealed that Sandhoff mice without TNF- showed an ameliorated disease course. The double knockout mice showed prolonged lifespan and reduced weight loss when compared to hexb knockout. Furthermore, removal of TNF- from Sandhoff mice improved their performance in several neurological tests such as wire hang, rotorod and righting response tests. Using thin layer chromatography, we found no discernible difference in the levels of accumulated G_{M2} and G_{A2} in the cerebral cortex and cerebellum. We propose that neurological improvement was achieved due to reduced neuro-inflammatory condition rather than localized correction of neuronal storage. In conclusion, our results reveal TNF- as a broadly relevant cytokine in the progression of neurodegeneration and as a potential therapeutic target to attenuate neuro-pathogenesis.

Whole Genome Association Analysis of Dynamic Complex Traits. *R. M. Salem[1], E. N. Smith[2], S. S. Murray[2], G. S. Berenson[3], D. T. OConnor[1], N. J. Schork[1,2]* 1) Univ California, San Diego, La Jolla, CA; 2) Scripps Genomic Medicine, TSRI, La Jolla, CA; 3) Tulane University, New Orleans, LA.

Recent advances in human genetics and genotyping technologies have ushered a paradigm shift in genetic research from family based to whole-genome association (WGA), population based studies. This shift in emphasis has allowed researchers to probe the genetic basis of common complex traits in specific ways. Unfortunately, recent WGA studies have provided few insights into the genetic basis of many common complex diseases, identifying loci that explain only a small fraction of the variation. This is in part due to the complexity of the diseases themselves, but also due in part to study design issues. WGA studies have narrowly emphasized the case-control design. The case-control study design is an efficient and powerful approach to study disease risk factors. However, in case-control studies, complex traits are simplified, which typically have underlying quantitative liabilities, to a binary outcome (e.g., presence vs. absence). In reality, the study of complex traits is not always so simple nor are such simple strategies always effective. Instead, genetic researchers should move to studies of dynamic complex traits (DCTs), that use longitudinal or temporal information in, for example, prospective cohort designs. The study and analysis of DCTs in longitudinal contexts can offer insights into disease pathogenesis that are not achievable in other study designs and research settings. Statistical methods for the assessment of DCTs are challenging, and many are known to be inappropriate or perform poorly or do not fully utilize all available data. Height data from the Bogalusa Heart Study, a long-term study concerned with the early natural history of CVD of children aged 5 to 17, is used to illustrate these issues. Strategies for efficient WGA analysis of DCTs, including both novel and traditional analysis are developed and explored, and areas that demand further consideration are presented. Ultimately, this work has the potential to both shed light on the most appropriate approach to the WGA analysis of DCTs and help promote the use of DCTs in genetics research.

The Chromosome: What is it? *K. M. Polacek[1,2], J. C. Walz[2], S. L. Elrod[2]* 1) Fielding Graduate University, Santa Barbara, CA; 2) California Polytechnic State University, San Luis Obispo, CA.

To the learner, the language of genetics is filled with complicated terminology and jargon that experts take for granted. To successfully learn major genetics concepts, students must master these idiomatic and often confusing terms. Specifically, research has shown that students have difficulty fully understanding the nature of chromosomes, which are arguably an essential genetic concept. For example, students may believe that a condensed metaphase chromosome is a pair of chromosomes. Given that textbooks are a common reference source for students, we reviewed 6 current texts for the words and concepts found in various textbook features used to describe the term chromosome. Our preliminary analysis revealed significant inconsistencies and deficiencies across the textbooks. Glossary definitions varied in several ways: one did not include the fact that chromosomes contain DNA; another did not include the term chromosome; one text did not have a glossary at all. The indexes contained between 20-101 headings and sub-headings for the term chromosome, frequently with no page number indicated for the actual term. Even when a page number was indicated, the definition found on that page was not descriptive; one text defined chromosomes as discrete structures of DNA. Additionally, figures of chromosomes included photomicrographs and drawings of replicated, unreplicated, condensed, and uncondensed chromosomes; and, there was variation in the inclusion of terms such as allele, sister chromatid, and homologous chromosomes in associated figure captions. Our in-depth analysis of textbook features used to describe the chromosome and related terms (i.e., chromatid) will be presented. We will also suggest ways in which textbook features might be modified to enhance both the teaching and learning of genetics. As a ubiquitous teaching tool, the textbook is an ideal place to begin addressing fundamental misunderstandings in genetics. This analysis, in combination with investigations into student understanding using concept inventories and other authentic assessment measures, will contribute to the improved student learning of important genetic concepts.

Identification of cytogenetic abnormalities in prenatal specimens by high-resolution microarray. *L. G. Shaffer, S. Alliman, J. Coppinger, B. A. Bejjani, B. A. Torchia* Signature Genomic Laboratories, Spokane, WA.

Microarray-based comparative genomic hybridization (aCGH) is a powerful genetic testing tool for the detection of chromosome abnormalities in individuals with mental retardation and congenital anomalies. However, few prospective prenatal studies have been reported. We performed high-resolution aCGH using either a bacterial artificial chromosome (BAC) or oligonucleotide microarray on 138 prenatal samples received between November 2007 and April 2008. Of these 138 samples, 85 were referred for abnormal ultrasound; clinically significant results were identified in five of these cases, and unclear results requiring testing of parental samples for full interpretation were reported in five. By subsequent parental testing and analysis of gene content and CNV databases, all five unclear results were interpreted as benign CNVs. In 53 samples referred for AMA, family history, or parental concerns, four benign CNVs were detected. The detection rate of clinically significant chromosome abnormalities in our prenatal population (3.6%) is lower than that reported for postnatal specimens. However, these results show a substantial increase in the detection rate compared to our recently reported yield of 1.1% (2/151) in prenatal specimens analyzed using a targeted microarray. In both study populations, all prenatal samples had previous normal karyotypes; samples with known abnormal karyotypes were excluded. These results suggest the yield of chromosome abnormalities detected by microarray analysis would be higher in a prenatal population not already tested by karyotyping.

Clinical overlap between Joubert and Pallister-Hall syndromes suggests a role for ciliary proteins in sonic hedgehog signaling pathways. *M. Parisi, D. Doherty, D. Knutzen, P. Chance, I. Glass* Dept Ped/Div Gen & Develop, Children's Hosp & Reg Med Ctr, Seattle, WA.

Pallister-Hall syndrome (PHS) is an autosomal dominant disorder characterized by polydactyly, hypothalamic hamartomas, bifid epiglottis, imperforate anus, pituitary insufficiency, mental retardation, and renal abnormalities. Mutations in GLI3, a gene important in the Sonic Hedgehog (SHH) pathway, are identified in ~95% of affected individuals. Although hypothalamic hamartomas are considered diagnostic, epiglottic abnormalities are also a useful sign. Joubert syndrome and related disorders (JSRD) are autosomal recessive ciliary conditions with a distinctive cerebellar malformation known as the "molar tooth sign" (MTS), hypotonia, mental retardation, apnea/tachypnea, and oculomotor apraxia. Polydactyly, oral frenulae, renal cystic disease, and encephaloceles are variable findings. We report two cases with overlap between PHS and JSRD. Case 1 was a male infant with postaxial polydactyly of the hands and bifid great toes. He had midline upper lip and tongue grooves, redundant oral frenulae, and an abnormal epiglottis with midline cleft. A diagnosis of PHS was considered, but no causative GLI3 mutation was found. An MRI repeated at 2 years showed a MTS, consistent with JSRD. JSRD genetic analysis is pending. Case 2 was a male with coarctation of the aorta, bifid epiglottis, postaxial polydactyly of the hands, and preaxial polydactyly of the feet. He developed growth hormone deficiency. MRI scan was normal as was GLI3 analysis. Repeat MRI scan for an expanding nasal dermoid cyst showed the MTS. Testing for mutations in 4 JSRD genes was normal. These two cases have epiglottic abnormalities and polydactyly consistent with PHS, but cerebellar findings of the MTS. Thus far, no genetic cause has been identified, but they most likely have recessive mutations in a JSRD gene. The overlap between PHS and JSRD suggests that the primary cilium plays a role in SHH signaling pathways, as has been shown in mouse models. Thus, ciliary genes may affect GLI3 expression and developmental pathways that determine midline hindbrain, laryngeal, and craniofacial structures and polydactyly.

Stochastic DNA methylation of mouse retrotransposons depends on age of the insertion. *D. L. Mager[1,2], M. Reuter[3], Y. Zhang[1,2], D. Reiss[1,2]* 1) Terry Fox Laboratory, BC Cancer Research Centre, Vancouver, BC, Canada; 2) Dept. of Medical Genetics, University of BC; 3) Research Dept for Genetics, Evolution and Environment, University College London, United Kingdom.

Phenotypic variation stems from both genetic and epigenetic differences between individuals. To elucidate how phenotypes are determined, it is necessary to understand the forces that generate variation in genome sequence as well as in its epigenetic state. In both contexts, transposable elements (TEs) may play an important role. It is well established that TE activity generates genetic variation, but recent research also suggests that TEs contribute to epigenetic variation. Stochastic epigenetic silencing of some TE insertions in mice has been shown to cause phenotypic variability between individuals. However, the prevalence of this phenomenon as well as its temporal dynamics are unknown. In this study, we used cell-to-cell comparisons of Endogenous Retrovirus (ERV) DNA methylation patterns in individual mice to show that silencing goes from stochastic to stable as insertions age. Variable methylation is frequent among recent insertions, which can show different methylation levels between mice as well as between cells of a same individual. Older insertions, in contrast, show stable methylation patterns both between cells and between individuals. These data are consistent with a proposed scenario in which variable methylation is due to a molecular conflict between forces promoting and opposing methylation. Our results emphasize the significance of previous studies demonstrating that TEs can contribute to phenotypic variability through their stochastic silencing. Indeed, variable methylation between individuals mediated by TEs is not a sporadic phenomenon but likely occurs for many recent TE copies. These findings also suggest that TE-mediated epigenetic variability is a dynamic phenomenon and affects different loci over time.

Unexpected Resolution of Neuroimaging Findings in a Patient with L-2 Hydroxy Glutaric Aciduria 12 Years Later. *A. Rajadhyaksha, E. Pacheco, K. Wierenga, P. Jayakar* Miami Children's Hospital, Miami, FL.

Introduction: L-2 Hydroxyglutaric Aciduria is rare neurodegenerative autosomal recessive disorder reported in less than 100 individuals. It is characterized by a static or slowly progressive course with psychomotor regression,mental retardation, seizures, macrocephaly and MRI findings of subcortical leukoencephalopathy with cavitations. Several studies have reported a correlation between the severity of clinical manifestations and the extension of the lesions by neuroimaging. **Case Report:** Patient RS first presented at 15(Hispanic & Scandinavian ancestry) with dysarthria, macrocephaly, seizures, intentional tremors and developmental delays. MRI showed extensive symmetrical signal abnormality involving the dentate nuclei of the cerebellar hemisphere, basal ganglia region, periventricular white matter and extension to cortical subcortical regions in the bifrontal regions, temporoparietal region and along the right insular cortex. Plasma amino acids showed increased lysine levels and urine organic acid revealed elevations of 2-OH Glutaric Acid confirmed by stable isotope dilution GC-MS revealing increases in L2 Hydroxyglutaric Acid enantiomer of 1623 mmol/mol creat (NL 1.3-19) and D2 Hydroxyglutaric Acid of 9.9 mmol/mol creat (NL 2.8-17). RS returned 12 years later for a reevaluation. Clinically he has done extremely well and has had no progression in symptoms. He is now 26 years old and drives to a job with a store. Though mildly delayed, he has graduated from school and completed some college courses. His seizures remain well controlled but tremors and mild dysarthria persists. A recent MRI revealed an improvement in the signal abnormality involving the dentate nuclei of the cerebellar hemisphere and basal ganglia but increased cerebral atrophy when compared to the prior scan. DNA mutation testing and repeat metabolic workup is in progress. **Conclusion:** With emerging treatment modalities, this disease should be part of a differential diagnosis in patients with macrocephaly and abnormal MRI. To our knowledge and a review of literature, there is no known case reported with improvements seen clinically and on neuroimaging studies.

Deep Re-Sequencing of Schizophrenia Candidate Genes. *J. J. Crowley[1,2], P. Sklar[3], S. Purcell[3,4], J. A. Lieberman[5], M. B. Morgan[6], O. Hall[6], L. R. Lewis[6], D. M. Muzny[6], A. Sabo[6], D. A. Wheeler[6], R. A. Gibbs[6], P. F. Sullivan[1]* 1) Genetics, University of NC, Chapel Hill, NC; 2) School of Pharmacy, University of NC, Chapel Hill, NC; 3) Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, MA; 4) The Broad Institute of Harvard and MIT, Cambridge, MA; 5) Department of Psychiatry, Columbia University, and the New York State Psychiatric Institute, New York, NY; 6) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

There are ~10 genes for which there is compelling evidence for involvement in the etiology of schizophrenia (*COMT, DAOA, DISC1,DRD2, DRD3, DTNBP1, HTR2A, NRG1, SLC6A3, SLC6A4*). The pattern of results for these genes suggests that there may be sequence variants that have not yet been discovered, and existing re-sequencing have been limited. To address this limitation, as part of the NHGRIs Medical Re-Sequencing Project (in conjunction with the Gibbs lab at Baylor), we have re-sequenced the coding regions, 5 and 3 UTRs, splice sites, promoters and conserved intronic regions of these genes in 751 cases with schizophrenia from the CATIE trial and 747 controls. Traditional Sanger sequencing was used for SNP detection and 454 sequencing technology was used for SNP confirmation. In the schizophrenia cases, a total of 338 novel and 122 known SNPs were identified. The novel SNPs showed the following counts and average minor allele frequencies: intronic (176, 0.89%), coding non-synonymous (65, 0.35%), coding synonymous (52, 0.21%), splice site (15, 0.53%), 3UTR (14, 0.33 %), promoter region (13, 0.52%) and 5 UTR (3, 1.02%). Variants that were private to one individual comprised 190 (56%) of the novel SNPs. In total, cases possessed 21,491 minor alleles among these genes and 3,132 (15%) are from novel variants. Thus, each patient had about 2.5 known and 0.5 novel SNPs per gene. Analysis of the matched control data is in progress and will allow us to search for risk and protective factors for schizophrenia etiology. We aim to use a two-stage design where all significant and marginally significant findings from this cohort are followed up in larger case-control samples.

Homozygosity Mapping of Pigmented Hypertrichotic Dermatosis and Insulin-Dependent Diabetes Mellitus (PHID): Localization to a 1.4 Mb region of 10q22.1. *S. Cliffe[1, 2], T. Roscioli[1, 2, 3], J. Prendiville[4], M. Wong[5], K. Hussain[6], C. James[6], R. C. M. Henekam[6, 7, 8], M. F. Buckley[1, 2], R. Lindeman[2, 9]* 1) Molecular & Cytogenetics Unit, Department of Haematology and Genetics, South-Eastern Area Laboratory Service, Randwick, Sydney, Australia; 2) Centre for Vascular Research, University of New South Wales, Sydney, Australia; 3) Department of Molecular and Clinical Genetics, Royal Prince Alfred hospital, University of Sydney, Sydney, Australia; 4) Division of Pediatric Dermatology, Department of Pediatrics, British Columbias Childrens Hospital, and University of British Columbia, Vancouver, Canada; 5) Department of Immunology and Allergy, Childrens Hospital Westmead, Sydney, Australia; 6) Department of Endocrinology, Great Ormond Street Hospital for Children NHS Trust and the Institute of Child Health, University College London, London, UK; 7) Clinical and Molecular Genetics Unit, Institute of Child Health, London, UK; 8) Department of Paediatrics, Academic Medical Centre, Amsterdam, The Netherlands; 9) School of Medical Sciences, University of New South Wales, Sydney, Australia.

Pigmented hypertrichotic dermatosis and insulin-dependent diabetes mellitus (PHID) is an autosomal recessive condition that has been reported in 5 families. The dermatosis documented in PHID consists of pigmented hypertrichotic patches and induration on the upper inner thighs. Insulin-dependent diabetes mellitus (IDDM) is observed in 83% of cases with an age of onset of 9-15 years. Pancreatic hypoplasia has been reported in 2 of 6 patients with no evidence of pancreatic autoantibodies. Consanguinity is present in 4 families. High-density SNP genotyping was used to define regions of identity by descent in the affected individuals. This analysis identified a single shared 6.6Mb region at Chr10q22.1, encompassing 62 known and predicted genes. 12 of these genes were selected for sequencing on the basis of tissue expression and predicted function. No protein-coding sequence variations were detected, however heterozygous intronic SNPs further defined the critical region to a 1.4 Mb region containing 14 genes - sequencing of these genes is underway.

Acceptability of Breast Cancer Risk Assessment Using an Internet Family History Tool. *G. L. Wiesner[1], C. Simon[2], A. Lynn[3], L. Acheson[3]* 1) Dept. of Genetics; 2) Dept. of Bioethics; 3) Dept. of Family Medicine, Case Western Reserve University, Cleveland, OH.

Internet methods of family history risk collection can identify high risk women who would benefit from increased surveillance and genetic testing. This study assesses the acceptability and feasibility of using a computer-assisted family history tool to detect high risk patients in a busy breast clinic. A qualitative semi-structured interview was performed with 65 women (40% Af-Am; 48% college) about the potential use of an Internet tool to collect, store and analyze family history data for cancer risk. 12% felt their family history of cancer was absolutely/mostly private; 97% were comfortable providing family history of cancer to their own doctor and 97% felt that their relatives would also be very/mostly comfortable with them sharing the relatives cancer history with their doctor. 1595 consecutive women attending the clinic were then invited to input their family cancer history into the validated GREAT (Genetic Risk Easy Assessment Tool) that calculates breast cancer/BRCA mutation probabilities and generates a personalized report. 51% of the 1595 women had a family or personal history of cancer. 326 women responded to the invitation with 116 consenting and 194 declining (mean age 56, 43% Af-Am); 37% did not have a computer/internet access, and 26% were concerned about privacy/internet security. To date, 76 have completed the GREAT (mean age 56, 16% Af-Am, 22% with a history of breast cancer); 28% received reports indicating increased risk for HBOC; all were considered appropriate for genetic counseling. >90% found the GREAT easy to navigate, personal report easy to understand, and the time taken not lengthy. Most planned to talk with family members and show the report to relatives. Our quantitative study supports our qualitative analysis, in that most women found the web-based GREAT an acceptable means of personal and family cancer risk assessment in the breast clinic. Lack of internet access and concerns about security posed barriers for some would-be participants. Ongoing investigations are aimed at understanding the concerns of women at risk for breast cancer.

SNP genotyping in a proband with apparently balanced translocation identifies a microdeletion in 3q and implicates ALCAM in delayed cranial ossification. *N. Sobreira[1], E. Squibb[2], G. Steel[1], A. Hamosh[1], G. Thomas[2], D. Valle[1]* 1) Johns Hopkins University, Inst. of Genetic Medicine, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD.

Apparently balanced de novo chromosomal translocations occur in approximately 1 in 2000 newborns and are associated with a 2-3 fold increased risk of malformations. We studied a 3 generation pedigree in which delayed cranial membranous ossification (OMIM 155980) cosegregates with an apparently balanced reciprocal translocation between 2p15 and 3q13.11. In addition to an abnormal skull the proband had thinning of the splenium of the corpus callosum, patent ductus arteriosus, and cataract. His sister, mother and maternal grandmother had a soft skull at birth and all had an apparently balanced translocation, t(2;3)(p15;q12). To access this rearrangement at higher resolution, we performed a whole genome SNP genotyping (Illumina 550) and found a region on 3q13.11 in the area of the cytogenetic breakpoint that showed 124 SNPs distributed over 550 kb with reduced intensity and apparently homozygosity. FISH confirmed the microdeletion predicted by SNP genotyping. This deletion at 3q13.11 removes ALCAM, a gene that encodes a cell adhesion molecule involved in osteoblast differentiation and CBLB, a gene that encodes an E3 ubiquitin-protein ligase. Using FISH probes in our patient, we narrowed the region of breakpoint at chromosome 2 to a region of 23 kb intergenic region. Of 9 previously reported patients with deletions involving the proximal segment of 3q13, no description of the shape or calcification of the skull was provided but 4 had agenesis of the corpus callosum. Although ALCAM and CBLB are both expressed in the brain, we speculate that ALCAM is more likely to be involved in this phenotype since it is also involved in osteoblast differentiation. In this case SNP genotyping, proved to be an excellent tool for precisely evaluating an apparently balanced translocation and revealed a cryptic deletion implicating candidate genes for this phenotype.

Lymphoblastoid cell lines as a proxy to brain for identification of genes in response to lithium treatment. *H. Chen[1], R. McEachin[1], N. Wang[2], X. Zhao[2], M. McInnis[1], M. Burmeister[1,2]* 1) Psychiatry, University of Michigan Medical School, Ann Arbor, MI; 2) Molecular and Behavioral Neuroscience Institute, University of Michigan Medical School, Ann Arbor, MI.

To date, study of lithium action has largely focused on animal models or postmortem human brain tissue. However, in future clinical practice, tissue from living patients will be required to assay genetic variation influencing treatment responses. Patients' brain tissue will not be available for such studies, so we explored the use of lymphoblastoid cell lines (LCLs) to identify genetic influences in lithium response. We assessed the effects of lithium on cell proliferation by culturing LCLs with the supplement of 0, 1, 2, 4, 6, and 10 mM LiCl, and microscopically counted the number of cells and estimated the portion of non-viable cells, respectively. In testing the hypothesis that lithium influences gene expression in this cell type, we assayed the expression of ~22,000 transcripts (genes) with the Illumina BeadChip microarray platform. We found that lithium treatment at 2 mM concentration was not grossly deleterious to cell proliferation, while at higher than 2 mM cell proliferation was inhibited. With the expression levels of ~22,000 transcripts (genes) determined, we found 36 genes significantly changed expression patterns in response to 1mM Li after applying a false discovery rate test (FDR < 0.05 and fold change > +/-15%). TaqMan assays confirmed 6 of 7 genes tested. Based on dbEST data, 33 of the 36 lithium-responsive genes in LCLs are also expressed in brain. Comparing our results to those seen in mouse brain, 11 of the 36 are common (same direction change) in both types of tissue. Functional analysis reveals transcription regulation as the main biological them discovered in this experiment. Our data supports the use of LCLs as a model for understanding the molecular basis of lithiums therapeutic action, and for identification of genetic variants to test allelic association with treatment responsiveness in bipolar disorder.

Assessing regulatory potential and functional consequences of Type 2 diabetes-associated variants on 9p21. *M. L. Stitzel[1], P. Deodhar[1], L. J. Scott[2], A. U. Jackson[2], N. Narisu[1], A. Swift[1], M. Boehnke[2], F. S. Collins[1]* 1) Genome Technology Branch, NHGRI/NIH, Bethesda, MD; 2) Dept. Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

Variants within a 9.5 kb linkage disequilibrium block on chromosome 9p21, ~125 kb upstream of the heavily studied genes *CDKN2A/2B*, have been associated with type 2 diabetes (T2D) and decreased beta cell function in multiple studies and populations. Another gene on the opposite strand, *ANRIL*, is also a potential candidate for driving the T2D association, but its noncoding RNA is much less well characterized. Independent studies in mouse indicate that overexpression of *CDKN2A* (p16) inhibits beta cell proliferation. Taken together, these observations suggest the following hypothesis: (1) the associated region in humans harbors regulatory elements, (2) these elements regulate *CDKN2A*, and (3) the causal variant(s) increase expression in islets. We have cloned the entire T2D-associated LD block, as well as two smaller evolutionarily constrained sequences residing within this block, from risk and non-risk haplotypes present at ≥ 5% frequency in FUSION samples and tested them for enhancer activity in a minimal promoter luciferase assay in both beta cell-like (INS-1E) and non-beta cell (HeLa) lines. In preliminary experiments, we have observed a decrease in luciferase activity with these sequences. We are testing these elements for silencer activity and for specific enhancer/silencer activity of the *CDKN2A* promoter and cloning additional haplotypes present at a frequency of ≥ ~1% for testing. In addition, we are analyzing effects of the risk-associated variants on allele-specific and overall expression levels of *CDKN2A/B* and the putative noncoding transcript *ANRIL* in fibroblasts, peripheral blood lymphocytes, monocytes, adipose, and pancreatic islets. Though challenging, we expect these studies of allele-specific gene regulation in 9p21 will reveal possible mechanisms for T2D susceptibility.

Clinical Heterogeneity of Muenkes Syndrome in a Pregnant Mother and Her Neonate. *B. M. O'Brien[1], D. Abuelo[2], A. Oh[2], M. Vechiotti[2], C. Slack[1], N. Shur[2]* 1) Women and Infants Hospital at Brown,University, Providence , RI; 2) Hasbro Childrens Hospital at Brown University, Providence RI.

28 year old G3P1 presented in the mid-trimester for genetic counseling secondary to a history of craniosynostosis of an unknown suture. She underwent surgery at 12 weeks of age with no further surgeries or genetic evaluation. Her past medical history was also significant for Type I diabetes mellitus. She had no other abnormalities noted on exam, although she clearly had an abnormal head shape. Of note, she had normal appearing digits, normal hearing and had no learning difficulties. Her family history is significant for her 8 year old daughter (conceived with a different father) also having craniosynostosis, requiring two surgeries. A paternal uncle and his granddaughter also had craniosynostosis with a distant relative dyng in the neonatal period of "sudden death." The patient was counseled that it appeared that her family had an autosomal disorder, with a 50% risk that the fetus would inherit the disease causing gene. The patient declined any further investigation prenatally. She has a third trimester ultrasound that revealed subtle changes in the conformation of the fetal skull suggestive of craniosynostosis. In retrospect, it also appeared that there was midface hypoplasia. She was induced at 39 weeks due to maternal diabetes and the neonate had obvious dysmorphic features as well as craniosynostosis. His head circumference was at the 50th percentile, with brachycephaly and turricephaly. He displayed hypertelorism and significant hypoplasia of the midface. His neurological exam was nonfocal with no evidence of significant hypotonia. The diagnosis was confirmed with a Pro250Arg mutation in FGFR3. The child was admitted at one month of age with apnea episodes due to upper airway obstruction. He was found to have choanal stenosis and a deviated septum. Sudden death has been reported in association with upper airway obstruction in Muenkes. This case demonstrates the tremendous variability of Muenkes as well as the importance of counseling about the possibility of upper airway obstruction and even sudden death in this syndrome.

Inflammatory Gene Associations with Acute v. Chronic Coronary Artery Disease (CAD). *N. Ginwala[1], M. Li[1], M. S. Burnett[1], N. Mehta[1], A. Qasim[1], S. Restine[1], L. Pruscino[1], M. Wolfe[1], H. Chandrupatla[1], L. Satler[2], A. Pichard[2], R. Waksman[2], Z. Chen[1], J. He[1], J. Devaney[1], B. Keating[1], H. Hakonarson[1], S. E. Epstein[2], D. Rader[1], M. P. Reilly[1]* 1) Cardiovascular Medicine, University of Pennsylvania, Philadelphia, PA; 2) CVI/ MRI/Washington Hospital Center.

Background: Many inflammatory genes have been implicated in atherosclerotic CAD. It is unknown whether these genes relate to atherosclerosis or to acute clinical complications. Methods: The ITMAT Broad CARE (IBC) array is a 50K SNP array created to assess candidate genes (~2000) for cardiovascular disease. We examined inflammatory genes (N=27; adhesion molecules, chemokines, cytokines, metalloproteinases and their inhibitors, phospholipases, acute phase proteins) that may differentiate acute v. chronic CAD in a Caucasian, angiographic CAD case-control study (PennCATH: 509 acute cases, 497 chronic cases, 498 controls) with replication in a second CAD study (Medstar: 421 acute cases, 454 chronic cases, 447 controls) using Affymetrix 6.0 data. Results: There was no significant population stratification. In age and gender adjusted models in PennCATH, we found CAD associations for 19/27 genes, but with different patterns. Most genes related to both acute and chronic CAD [eg VCAM1 rs3917012[C] vs. control, all cases OR 1.31 (1.10-1.58 95% CI), p=0.003; acute cases 1.33 (1.07-1.65), p=0.01; chronic cases 1.30 (1.06-1.60), p=0.01]. Several genes showed differential associations, eg MMP3 was associated with acute [rs3020919[A], 1.36 (1.08-1.72), p=0.008], but not chronic CAD [0.97 (0.78-1.21), p=0.83; acute v. chronic p=0.006] whereas ICAM4 was associated with chronic [rs2228615[A], 0.84 (0.69-1.01), 0.05], but not acute CAD [1.02 (0.84-1.25), p=0.82; acute v. chronic p=0.008]. Of 19 genes associated with CAD in PennCATH, 11 replicated association in Medstar. Conclusion: We confirm associations of many inflammatory genes with CAD and show early evidence for differential associations with acute v. chronic CAD. The angiographic phenotype may aid in identifying genes for atherosclerosis versus those related to acute clinical complications only.

Induction of PGC-1 expression in Huntingtons disease transgenic mice rescues neuronal dysfunction and neurodegeneration. *T. Tsunemi[1], J. Au[1], A. R. La Spada[1,2]* 1) Department of Laboratory Medicine, University of Washington, Seattle, WA; 2) Center for Neurogenetics & Neurotherapeutics, University of Washington, Seattle, WA.

Huntingtons disease (HD) is an autosomal dominant disorder characterized by cognitive decline and involuntary movement. Expansion of a CAG repeat in the huntingtin (htt) gene is the cause of this disease. Pathogenesis results from production of htt protein with an expanded polyglutamine (polyQ) tract that misfolds and is resistant to proteasomal degradation. An important clue to selective neuronal vulnerability in HD has been mitochondrial oxidative phosphorylation defects in the striatum of HD patients, and modeling of HD in rodents by administration of mitochondrial toxins such as 3-nitropropionic acid. Another feature of HD pathogenesis is production of polyQ-expanded htt peptide fragments that localize to the nucleus and there disrupt transcription. Studies done on HD N171-82Q transgenic mice in our laboratory suggest that polyQ-expanded htt interferes with nuclear transcription programs responsible for mitochondrial biogenesis and oxidative phosphorylation. PPAR co-activator 1 (PGC-1) is a key transcription regulator of mitochondrial physiology, and appears to be the target of transcription interference by mutant htt protein. To test if restoration of PGC-1 function is sufficient to ameliorate neurological disease progression and striatal degeneration in HD mice, we have crossed HD N171-82Q mice with inducible PGC-1 transgenic mice. By incorporating Rosa26-rtTA mice into this breeding scheme, we derived triple transgenic mice whose expression of PGC-1 was found to be two times higher than N171-82Q controls upon doxycycline treatment. Analysis of littermate cohorts derived from these crosses shows that induction of PGC-1 expression significantly improves neurological function in HD transgenic mice, based upon rotarod performance and other motor tests. Surprisingly, PGC-1 over-expression also markedly decreased accumulation of misfolded htt protein in the brains of HD transgenic mice. Enhancing PGC-1 function could thus be a viable therapeutic intervention in HD patients.

Congenital Erythropoietic Porphyria: Viable Murine C73R Homozygotes, Knock-In Model of the Most Common Human Mutation. *D. Bishop, S. Clavero, R. J. Desnick* Genetics & Genomic Sciences, Mount Sinai School of Medicine, New York, NY.

Congenital erythropoietic porphyria (CEP) is an autosomal recessive disorder caused by the deficient activity of the fourth enzyme of heme biosynthesis, uroporphyrinogen III synthase (UROS). In humans, phenotypic severity correlates with the amount of residual UROS activity and varies from fetal lethality to only cutaneous lesions due to photodynamic damage upon exposure to sunlight. Many patients have transfusion-dependent disease. Bone marrow transplantation is curative but associated with increased morbidity and mortality. To develop animal models for therapeutic efforts, we used homologous recombination to create new models of murine CEP with varying severity and viabilities, including the homozygous viable C73R mouse that is the counterpart of the most common human CEP genotype. In addition, we have generated a homozygous viable V99L mouse and a homozygous lethal null mouse. The various combinations of these and previously reported hypomorphic alleles resulted in a range of phenotypes and demonstrated that less than 1% housekeeping enzyme is fetal lethal, even in the presence of 30% erythroid activity. The C73R/C73R mouse was obtained by interbreeding C73R/V99L mice on a mixed C57Bl/6, SV129, CD1, and FVB/N background. This mouse has a fetal viability of about 20% of wild-type, but once surviving past 5-10 days, appears to have a normal lifespan, albeit with reduced growth weights. The newborn mice are runted, pale, and anemic with an erythrocyte (RBC) count of 5.10.5x10^6/l that was half that of normal mice (9.80.9). The RDW was increased (36.91.3 vs 17.70.9%) due to microcytosis. The reduced RBC count and a 10x elevated platelet count (234 vs 19x10^3/l) suggested hemolytic anemia. The newborn C73R mice were highly fluorescent over their entire bodies and produced dark brown urine that contained high concentrations of uroporphyrins. Urinary URO I was 26718 nmoles/mg creatinine, but undetectable in normal mice. The URO I/III ratio was 7.81.0. COPRO I was 22.44.2 vs 0.30.1, while the COPRO I/III ratio in normal mice was 0.090.01. Due to the ease of genotyping by porphyrin fluorescence, they make attractive models for therapeutic endeavors.

A High-density Haplotype Resource of 94 Inbred Mouse Strains. *E. Kostem[1], H. M. Kang[1], A. Kirby[2], C. Wade[2], B. Han[1], M. Bogue[4], F. Johnson[7], K. Frazer[6], E. Beilharz[5], D. Cox[5], E. Eskin[1], M. Daly[2,3]* 1) Computer Science Department, University of California, Los Angeles, Los Angeles, CA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) The Jackson Laboratory, Bar Harbor, ME; 5) Perlegen Sciences, Inc., Mountain View, CA; 6) Scripps Genomic Medicine, La Jolla, CA; 7) National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina.

Due to the importance of the mouse as a human disease model, phenotypic variation among inbred mouse strains form a bedrock of modern medical research. A key step in determining the genetic underpinnings of this phenotypic variation is developing a catalogue of the genetic variation among inbred mouse strains. A recent whole genome resequencing study of 15 inbred mouse strains captured a significant fraction of the genetic variation among a limited number of strains. The availability of hundreds of inbred strains, including over 190 stocks available from the Jackson Laboratory, motivates the need of a high-density variation map for a larger set of strains. In this study, we collected a dense set of genotypes from 94 inbred mouse strains containing 10.77 million genotypes over 121,433 single nucleotide polymorphisms (SNPs), dispersed at 20kb intervals on average across the genome, with an average concordancy of 99.942% with previous SNP sets. Using an analysis of shared segments, we identified an average of 8.34 distinct segments over 94 strains, and 4.70 over 73 classical inbred strains across the genome, suggesting a limited genetic diversity between the strains. Combining with additional 7,570 gap-filling SNPs, we further imputed the untyped or missing genotypes of 94 strains over 8.27 million Perlegen SNPs. The average imputation accuracy among classical inbred strains is estimated to 97.8% overall. Approximately 70% of the genotypes (446,110,962 in total) are imputed with high confidence and achieve an accuracy of 99.7%.

***MYC* negative Burkitts lymphoma with 11q duplication involving the *MLL* gene.** *G. D'Amours[1,3], R. Absi[1], D. Dal Soglio[1], J.-C. Fournet[1], M. Blagdon[2], E. Lemyre[3], R. Fetni[1]* 1) Département de Pathologie; 2) Département d'Hématologie; 3) Service de Génétique médicale, CHU Sainte-Justine, Université de Montréal, Québec, Canada.

Burkitts and Burkitt-like lymphoma represents approximately 40% of non-Hodgkins lymphomas (NHL), and 3-4% of all childhood malignancies. Its diagnosis is based on clinical presentation, morphological and immunophenotypic features, combined with cytogenetic and molecular findings. Most cases involve translocation of the *MYC* gene, located at 8q24, to an immunoglobulin locus. Classic translocation involves 14q32, and is present in 85% of *MYC* positive cases. Less frequently, the translocation partner is either chromosome 2 at band q11, or 22q11, in 5% and 10% of cases respectively. Only 10% of Burkitts lymphomas are negative for this rearrangement. Little data are available on the oncogenic mechanism of the *MYC* negative Burkitts lymphomas. We report the case of a 12-year-old boy, who presented with pain in the right thigh, limp, fatigue and weight loss. Clinical exam revealed a mass on the right iliac fossa and splenomegaly. There was no biopsy of the principal mass performed. Bone marrow morphology and immunophenotype were suggestive of Burkitts lymphoma, except for the absence of IgM. FISH analysis showed the absence of *MYC* rearrangement. G-banding karyotype revealed an abnormal chromosome 11, consisting of either a derivative from a t(11;12) or an 11q duplication. Analysis with whole chromosome 12 painting excluded the possibility of a t(11;12). In order to characterize the segment duplicated, the LSI *MLL* (11q23) Dual-Color Break Apart Probe was used. FISH analysis showed 3 *MLL* signals in 77% of interphase nuclei, with two of these signals in close proximity. Analysis of metaphase cells and the order of the green and red signals on interphase nuclei revealed an inverted duplication of 11q13q23.3, resulting in trisomy of this segment, with a telomeric breakpoint distal to *MLL* locus. Trisomy 11q is a rare but recurrent imbalance in B cell tumors. Further cytogenetic and molecular investigations of negative *MYC* Burkitts lymphomas could help to characterize this entity of B cell tumors.

Interaction between IRF6 and TGFA contributes to the risk of cleft lip/palate. *A. Letra[1], R. F. Fonseca[3], R. Menezes[1], T. H. McHenry[1], S. Daack-Hirsch[4], M. L. Marazita[1,5], E. E. Castilla[6], B. C. Schutte[7], I. M. Orioli[3], J. M. Granjeiro[8], A. R. Vieira[1,2,7]* 1) Dept Oral Biology and Center for Craniofacial and Dental Genetics, Univ of Pittsburgh School of Dental Medicine, Pittsburgh, PA; 2) Dept Pediatric Dentistry, Univ of Pittsburgh School of Dental Medicine, Pittsburgh, PA; 3) ECLAMC at Dept Genetics, Federal University of Rio de Janeiro, RJ, Brazil; 4) College of Nursing, Univ Iowa, Iowa City, IA; 5) Dept Human Genetics, Graduate School of Public Health, Univ Pittsburgh, Pittsburgh, PA; 6) ECLAMC at Oswaldo Cruz Foundation, RJ, Brazil; 7) Dept Pediatrics, College of Medicine, Univ Iowa, Iowa City, IA; 8) Dept Cell and Molecular Biology, Fluminense Federal University, RJ, Brazil.

Studies of tooth agenesis suggest that IRF6 and TGFA may interact. Tooth agenesis is commonly found in individuals with CL/P; hence we used three cohorts to evaluate if IRF6 and TGFA interaction also contributes to CL/P. Markers in/nearby IRF6 and TGFA were tested for case-control analyses in 1,000 Brazilian individuals. We looked for evidence of gene-gene interaction between IRF6 and TGFA in our cohort and additionally in 142 case-parent triads from South America and 861 families by testing if associated markers were overtransmitted together. Irf6 and Tgfa expression was analyzed by immunohistochemistry in normal and Irf6 knockout mice. Both IRF6 and TGFA showed association with CL/P subtypes in the Brazilian cohort (p=0.00001). Statistical evidence of interaction was found for all data sets (p=0.01 for Brazil; p=0.046 for South America, and p=0.003 for the 861 families). Attributable fraction calculations suggest that such interaction may explain 1% - 10% of all CL/P cases. Expression of Tgfa was decreased in embryos that lacked Irf6. We provide further evidence that IRF6 and TGFA contribute to CL/P. Moreover, IRF6-TGFA interaction appears to contribute to as much as 1% to 10% of CL/P cases. The IRF6-knockout model further support the evidence of IRF6-TGFA interaction we found in humans. NIH grants R21-DE016718, R01-DE016148, P50-DE016215; CAPES/BEX3413055, CNPq 30885/2006-6, FAPERJ (E-26/152.831/2006).

A robust copy number variation discovery algorithm for multiple array platforms. *D. Pinto, J. Zhang, B. Thiruv, Z. Wang, L. Feuk, P. Hu, C. Greenwood, S. W. Scherer* The Centre for Applied Genomics and Program in Genetics and Genome Biology, the Hospital for Sick Children and University of Toronto, ON, Canada.

Developments in microarray design and data analysis are crucial for accurately detecting copy number variation (CNVs) on a genome-wide scale. There is an unmet need for algorithms that can detect CNVs with high sensitivity and specificity. We have developed an algorithm, *iPattern*, which calls CNVs from intensity data derived from SNP or CGH arrays. *iPattern* uses non-parametric density-based clustering to categorize sample loci into different groups when compared to reference samples by using an optimal moving window-based approach. The largest cluster of unrelated samples is chosen as reference, and samples with higher or lower intensities are assigned as relative CNV gains or losses. *iPattern*'s performance was evaluated using simulated and real data. Simulation studies were carried out on synthetic data derived from various X chromosome copies, and clustering parameters were chosen to maximize sensitivity while setting the false discovery rate (FDR) to 3%. *iPattern* was tested on HapMap data generated using the Affymetrix SNP 6.0 (268 samples) and the Illumina Beadchip 1M (103 samples). From these datasets we detected 28,331 and 4,719 CNVs, respectively, accounting for 106 and 46 CNVs/sample. About 90% of the calls from both platforms overlapped known CNVs in the Database of Genomic Variants. The quality of CNV calls was further assessed by examining inheritance patterns in parent-child trios from control data and in a disease cohort of 350 families. The fraction of CNV calls in children not detected in parents was 8.3%, a significant improvement over other available tools. Considering that an unknown proportion of these calls consist of *de novo* CNVs, the actual sum of false discoveries (i.e. combination of false-positive and false-negative rates) is likely lower. Finally, sensitivity and specificity estimates using replicate samples indicated that *iPattern* had 1.7 times higher sensitivity than that of another method at a similar FDR. Our data show that *iPattern* is currently the most robust CNV calling algorithm for analysis of Affymetrix SNP 6.0 and Illumina 1M array data.

Genomic imbalance as a cause of fetal and infant death. *J. Gerfen[1], L. K. Conlin[1,2], M. Berman[2], D. DiPatri[1], S. Kasperski[1], R. D. Wilson[1], L. Ernst[1], N. B. Spinner[1,2]* 1) The Childrens Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania School of Medicine, Philadelphia, PA.

The cause of fetal and neonatal death is unknown in 50% of cases. While cytogenetic abnormalities make a significant contribution to early fetal loss (peak frequency at 12-15 weeks), chromosome abnormalities play a lesser role in fetal loss after 24 weeks. Recent technologic advances offer the opportunity to search for smaller genomic imbalances that would have been missed by chromosome analysis. We used genome-wide SNP array analysis to study a cohort of 111 patients who died before birth, within the first year of life, or following pregnancy termination due to multiple malformations. We identified an average of five copy number alterations (10 SNPs for heterozygous calls, 5 SNPs for homozygous deletions) per patient. To prioritize the potential significance of the deletions and duplications identified (pathogenic versus benign copy number variation), we developed a program called PErl COpy Number of Potential Interest (PECONPI). PECONPI assigns a score to each deletion or duplication based on its frequency in controls (in house and literature), genetic content, size, and number of copies. Higher PECONPI scores indicate a higher likelihood to be pathogenic. We found 549 genomic deletions or duplications, and 56 were scored to indicate exonic involvement with no overlap with controls. So far, we have identified six abnormalities that we believe were the cause of death, including a homozygous deletion of the glycine decarboxylase gene in a neonate who died of non-ketotic hyperglycemia, a mosaic deletion of 11q in a patient who died of neuroblastoma, and a 2q14 deletion including the Gli2 gene in a stillborn fetus with a brain malformation. Parental samples were available for five patients, two of whom had duplications that were potentially pathogenic based on literature reports (3q29, 16p11.2). Both variants were inherited from a phenotypically normal parent and thus it is not likely to be the cause of demise for these individuals. Work is ongoing to investigate the remaining patients and to further characterize the role of genomic imbalances in fetal and infant death.

Glutaric Aciduria Type II presenting with lipid myopathy, progressive leukodystrophy; intrafamilial variation in two siblings. *W. Al-Hertani[1], A. Mineyko[2], P. Humphreys[2], P. Chakraborty[1], M. T. Geraghty[1]* 1) Dept Medical Genetics, CHEO, Ottawa, ON, Canada; 2) Department of Neurology, Childrens Hospital of Eastern Ontario, Canada.

Glutaric Aciduria Type II (GAII) is an autosomal recessive disorder caused by a deficiency of Electron Transfer Flavoprotein (ETF) or ETF-ubiquinone oxidoreductase (ETFQO). ETF and ETFQO play an important role in the transfer of electrons from the breakdown of fats and proteins to ubiquinone in the respiratory chain. We report a 4 year old female who presented at 6 months with significant hepatomegaly, hypotonia, profound myopathy requiring ventilation for 2 months. At presentation there was a mild hyperchloremic acidosis with elevated muscle enzymes. Plasma glucose, ammonium, lactate and amino acids were normal. Urine organic acids showed dicarboxylic aciduria. Plasma acylcarnitines showed elevations in long chain species consistent with atypical GAII or a long chain defect. EMG showed no activity while nerve conduction was normal. Liver biopsy showed moderate to severe fatty infiltration. Six weeks into the course muscle biopsy showed a resolving lipid myopathy with mild mitochondrial changes on electron microscopy. Deficiencies in Complexes I/III and II/III were reported in muscle but not liver. Several months after recovery brain MRI showed a progressive leukodystrophy. CoQ levels at that time were normal in muscle and leukocytes. Analysis of fatty acid oxidation in fibroblasts was reported as normal in 2 laboratories but abnormal and non diagnostic in a third. Western blot and enzyme activity levels showed normal ETF but mildly reduced ETFQO levels and low activity (0.44nmol/min/mg; normal 0.8-2.4; typical affected:<0.2). Sequence analysis of the ETFDH gene showed 2 mutations. One is a previously reported mutation (nt51insT) the other (E314K) has not been published to date. The probands 9 year old brother has both mutations, abnormal acylcarnitines and absent ketones on overnight fasting, but is asymptomatic. Because of advancing leukodystrophy unresponsive to high dose riboflavin and CoQ, the proband was started on D,L betahydroxybutyrate and we are following the response.

Comparison of BiGS GWAS results with other GWAS studies of Bipolar Disorder. *D. L. Koller[1], T. Foroud[1], X. Xuei[1], H. J. Edenberg[1], J. I. Nurnberger[1], W. Berrettini[2], W. Byerley[2], W. Coryell[2], E. Gershon[2], W. Lawson[2], M. McInnis[2], F. McMahon[2], J. P. Rice[2], W. Scheftner[2], P. Zandi[2], N. Schork[3], J. Kelsoe[3]* 1) Indiana Univ Sch Medicine, Indianapolis, IN; 2) BiGS Consortium; 3) Univ Calif-San Diego.

We have recently completed genotyping of a case-control study of bipolar disorder (the BiGS study, dbGAP filtered dataset,n=1021 cases); primary results are presented in a companion abstract. GWAS studies of bipolar disorder have been published by the Wellcome Trust Case Control Consortium (Nature 447:661, n=1868) and the StepBD consortium (Mol Psych 13:558-569, n=1461). We compare results from these three studies, all of which focused on type I bipolar cases. Loci with evidence of association across multiple bipolar GWAS were identified by computing the product of the three allelic association P-values for SNPs included in the Affymetrix 500K array (used for WTCCC and StepBD), which are a subset of the Affymetrix 6.0 array (BiGS). Chromosomal regions were identified containing multiple SNPs with P-value products less than 10^{-6}, to prevent the detection of single SNPs with little or no support from nearby markers. We then further restricted our interest to regions achieving a nominal p-value less than 0.01 in the BiGS study and with the same risk allele detected in at least one of the published studies (Wellcome or StepBD). We detected 8 regions meeting these criteria in BiGS and one of the other two studies, and 2 regions (*SYNE1* and *CDH11*) with association evidence from all three studies. Notably, evidence of replication across the bipolar GWAS studies occurs primarily for SNPs with p-values that do not reach the thresholds for genome-wide significance. The vast majority of the findings were not among the top 1000 SNPs in the respective studies. This is consistent with the conclusions of Baum et al. (Mol Psych 13:466). We conclude that follow-up studies should include these commonly detected regions, as well as candidates with evidence of association from non-GWAS studies, and not focus entirely on the chromosomal regions providing the highest level of statistical significance in any one study.

Analysis of the EAAT2 glutamate transporter (*SLC1A2*) locus as an 11p13 positional candidate for autism. *G. D. Schellenberg for the Autism Genome Project* U Pennsylvania.

Autism is a developmental disorder defined by deficits in reciprocal social behaviors, communication and patterns of repetitive behaviors and restricted interests. Approximately 1 in 150 individuals are affected by an autism spectrum disorder (ASD), with twin and family studies indicating a predominantly genetic etiology. The Autism Genome Project (AGP), a large international collaboration, previously reported a Phase I linkage analysis on a sample of >1100 multiplex families (*Nat Genet* 39: 319, 2007). In addition to ancestry and gender effects on linkage, the most prominent specific locus to emerge corresponds to a region on 11p13. Peak linkage (Z_{lr} = 3.57) was observed at marker rs2421826 at 52 cM, with a significant increase observed in a subset of families with one or more affected females (Z_{lr} = 4.37). Of the genes located in the region flanking peak linkage, *SLC1A2*, which encodes the EAAT2 glutamate transporter, emerged as a plausible candidate gene. To test the hypothesis that *SLC1A2* harbors common and/or rare alleles conferring risk for autism, the AGP performed allelic association and exploratory resequencing analyses. Resequencing studies involved a sample of 200 unrelated probands and 100 unrelated control subjects and amplimers covering all coding and 5 untranslated exons. Several novel synonymous and nonsynonymous variants were detected in probands, however, the observed variation does not suggest a likely mutation burden. Association analysis was conducted using 35 SNPs chosen to index common haplotypes across ~85 kb of exonic and 5 and 3 flanking sequence. Genotype data from a combined multiplex/simplex sample of 2,668 families was assessed for quality control and Hardy-Weinberg. Resulting data were analyzed using FBAT based on stringency of autism diagnoses and revealed an excess of nominally-significant P-values across a large block of linkage disequilibrium, and in particular its 5 end. Ten SNPs demonstrated P-values <0.05 and five SNPs with P-values <0.01. These results, and substantial linkage to autism at 11p13, provide compelling but not fully convincing evidence that variation in *SLC1A2* affects autism susceptibility.

A 5.7Mb deletion at chromosome 14q22-q23 in a child with short stature, polydactyly, and mild dysmorphic features. *A. N. Filose, G. E. Tiller* Department of Genetics, Kaiser Permanente, Los Angeles, CA.

We describe a 4 year old boy with a 5.76Mb deletion on chromosome 14 using comparative genomic hybridization (CGH). Clinical evaluation as an infant revealed hypotonia, large anterior fontanelle, hypertelorism, distal postaxial polydactyly, and normal brain MRI and 46,XY karyotype. Subsequent evaluation at 3 years of age was remarkable for short stature, mild developmental delay, and dysmorphic features including relative macrocephaly, mild proptosis, hypertelorism, prominent forehead, and long narrow nose with anteverted nares. A formal ophthalmologic examination was unremarkable. CGH analysis revealed a de novo 5.76Mb interstitial deletion extending from 14q22.1 to 14q23.1. Approximately 35 genes are within the deleted region, including SPG3A, PYGL, BMP4, and GCH1. Most notable of these is BMP4, in which mutations are associated with eye, brain, and digital anomalies. Deletions in this region are rare, with perhaps 11 cases described in the literature to date. The 14q deletions previously reported are similar in size and location to this patient. The majority of cases described exhibit bilateral anophthalmia; unilateral anophthalmia, brain anomalies, developmental delay, and polydactyly are also frequent, but not universal findings. This case may represent a milder form of an emerging deletion syndrome.

The effects of linkage disequilibrium in large scale SNP datasets for Multifactor Dimensionality Reduction. *B. J. Grady, E. S. Torstenson, M. D. Ritchie* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

In the analysis of genome-wide association studies (GWAS), an important consideration is the power of analytical methods to identify correct predictive models of disease. When trying to get power from such analytical methods, a confounding factor up to this point has been the presence of linkage disequilibrium in GWAS datasets. In order to look at the effect of LD on association analysis, in particular with respect to detecting gene-gene interactions, the genomeSIMLA data simulation software package was used to simulate SNPs in LD and data was then analyzed for two-locus interactions using Multifactor Dimensionality Reduction (MDR). MDR is a non-parametric statistical method for detecting gene-gene and gene-environment interactions. MDR performs a dimensional reduction by assigning multi-locus genotypes to either high or low risk groups and using this model to predict disease status. Using genomeSIMLA, we simulated datasets with varying proportions of SNPs in LD in which between 15% and 95% of the SNPs were in LD with at least one other SNP in the dataset, where LD is defined by an r2 of at least 0.8. In addition, we simulated three different scenarios for the disease susceptibility loci: a model in which both SNPs are in separate blocks of LD; a model with one SNP in an LD block and the other not in LD with any other SNPs; a model of two SNPs in the same block of LD. Multiple penetrance functions were then used to create varying effect sizes. Results from these analyses indicate that higher levels of LD begin to challenge the MDR algorithm such that the ability to detect the functional locus is decreased; however, there is ample power to detect the SNPs in the blocks of LD with the functional locus. This simulation study indicates that the use of MDR in large scale SNP data with varying amounts of LD can be fruitful as long as one pays attention to the LD patterns within the dataset.

Analysis of Copy Number Variants (CNVs) in a Genomewide Association Study of Bipolar Disorder (BPD). *K. P. Shah[1], D. Absher[5], J. Xu[1], M. Bennet[6], L. J. Scott[2], R. C. Thompson[3], W. Guan[2], M. Flickinger[2], F. Meng[4], A. Southwick[6], A. F. Schatzberg[7], J. D. Barchas[8], W. E. Bunney Jr.[9], E. G. Jones[10], M. Burmeister[3,4], H. Akil[4], S. J. Watson[4], M. Boehnke[2], R. M. Myers[6], J. Li[1]* 1) Dept of Human Genetics; 2) Biostatistics; 3) Psychiatry; 4) Molecular & Behavioral Neuroscience Inst, Univ. of Michigan, Ann Arbor, MI; 5) HudsonAlpha Inst. for Biotechnology, Huntsville, AL; 6) Stanford Human Genome Ctr; 7) Dept of Psychiatry and Behavioral Sciences, Stanford Univ., Palo Alto, CA; 8) Weill Medical College, Cornell Univ., New York, NY; 9) Dept of Psychiatry & Human Behavior, Univ. of California, Irvine, CA; 10) Ctr. for Neuroscience, Univ. of California, Davis, CA, USA.

We performed a GWAS of BPD involving genotyping 550,000 SNPs in 1,147 BPD cases and 778 unrelated controls. Samples are European Americans frequency-matched by self-reported ancestry. SNP-based analysis results are reported in a separate abstract (Scott et.al.). As CNVs may account for additional disease risks we set out to examine their potential contribution to BPD. From genotyping intensity data we identified 41,412 CNVs, averaging 22 per sample. Of these, 29,541 common CNVs, defined as spanning 2 SNPs and occurring in 3 samples, fall into 1,700 unique loci. The remaining 11,871 CNVs, seen in only 1-2 samples, fall into 10,436 rare CNV loci. Together the 12,136 CNV loci cover 623 Mb (22% of the genome). 54% have not been reported before (Database of Genomic Variants); 43% are within 5 kb of RefSeq genes. About 78% contain deletions, 22% contain amplifications, and 1% contain both. A higher proportion of rare CNV loci are near genes (45% vs 32%) than common CNV loci, suggesting differences in selective pressure in genic regions. Preliminary case-control comparisons of CNV frequencies revealed none that reached genomewide significance. To increase power, we are currently combining our study with other GWAS of BPD to detect signals of association for both SNPs and CNVs. The authors are members of the Pritzker Neuropsychiatric Disorders Research Consortium, which is supported by the Pritzker Neuropsychiatric Disorders Research Fund L.L.C.

Mosaic Chromosome 5q Deletion in Mother and Daughter Delineated by Genomewide SNP Microarrays. *R. Lebo[1], J. Collins[2], M. Khalifa[3], P. Hong[1], P. Cifuentes[4], E. Mansfield[5]* 1) Dept Pathology, Akron Children's, Akron, OH; 2) Div Molecular Diagnostics, Affymetrix, Santa Clara, CA; 3) Div Genetics, Dept Pediatrics, Akron Children's; 4) Div Cytogenetics, Affymetrix; 5) Div Scientific Applications, Affymetrix.

Mosaic chromosome 5q microdeletion in mother and daughter was identified by a 437 BAC site Spectral Genomics microarray. The mother and daughter were confirmed to share mosaic microdeletions by BAC FISH to metaphase cells. The daughter has bilateral clinodactyly of the little finger, partial clinodactyly of the second and third toes, downward slanting palpebral fissures, cup shaped prominent ears, micrognathia with elongated smooth filtrum and prominent maxilla, and delayed speech development. Both parents are phenotypically normal. To delineate these deletions, confirm paternity, and identify de novo mutations, the Affymetrix 6,000,000 site SNP 6.0 microarray was employed. Mosaic deletion of the 125 kb region in chromosome band 5q23.3 disrupting the ADAMTS19 gene was again confirmed in both the mother and daughter. ADAMTS19 is a metalloproteinase involved in tissue remodeling and angiogenesis and expressed most abundantly in fetal tissue. Several additional de novo duplication and deletion sites were found in the daughter as well as multiple copy-neutral LOH regions including three Megabase regions on Xp11.13, Xq22.3 and 3p21.1. These gene rich regions encode multiple cell cycle regulators (PARP3, PBRM1, RASSF1,TUSC4), DNA repair genes (BAP1, PBRM1, PCBP4, RBM6) and several candidate mental retardation genes involved with axon guidance (SEMA3F, RHOA,SEMA3B, GNAI2, SEMA3G) or tight junction formation (EPB41L1, RHOA, CASK, GNAI2, MYL9). Together the concert of molecular changes in the daughter's genome identified with the Affymetrix SNP array could explain her abnormal phenotype. This case demonstrates (1) the application of genomewide SNP analysis to obtain data quickly and thoroughly on complex cases, (2) confirming mosaic deletions by FISH analysis of metaphase chromosomes, and (3) an abnormal phenotype may require extensive analysis to determine the source.

Multiple, rare, segregating variants may be responsible for familial combined hyperlipidemia. *E. Wijsman[1], J. Rothstein[1], J. Brunzell[1], R. Krauss[2], A. Lusis[3], A. Motulsky[1], G. Jarvik[1]* 1) Univ. of Washington, Seattle, WA; 2) Univ. of California, Berkeley, CA; 3) Univ. of California, Los Angeles, CA.

Cardiovascular disease remains the leading cause of death in Western societies. Familial combined hyperlipidemia (FCHL) is a complex disorder leading to increased cardiovascular disease risk. It is characterized by the presence of elevated cholesterol, triglyceride (TG), and apolipoprotein B (APOB) levels, with also associated changes in low-density lipoprotein (LDL) levels and size, measured as peak particle diameter (PPD). We previously showed evidence (lod > 3 or log Bayes factor, BF > 1) for linkage of PPD to chromosome (chr) 9 in a single pedigree, and to chr 11 jointly in 4 large pedigrees (N=255 individuals), as well as suggestive evidence for linkage to chr 14 and 16 [ATVB 24:1942, 2004]. Here we extend analysis to additional phenotypes (logTG, APOB), to additional markers, and to 18 additional pedigrees (N=542). We used whole chromosome multipoint Markov chain Monte Carlo (MCMC) methods to compute parametric lod scores and BFs for joint oligogenic segregation and linkage analysis (OSLA). APOB was adjusted for LDL and PPD, PPD was adjusted for logTG, and all 3 traits were adjusted for age, sex, and BMI prior to analysis. Additional dense genotyping increased evidence for linkage of PPD to chr 9 (lod=4.07) and narrowed the location to 28-37 cM, and analysis of all 22 pedigrees identified chr 11 at ~115 cM as the region with strongest linkage evidence for PPD and log TG across all pedigrees (log BF=2.25 and 1.5, respectively). Additional evidence of linkage of logTG across all families was also obtained for chr 7 (log BF=1.5) and 14 (log BF=1.5), and strong support for linkage in one or a few families was obtained for PPD (chr 10p, log BF=2.5) and for APOB (log BF=1.5, lod=3.1). Each large pedigree typically supported linkage to at least two genomic locations with log BF=1-2 and with identifiable models from OSLA, but with little overlap in the identified regions across families. These results suggest that multiple rare variants are segregating, and that use of large pedigrees may be the most useful strategy to identify causal variants for these traits.

Identification of *VANGL1* variants associated with neural tube defects. *Z. Kibar[1], M. Kooistra[2], P. Fortin[2], S. Salem[2], P. De Marco[3], E. Merello[3], A. G. Bassuk[4], V. Capra[3], P. Gros[2]* 1) Obstetrics and Gynecology, CHU Sainte Justine and University of Montreal, Montreal, QC, Canada; 2) Department of Biochemistry, McGill University, Montreal, QC, Canada; 3) Laboratorio del Servizio di Neurochirurgia, Instituto G. Gaslini, Genova, Italy; 4) Department of Pediatrics, University of Iowa, Iowa City, Iowa, USA.

Neural tube defects (NTDs), including spina bifida and anencephaly, represent a group of common and severe congenital malformations affecting 1-2 per 1000 birth. They are caused by failure of the neural tube to close during early development. Their etiology is complex involving both environmental and genetic factors. We have recently reported three mutations in the planar cell polarity gene *VANGL1* in NTDs, which are most likely pathogenic based on genetic and functional data. To better understand the role of *VANGL1* in the development of NTDs, we analyzed this gene by direct sequencing in a large and well-characterized cohort affected with various forms of NTDs including cranial, open and closed spinal dysraphisms. The cohort consisted of 219 Italian patients recruited at the Spina Bifida Center of the Gaslini Hopsital in Genova, Italy and 480 patients recruited at the Children's Memorial Hospital in Chicago, Illinois, United States. The latter included patients of various ethnic origins including Caucasian, African Americans and Latin Americans. The control group consisted of 205 unrelated healthy random Italian individuals and 1200 individuals from the Human Genome Diversity Project. Sequence analysis of *VANGL1* identified four variants, R181Q, L202F, T251M and R517C,that were absent in all ethnically-matched controls analyzed. These variants affect highly conserved amino acid residues. We are currently validating the pathogenicity of these variants by various biochemical assays in vitro and in vivo. We are also conducting a dense single nucleotide polymorphism (SNP) association study (10 SNPs) to identify alleles, genotypes and haplotypes at *VANGL1* that confer a high risk for NTDs. Our preliminary results provide further evidence supporting the role of *VANGL1* as a strong player in development of spinal NTDs.

Linkage and Association on Chr 8p21 in Schizophrenia. *M. D. Fallin[1,4], V. K. Lasseter[3], D. Avramopoulos[2,3], P.-L. Chen[2], K.-Y. Liang[4], Y. Liu[2], J. McGrath[3], G. Nestadt[3], P. Wolyniec[3], D. Valle[2], A. E. Pulver[3]* 1) Dept of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 3) Dept of Psychiatry, Johns Hopkins School of Medicine, Baltimore, MD; 4) Dept of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Many linkage studies have identified a locus for schizophrenia (SZ) on Chromosome 8p21, including a recent ~6000-SNP linkage analysis of 831 pedigrees from 8 site that showed linkage to a 1Mb region from rs1561817 to rs9797 (Zmax=3.2, p=0.0004). Our 132 European Caucasian families from Johns Hopkins (JHU) contributed the strongest linkage evidence in this region among the sites. We carried out SNP fine-mapping of 4.36 Mb surrounding this linkage signal (1402 SNPs, average 3.1Kb density) on 103 of our 132 families that were most informative for 8p-linkage. Using 70 of these fine-mapping SNPs, selected to be pairwise uncorrelated (r^2<.05), we continued to see linkage (maximum NPL of 6.95 (p=2.95x10-10)) at rs11994515, in the center of the multi-site scan peak. Family-based association in these pedigrees showed modest support (p<0.05) for 13 of the 32 genes in the region, with the strongest signals for two SNPs 5 of ADRA1A, both with nominal p-values <0.001, and a concentration of 5 nominally significant SNPs in DPYSL2, a gene located ~100 kb telomeric of ADRA1A and previously associated in our family-based studies in the Ashkenazim (Liu et al 2008; Fallin et al., 2005). We performed an additional case-control study of a refined 2.8Mb section (25.7 - 28.5Mb, 23 known genes) using 970 SNPs (r^2.8) in 713 independent SZ/SZA cases and 1448 unrelated controls. Of the 970 SNPs, 12% showed nominal significance at p<0.05, and 3 SNPs showed a study-wide p<0.10 after permutations accommodating the multiple tests performed (rs6983735, rs6558061, rs4545109). Our strongest signal, located 13kb upstream of DPYSL2 at 26,476,491, achieved a nominal p = 0.000045 and study-wide p = 0.025. Further analyses by sex and SZ sub-phenotypes are now in progress.

Animal model of SPG6 hereditary spastic paraplegia. *Y. Y. Kisanuki[1], S. Rainier[1], J. Moore[1], T. Saunders[2], J. E. Wilkinson[3], J. K. Fink[1,4]* 1) University of Michigan, Neurology; 2) Internal Medicine; 3) Pathology; 4) Geriatric Research Education and Clinical Center, Ann Arbor Veterans Affair Medical Center, Ann Arbor, MI.

The hereditary spastic paraplegias (HSPs) are clinically and genetically heterogeneous disorders characterized by progressive lower extremity weakness and spasticity. SPG6 HSP is a particularly severe, autosomal dominant form of HSP. Our laboratory identified the SPG6 locus (15q11.1)and showed that *NIPA1* mutations cause SPG6 HSP. No treatments to stop, reverse, or prevent progressive disability are available. NIPA1 mutations are predicted to be pathogenic through gain of function because individuals with Prader-Willi/Angelman syndrome who have chromosome 15 deletions including the SPG6 locus do not develop progressive spastic paraplegia. NIPA1 mutations c.G316C and c.G316A, both resulting in p.G106R, are reported in SPG6 HSP.

We created transgenic rats in which the mutant human $NIPA1^{G106R}$ is expressed under the control of *Thy1.2* promoter. We analyzed 10 transgenic lines. These rats exhibit age-dependent (onset ~12 weeks), progressive hindlimb motor impairment. They exhibit hind limb clasping or extensor rigidity when lifted by their tails. Beginning at 16 to 20 weeks, gait becomes markedly abnormal with outwardly rotated hind limbs and scooting or hopping rather than stepping. They show difficulty in walking on rotating drum and narrow beam. Neuropathologic analysis reveals marked axonal degeneration in the spinal cord, particularly corticospinal and spinocerebellar fibers without primary myelin loss. Brain, muscle, and peripheral nerve do not show significant pathology. Spinal cord neuron cell bodies are preserved.

Behavioral and neuropathologic features of $NIPA1^{G106R}$ transgenic rats are parallel to those of human HSP. These animals are a valid model of SPG6 HSP and an important resource to explore its pathogenesis and treatment. Furthermore, our observations support the hypothesis that NIPA1 mutations are pathogenic through toxic gain of function mechanism.

Whole Genome Bisulphite Sequencing by High-Throughput Oligonucleotide Ligation Sequencing. *M. A. Barker[1], V. L. Boyd[1], Y. A. Sun[1], M. D. Rhodes[1], L. W. Jones[1], C. K. Monighetti[1], S. J. Stanley[1], V. I. Bashkirov[1], K. J. McKernan[2], F. M. De La Vega[1]* 1) Applied Biosystems 850 Lincoln Centre Drive Foster City, CA 94404; 2) Applied Biosystems 500 Cummings Center beverly MA 01915.

Methylation of CpG motifs throughout the genome plays a critical role in many cellular processes within the cell, including differentiation, chromosome stability, regulation of gene expression and preventing transcription of repetitive or alien sequences. Accordingly, aberrant methylation patterns have been linked to many diseases, and play a major role in the initiation and progression in the majority of cancers. Bisulphite sequencing is the method of choice for characterizing the methylation status of each CpG in a given region, however until recently bisulphite sequencing has been limited to region specific analysis. The introduction of next generation sequencing technologies removes this limitation, allowing hypothesis-free analysis of the entire methylome. Here we present a technique that harnesses the ultra-high throughput of the SOLiD System, a sequencing platform based on massively parallel cycled fluorescent oligonucleotide ligation and cleavage, with the single base level resolution of bisulphite sequencing, enabling genome wide methylation analysis. A novel adaptation to the fragment library protocol enabled the DNA library to be treated with bisulphite after the addition of sequencing adapters. The resulting bisulphite converted library was then subjected to emulsion PCR and sequencing using standard sequencing protocols. Alignment of the resulting reads to the reference genome present some challenges due to the length of the read and the reduction in sequence specificity after bisulphite conversion. Methods have been developed to address these problems. We believe the combination of gold standard bisulphite sequencing with the unprecedented throughput of next-generation sequencing removes long standing technical roadblocks to large scale methylation analysis at single base resolution, and will enable significant advances in the field.

A Genome-Wide Association Study (GWAS) for fractional exhaled nitric oxide (FeNO) levels in the Hutterites. *E. E. Thompson, S. Kuldanek, L. Pan, C. Ober* Department of Human Genetics, The University of Chicago, Chicago, IL.

Elevated levels of FeNO are a measure of airway inflammation. To date, no population-based studies have examined the heritability and genetic basis of FeNO. We measured FeNO, total serum IgE and lung function (FEV_1) and performed skin prick allergen tests (SPT) and studies of bronchial hyperresponsiveness (BHR) to methacholine in 561 Hutterites, a founder population of European descent. Levels of FeNO were significantly correlated with IgE ($P = 1.14 \times 10^{-6}$ after adjusting for age and sex) but not with FEV_1 ($P>0.1$) or BHR ($P>0.1$). FeNO was highly heritable ($H^2=1.0$, s.e.= 0.17) in the sample. We then performed a GWAS of ln FeNO using the Affymetrix GeneChip Mapping 500k Array. High quality genotypes for 295,307 autosomal SNPs with minor allele frequencies 0.05 were analyzed using a test of association that takes into account the relatedness between all pairs of Hutterites. Four SNPs met criteria for suggestive significance in this sample ($P<2.44 \times 10^{-5}$), including one on chromosome 11 upstream of a gene previously implicated in inflammation and Th cell differentiation ($P=3.56 \times 10^{-6}$), one on chromosome 2 ($P=2.26 \times 10^{-5}$) that is also associated with SPT in our sample ($P=0.007$), and a pair of SNPs in strong linkage disequilibrium also on chromosome 1 ($P<2.44 \times 10^{-5}$). The latter two SNPs are also associated with asthma in our sample ($P<0.037$). Here, we report the first GWAS for FeNO, a non-invasive marker of airway inflammation. We show that this trait is highly heritable and identify potential candidate genes influencing FeNO levels and, possibly, asthma and allergic phenotypes. Supported by NIH grant HL085197.

IL-6 cytokine pathway genes regulate cell death in inherited photoreceptor degenerations. *C. Jiang[1], M. Szego[1], L. Pacione[1], A. Miyajima[2], T. Hudson[3], R. Nadon[3], R. McInnes[1]* 1) Hosp for Sick Children, Toronto, Canada; 2) Univ of Tokyo, Tokyo, Japan; 3) McGill Univ, Montreal, Canada.

We previously reported that in inherited photoreceptor degenerations, the mutant photoreceptors (PRs) are at a constant risk of death (Clarke et al. Nature 2000). Using microarrays to identify genes that mediate the constant risk, we find up-regulation of a putative IL-6 cytokine pathway in 3 mutant PR mouse models, when 60-90% of PRs are still alive: in the $Rds^{+/-}$ model, *Oncostatin M* (2X up by qPCR)*Oncostatin M receptor* (*Osmr*)(2.6X up)*Stat3* (2.3X up)the transcription factor (TF) *C/EBP* (3.2X up), with increases in the cognate proteins Osmr (3X up), Stat3 (2.6X fold), and pStat3 (the active TF form of Stat-3), 5.8X up) (all $p<0.01$). These increases were predominantly in Müller glia, but the increased *C/EBP* mRNA was pan-retinal, including PRs. Since exogenous IL-6 cytokines have been shown to slow PR death and also increase Müller cell pStat3, we asked whether the *endogenous* increases in IL-6 pathway genes in mutant retinas were a survival response, and generated mutant PR models with *Osmr* or *C/EBP* loss of function (LOF) mutations. *Osmr* LOF decreased PR survival: 4 month old $Rds^{+/-}$;$Osmr^{-/-}$ retinas had 12.5% fewer PRs vs. *wt* (n=9, $p<0.05$), and 31 day-old *Tg(RHO P347S)*;$Osmr^{-/-}$ retinas had 13.5% fewer PRs (n=6, $p<0.01$). The putative IL-6 response pathway (above), if predominantly activated through the Osmr, should exhibit a decline in pStat3 levels in the absence of *Osmr*. Unexpectedly, *Osmr* LOF had no effect on pStat3 levels in $Rds^{+/-}$;$Osmr^{-/-}$ retinas, indicating that pStat3 activation is mediated through other IL-6 cytokines or other pathways. In contrast to the *Osmr* LOF, *C/EBP* LOF increased mutant PR survival:8-month old $Rds^{+/-}$;$C/EBP^{-/-}$ retinas had 18% more PRs vs. *wt* (n=5, $p<0.005$). We conclude that in mutant PRs 1) up-regulation of the *Osmr* is a survival response; 2) up-regulation of the *C/EBP* transcription factor is pathogenic, and therefore 3) *Osmr* and *C/EBP* act either in different pathways or different cells, in response to a PR mutation; 4) the partial effects of *Osmr* & *C/EBP* LOF indicate that other genes also mediate the constant risk of death.

Genome-wide detection and association of copy number aberrations in Late-Onset Alzheimer Disease. *GW. Beecham[1], ER. Martin[1], M. Slifer[1], J. Gilbert[1], J. Haines[2], M. Pericak-Vance[1]* 1) Miami Institute for Human Genomics, University of Miami, Miami, FL; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Late-Onset Alzheimer Disease (LOAD) has a strong but complex genetic component. One potential source for LOAD genetic risk that has received little attention is copy number variations (CNVs). To investigate the role of CNVs in LOAD, we evaluated multiple algorithms that use SNP genotype data for CNV detection and association, including Hidden Markov Models, and segmentation algorithms. Algorithms were evaluated using synthetic data with known deletions derived from X-linked data. We then applied the top performing tests to LOAD genome-wide association SNP intensity data from the Illumina 550k HumanHap beadchip. Promising regions were then tested for association using a permutation test. Additionally, single marker tests for differences in intensities were evaluated, including Students t-test, chi-square test, Mann-Whitney U test, and a mixture model for batch effect correction. Over twenty CNVs were significantly associated with LOAD using multiple algorithms. Many of the CNVs were under consensus linkage signals on 2q33, 6q12, 6q15, 10p12, 10q26, 12p11, 21q22, and 19q13 (unlinked to ApoE) and others were found at biological and locational candidate genes such as MAPT, CBS, SCARB1, ECHS1, PSMB7, and POMT1, many of which also have previously reported significant association results for LOAD. These regions should be targeted for further analysis, and their implication shows that CNVs likely play a role in LOAD risk that cannot be ignored.

Influence of Genomic Variance on the Transcriptome in Human Brain Tissues. *J. Gibbs[1,2], M. van der Brug[1], D. Hernandez[1,2], S. Lai[1,4], B. Traynor[1,3], M. Cookson[1], A. Singleton[1]* 1) Laboratory of Neurogenetics, National Institute on Aging, NIH, Bethesda, MD; 2) Department of Molecular Neuroscience and Reta Lila Weston Institute of Neurological Studies, IoN, UCL, London, UK; 3) Department of Neurology, John Hopkins University, Baltimore, MD, USA; 4) Department of Neurology, Chang Gung Memorial Hospital and College of Medicine, Taiwan.

Variation of gene expression effects development, function and risk of neurological disease within brain tissue. Multiple genomic sources contribute to variation of gene expression; including DNA sequence variation, genomic modifications such as methylation and expression of mircoRNAs (miRNA). The technologies are present now such that it is feasible to investigate the interrelatedness of genomic variance and the transcriptome from a whole genome perspective. The content and context of this data allows us to begin to interrogate genetic and epigenetic variation and their effects on transcript expression. Identifying the links between genomic variance and differences in expression, expression quantitative trait loci (eQTL), will facilitate our ability to begin to build functional maps of genomic regions within the human brain. Having such a map is useful not only for understanding genomic regions and the regulation of normal gene expression but also for association studies linking genomic loci with disease. In this study we have collected tissue from four brain regions (frontal and temporal cortex, cerebellum and pons) from 150 individuals. For each individual we genotyped 550,000 single nucleotide polymorphisms (SNPs) and in all four brain regions measured DNA methylation at 27,500 CpG islands, expression of 700 microRNAs (miRNAs) and 22,000 gene transcripts (mRNAs). Within each brain region analysis were performed to identify correlations by modeling pairings of different data types. Across regions analysis were performed to identify expression and methylation differences as well differences within the region specific correlations.

A weighted permutation method for efficient control of population structure. *K. Zhao[1], M. Nordborg[2], P. Marjoram[3], C. D. Bustamante[1]* 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 2) 2Molecular and Computational Biology, University of Southern California, Los Angeles, CA; 3) 3Division of Biostatistics, University of Southern California, Los Angeles,CA.

One of the main challenges in genome-wide association mapping is accounting for the confounding effects of population structure and cryptic relatedness. Since large sample sizes are often required for mapping complex traits, these confounding effects can be a significant source of spurious associations. Most current methods for solving this problem rely on inclusion of population structure estimates as covariates in ordinary least-squares regressions. However, for many complex pedigrees, these terms are not sufficient to account for all degrees of relatedness. Mixed model approach was effective in dealing with various levels of relatedness, but the normality assumption of phenotypic residual is usually not held. Here we presented a weighted permutation method, which improves upon the efficiency of these approaches. First, we estimated the relatedness between individuals from the genome-wide markers. We then perform a permutation test which weights phenotype by the relatedness matrix. By applying this method to various data sets ranging from Arabidopsis to dog to human, we show that our method effectively controlled the false positive rates. Using extensive simulations, we also demonstrate that our approach has very good power while controlling genome-wide false positives. Since our simulations vary many parameters simultaneously (e.g., causal SNP allele frequency, number of causal SNPs, the informativeness of population structure of causal SNPs, etc.), it provides one of the most thorough comparisons of existing approaches for controlling confounding effects of population structure and cryptic relatedness.

Inferential Genotyping in Mormon Founders and Utah pedigrees. *J. Gitschier* Dept Medicine & Inst Human Genetics, UCSF, San Francisco, CA.

One concern in human genetics research is maintaining the privacy of individuals who contribute samples for investigation. While this concern is raised typically in the context of private medical information, I would argue that a signficant contributor to loss of privacy may lie with genealogical investigations, as much information is freely available online through a variety of websites, thus facilitating the discovery of genetic relationships. During sabbatical in the laboratory of Chris Tyler-Smith (Wellcome Trust Sanger Center), I genotyped the Y chromosome of HapMap samples with 16 short tandem repeat (STR) markers as well as lineage specific markers to determine whether the Y chromosome genetic information in this sample was consonant with the purported ancestry of the subjects. As one of the HapMap populations (CEU) is comprised of Utah pedigrees of European descent, I then queried whether the contributors of these samples might be descendents of Joseph Smith and Brigham Young, two founders of the Latter-day Saints. Remarkably, through iterative use of two online archives, FamilySearch and Sorenson Molecular Genetic Foundation, I was able to infer the Y chromosome STR haplotypes of these two founders. Although none of the CEU contributors appeared to be direct descendents of the two men, based on haplotype analysis, I was able to make predictions for the surnames of the CEU participants by the same process. For more than half of the unrelated CEU samples (16/30), at least one exact match was revealed and for 13 of these, a single surname was associated. For the remaining 14 samples, a match was nearly perfect, with only one or two of the microsatellite markers varying, typically by only one repeat unit, as might be expected through microsatellite instability within a pedigree. By contributing samples and information to repositories specializing in genetic genealogy, individuals make important contributions to our collective knowledge, but they do so at the risk of revealing personal information shared by unwitting relatives. This problem will be exacerbated as genome-wide markers and sequences, which may bear physical, health and behavioral information, emerge and are employed in genealogical research.

Neuronal autophagy induction requires mTOR and protects against misfolded protein stress in inherited neurodegenerative disorders. *J. E. Young[1], R. A. Martinez[1], A. R. La Spada[1,2]* 1) Department of Laboratory Medicine, University of Washington, Seattle, WA; 2) Center for Neurogenetics & Neurotherapeutics, University of Washington, Seattle, WA.

Autophagy is emerging as a critical stress response pathway in many human diseases, including neurodegenerative ones. Despite the reported protective effects of autophagy, little is known about how neurons activate this integral response. To investigate the role of autophagy in neurodegeneration, we developed a primary neuron model of autophagy induction. Conversion of unconjugated LC3-I to phosphatidylethanolamine-conjugated LC3-II is a reliable method for assaying autophagy induction. The LC3-I to LC3-II conversion can be monitored by a change in subcellular distribution, going from a diffuse to punctate appearance when associated with autophagic vesicles, or, by observing a molecular weight shift upon Western blot analysis. To study neuronal autophagy, we cultured primary cortical neurons from transgenic mice that ubiquitously express GFP-tagged LC3. By subjecting GFP-LC3 neurons to systematic nutrient withdrawal, we documented robust autophagy activation, both by GFP-LC3 puncta formation and accumulation of LC3-II on immunoblots. Testing of various culture components allowed us to attribute neuronal autophagy induction to loss of the key growth factor insulin. Induction of autophagy, secondary to insulin deprivation, is dependent on mTOR inhibition, and could be abrogated by treatment with 3-methyladenine, or shRNA knock-down of beclin-1. To test if autophagy is induced by misfolded proteins in our primary neuron culture system, we expressed polyglutamine-expanded androgen receptor (polyQ-AR), the protein responsible for X-linked spinobulbar muscular atrophy, in primary cortical neurons from GFP-LC3 mice. Although polyQ-AR expressing neurons ultimately die an apoptotic death, autophagy was induced prior to cell death and significantly protected polyQ-AR expressing neurons from cell death. These results suggest that neurons are capable of inducing autophagy via a canonical pathway, and that autophagy can protect neurons from misfolded protein stress in inherited neurological diseases.

Association analysis of *NGFB* suggests a different genetic contribution to primary vs. substance-induced affective disorders. *DH. Cui[1,4], H. Zhang[1,4], H. R. Kranzler[5], H. P. Blumberg[1,4], A. R. Tyrka[6], BZ. Yang[1,4], F. Wei[1,4], L. L. Carpenter[6], L. H. Price[6], J. Gelernter[1,2,3,4]* 1) Dept Psychiatry, Yale Univ, West Haven, CT; 2) Dept Genetics, Yale Univ, School Med, New Haven, CT; 3) Dept Neurobiology, Yale Univ, School Med, New Haven, CT; 4) VA CT Healthcare Center, West Haven, CT; 5) Dept Psychiatry, Univ. of CT, School Med, Farmington, CT; 6) Dept. Psychiatry & Human Behavior, Brown Univ, Providence, RI.

Affective disorders (AFD), characterized by extremes of mood, are genetically influenced. We genotyped 1536 SNPs in or near 135 candidate genes in 868 European-American (EAs) and 348 African-American (AAs) using an Illumina GoldenGate Array. HelixTree software was used for association analysis. We focused on nerve growth factor (*NGFB*) gene. There was evidence for significant association to AFD of 4 of 15 SNPs genotyped in *NGFB* in EAs, and of 1 SNP in AAs. We re-analyzed these 15 SNPs using Haploview and FBAT software for case-control and family samples, respectively. Among 868 EAs, 372 were affected with AFD, including 182 with primary AFD (PAFD), 190 with AFD that was comorbid with drug dependence (CAFD), and 472 screened controls. Among 348 AAs, 164 were CAFD and 184 were controls. The family sample included 198 subjects in 77 EA families and 131 subjects in 49 AA families, with all affected subjects CAFD. 4 SNPs were associated with EA AFD (p=0.004-0.048). After stratification analysis, among EAs, 6 SNPs were significantly associated with PAFD (p=0.003-0.036), but none were associated with CAFD. In AA, 2 SNPs showed nominal association to CAFD (p=0.019 and 0.042). No markers were associated in the family sample. In haplotype analysis, these 15 markers formed 3 blocks in both the EA and AA populations. In EAs, TGG in block1 and AC and GT in Block2 were significantly associated with AFD (p=0.004-0.034). After stratification analysis, GG (p=0.0035) and AA (p=0.0035) in block3 were significantly associated with EA PAFD, as were TGG (p=0.037) and AC (p=0.0058). No haplotypes were significantly associated with CAFD in EAs or AAs. We conclude that *NGFB* is a risk gene for PAFD, but not for CAFD, suggesting that PAFD and CAFD have different genetic contributions.

Sequencing Candidate Genes for familial Thoracic Aortic Aneurysms and Dissections. *D. C. Guo[1], L. Wang[1], L. Li[1], N. Avidan[1], V. Tran-Fadulu[1], H. Pannu[2], S. Scherer[3], D. M. Milewicz[1]* 1) Dept Internal Medicine, Univ Texas/Houston Med Sch, Houston, TX; 2) Dept Nerosurgery, Univ Texas/Houston Med Sch, Houston, TX; 3) Hum Genome Center, Baylor College of Medicine, Houston, TX.

Thoracic aortic aneurysms leading to aortic dissections are inherited primarily in an autosomal dominant manner (FTAAD). Studies have determined that there is significant genetic heterogeneity for FTAAD; 4 genes have been identified through positional cloning that account for 20% of the disease. Mutations in genes for smooth muscle cell (SMC)-specific isoforms of two contractile proteins, alpha actin (ACTA) and beta-myosin (MYH11), are responsible for 14% and <1% of FTAAD, respectively. Since mutations in various components of the cardiac contractile unit lead to hypertrophic cardiomyopathy, we hypothesized that mutations in genes encoding other components of the SMC contractile unit may lead to familial TAAD. We have sequenced 16 candidate genes in 94 DNA samples from affected individuals from unrelated FTAAD families. DNA sequencing identified 24 novel nucleotide alterations in the coding regions of 12 genes. Sequencing of DNA from the probands families confirmed that 10 novel alterations in 8 genes segregate with TAAD in the families. These alterations are not present in 100 ethnically matched controls. Five alterations disrupted amino acids that are highly conserved and are predicted to disrupt the protein structure (http://genetics.bwh.harvard.edu/pph/). For example, a novel missense mutation alters the calmodulin binding domain of myosin light chain kinase (MYLK, S1759P). Phosphorylation of S1759 regulates MYLK activity by preventing calmodulin activation of MYLK and the mutation is predicted to similarly prevent calmodulin binding. These results support that hypothesis that genes encoding other components of the SMC contractile complex lead to FTAAD. Furthermore, this candidate gene approach has the potential to rapidly identify additional genes leading to FTAAD.

Pseudoaminopterin syndrome: case report with new characteristics. *M. Cernach, D. Brunoni, N. Sobreira, A. Perez*
Centro de Genetica Medica, UNIFESP-EPM, Sao Paulo, Brazil.

Fetuses exposed to aminopterin during the 8th-9th week of development may show aminopterin embryophathy (AE). Surviving children have a very specific phenotype that included unusual face, skull, and skeletal abnormalities. In 1987, Fraser et al. described 2 children with multiple malformations characteristic of the aminopterin syndrome but without any evidence of exposure to aminopterin in the mothers and suggested that this represents a new syndrome, the aminopterin syndrome-like sine aminopterin (ASSA) syndrome. Stevenson et al. (2004) described a male twin of a 40-year-old Hispanic mother born at 32 weeks of gestation with trisomy 9 and findings similar to pseudoaminopterin syndrome. It is also possible that a cryptic duplication involving part of chromosome 9 could contribute to the phenotype seen in patients with pseudoaminopterin syndrome. Here we describe a girl, 9 years old, born to unaffected first cousin parents. She has short stature, microcephaly, broad forehead with high hair implantation, central verticil; sparse and fine hair, areas of alopecia; arched eyebrows with upturned hair, synophris; ocular hypertelorism, epicanthal folds, palpebral ptosis; oligodontia; low-set and small ears with antihelixes hypoplasia; brachydactyly, bilateral clinodactyly of the 4th and 5th fingers; hypoplasia of the 4th metacarpal and clinodactyly of the 4th and 5th toes; overlap of the second over the third toe; bilateral hip luxation. Echocardiogram showed patent foramen ovale and pulmonary congenital disease. Abdominal ultrasound showed left posterior diaphragmatic hernia, absence of spleen and horseshoe kidney. She and her mother have a karyotype with 46, XX, inv9qh what have been described like a polymorphism, but, because of the possible involvement of chromosome 9 in ASSA, the CGH array will be done in this patient. Although this patient has some characteristics did not describe before in patients with ASSA syndrome, like: oligodentia,diaphragmatic hernia, absence of spleen, and horseshoe kidney, her phenotype suggest she has ASSA syndrome. However, we do not exclude the possibility that this is a different condition not described previously.

Altered Cytokine Signaling in Vascular Ehlers Danlos Syndrome (vEDS). *T. K. Cooper[1,3], Q. Zhong[1], U. Schwarze[2], M. Pepin[2], P. Byers[2], H. C. Dietz[3]* 1) Hershey Medical Ctr; 2) Univ of Wash; 3) Johns Hopkins.

vEDS is a severe connective tissue disorder caused by deficient type III collagen (Col3) due to intracellular retention and/or degradation of the mutant protein. Affected patients die prematurely due to rupture of arteries throughout the circulation. Historically, it has been inferred that disorders caused by mutations in connective tissue proteins manifest an obligate predisposition for tissue failure due to loss of structural integrity. This tenet has recently been challenged and refuted for Marfan syndrome (MFS), where a deficiency of fibrillin-1 leads to failed matrix regulation of TGF, and TGF antagonists can attenuate most manifestations in mouse models. Phenotypic overlap has been observed between vEDS and Loeys-Dietz syndrome, another vascular disease associated with increased TGF signaling. On this basis, we considered alternative pathogenetic mechanisms for vEDS. The Col3 N-terminal propeptide (Col3Npep) has curious properties including extreme evolutionary conservation, increased length for a signal peptide and apparent structure with 10 predictably spaced cysteine residues. Col3Npep shows substantial homology with the CR domains in chordin, an extracellular antagonist of TGF superfamily members, prominently the bone morphogenetic proteins (BMPs). Expression of recombinant Col3Npep in normal cells did not cause accumulation of pSmad2 (a mediator of TGF signaling) in response to TGF1 stimulation; this response was also normal in cultured vEDS fibroblasts. In contrast, expression of Col3Npep in control vascular smooth muscle cells reduced pSmad1/5 (a marker and mediator of BMP signaling) in response to BMP7. By extension, we hypothesized that vEDS cells that fail to secrete appropriate levels of Col3Npep would show increased BMP signaling. Indeed, cultured vEDS fibroblasts show increased accumulation of pSmad1/5 after pulse stimulation with BMP7 and at steady state when grown in the presence of 20% serum. We are currently analyzing a mouse model of vEDS and plan a therapeutic trial with a BMP antagonist. The propetide of other fibrillar collagens shares homology with chordin, highlighting the potential relevance to other collagenopathies.

The eMERGE Network: A national consortium of electronic health record-linked biobanks furthering large-scale genetic research. *W. A. Wolf[1], R. L. Chisholm[1], C. G. Chute[2], G. Jarvik[3], E. Larson[3], D. R. Masys[4], C. A. McCarty[5], D. M. Roden[4], J. P. Struewing[6]* 1) Northwestern University, Chicago, IL; 2) Mayo Clinic, Rochester, MN; 3) Group Health Cooperative/University of Washington, Seattle, WA; 4) Vanderbilt University, Nashville, TN; 5) Marshfield Clinic Research Foundation, Marshfield, WI; 6) National Human Genome Research Institute, Bethesda, MD.

Medical research institutions are developing biorepositories of genomic DNA coupled to electronic health record (EHR) information generated by routine clinical care. The goal of the Electronic Medical Records and Genomics (eMERGE) Network (www.gwas.net), organized by NHGRI in late 2007, is to investigate how such resources can be leveraged for genome and informatics science, with extensive ELSI input. Each of the five participating sites will use natural language processing or other tools to identify cases with defined phenotypes and controls for genome wide analyses in ~15,000 subjects, and will share data with the scientific community through NIHs dbGaP. The target phenotypes include asthma, type II diabetes, low HDL, cataracts, myocardial infarction, peripheral arterial and carotid disease, normal QRS duration, late life dementias (Alzheimers disease), and statin adverse events. Initial studies underway include testing computational algorithms to identify subjects meeting phenotype criteria, comparing these tools across diverse EHR systems, assessing the potential for combining cases or controls from different sites, and initiation of mechanisms to optimize community consultation. The goal of these studies is to contribute to our understanding of disease and develop recommendations to improve the utility of EHRs for research, setting the stage to integrate genomic and EHR data to achieve the vision and inform best practices for personalized medicine.

Genome-wide Association Study of Parkinson's disease by using 550K SNP Array. *W. Satake[1, 2], Y. Nakabayashi[1], I. Mizuta[1], T. Kawaguchi[3], T. Tsunoda[3], M. Kubo[3], S. Sakoda[2], M. Yamamoto[4], N. Hattori[5], M. Murata[6], Y. Nakamura[3], T. Gasser[7], A. B. Singleton[8], T. Toda[1]* 1) Div Clinical Genetics, Osaka Univ Grad Sch Med, Suita, Osaka, Japan; 2) Dept Neurol, Osaka Univ Grad Sch Med, Japan; 3) Cent Genomic Medicine, RIKEN, Japan; 4) Dept Neurol, Kagawa Prefectural Central Hosp, Japan; 5) Dept Neurol, Juntendo Univ Sch Med, Japan; 6) Dept Neurol, Musashi Hosp, NCNP, Japan; 7) Dept Neurodegenerative Diseases, Univ Tübingen, Germany; 8) Molecular Genetic Unit, Lab Neurogenetics, NIA/NIH, USA.

Parkinson's disease (PD), one of the most common neurodegenerative disease, is caused by multiple genetic and enviromental factors. We performed a Genome-Wide Association Study of PD, using Illumina HumanHap550 Array. Subjects were 1,012 PD patients and 2,573 controls (Sample call rate0.95) of Japanese ancestry. After SNP QC filter (a SNP call rate0.95, a MAF0.05, and HWE with a P0.001), high quality genotypes of 438,886 common SNPs were obtained (the average SNP call rate was 0.999). We excluded the samples with the cryptic duplicate and relatedness (MZ twin and 1-2 degree) through computing IBS probabilities, and the individuals who seemed to have non-Japanese ancestry were also excluded using multidimensional scaling. After these exclusions, 988 cases and 2,521 controls remained for the analysis. Genomic control method indicated that there was little evidence of any general inflation of the test statistics (genomic inflation factor = 1.05). We assessed each SNP for association with PD using a Cochran-Armitage trend test. A total of 127 SNPs were significant at the $P < 10^{-4}$. The most significant SNP was rs11931074 ($P=6.17 \times 10^{-13}$) and its neighbors, located in the 7 kb downstream - intron 4 of -synuclein. The second most significant locus included the EST on ch11q25 ($P=5.6 \times 10^{-7}$), which was newly identified as a potential susceptibility for PD. The MAPT locus was not identified significant in our study, because, unlike Caucasian, risk SNPs in the MAPT locus were monomorphic in the Japanese population, suggesting genetic heterogeneity of PD among races. Our finding will play an important role in clarification of the etiology of PD.

Identification of putative bipolar disorder susceptibility gene on chromosome 15q25-26. *J. A. Donald[1], E. Z. McAuley[2,3], J. M. Fullerton[2,3], I. P. Blair[3,4], P. B. Mitchell[5,6], P. R. Schofield[2,3]* 1) Dept Biological Sci, Macquarie Univ, Sydney, Australia; 2) Prince of Wales Medical Research Institute, Sydney, Australia; 3) Faculty of Medicine, University of New South Wales, Sydney, Australia; 4) ANZAC Research Institute, Sydney, Australia; 5) School of Psychiatry, University of New South Wales, Sydney, Australia; 6) Black Dog Institute, Prince of Wales Hospital, Sydney, Australia.

Previous linkage studies of mood and psychotic disorders have implicated a susceptibility locus on 15q25-26. We have also reported significant linkage to this region (two-point LOD 3.38 at D15S130) using 35 Australian multigenerational pedigrees affected with broad definition bipolar disorder (McAuley et al. Molecular Psychiatry, in press). Here we present the results of a positional association study to identify putative candidate genes under the linkage peak. We identified a 6.2Mb candidate region defined by the Zmax-1 linkage confidence interval and further mapped recombination breakpoints from family specific haplotypes to define a 2.7Mb high priority region. We selected a total of 376 SNPs at 20k resolution across the 6.2Mb interval, with increased resolution across the high priority region, for genotyping and association analysis in an Australian case-control cohort, comprising 187 cases and 199 controls. Association analysis identified 16 SNPs with uncorrected p 0.05, 13 of which lie in the high priority region, and 8 of which cluster in a 63kb window spanning exons 1-4 and including 16kb upstream of ST8SIA2. Haplotype analysis reveals a 6 SNP block which is overtransmitted to cases compared to controls (0.42 vs 0.32; global p = 0.034, haplotype specific p = 0.007). These data implicate ST8SIA2 as a putative bipolar susceptibility gene within the 15q25-26 linkage region. Interestingly, this gene has previously been reported in association with schizophrenia in Japanese and Chinese cohorts, and provides an attractive functional candidate which may constitute a general susceptibility factor to both schizophrenia and affective disorders.

Population Structure in Mongolia from a Mitochondrial DNA Perspective. *L. Pipes[1], A. A. Pai[2], D. Labuda[3], T. G. Schurr[2]* 1) Department of Biology, Swarthmore College, Swarthmore, PA; 2) Department of Anthropology, University of Pennsylvania, Philadelphia, PA; 3) Department of Pediatrics, University of Montreal, Quebec, Canada.

Mongolia has experienced a complex series of demographic movements over the past 10-20 millennia that have shaped the patterns of its modern human genetic variation. However, modern populations in Mongolia have not been extensively studied for DNA diversity, nor has the genetic contribution of Mongolians to the gene pools of contemporary populations in Southeast Asia and Oceania been fully resolved. Archaeological evidence from as early as the late Neolithic suggests the presence of both West and East Eurasian cultures in this region. Later demographic movements involving the emergence of the Mongolian and later Manchu Empires have further convoluted Mongolias population structure. To clarify the complex population history of Mongolia, we analyzed variation in the mtDNAs of 190 individuals from several Mongolian ethnic groups, including the Uriankhai, Zakhchin, Derbet, Khoton and Khalkha. We screened all samples for phylogenetically informative coding region SNPs and sequenced HVSI to assess control region variation in them. Our data suggest that the mtDNA diversity present in our population is consistent with the general pattern of variation observed in East Asia, with the most frequent haplogroups being C, D and G. Haplogroup variation in Mongolian ethnic groups reveals considerable maternal diversity with a predominance of basal M types. Interestingly, the Mongolians also possessed West Eurasian haplogroups, such as H, J and K, which are not commonly observed in East Asia, even at low frequencies. The main ethnic group in Mongolia, the Khalkha, was highly variable with respect to mtDNA haplotypes in comparison with the other ethnic groups, and clearly distinct from the Khoton and Zakhchin, as evidenced by distance measures. Overall, these data provide insights into the origins and affinities of these populations, their relationships with East Asian groups and neighboring Turkic speaking groups, including indigenous Altaians, and their possible role in the peopling of the Americas.

Genomewide associations with 10 nuclear magnetic resonance (NMR) subfractions of LDL, VLDL, and HDL among 12,000 Caucasian women from the WGHS. *D. Chasman[1], S. Mora[1], G. Paré[1], R. Zee[1], A. Parker[2], J. Miletich[2], P. Ridker[1]* 1) Preventive Med, Brigham & Women's Hosp, Boston, MA; 2) Amgen, Inc., Cambridge, MA.

While measurement of the standard clinical lipid fractions LDL, HDL, and triglycerides is invaluable for managing cardiovascular disease, measurement of subfractions of these lipoproteins by NMR reveals greater detail about lipid metabolism and may provide deeper insights into lipid-based cardiovascular risk. Specifically, NMR techniques can resolve LDL, HDL, and VLDL particles according to physical size (and thus density and composition), allowing determination of plasma concentration for four subfractions of LDL, as well as three subfractions each of HDL and VLDL. To better understand the full spectrum of genes and genetic variants influencing the NMR lipid subfractions, we performed a genomewide association study among 12,000 participants in the Womens Genome Health Study (WGHS) with verified Caucasian ancestry. The analysis revealed 23 loci at genomewide significance ($P5x10^{-8}$), almost all of which were consistent with current knowledge about lipid metabolism. Two loci, *FADS1/FADS2* (rs1535 for large LDL and HDL) and *PLTP* (rs6065906 for small HDL) were identified exclusively on the basis of genomewide associations with NMR subfractions and not with the conventional measurements of LDL, HDL, or triglycerides. An additional genomewide association in a gene-free region of 16p13.2 (rs1466405) with the NMR assay triglycerides appears to be entirely novel and was confirmed at sub-genomewide significance in the conventional measure of triglycerides. Our analysis further identified a broad range of association modes, with some variants exerting similar effects on several NMR subfractions at once (e.g. rs714052 at *MLXIPL* for subfractions of VLDL), others specifically influencing only one or two NMR subfractions (e.g. rs6709906 at *ABCG5/8* for large LDL), and still others having reciprocal effects on the NMR subfractions (e.g. rs5880, rs5883, and rs3764261 at *CETP* for subfractions of LDL and HDL). Thus, the study reveals highly detailed relationships among genetic determinants of plasma lipid subfractions as well as one novel associated locus.

SNP arrays in the cytogenomics lab: Telling us things we didnt know. *B. D. Thiel[1], L. K. Conlin[1,2], D. Dipatri[1], X. Gai[1], M. Xie[1], J. C. Perin[1], T. H. Shaikh[1,2], P. White[1], J. Glessner[1], C. Kim[1], L. M. Medne[1], C. Bonnemann[1], L. Campbell[1], D. Clark[1], I. D. Krantz[1], H. Hakonarson[1], N. B. Spinner[1,2]* 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) The University of Pennsylvania, Philadelphia, PA.

Array based platforms are now becoming standard in the cytogenetics laboratory due to their superb resolution for identification of genomic abnormalities. While CGH platforms have been the most frequently used to date, SNP genotyping arrays are proving to be outstanding for identifying abnormalities as well as providing mechanistic insights into complex rearrangements. We have validated the Illumina Human Quad610 SNP array for use in our clinical cytogenetics laboratory, detecting all of the known abnormalities (200 kb, 20 SNPs) in a test set of 117 patients with deletions or duplications. We also studied a group of 176 patients with unknown diagnoses and identified numerous abnormalities that were below the resolution of standard cytogenetics, including deletions, duplications, hidden mosaics, uniparental isodisomy, and patterns of meiotic crossing over that lead to complex chromosomal aberrations. We identified 55 variants (31%; 19 deletions/36 duplications), whose pathogenicity we could not completely predict (parental studies pending). We were also able to identify a change we believe is pathogenic in 17 patients (10%) including 10 deletions (6 novel,1 novel mosaic and 3 known), 5 duplications (2 novel, 3 known), and 2 complex rearrangements. One whole chromosome mosaic that had been missed by cytogenetic analysis (mos +14) was identified. In this case, genotype information revealed the mechanism as nondisjunction after crossing over in meiosis I. The most complex patient had XX and XY cell lines, and analysis of his genotype revealed him to be a parthenogenic chimera, with the XX cell line derived completely from the maternal genome. These unusual patterns of inheritance could only be identified using the intensity data in combination with the genotyping data offered on the SNP array platform. This work highlights the utility of the SNP array platform in both the clinical research cytogenetic laboratory.

Association between dopamine D4 receptor (*DRD4*) -521 C/T polymorphism and sensation seeking behavior in female alpine skiers and snowboarders. *C. J. Thomson[1], C. W. Hanna[2], P. Wang[1], K. L. Morton[1], M. R. Beauchamp[1], J. L. Rupert[1]* 1) School of Human Kinetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Department of Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada.

Previous research has shown a large genetic influence over personality traits, especially sensation seeking (SS). One gene thought to influence this behavioral trait is *DRD4*, in which variants have been associated with SS and novelty seeking in some, but not all studies. The inconsistencies between studies may be due to heterogeneity in both the behaviors and the populations being assessed. Some studies included only males and few studies have *a priori* analyzed males and females separately. SS has been associated with high-risk sports, including skiing; however this is the first study to address the possibility that genetics may play a role in individuals inclination towards SS in sport. Using the Contextual Sensation Seeking Questionnaire for Skiing (CSSQ-S), developed and validated for this study, and the Zuckerman-Kuhlman Personality Questionnaire (ZKPQ), levels of SS in males and females were analyzed in association with -521 C/T. Behavioral analysis of skiers (N = 201) revealed a significant correlation (r^2= 0.497, p 0.001) between skier behavior (CSSQ-S) and skier personality scores (ZKPQ). Preliminary genotype analysis (N = 50, ongoing) revealed allele frequencies of 0.52C and 0.48T. A significant association was found between the T allele (CT and TT genotypes) and low contextual skiing SS behavior in the females (N = 25, p = 0.04, ^{2} = 0.2), along with a non-significant trend between ZKPQ SS scores and -521 C/T (p = 0.06). No association, however, was found in males (N=25, p = 0.97). This study supports the hypothesis that alleles of the *DRD4* -521 C/T polymorphism are associated with context-specific SS behaviors in females, but not in males. Whether the lack of association in males is due to variations in the biochemical properties of the dopamine receptor or whether social pressures differentially influence male and female sensation-seeking behavior are areas that require further investigation.

Chromosomal Translocation t(5;7)(q14;q31) and Missense Mutations Implicate the Voltage-Gated Potassium Channel Kv4.2 gene, KCND2, on 7q31 in Autism. *A. Mikhailov[1], S. Choufani[2], J. Skaug[2], D. Kolozsvari[2], C. Marshall[2], S. W. Scherer[2], J. B. Vincent[1]* 1) Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) The Hospital for Sick Children, Toronto, Canada.

Autism or autistic disorder (AD; MIM 209850) has a prevalence of 3-7/1000 among children. Evidence suggests that multiple interacting genetic factors are involved in AD, but the identity and the exact number of genes remain unknown. Numerous genome-wide linkage studies have suggested that chromosome 7q may harbour susceptibility gene or genes for autism and a number of reports have also identified AD patients with cytogenetic abnormalities mapping to this region. We have identified a male autism patient with a balanced de novo translocation t(5;7)(q14;q31). We have mapped the 5q and 7q translocation breakpoints using fluorescence in situ hybridization (FISH) and have identified BAC clones spanning both breakpoints. A patient with speech and language disorder and developmental delay with translocation t(2;7)(p23;q31.1), was reported by Lai et al, 2000, where the breakpoint maps within ~100Kb of the 7q breakpoint in our subject. For KCND2, the closest coding gene to these two 7q31 breakpoints, an amino acid sequence variant N544S was identified in one proband.Upon further direct sequencing analysis of about a 1000 unrelated autism probands, two additional sequence variants,F538S and R539L, were identified in two unrelated probands. It is notable that all three sequence variants are within a region of 5 amino acids and might indicate an important functional region. *KCND2* encodes the brain-specific voltage-gated potassium channel Kv4.2 (Shal-related). Kv4.2 is critical in controlling the excitability of neurons, and is regulated at the synapse by PSD-95. Other synaptic proteins have already been implicated in autism, such as neuroligins 3 and 4, neurexin 1, SHANK3, also dipeptidyl-peptidase-like proteins DPP6 and DPP10. Interestingly, Kv4.2 forms complexes with DPP6 and DPP10 to generate neuronal subthreshold A-type channels. These important findings implicate the KCND2 gene in autism and extend our understanding of a neurobiological pathway involved in the etiology of autism.

Mitochondrial D-loop genetic variation is associated with frailty in Caucasians from the Cardiovascular Health Study (CHS). *S. McGuire[1], M. L. Biggs[2], A. L. Rea[1], A. O'Connor[1], B. Beamer[3], M. D. Fallin[4], A. Chakravarti[1], L. P. Fried[5], J. Walston[3], D. E. Arking[1]* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Dept of Biostatistics, University of Washington Sch Public Health and Community Medicine, Seattle, WA; 3) Div of Geriatric Medicine and Gerontology, Johns Hopkins University Sch Med, Baltimore, MD; 4) Bloomberg Sch of Public Health, Johns Hopkins University, Baltimore, MD; 5) Mailman Sch Public Health, Columbia University Medical Center, New York, NY.

Frailty is a geriatric syndrome characterized by reduced muscle strength, mobility and physical activity, and vulnerability to adverse health outcomes. A compelling case can be made that dysregulation of energy metabolism, whose key components are encoded by the mitochondrial genome, can lead to tissue function decline, and ultimately phenotypic changes that may underlie frailty. To investigate whether inherited genetic variation in the mitochondrial genome is associated with frailty, we fully resequenced mtDNA from 157 younger frail cases (mean age=77.8, 42 males and 115 females) and 157 older robust controls (mean age=81.9, 41 males and 116 females) drawn from CHS, a longitudinal study of adults 65 years and older designed to identify risk factors and outcomes of cardiovascular disease. Frailty was defined as the presence of 3 of 5 frailty components (weakness, slowness, weight loss, exhaustion, and low physical activity) at baseline. Participants were excluded based on the presence of confounding medical conditions, including stroke, Parkinsons disease, or dementia, and given the limited number of non-Caucasians they were also excluded. Only 1 SNP, mt204 in the D-loop, was found to be significantly associated with frailty after multiple test correction using permutation (P0.001). In sex-stratified analyses, we identified a male-specific association for mt146 (P0.003) and female-specific association for mt228 (P0.041). These results indicate that mitochondrial variation may have an impact on frailty susceptibility in Caucasian populations, and involvement of the D-loop suggests that the mechanism may involve altered mitochondrial replication efficiency.

Regulation of ATM recruitment to damaged DNA. *P. Bradshaw[1], M. S. Meyn[1,2,3]* 1) Prog Genetics & Genome Biol, Hospital for Sick Children, Toronto, ON, Canada; 2) Dept Molecular Genetics, Univ of Toronto, Toronto, ON, Canada; 3) Dept Paediatrics, Univ of Toronto, Toronto, ON, Canada.

ATM, the protein kinase deficient in the cancer predisposition syndrome ataxia-telangiectasia, controls the major DNA double strand break (DSB) repair pathway in human cells. Accumulation of MRN-activated ATM protein at DSB sites leads to local phosphorylation of ATM target proteins and creation of regions of modified chromatin that serve as scaffolds for repair proteins. In order to better understand ATMs role in the DNA damage response, we generated DSBs in predefined nuclear regions of human fibroblasts with UVA light + Hoechst dye. ATM is detected at photo-induced DNA damage as early as sixty seconds post damage and prior to the DNA damage response factors H2AX and 53BP1. Unlike H2AX, ATM does not persist at damage sites, as maximal accumulation of ATM occurs between ten and thirty minutes post damage. We find that ATM displays tight spatial localization with damaged DNA, in contrast to progressively diffuse foci formed by Mre11, H2AX, 53BP1 and Rif1. Consistent with this observation, FRAP data indicates that GFP-tagged ATM is stably associated with DNA damage sites. Accumulation of both endogenous ATM and GFP-ATM at DNA damage sites is undetectable in cells deficient in Mre11, a component of MRN. In contrast, mutating the ATM 1981 phosphorylation site from serine to alanine impaired but did not block accumulation of GFP-ATM. Further, over-expression of the telomeric protein TRF2, but not the related protein TRF1, attenuates GFP-ATM accumulation at DNA damage sites and impairs phosphorylation of ATM, H2AX and p53. Our data indicate that ATM differs from many DNA damage response proteins in its rapid, localized association with damaged DNA, behavior consistent with idea that ATM stably associates with DSBs. ATM recruitment to damage sites requires functional MRN, while optimal accumulation of ATM at damaged DNA entails phosphorylation at serine 1981. In contrast, interactions with TRF2 dampen the ATM response to DSBs, suggesting TRF2/ATM interactions promote local repair of DNA damage while inhibiting ATM-dependent global DNA damage responses.

A family study using a novel ascertainment strategy replicates locus linked to plasma Factor XII activity on 5q33 and identifies novel loci on 8q24 and 1p36. *F. Gagnon[1], G. Antoni[1], Y. Luo[1], A. Tuite[1], D. Bulman[2], P. Wells[2]* 1) School of Public Health, Univ Toronto; 2) Ottawa Health Research Institute, Canada.

We took advantage of a common and well-characterized major gene variant associated with venous thromboembolism (VTE), i.e. Factor V Leiden (F5L), to localize Quantitative Trait (QT) loci underlying variation in plasma Factor XII activity (FXII). FXII is correlated to VTE and has emerged as a promising therapeutic target with reduced bleeding risk. Identifying FXII QT loci will provide clues as to the mechanisms underlying VTE, as well as better risk profiling opportunities for its prevention. We ascertained five extended French-Canadian families on a proband not only having a history of VTE, but also carrying the major gene variant F5L, with the goal of reducing genetic and clinical heterogeneity; and measured ~30 hemostatic/lipid QT, along with environmental covariate data, in all members (n=267). We did a genome-wide oligogenic linkage analysis (1079 microsatellites) of FXII, based on Bayesian MCMC methods and covariate adjustments. We provide evidence for 3 QT loci located on chromosome (ch) 5, 8 and 1, with posterior probabilities of linkage (computed as Intensity Ratios in 2 cM interval) of 240, 87 and 25, respectively. The ch5 locus corresponds to the F12 gene, which has been implicated in variation of FXII in the GAIT (Genetic Analysis of Idiopathic Thrombophilia) study. The ch8 (8q24) and ch1 (1p36) loci are novel. Adjusting for anti-thrombotic treatment did not affect the signal on ch8 but decreased by ~ 50% the signals on ch5 and ch1. Adding F5L in the model did not modify the linkage signals on ch5 and ch1 but reduced it by ~35% on ch8, suggesting that the latter locus interacts with F5L. We are investigating pleiotropic effects with other QT/VTE, as well as epistasis. In conclusion, using innovative ascertainment and analytic strategies, we localized strong linkage signals for FXII, demonstrating that it is possible to detect linkage with a relatively small but carefully selected sample. Attempts to replicate the loci will be done in two independent French samples with complementary designs.

SNP allele differentiation provides independent confirmation of genomic imbalance. *J. H. Tepperberg, I. Gadi, B. Williford, V. Jaswaney, J. Kesler, P. R. Papenhausen* Dept Cytogenetics, Laboratory Corp America, Res Triangle Pk, NC.

The whole genome 1.8 million feature SNP/copy number microarray (Affymetrix, Inc.) provides high-resolution detection of DNA copy number changes in individuals with idiopathic mental retardation and developmental delay. One of the unique features of the SNP based microarray is the specific SNP allele difference confirmation of DNA copy number changes and designation of copy neutral homozygosity correlated with UPD and consanguinity. The SNP allele call is not dependent on copy number changes and therefore provides a secondary confirmation of genomic aberrations. The specific allele designation was found to be essential for the precise identification of true gain and loss and base pair boundary determination required for precise genotype-phenotype correlation. This polymorphic nucleotide allele difference provides confirmation by identifying regions of loss of heterozygosity associated with deletions, allele specific dosage gain associated with duplications, and long contiguous stretches of homozygosity (LCSH) associated with UPD and consanguinity. For example, only one SNP allele possibility exists for all targets within a deletion interval or within regions of homozygosity (i.e., no heterozygosity, only alleles A or B). The absence of heterozygosity becomes confirmation of the deletion segment. Four possible SNP genotype clusters are generated across duplicated intervals (AAA, AAB, ABB, BBB). The dosage ratio of these genotypes provides confirmation of the duplicated chromosomal segment. Three SNP clusters (AA, AB, BB) would indicate the absence of a true duplication. The SNP allele dosage differentiation is thus a powerful independent confirmation of chromosome copy number aberrations and reduces the need for secondary follow-up in the proband. We will present characteristic patterns of allele specific copy number analyses of microdeletions (including nullosomy X), duplications and copy neutral LOH associated with LCSH. Further applications would be to use the SNP allele dosage percentage to evaluate constitutional low-level mosaicism and DNA amplification in oncology.

NRG1 SNPs associated with the schizophrenia phenotype in Hispanic Populations. *H. Raventos[1], J. M. Peralta[2], C. Walss-Bass[3], A. Ontiveros[4], H. Nicolini[5], R. Mendoza[6], L. Almasy[2], M. Escamilla[3]* 1) CIBCM, Univ Costa Rica, San Pedro, San Jose, Costa Rica; 2) Soutwest Foundation for Biomedical Research, San Antonio, TX; 3) Department of Psychiatry, University of Texas Health Science Center, San Antonio, TX; 4) Center of Investigation, School of Medicine, INFOSAME, Monterey, Mexico; 5) Medical and Family Research Group, Carraci S. C, Mexico DF; 6) Department of Psychiatry, David Geffen School of Medicine at UCLA, Torrence, CA.

The neuregulin 1 gene (NRG1) represents one of the most promising candidate genes associated with schizophrenia (SC). The evidence comes both from positive linkage findings on chromosome 8p12-p21 and association studies in several populations including Iceland, Scotland, the United Kingdom, China, Japan and Costa Rica. In this multi-centric schizophrenia study, we analyzed 662 Hispanic multiplex families, recruited from the Southwest USA, Mexico and Costa Rica. Patients were diagnosed by a consensus best estimation process based on DSMIV criteria. Two different affected/unknown phenotypes were constructed for analysis based on best estimated diagnosis: SC (n=472) and PHIST, patients with psychosis history regardless of their primary diagnosis (n=684). A total of 69 SNPs covering the ~1MB of the NRG1 gene were typed by Illumina with a custom SNP array. Association analyses were conducted on both, SC and PHIST, phenotypes with the 69 SNPs targeting NRG1 using FBAT under the assumption of an additive biallelic model. We found strong association between SC and rs10093683 (|z|=2.633, p=0.008) and in a lesser degree with rs3924999 (|z|=2.062,p=0.039), rs12547858 (|z|=2.180, p=0.029), rs13259346 (|z|=2.104, p=0.035) and rs2439322 (|z|=2.046, p=0.041). Also, rs10093683 (|z|=2.152, p=0.031) together with rs7812718 (|z|=2.334, p=0.020) were slightly suggestive of association with PHIST. None of these results are significant after a Bonferroni correction for the non-independence of the tests (=0.004). However, with a less conservative RFDR (=0.025) some of the results are still significant.

Whole Population, Genomewide Mapping of Hidden Relatedness. *A. Gusev[1], J. K. Lowe[2,3,4], M. Stoffel[5], M. J. Daly[3,6,7], D. Altshuler[3,4,7,8], J. L. Breslow[2], J. M. Friedman[2,9], I. Pe'er[1]* 1) Columbia University, NY, NY; 2) The Rockefeller University, NY, NY; 3) Broad Institute, Cambridge, MA; 4) Dept of Molecular Bio, MGH, Boston, MA; 5) ETH Zurich, Zurich, Switzerland; 6) Ctr for Human Gen Res, MGH, Boston, MA; 7) Dept of Medicine, HMS, Boston, MA; 8) Dept of Genetics, HMS, Boston, MA; 9) Howard Hughes Med Institute, Chevy Chase, MD.

Identifying and quantifying the sharing of genetic material between individuals within a population is an important step in accurately using genealogical relationships for disease analysis as well as improving our understanding of demography. However, exhaustive pairwise analysis which has been successful in small cohorts cannot keep up with the current torrent of genotype data. We present GERMLINE, a robust algorithm for identifying pairwise segmental sharing which scales linearly with the number of input individuals. Our approach is based on a dictionary of haplotypes, used to efficiently discover short exact matches between individuals and then expand these matches to identify long, nearly-identical segmental sharing that is indicative of relatedness. We use GERMLINE to survey hidden relatedness both in the HapMap and in a densely typed island population of 3,000 individuals. We verify that GERMLINE is in concordance with other methods when they can process the data, and also facilitates analysis of larger scale studies. We also demonstrate novel applications of precise analysis of hidden relatedness to detection of haplotype phasing errors and structural variation. We show that shared segment discovery can help identify phasing errors and potentially resolve them. Additionally, we use detected identity of genomic segments to expose polymorphic deletions that are otherwise challenging to detect, with 8/14 deletions in the HapMap samples and 153/200 deletions in the island data having independent experimental validation. Reinforcing the potential for a population-based approach to linkage analysis, we have successfully begun applying GERMLINE to larger and more out bred populations, as well as to quantitative trait mapping using shared haplotypes - identifying a novel haplotype associated with an increase in plant sterol levels.

Identifying Balanced Translocation Embryos and Normal Embryos, using combine method of FISH and Polymorphic Markers in PGD analysis. *A. Aviram-Goldring, J. Shamash, H. Resnik-Wolf, J. Dor, J. Levron, M. Dekel, E. Pras, S. Rienstein* Danek Gertner Institute of Human Genetics, Sheba Medical Center,Tel Hashomer, 52621 Tel Aviv, Israel.

Purpose: Our goal was to develop an improved PGD method by combining FISH and segregation mode of polymorphic markers. By using those methods, we can identify balanced, unbalanced and chromosomally normal embryos, and avoid implantation of affected embryos due to unbalanced translocation. Methods: IVF, embryo biopsy and PGD using FISH with different probe combinations, provided the possibility of identification the embryos. Special polymorphic markers, located close to the specific translocation breakpoint, were selected for segregation analysis of the blastomers. Results: A 25 year old female, carrier of Robertsonian translocation 45,XX, t(15;21)(p10;p10) attended our reproductive center for PGD. She had experienced two selective terminations of trisomy 21 pregnancies and three spontaneous abortions. She underwent IVF followed PGD using FISH with probes for chromosomes 15 and 21 and a pregnancy was achieved. Amniocentesis revealed that the embryo carried the balanced translocation. UPD was excluded and a healthy child was born. Two years later, she delivered another healthy normal child using the same procedures. With parents consent, segregation mode of polymorphic markers was analyzed in DNA extracts from their blood, amniotic fluid of the balanced translocated embryo, and blastomers derived from remaining abnormal embryos in order to determine the translocation status. Fourteen polymorphic markers within chromosome 15 and 21 were applied to identify the balanced translocated embryos and the normal karyotype. Conclusion: Our preliminary results indicate that the polymorphic markers segregation method is capable of distinguishing between normal, balanced, unbalanced translocation embryos. A larger cohort of chromosomal carriers should be investigated in order to improve the crucial steps in single cell DNA amplification. By using this method we might eliminate infertility and other problems that might affect balanced translocation carriers in the next generation.

Copy number variation screening with the 500K SNP array in patients with mental retardation. *K. Kobayashi[1], T. Mure[1,2], K. Kaneshiro[1], T. Chiyonobu[1,4], A. Nishimura[3], K. Hirai[5], M. Morimoto[3], M. Matsuo[2], J. Inazawa[6], T. Toda[1]*
1) Division of Clinical Genetics, Department of Human Genetics, Osaka University Graduate School of Medicine, Osaka, Japan; 2) Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan; 3) Department of Pediatrics, Kyoto Prefectural University of Medicine, Kyoto, Japan; 4) Department of Pediatrics, Akashi Municipal Hospital, Akashi, Japan; 5) Department of Pediatrics, Kyoto Prefectural Disabled Children's Development Support Center, Kyoto, Japan; 6) Department of Molecular Cytogenetics, Tokyo Medical and Dental University, Tokyo, Japan.

The genetic factors underlying mental retardation (MR) are very heterogeneous. Recent studies have identified a number of genes involved in MR, but the current understanding of the monogenic causes of MR is far from complete. Investigation of chromosomal rearrangements in patients with MR has proven particularly informative in the search for novel causative genes. In this study we used the Affymetrix 500K SNP array together with the GEMCA software to screen for novel pathogenic copy number variations (CNVs) in 27 children with unexplained mental retardation. After excluding the regions which overlapped with reported CNVs seen in normal individuals, we found 16 CNVs in ten patients as candidates for the causative regions of MR. They include seven duplications and nine deletions ranging in size from 47 kb to 16 Mb, which were all confirmed by qPCR. Three of the candidate CNVs overlapped with known deletion or duplication syndromes, namely 22q11.2 deletion syndrome, Sotos syndrome, and Potocki-Lupski syndrome. Of the 13 remaining candidate CNVs, one is a 16 Mb deletion on chromosome 7q33-q36.1. The others remain to be further elucidated in order to identify causative genes of MR. The 500K SNP array is a powerful tool for the genetic analysis of patients with MR.

Mutations in GDF6 Associated with Klippel-Feil Syndrome Types I-III. *R. Clarke[1], M. Tassabehji[2], Z. Zhao[3], E. Hilton[4], J. McGaughran[5], E. Howard[6], M. Malass[2], D. Donnai[2], A. Diwan[7], F. Manson[4], Z.-M. Fang[1]* 1) St George Hosp, Sch Medicine, Univ of NSW, Kogarah, Australia; 2) Academic Unit of Medical Genetics, University of Manchester, St Mary's Hospital, Hathersage Road, Manchester M13 0JH, UK; 3) Department of Psychiatry and Human Genetics and Center for the Study of Biological Complexity, Virginia Commonwealth University, Richmond, Virginia 23298, USA; 4) Centre for Molecular Medicine, University of Manchester, Manchester, UK; 5) Queensland Clinical Genetics Service, Royal Children's Hospital and Health District, Herston Road, Herston , Brisbane 4029, Queensland, Australia; 6) National Genetics Reference Laboratory, St. Mary's Hospital, Manchester, UK; 7) Spine Service, St George Hospital, Kogarah, NSW 2217, Australia.

Klippel-Feil syndrome (KFS) is best characterized by congenital fusion of cervical vertebrae and is of unknown aetiology. KFS is characterised by genetic heterogeneity, with autosomal dominant, recessive and sporadic forms, and a great degree of clinical variability even within affected families. We identified a chromosomal inversion inv(8)(q22.2q23.3) segregating in a large KFS family with a unique autosomal dominant form of KFS associated with carpal/tarsal fusion and severe vocal impairment. Chromosome analyses localised the proximal inversion breakpoint downstream of GDF6, a member of the bone morphogenetic protein (BMP) family implicated in vertebral development and carpal/tarsal fusion in Gdf6 mouse models. GDF6 missense mutations identified in both familial and sporadic cases of KFS confirmed the role of GDF6 in KFS (Types I-III). The discrete patterns of Gdf6 expression during development show precise positional correspondence with the fusions and associated anomalies displayed in both KFS families and in knockout mice. Phenotypic gradients also appear to implicate GDF6s role as an extracellular morphogen. The staggering range of developmental phenotypes indicate a role for GDF6 in development of joints, cartilage, bone, tendon, nerve, kidney, spine, hand, foot, ear, face, mouth, throat and larynx development with important roles in posture, facial structure, dexterity, hearing, mirror movements and vocal development.

***PAX2* Novel Missense Mutation Causes Optic Nerve Colobomas of Variable Severity.** *H. Feret[1], E. Pierce[2], M. Bower[3], X. Wang[3], M. Falk[1]* 1) Human Genetics, CHOP, Philadelphia, PA; 2) Ophthalmology, CHOP/UPENN, Philadelphia, PA; 3) Genetics & Metabolism, U Minnesota, Minneapolis, MN.

PAX2 mutations cause autosomal dominant renal-coloboma syndrome or isolated optic nerve colobomas, with reduced penetrance and variable expressivity. We report a kindred with a *PAX2* novel missense mutation. Five individuals have optic colobomas and/or morning glory syndrome of varying severity, including several asymptomatic individuals. The proband is a 13-year-old girl with bilateral optic nerve colobomas with pits, history of tracking difficulties and nystagmus, 20/25-30 visual acuity, nyctalopia, headaches, post-pubertal obesity, severe infections, cervical kyphosis, and mild dysmorphism. One sister has mild bilateral morning glory syndrome with increased optic nerve size and abnormal retinal blood vessel pattern only on funduscopic photograph, normal vision, and resolved strabismus; one sister has abnormal optic nerves with large excavated cups and unusual vascular problems and 20/40 visual acuity; a brother has asymmetric optic nerve colobomas, impaired visual acuity, esotropia, and astigmatism. The father has asymmetric optic nerves and amblyopia. All have photophobia. Additional findings include learning/behavior problems and delays, headaches, hypotonia, failure to thrive, mitral valve prolapse, absence seizures, hypertelorism, and recurrent anaphylaxis. Paternal grandfather had kidney and bladder cancer. *PAX2* analysis in the proband revealed a c.250G>A transition resulting in an exon 3 Glycine to Serine substitution (G84S). Mutation confirmation in affected family members is underway. Almost all reported *PAX2* mutations result in a truncated PAX2 protein. Two other missense mutations have been reported, and both reside in the conserved paired box domain. One of these results in a similar Glycine to Serine substitution (G76S), in a kindred with a three generation history of kidney failure and mild or asymptomatic optic disc anomalies (Devriendt et al., Hum Genet 1998). These cases suggest *PAX2* mutation analysis be considered in cases of AD optic nerve colobomas/morning glory syndrome, regardless of renal manifestations or symptomatic visual impairment.

Keratin 1 (KRT1), a gene prioritized by age-correlated transcriptional profiling of 1,240 individuals, exhibits SNP genotype x age interaction in genome-wide association. *J. W.Jr. Kent[1], T. D. Dyer[1], H. H. H. Goring[1], J. Charlesworth[1], V. P. Diego[1], J. E. Curran[1], M. P. Johnson[1], M. Carless[1], J. B. M. Jowett[2], M. C. Mahaney[1], L. Almasy[1], J. W. MacCluer[1], E. K. Moses[1], J. Blangero[1], S. Williams-Blangero[1]* 1) Dept. of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) International Diabetes Institute, Caulfield, Victoria, Australia.

Individual humans age at different rates, but the causes of heritable variation in biological aging are largely unknown. Microarray expression profiling allows direct investigation of differences in gene expression with age. Göring et al. (Nat Genet 2007; 39:1208-1216) examined genome-wide gene expression in lymphocytes from 1,240 Mexican Americans in the San Antonio Family Heart Study (SAFHS) and identified 750 autosomally-encoded transcripts that are cis-regulated, i.e., their expression quantitative trait loci map to their structural genes. Here we have identified a subset of 30 validated, cis-regulated autosomal transcripts that exhibit significant (5% false discovery rate) correlation with age and polygenic genotype by age (GxA) interaction. Within this subset, a transcript of the gene keratin 1 (KRT1) ranks highest by joint evidence for cis-regulation, age correlation, and GxA. KRT1 encodes an important structural component of the spinous and granular layers of epidermis, and haplotype variants have been associated with variation in wound healing, a process that is profoundly impacted by aging. Of 34 haplotype-tagging SNPs at the KRT1/1B locus genotyped in 858 SAFHS individuals, 23 show genome-wide significant evidence of association ($P<1.3x10-7$) with KRT1 expression. 11 show locus-wide evidence ($P<0.0015$) of SNP genotype x age interaction (SxA), including rs2741158 (association: P=9.3 x10-52; SxA, P=0.0002) and rs939607 (association: P=1.3 x10-27; SxA, P=8.8 x10-5). These results demonstrate the efficacy of a multidimensional approach to gene prioritization, and identify KRT1 as a target for molecular dissection of the mechanisms of differential aging.

Genome wide copy number polymorphism study of sporadic Parkinson disease. *D. Malhhotra[1], S. Yoon[1], D. Hernandez[2], P. Abou-Sleiman[3], S. McCarthy[1], V. Makarov[1], J. Kendall[1], A. Leotta[1], A. Bhandari[1], A. Singleton[2], J. Sebat[1]* 1) Cold Spring Harbor Laboratory, Cold spring harbor, NY; 2) NIA Porter Neuroscience Research Center, Bethesda, MD-20892; 3) Institute of Neurology, University College London, UK.

We performed a two staged genetic association study to investigate the hypothesis that copy number variants (CNVs) comprise a significant proportion of genetic risk factors for sporadic Parkinson disease (PD). In Stage I, we used a cross platform CNV validation approach by individually scanning genomes of 159 late onset Caucasian PD cases, 151 early onset PD cases and 228 matched control samples on two CNV discovery platforms, i.e 85K genome wide ROMA (Representational Oligonucleotide Microarray Analysis) and 550K Illumina Hapmap Single Nucleotide Polymorphism (SNP) Chip. We found evidence for several novel rare recurrent and non recurrent CNVs in PD cases which might play an important role in disease pathophysiology. Among the most compelling findings from Stage I cross platform validated novel rare recurrent CNVs include i) a partial duplication of gene, PARD3 in 2 late onset PD cases ii) deletion of autophagy gene ATG12L, in 2 early onset PD cases and iii.) a duplication involving exons 5-8 of Parkin (PARK2) gene in 2 siblings with early onset PD in a family with history of PD. We also tested association of 181 accurately genotyped common CNVs with risk of sporadic PD but did not detect any significant association. In Stage II, genome wide CNV scans of an additional independent cohort of 431 late-onset sporadic Caucasian PD cases and 365 matched Caucasian controls were performed using Illumina 550K SNP chip. Interestingly, we observed a rare duplication of another autophagy gene, ATG5 in a sporadic late onset PD case. Autophagy genes play an important role in controlling neurodegeneration and our results provide new evidence for their role in PD. Our large scale CNV study of sporadic PD cases and controls has identified several potentially interesting new candidate genes which could be important in etiology of PD.

Overlapping risk loci for bipolar disorder and schizophrenia: analysis of 40 dopaminergic pathway genes. *V. Nimgaonkar[1,2], M. E. Talkowski[1], H. Mansour[1], J. Wood[1], L. McClain[1], K. Prasad[1], D. Montrose[1], K. Chowdari[1], D. Axelson[1], B. Birmaher[1], D. Lewis[1], E. Frank[1], D. Kupfer[1], T. Monk[1], S. Faraone[2], N. Laird[2], J. Smoller[2], M. Thase[2], P. Sklar[2], B. Devlin[1,2]* 1) Departments of Psychiatry, Neurobiology, and Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) Consortium.

Background: A shared genetic etiology for bipolar disorder (BP1) and schizophrenia (SZ) / schizoaffective disorder (SZA) has been proposed but never comprehensively tested. Motivated by previous associations and epistatic interactions between dopaminergic (DA) genes and SZ, we evaluated the hypothesis of overlapping risk loci for BP1 and SZ/SZA from the DA pathway.

Methods: We tested 431'tag' SNPs ($r^2 < 0.9$) chosen to represent all publicly avialable common variations from 40 DA genes simultaneously in both disorders. Our cohorts included 526 BP1 cases, 531 SZ/SZA cases, and 477 screened adult controls.

Results: Gene-based tests suggested a common risk factor for both disorders, the Dopamine D3 receptor gene (*DRD3*), following Bonferroni correction. Disorder specific tests were noteworthy for BP1 at *DDC*, *DRD1IP*, and *FREQ*; *DRD2* was associated with SZ/SZA. Analyses of individual SNPs yielded overlapping associations for these disorders at 15 SNPs, representing 60% of all nominally significant SZ associations and 41% of all BP1 associations ($p < 0.05$ in both disorders).

Conclusion: Our results suggest shared DA risk factors for BP1 and SZ/SZA, as well as disorder specific associations. Replicate studies are required. *Additional co-authors from affiliation #2: M. Allen, C. Bowden, J. Calabrese, R. El-Mallakh, A. Fagiolini, M. Fossey, E. Friedman, L. Gyulai, P. Hauser, T. Ketter, J. Loftis, L. Marangell, D. Miklowitz, A. Nierenberg, J. Patel, G. Sachs*.

Variation in the Atrogin-1 Gene (FBXO32) in Patients Experiencing Statin-Induced Severe Adverse Events. *A. M. K. Brown, V. Normand, Y. Renaud, J.-C. Tardif, M. S. Phillips* Genome Quebec and Montreal Heart Institute Pharmacogenomics Centre, Montreal, QC, Canada.

Statins are among the most highly prescribed medications in the world. One of the most common adverse events observed in patients taking statins is muscle toxicity that can range from isolated pain to life-threatening rhabdomyolysis. Recently, Hanai et al. (JCI. 2007) tested the hypothesis that the Atrogin-1, a muscle specific protein highly expressed during atrophy, may be involved in a patients sensitivity to statins. They observed that Atrogin-1 expression was significantly higher in patients experiencing muscle pain while on statins and showed that muscle cell damage increased in both muscle cells in culture and zebrafish upon addition of statins. As part of a large Genome Canada project, we are currently in the midst of collecting a cohort of 2,500 patients experiencing statin-induced adverse events (myalgia, severe myotoxicity, and rhabdomyolysis) and 2,500 controls (patients receiving statin therapy without muscle-related adverse reaction). With access to our unique cohort, we have decided to test Hanai et als observation in humans experiencing statin induced adverse events to determine if underlying variation within the Atrogin-1 gene (FBXO32) differs between cases and controls. In order to test this hypothesis, we have sequenced the FBXO32 gene in 96 selected patients experiencing severe statin-induced muscle toxicity. The sequencing reactions included all coding regions plus 1kb upstream and downstream for both isoforms of the gene. In total, 71 SNPs and 1 microsatellite have been observed. Forty of the SNPs are novel, and have not been publicly reported as of build 128 of dbSNP. We are now screening these observed variations in our control population to see if there are any associations that can be made. To this end, we have developed genotyping assays on the Sequenom MassArray platform to screen for all 72 variations in our populations. The resulting association analysis, using both single SNPs and haplotypes, will show if variation within the FBXO32 plays a role in the pathogenesis of statin-induced muscle toxicity.

Most L1 retrotransposition events occur in embryogenesis and are not inherited. *H. Kano[1], E. M. Ostertag[2], I. Godoy[1], G. L. Gerton[3], T. Merdiushev[3], H. H. Kazazian Jr.[1]* 1) Dept Genetics, Univ Pennsylvania, Philadelphia, PA; 2) Transposagen Biopharmaceuticals Inc. Philadelphia, PA; 3) Center for Research on Reproduction and Womens Health, Univ Pennsylvania, Philadelphia, PA.

L1s are abundant retrotransposons that comprise ~17% of the human genome. Despite having a great impact on the genome, relatively little is understood about L1 biology. However, because the genome is littered with L1s, the prevailing view has been that L1 retrotransposition occurs nearly exclusively in germ cells. Indeed, several studies of L1 transgenic mice have demonstrated that L1 retrotransposition can occur in germ cells, but also in the early embryo, using L1s driven by a heterologous promoter, not the natural L1 promoter. To characterize definitively the timing of human L1 retrotransposition, we studied transgenic mouse and rat models harboring a highly-active human L1 under the control of its endogenous promoter. L1 insertions were seen in more than 60% of the transgene containing mouse offspring and 100% of transgene containing rat offspring. In addition, L1 insertions were found in 5-10% of mouse and rat offspring lacking the transgene. All de novo L1 insertions observed in offspring were somatic, because they were rarely if ever inherited by the next generation. These non-heritable L1 insertions were seen even in mice and rats without L1 transgene, suggesting that L1 RNA can be carried over from ova and sperm and integrate into the genome during embryogenesis. In fact, as further evidence of RNA carryover we found L1 RNA and L1 insertions in individual blastocysts that lacked L1 transgene. We also found abundant L1 RNA from the L1 transgene in spermatogenic cells but relatively weak evidence of L1 insertion. On the other hand, L1 retrotransposition events were much more apparent in embryos than in spermatogenic cells. Thus, it appears that most L1 retrotransposition events occur in embryogenesis, suggesting a role for L1 insertions in human development and disease. That L1 RNA present in one generation can alter the somatic DNA of a subsequent generation is another example of the non-canonical role RNA can play in determining the human phenotype.

Childhood Acute Lymphocytic Leukemia: A Cytogenetic and FISH Perspective. *T. K. Jansz, G. Shikora, R. Kazi, J. Jacob, A. Gruia, M. Nouri, J. Mo, D. Assenza, C. Bowman, A. Aviram-Goldring* Cytogenetis, North Shore Long Island Jewish Medical Center, New Hyde Park , NY.

Acute Lymphocytic leukemia (ALL), the most common form of cancer in children is an important area of research and clinical study. Clonal proliferation of these hematopoetic cells is often the result of genetic abnormalities. It is known that the molecular presentation of such abnormalities, frequently chromosomal translocations, has a strong correlation to both the mechanism and prognosis of ALL treatment. The purpose of this study is to compare commonly accepted genetic aberrations of ALL in literature with the abnormalities observed in the community served by the Long Island Jewish Medical Center. Data for regional, gender, and chromosomal abnormalities were analyzed for trends. Sixty-four ALL patients, with ages from 1 to 20yrs were analyzed during 2006-2008. Twenty bone marrow karyotypes were analyzed from each patient. FISH was also performed using BCR/ABL, TEL/AML1, MLL, 4, 5, 7, 8,9,10,17 and inv(16) probes (Abbott Molecular,IL). Of the 64 patients, 16 had normal karyotypes (25%), and 48 had abnormal karyotypes (75%). Of the total patients, 26(40.6%) indicated a hyperdiploid state, 28(43.4%) had abnormalities in BCR/ABL, TEL/AML, MLL, or other translocations, 8(12.5%) had deletions in chromosomes, and 4(6.25%) had other chromosomal abnormalities. Increase in abnormal karyotypes were seen in Queens, Nassau, Suffolk, Bronx and Brooklyn in descending order of prevalence. Although our data reaffirmed the validity of some of the predicted prevalence of the accepted researched texts, an increased prevalence of hyperdiploidy and the TEL/AML translocation were observed in our community. The data collected revealed some significant regional trends with Queens and Nassau, NY as giving rise to the most pediatric patients presenting with ALL as well. This study emphasized the value of analyzing community data and its contributions in genetic analysis for the diagnosis and treatment outcomes of childhood acute lymphocytic leukemia.

LD-based SNP discovery and genotype calling from DNA sequence data. *P. Scheet* Center for Statistical Genetics, Dept. of Biostatistics, University of Michigan, Ann Arbor, MI.

The advent of high-throughput DNA sequencing technologies promises to allow detailed surveys of human genetic variation. However, current sequencing technologies are prone to nontrivial error rates. Furthermore, the depth of sequenced reads for a given individual is not uniform and may leave some loci with sparse coverage of mapped reads. These factors contribute to difficulties in calling individual genotypes or verifying whether individual loci are polymorphic. The dependence of alleles at nearby loci (linkage disequilibrium; LD) provides a sort of built-in redundancy of sequenced loci. Here, I adapt a model for LD among tightly-linked SNP markers to DNA sequence data for the purpose of explicitly taking account of this dependence, thereby allowing one to "borrow strength" from nearby markers when making single-marker inferences, where read depth may be sparse. Since quality scores associated with individual reads contain information about the accuracies of the estimated alleles, I fit the model directly to likelihoods for the true genotypes to account for uncertainties in the allele calls, and compare the utility of this approach to fitting the model to the allelic counts or called genotypes. In addition, by allowing for multiple alleles at each site, including a null allele, I can accommodate the presence of tri-allelic SNPs and short deletions segregating in the population. I apply the method to simulated data as well as to data from The 1000 Genomes Project to demonstrate that the incorporation of LD information leads to an improvement in polymorphism discovery and obtaining accurate probabilities of individual genotypes. These methods are implemented in the software package fastPHASE.

Gene set analysis of bipolar disorder using whole-genome SNP data. *Y. Meng[1,2], M. Ogdie[1,2], M. Ferreira[1,2], H. Gurling[3], D. Blackwood[4], A. Corvin[5], N. Craddock[6], P. Sklar[1,2], S. Purcell[1,2]* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, USA; 2) Stanley Center for Psychiatric Research, Broad Institute of Harvard and MIT, Cambridge, USA; 3) Department of Mental Health Sciences, Windeyer Institute of Medical Sciences, University College London, UK; 4) Division of Psychiatry, University of Edinburgh, UK; 5) Trinity Centre for Health Sciences, St James's Hospital, Trinity College Dublin, UK; 6) Department of Psychological Medicine, Cardiff University, UK.

Most current approaches to whole-genome association studies (WGAS) test each variant sequentially and without regard to the genetic context. Although this comprehensive and agnostic approach has advantages, when high degrees of allelic and locus heterogeneity exist, alternative analytic strategies might perform better. Bipolar disorder is a complex genetic disease that likely displays just such high levels of heterogeneity. We recently performed a meta analysis [Ferreira et al.] of three independent GWASs of bipolar disorder, which supported association with the alpha-1C subunit of the L-type voltage-gated calcium channel gene, *CACNA1C* (combined P = 7.0 × 10-8, rs1006737). *CACNA1C* is one of 27 genes known to code for the calcium ion channel. To more deeply test the hypothesis that ion channel dysfunction is critical in bipolar disorder, we leveraged the coverage of whole-genome data to interrogate variation in this entire set of functionally-related genes, containing over 900 SNPs. The 27 genes are grouped according to subunit (coded A1, A2D4, B and G) and A1 subtype (P/Q, N, L, R and T). We applied a multi-locus set-based test at the level of pathway, subunit, subtype and gene. The results indicated a strong specificity of L-type alpha 1 subunit genes (P=0.0003) (with *CACNA1D* and *CACNA1S* showing association, P=0.019 and 0.002). Removing *CACNA1C*, the pathway, A1 subunit and L-type genes remained significant (P=0.0024 and 0.003 respectively). These results provide convergent support for *CACNA1C*: the genes are functionally related but statistically independent in terms of variation. We further discuss the methodological strategies to gene-based and pathway-based association analysis.

Intellectual Property Challenges for Development of Multi-gene Diagnostic Tests. *S. Chandrasekharan, R. Cook-Deegan* GELP, Duke University, Durham, NC.

Advances in technologies for sequencing and genotyping make it possible to test for hundreds of genetic variations and mutations simultaneously. Such diagnostics could potentially be faster, more comprehensive and cost effective and are well suited to evolving clinical and research needs, especially as additional mutations continue to be discovered. However, the development of chip or microarray based multi-gene diagnostics faces several challenges. One obstacle may be a complex intellectual property (IP) landscape. Difficulty in securing freedom to operate could prove a major impediment to the development of such promising diagnostics. To better understand the effects of patents and licensing on the development of such new tests, we studied genetic testing for three conditions, hearing impairment, spinocerebellar ataxia and Long QT syndrome (LQTS), which are characterized by mutations in multiple genes. We created intellectual property landscapes by identifying patents that cover relevant gene sequences, or mutations/variants and methods for diagnosing these syndromes. We also searched the scientific literature and patent databases to identify chip based diagnostics for these conditions that may be potentially developed for clinical testing. We identified several pending patent applications on microarray diagnostics for hearing loss and LQTS and other channelopathies that contain overlapping claims and include all patented mutations. We also identified licensing data for relevant patents from publicly available resources and interviews conducted with experts. Our preliminary analysis provides evidence for potential IP barriers to the development of such multigene tests. They include possible blocking effects of exclusively licensed patents for common gene mutations (hearing loss and Long QT), increased royalty payments for multiple licenses required from many different owners (SCA testing) and difficulty in assembling IP required for comprehensive testing of all alleles because of dominant positions of exclusive licensees (SCA, LQTS). Further studies will involve detailed analysis of claims to assess scope of patents and if potential uses in multi gene chips are precluded.

A large-scale high-density linkage study of autism identifies multiple genome-wide significant loci. *D. E. Arking[1], L. A. Weiss[2], C. W. Brune[3], K. West[1], E. H. Cook[3], M. J. Daly[2], A. Chakravarti[1]* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Broad Institute of Harvard and MIT, Cambridge MA; 3) Institute for Juvenile Research, University of Illinois at Chicago, Chicago, IL.

Autism is a childhood neuropsychiatric disorder that, despite high heritability, has largely eluded efforts to identify genetic variants underlying its etiology. Using Affymetrix arrays we genotyped ~4,000 samples comprising 802 affected sib-pairs (ASPs) for ~500,000 SNPs. Samples were obtained from the NIMH Autism Genetics Initiative and AGRE, with each family having at least 1 child diagnosed with autism and a second child classified as autism, broad spectrum, or Not Quite Autism. We performed two genetic studies: a family-based linkage analysis (this abstract) to search for loci that harbor multiple, likely rare, susceptibility alleles, and, an association analysis to examine the role of common variants (Weiss et al., this meeting). For linkage analysis, we removed SNPs with frequency 20%, 1% missing data, 1 Mendelian errors, or in Hardy-Weinberg disequilibrium (P0.001) resulting in ~180,000 high-quality SNPs. Non-parametric ASP linkage was performed using MERLIN with linkage disequilibrium (LD) modeled by clustering SNPs with pair-wise r^2 0.1, revealing 4 significant (lod 3.6) peaks at 6q25.2, 15q25.3, 17p12, 17q11.2, and 1 highly significant (lod=5.7) peak at 6q27. To verify that these results were not due to artifacts introduced by clustering or from SNPs in high LD, we removed all SNPs with pair-wise r^2 0.2, and observed no significant change in linkage peaks. We also performed analyses using every other SNP, and again, observed no significant change, indicating that these results are unlikely to be influenced by nearby LD or poor genotyping assays. Aside from 15q25.3 and 17q11.2, these loci show little overlap with previous reports, and none of the loci overlap with suggestive regions of association. In summary, we have used high-density SNP genotyping to identify 5 genome-wide significant loci that contribute to autism susceptibility, and likely harbor rare variants exhibiting allelic heterogeneity.

Genome Wide Association Studies of Angiographic Coronary Artery Disease. *MP. Reilly[1], M. Li[1], MS. Burnett[2], A. Qasim[1], NN. Mehta[1], S. Restine[1], M. Wolfe[1], A. Edmondson[1], I. Stylianou[1], J. Devaney[2], B. Keating[1], T. Cappola[1], H. Hakonarson[1], Z. Chen[1], C. Knouff[3], V. Mooser[3], SE. Epstein[2], DJ. Rader[1], WTCCC, MI-GEN Consortium, Ottawa Heart Study, ADVANCE, Intermountain Heart Study, Emory CV Gene Bank* 1) Univ of Pennsylvania Medical Center; 2) Cardiovascular Research Institute/MRI/Washington Hospital Center; 3) GlaxoSmithKline.

Recent genome wide association studies (GWAS) identified a few novel loci for coronary artery disease (CAD), in particular at 9p21. However, no GWAS have been reported where CAD cases & controls were classified using gold-standard coronary angiography. We performed combined analysis of two case-control GWAS of angiographic CAD in Caucasians (Affymetrix 6.0; cases had >50% stenosis 1 vessel; controls w/ normal angiography): PennCATH (N=1401; 470 MI-CAD acute cases, 463 non-MI CAD chronic cases, 468 controls); Medstar (N=1322; 421 MI-CAD, 454 non MI-CAD, 447 controls). Sample call rates were >95% (mean 98%). SNPs studied had MAF >1%, were in HWE (p>10-7), with call rates >95%. There was no significant population stratification (0.99-1.03). Age & gender adjusted analyses of genotyped (PLINK) and imputed (MACH imputed and SNPTest association) SNPs included all CAD cases vs. controls & subgroups of MI/non MI cases vs. controls. Analysis replicated the 9p21 locus (best SNP vs. controls; all CAD (P = 1.2x10-8), MI-CAD (P = 8.9x10-10), non MI-CAD (P = 4.4x10-4). Several novel SNPs with CAD associations p<1x10-7 were identified. Stage 2 in silico replications (SNP p<10-3) are ongoing in 5 independent CAD GWAS (7,000 cases) with stage 3 genotyping (meta-analysis SNPs p<5x10-8) in 3 more angiographic CAD studies (5,000 cases). Conclusion: Initial findings suggest that our angiographic CAD GWAS replicates findings in clinical CAD GWAS, but also will identify novel CAD loci. An angiographic phenotype may identify loci related to coronary atherosclerosis itself (atherosclerosis locus), or those related to acute clinical complications only (plaque rupture/thrombosis locus).

Familial Thoracic Aortic Aneurysms and Dissections: A Subset of Families with Thoracic Aortic Aneurysms in Men and Intracranial Aneurysms in Women. *S. K. Medrek[1], V. Tran-Fadulu[1], A. C. Braverman[2], D. M. Milewicz[1]* 1) Dept Internal Medicine, Univ Texas/Houston Med Sch, Houston, TX; 2) Dept Internal Medicine, Washington Univ School of Medicine, St Louis, MO.

Thoracic aortic aneurysms leading to type A dissections are usually inherited as an autosomal dominant condition with variable expression and decreased penetrance (FTAAD). Genetic heterogeneity for FTAAD is established and correlates with clinical heterogeneity. For example, FTAAD resulting from TGFBR1 or TGFBR2 mutations is associated with aneurysms and dissections of other arteries, including fusiform intracranial aneurysms. In our cohort of 450 families with FTAAD, we noted that approximately 10% of families had one or more members with intracranial berry aneurysms (ICA), in contrast to the fusiform aneurysms associated with TGFBR1/2 mutations. In three large families, multiple women with ICAs were confirmed to harbor the defective gene causing TAAD based on their location in the pedigree. Interestingly, males in these families tended to have TAAD and females tended to have ICA. Linkage analysis with DNA from the largest family with 12 affected members indicated that the phenotype was not linked to any of the known TAAD loci and no TGFBR1/2 mutations were identified, indicating that the subphenotype of TAAD/ICA is caused by a novel gene. Imaging of both the thoracic aortic and intracranial arteries is recommended in these families. Detection of a novel gene would increase the mechanistic and clinical understanding of both TAAD and ICA.

Hermansky-Pudlak Syndrome (HPS) as a genetic model for Idiopathic Pulmonary Fibrosis (IPF): The role of MUC1 in pulmonary fibrosis. *T. Markello[1], B. Pederson[1], M. Anahtar[1], G. Srivastava[1], K. O'Brien[2], B. Gocchicco[1], W. Gahl[1]* 1) Section on Human Biochemical Genetics, Medical Genetics Branch NHGRI, Bethesda, MD; 2) Intramural Program of the Office of Rare Diseases, OD, NIH, Bethesda MD.

The 8 subtypes of HPS include occulocutaneous albinism and a platelet bleeding disorder. Genetic subtypes 1 and 4 also exhibit fatal pulmonary fibrosis(PF), making them models for the interstitial lung disease, IPF. MUC1, a membrane glycoprotein associated with invasive epithelial cancers and interstitial lung diseases, is a component of regenerating type II pneumocytes. These cells have lamellar bodies which are lysosome-like organelles resembling those affected in HPS. We propose that MUC1 is mislocalized in HPS type II pneumocytes. Indeed, using blood from HPS patients archived over the past 15 years, we see a strong correlation between MUC1 serum levels (up to 20 times the upper limit of normal) and degree of fibrosis (decline in pulmonary function) among 100 HPS individuals. No overlap is seen between normal and HPS (with fibrosis). Normal blood level of MUC1(mean)= 120U/ml (range 109-150,n=8). HPS patients without PF = 250U/ml(60-572,n=46). HPS patients with moderate PF = 590U/ml(299-2079,n=33). HPS patients with severe PF = 2141U/ml(743-10165,n=21). We demonstrated that sustained elevation of serum MUC1 in 21 HPS patients predicted present or future pulmonary fibrosis and was correlated with disease progression. A previous and current therapeutic trial of HPS fibrosis investigated pirfenidone, a TGF-beta inhibitor that functions through the SMAD signaling pathway. One HPS patient receiving pirfenidone had 3 episodes of MUC1 elevation over 10 years of treatment, but always returned to normal, presumably because of pirfenidones inhibition of SMAD signaling. This patient exhibited no lung disease progression over those 10 years, a remarkable finding. We conclude that: 1) MUC1 serves as a biomarker for disease prediction and as an outcome parameter for therapy. 2) Pirfenidone dampens the fibrotic effects of TGF-beta stimulation and reduces the amount of MUC1 produced in the interstitium. 3) HPS serves as a genetically homogeneous model in which to study the therapy of pulmonary fibrosis.

Genome-wide scan for linkage to type 1 diabetes in 2,496 multiplex families from the Type 1 Diabetes Genetics Consortium. *W.-M. Chen[1,2], P. Concannon[1,3], C. Julier[4], G. Morahan[5], B. Akolkar[6], H. A. Erlich[7], J. E. Hilner[8], J. Nerup[9], C. Nierras[10], F. Pociot[9], J. A. Todd[11], S. S. Rich[1,2], Type 1 Diabetes Genetics Consortium* 1) Ctr Public Hlth Genomics, Univ Virginia, VA; 2) Dept Public Hlth Sciences, Univ Virginia, VA; 3) Biochemistry & molecular Genetics, Univ Virginia, VA; 4) Inst de Genomique CNG, France; 5) Ctr for Diabetes Research, WAIMR & Ctr Medical Research, Univ Western Australia, Australia; 6) Div Diabetes, Endocrinology and Metabolic Diseases, NIDDK, NIH, MD; 7) Roche Molecular Systems, CA; 8) PHS, Wake Forest Univ, NC; 9) Steno Diabetes Ctr, Denmark; 10) JDRF, NY; 11) JDRF/WT DIL, Cambridge Inst for Medical Research, Univ Cambridge, UK.

Type 1 diabetes (T1D) is a complex disorder arising from the combined actions of multiple genetic and environmental risk factors. Recent genome-wide association (GWA) studies have identified a number of common genetic variants that contribute to T1D risk; however, these studies have limited power to detect loci where multiple rare alleles contribute to T1D risk. To identify rare genetic variants that are linked to T1D, the Type 1 Diabetes Genetics Consortium (T1DGC) has assembled a large collection of multiplex T1D families consisting of 2,496 families with 2,881 affected sib pairs (ASPs) from 9 geographic regions. We report the results of a genome-wide scan for linkage using 6,090 SNPs in the T1DGC family collection. Evidence for linkage to T1D was detected in the HLA region (6p21.3), the insulin locus on chromosome 11p15.5, a region on 2q33 containing CTLA4, and a region on distal 6q (6q27), with LOD scores 215.3, 3.1, 3.3 and 5.2 respectively. To incorporate the potential heterogeneity effect of sex or age-onset on T1D, we utilized a model in which IBD sharing from an ASP was regressed on the probability distribution that is defined by the ASPs covariate values. This regression-based covariate analysis allowed us to identify an additional region on chromosome 19p13.3 with $p=8\times10^{-5}$. Our analysis also provided evidence of potential linkage to T1D with p.001 at additional regions on chromosomes 2q13, 10q21.1, 18p11.22, 19q13.11, and 19q13.4.

A Comparison of Approaches to Account for Uncertainty in Analysis of Imputed Genotypes. *J. Zheng, Y. Li, G. R. Abecasis, P. Scheet* Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI.

The recent availability of a high-density reference panel, such as "The HapMap", has allowed for the imputation of genotypes at single nucleotide polymorphism (SNP) markers that were untyped in a cohort or case-control study but that have been characterized in the reference panel. These imputation procedures, which are based on patterns of linkage disequilibrium (dependence of alleles at nearby SNPs; LD) allow direct testing of these SNPs in the study sample of individuals. A natural question from such a procedure is how best to take account of the uncertainty of the imputed genotypes. We simulated a set of genotype data to mimic that from realistic cohort-based association studies and quantitative trait values for genetic models with varying degrees of dominance, independently at 83,327 SNPs. After imputation, we obtained the conditional probabilities of each possible genotype at untyped SNPs. Here, we compare the performance of the following 3 strategies for dealing with the results from imputation: regression on the "best-guess" imputed genotype; regression on the allelic or genotypic "dosage"; and the use of mixtures of regression models. We consider a range of minor allele frequencies and imputation accuracies to compare the power of the different methods under multiple genetic models. We find that the "best-guess", which does not accommodate the uncertainty in the imputed genotype, performs the worst, although only when the imputation accuracies suffer. Only in specialized situations, with large genetic effects and low imputation accuracies, does the mixture model does give greater power than using the allelic dosage. We therefore conclude that for the most realistic settings for current genome-wide association studies, regressing the phenotype on the estimated allelic or genotypic dosage provides an attractive compromise between accuracy and computational tractability.

An epigenetically demarcated chromatin insulator at a boundary between X chromosome inactivated and expressed transcripts of the UBE1 gene. *K. E. Prothero, L. Carrel* Penn State College of Medicine, Hershey, PA.

In females, X chromosome inactivation silences most genes on one X chromosome. Nonetheless ~15% of human genes escape inactivation, and are expressed from both active (Xa) and inactive (Xi) Xs. Many escape genes cluster and are likely coordinately regulated. CTCF-bound insulators have been found at several boundaries between inactivated and escape genes, but their role in Xi expression is unclear. To further examine insulators in Xi expression and identify additional Xi regulatory sequences, we focused on the human escape gene, UBE1. We established that UBE1 has a distinctive gene structure and Xi expression pattern; two alternative 5 untranslated (UTR) exons are X inactivated whereas 2.1 kb downstream another alternative 5 UTR exon escapes inactivation. Eight overlapping constructs within the human UBE1 boundary region were tested for insulator function and a 330 bp sequence with enhancer blocking activity was identified. The expression boundary is also epigenetically marked; by bisulfite sequencing, the region is unmethylated on the Xi but heavily methylated on the Xa. Intriguingly, the orthologous mouse gene has similar gene structure, but all transcripts are X inactivated. Therefore, sequences regulating Xi expression should be absent at the mouse Ube1x locus. Indeed, the human UBE1 boundary region shares high sequence similarity with mouse Ube1x, except for a 600 bp region that includes the enhancer blocking activity. Further, all mouse Ube1x sequences tested lack insulator activity and were heavily methylated on the Xi. These data suggest proteins involved in human UBE1 Xi regulation will specifically bind the unmethylated boundary on the Xi. Intriguingly, CTCF consensus binding sites are not found in the insulator. Nevertheless, we are testing CTCF binding by chromatin immunoprecipitation and will determine whether this region utilizes novel CTCF-binding sites or whether Xi regulation involves additional proteins that bind insulator sequences. This small expression boundary at UBE1, together with the human and mouse genetic and epigenetic differences makes this an ideal locus to evaluate factors regulating Xi expression.

Genome-wide association for insulin resistance and secretion in 542 genotyped and imputed individuals. *F. Xiang[1], L. J. Scott[1], Y. Li[1], A. U. Jackson[1], C. J. Willer[1], H. M. Stringham[1], M. R. Erdos[2], L. L. Bonnycastle[2], K. Kubalanza[2], A. J. Swift[2], G. R. Abecasis[1], K. L. Mohlke[3], J. Tuomilehto[4], R. N. Bergman[5], F. S. Collins[2], R. M. Watanabe[5], M. Boehnke[1]* 1) Biostatistics, U Michigan, Ann Arbor, MI; 2) NHGRI, Bethesda, MD; 3) Genetics, U North Carolina, Chapel Hill, NC; 4) Nat'l Public Health Inst., Helsinki, Finland; 5) Physiology and Biophysics, Keck School of Medicine, U Southern Cal, Los Angeles, CA.

Understanding the genetic variation that underlies regulation of insulin secretion and resistance and glucose levels will enhance our understanding of glucose homeostasis and type II diabetes. Here, we seek to test for association of genetic variants with parameters from the frequently sampled intravenous glucose tolerance test (FSIGT): acute insulin response (AIR), disposition index (DI), insulin sensitivity (S_i), and glucose effectiveness (S_g). We analyzed FSIGT data on 542 normal glucose tolerant (NGT) individuals in 185 nuclear families from the FUSION study. Using genotypes for (a) >300,000 SNPs from the Illumina HumanHap300 BeadChip available on 240 of these individuals, and (b) genome scan/microsatellite data on all 542 of these individuals and additional family members, we imputed genotypes on ~2.1 million common autosomal SNPs in the 542 individuals. Imputation was in two stages. First, we imputed genotypes from SNPs from the HapMap CEU sample in the 240 FUSION GWA individuals. Second, we used the microsatellite genotypes to identify regions of IBD sharing between family members to support imputation of SNPs in the non-GWA individuals. We tested for trait-SNP association between normalized residuals of S_i, DI, AIR, and S_g after adjustment for sex, age, age^2, and birthplace under an additive model. Imputation more than doubled our available sample for association testing, resulting in substantially increased power compared to analysis of the GWA sample alone. Initial analysis revealed substantially strengthened evidence for association of AIR with variants upstream from a known T2D-predisposing locus. We currently are completing the analysis of all four traits genome-wide.

An inherited balanced translocation t(2;11)(p21;p15.1) disrupting PAX6 in a patient with bilateral aniridia. *L. A. Brown[1], D. Chai[1], A. Chou[1], R. Rupps[2], C. F. Boerkoel[2], P. Eydoux[1]* 1) Children's & Women's Health Centre of British Columbia, Vancouver, British Columbia, Canada; 2) Department of Medical Genetics, Children's & Women's Health Centre of British Columbia, Vancouver, BC Canada.

Aniridia is a rare developmental defect of the anterior segment of the eye. It can occur sporadically, but is often inherited in an autosomal dominant fashion. One third of patients with isolated aniridia are found to have a chromosomal abnormality involving chromosome 11p13 or a microdeletion of the region surrounding the PAX6 gene. The risk for an association with Wilms tumor in cases with aniridia occurs in WAGR (Wilms' Tumor-Aniridia-Genitourinary Anomalies-Mental Retardation) syndrome due to a deletion that includes the WT1 gene. We report a 3-year-old boy with familial bilateral aniridia. Cytogenetic analysis of the child revealed a balanced translocation between the short arms of chromosome 2 and 11, with breakpoints at 2p21 and 11p15.1. FISH for PAX6 and WT1 revealed no disruption of either gene. Subsequent FISH using probes distal to PAX6 confirmed the breakpoint to be between 11p13 -->11p15.1. Array CGH findings revealed that the child carried a paternally inherited interstitial deletion of 280 kb within 11p13. This deletion disrupts the ELP4 gene on the telomeric end and the PAX6 gene on the centromeric end. The breakpoint involving PAX6 was proximal to the locus recognized by the RP11-133E13 FISH probe and thus no modification of the gene was observed. The inherited translocation resulting in deletion of the PAX6 gene is the likely responsible factor for the patients aniridia. There is apparently no phenotype associated with the deletion of ELP4. Cryptic deletions involving both PAX6 and ELP4 have been previously described, although the majority occurred in patients with sporadic isolated aniridia. In addition, there are several reported cases of aniridia associated with a balanced chromosome translocation and an 11p13 breakpoint. The presence of a chromosomal rearrangement in this patient demonstrates the significance of genetic counseling for this patient as his offspring may inherit the balanced translocation and the subsequent disruption of the PAX6 gene.

Identification of small molecules suppressing rCGG-repeat-mediated neurodegeneration. *A. Qurashi, L. Ray, H. Liu, P. Jin* Dept Human Molec Genetics, Emory Univ Sch Medicine, Atlanta, GA.

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a progressive neurodegenerative disorder recognized in fragile X premutation carriers. Using Fruit fly, we have previously demonstrated that elongated noncoding CGG repeats in FMR1 allele as the pathogenic cause of FXTAS. Here we are utilizing this FXTAS fly model to identify small molecules that can ameliorate rCGG-mediated neuronal toxicity and lethality. We screened a collection of 2,000 FDA-approved, biologically active and structurally diverse small molecules for their ability in restoring the viability in rCGG-repeat expressing flies. We identified 20 compounds that could reverse the lethality with several of them potentially targeting to glutamate and inflammatory pathways. We further tested the effects of selected compounds on other established phenotypes of rCGG repeat expressing flies. Particularly Fluocilone Acetonide, besides rescuing lethality, can also rescue the locomotor abnormalities of rCGG-expressing flies. Fluocilone Acetonide targets and inhibits phospholipase A2 enzyme that mediates inflammation and oxidative stress. Through genetic screen, we identified a PLA2 fly ortholog that specifically modulates rCGG-repeats-mediated neuronal toxicity, but not polyglutamine-mediated toxicity. Our results demonstrate the utility of a Drosophila model for screening small molecule libraries, and suggest a specific role that PLA2 could play in the molecular pathogenesis of rCGG-mediated neurodegeneration.

Polymorphisms in the FTO gene are associated with type 2 diabetes in a population of South Asians. *L. de Koning[1], J. K. Haladyn[1], C. Xie[1], R. Do[2], A. Montpetit[3], P. Pais[4], S. Haque[5], K. Kazmi[6], T. Jayalath[7], S. Yusuf[1], J. C. Engert[2], S. S. Anand[1], Interheart genetics investigators* 1) Population Health Research Institute, McMaster University, Hamilton, Ontario; 2) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 3) The McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 4) Department of Medicine, St Johns Medical College, Bangalore, India; 5) Department of Cardiology, Bangabandhu Sheikh Medical University, Bangladesh; 6) Department of Cardiology, Aga Khan University, Karachi, Pakistan; 7) Professorial Medical Unit, Teaching Hospital, Peradeniya, Sri Lanka.

Background: Single nucleotide polymorphisms (SNPs) in the FTO gene are associated with an increased risk of type 2 diabetes (T2D), which may be mediated through increased body mass index (BMI). South Asians have an increased risk of T2D even at normal BMI. Objectives: To determine associations of SNPs in the FTO gene with T2D and HbA1c after adjusting for age, sex and adiposity measures (BMI, waist circumference[WC], hip circumference[HC] and waist to hip ratio[WHR]) in South Asians. Methods: Individuals of South Asian (n=1867) origin from the Interheart study were genotyped for FTO SNPs rs1421085, rs17817449, rs8050136, rs3751812, and rs9939609. Adiposity measures were measured in clinic, and T2D status was by self-report. Multiple regression with additive and recessive models was used for analysis. Results: Minor allele frequencies for FTO SNPs were 0.33 to 0.36. FTO SNPs were in strong linkage disequilibrium (pairwise R2 > 0.9). Under a recessive model rs17817449, rs3751812, and rs9939609 were significantly ($p<0.05$) associated with BMI but not with WC, HC or WHR. Under an additive model rs1421085, rs17817449, rs8051036, and rs3751812 were significantly associated with T2D. FTO SNPs rs1421085, rs8050136, rs3751812 and rs9939609 were significantly associated with HbA1c. Associations with T2D and HbA1c were not affected by adjustment for adiposity measures. Conclusions: In a population of South Asians, sequence variation in the FTO gene is associated with T2D, which is not mediated through adiposity measures.

Pedigree-Free Identity-By-Descent Mapping Applied To Large Scale SNP Genotyping Studies. *B. Merriman, Z. Chen, S. Strom, S. F. Nelson* Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

Large scale SNP genotyping studiesinvolving thousands of unrelated cases typed on whole-genome high density SNP Chipsare becoming increasingly common in genetic disease research. These are typically done in the context of linkage or association studies to localize the disease genes, but if any of the underlying risk factors has a strong founder effect, it can be more powerful to look specifically for this signature. Pedigree-Free Identity by Descent Mapping is technique we have been developing that has novel power to identify risk alleles with a strong strong founder effect, which is detected as seemingly unrelated individuals sharing a large, extended haploytpe. This method uses the high-density SNP genotyping data to directly infer large shared DNA fragments between such affected individuals, without relying on any pedigree information. We have demonstrated the basic power of the this approach in small scale studies, but if the are N subjects, the comparison process requires ~ N x N comparisons to find shared fragments, which is computationally costly when N is in the thousands. Moreover, finding fragments shared by 3 individuals requires ~ N x N x N comparisons, which becomes entirely impractical, as do all direct searches for higher order sharing. Here, we introduce an optimally efficient method for computing all large fragment sharing instances (sharing between pairs of subjects, triples, quadruples, etc) that scales like N in computational time. We illustrate this method by mapping all possible instances of apparent large IBD fragment sharing in the N ~ 18,000 Wellcome Trust Case Control samples genotyped on the Affymetrix 500k SNP set, and in the N ~ 2000 independent probands in the AGRE Autism Family samples genotyped on the Illumina 500k SNP set. We also use the ~1000 AGRE Affected Sibling Pair families to estimate the efficiency of Pedigree-Free IBD at detecting sibling IBD shared fragments, relative to rigorous IBD sharing calculations for the sibs using the parental genotypes.

Worldwide collection of genotype and phenotype data for HNPCC colon cancer and a model for the Human Variome Project (HVP). *R. G. H. Cotton[1], F. A. Macrae[2], Collaborators in the HVP and InSiGHT* 1) Genomic Disorders Research Centre, Melbourne, Australia; Human Variome Project; Department of Medicine, The University of Melbourne; 2) Department of Colorectal Medicine and Genetics, The Royal Melbourne Hospital, Parkville, Australia; InSiGHT.

InSiGHT has embraced the HVPs vision, and directed its attention to coordinating the submission of variant information derived from a wide range of diagnostic and research laboratories in Europe, Africa, USA, Canada, Japan and Australia, to its Locus Specific Database (www.insight-group.org). In parallel, integration of other mismatch repair databases serving useful functions of collating the literature, and other helpful annotations, is being unified onto a common LOVD platform to allow ready cross database interrogation. This is being supported by academic interest in defining search strategies used in clinical/laboratory services, to locate published literature relating to the variants in question, and subsequently developing automated text searching strategies to populate the InSiGHT databases. Complementing this, dedicated InSiGHT committees are formulating databases to capture phenotype data across clinical, functional and histopathological domains, again linked to variant findings. The aim is to develop a common portal to allow searching of all available data relating to particular variants, informed by generic databases, e.g. ENSEMBL, to allow the best informed interpretation of unclassified variant pathogenicity. To this end, an international, regionally represented, expert committee engaging a range of disciplines, has been assembled by InSiGHT to provide the best available interpretation of the variant data, with a process of dynamic updating. Interaction with EBI, NCBI and GEN2PHEN received a strong foundation through a meeting of the HVP in May. Mutual benefits to each have been explored, and a RoadMap for this and the entire process described. This work involving a team of committed bioinformatics teams and information system expertise, interacting with clinicians, geneticists and privacy experts, is proving a model for extrapolation to other genes and LSDBs worldwide.

Genome-wide association study of 2,400 cases of three common diseases and 1,000 shared controls in Taiwan. *C. H. CHEN, J. Y. WU, P. CHEN, M. M. T. LEE, J. Y. CHEN, S. F. HO, H. W. CHEN, C. L. HSU, C. S. J. FANN, A. T. A. CHENG, W. H. PAN, Y. T. CHEN* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

BACKGROUND We carried out a joint genome-wide association study to identify susceptibility genes to common diseases among Taiwan Han-Chinese, who account for 98% of the general population residing in Taiwan. **METHODS** A total of 2,400 cases, 1000 with bipolar I disorder, 1,000 with type 2 diabetes mellitus, and 400 with young onset hypertension, were recruited through the Taiwan Multicenter Genetic Medical Project and 1000 random controls were selected from The Han Chinese Cell and Genome Bank in Taiwan. All of the 3,400 samples were genotyped using the Illumina Hap550duov3 chip and the deCode CNV chips. Individual ancestry was estimated based on sets of random selected SNPs and compared with the Asian (CHB+JPT), Caucasian (CEU), and African (YRI) samples of the HapMap project. Genome-wide association analysis was carried out with genotype and allele-type tests as well as the Armitages trend test. Models with dominate, recessive, and additive inheritance modes were also considered. In addition, multi-pointanalyses were applied to summarize regions with multiple significant points. **RESULTS** For the 3,400 samples, 537,207 out of 561,466 SNPs (95.68%) have showed polymorphism and giving an average call rate of 99.91%. All of our samples shared similar genetic background with the Asian group of the HapMap project and indicated no substantial population structure existed among the samples. For bipolar I disorder, 2 SNPs were identified with significant signals ($p < 10^{-7}$) while 11 SNPs and 3 regions showed positive evidence ($10^{-7} < p < 10^{-5}$); for young onset hypertension, 8 SNPs and 4 regions showed positive evidence; for type 2 diabetes mellitus, 16 SNPs and 4 regions showed positive evidence. Copy number variation analysis with various algorithms showed a few sites were in association with the diseases separately. **SUMMARY** We have identified novel SNPs/regions associated with bipolar I disorder, type 2 diabetes mellitus, and young onset hypertension in Han-Chinese patients.

The absence of endothelin-2 (Edn2) partially rescues photoreceptor (PR) death in inherited PR degenerations (IPDs). *A. Bramall[1], L. Pacione[1], M. Szego[1], S. Boye[2], P. D'Orleans-Juste[3], W. Hauswirth[2], M. Yanagisawa[4], R. McInnes[1]* 1) Prog in Dev Biol, Hosp for Sick Children, Toronto, ON; 2) Dept Ophthalmology, Univ of Florida, Gainesville, FL; 3) Dept Pharmacology, Univ de Sherbrooke, Sherbrooke, QC; 4) Dept Mol Genetics, Univ of Texas SW Med Center, Dallas, TX.

IPDs are the most common monogenic cause of blindness in humans; the mutant PRs are at a constant risk of death (Clarke et al. Nature 2000). Using microarrays and qPCR to identify genes that mediate the constant risk, we found that the *Edn2* mRNA was 32-fold, 70-fold and 72-fold increased (all $p<0.005$) in the *Rds*$^{+/-}$, *Tg(RHO P347S)* and *Rd1*$^{-/-}$ mouse models of IPD, respectively; *in situ* hybridization revealed increased *Edn2* mRNA only in the mutant PRs. To determine if the increased Edn2 is pathogenic, we generated PR mutant mice with Edn2 loss-of-function alleles. At age 40 and 15 days respectively, *Edn2*$^{-/-}$ *; Tg(RHO P347S)* and *Edn2-/- ;Rd1*$^{-/-}$ retinas showed a 17% ($n=6$; $p<0.003$) and 33% rescue of PR degeneration ($n=5$; $p<0.007$); by 40 days, no rescue was detectable in the slower degenerating *Edn2*$^{-/-}$ *; Rds*$^{-/-}$ retinas. Unexpectedly, *Edn2*$^{-/-}$ *;Rd1*$^{-/-}$ retinal explants did not show any PR rescue at PN17, suggesting that the rescue effect might be mediated by a secondary consequence of deleting Edn2. To further separate extraocular from ocular effects of the Edn2 deletion on PR death, we restored *Edn2* mRNA expression to *Rd1*$^{-/-}$ levels in *Edn2*$^{-/-}$ *;Rd1*$^{-/-}$ PRs by AAV-mediated gene transfer. Re-introduction of *Edn2* mRNA in *Edn2*$^{-/-}$ *;Rd1*$^{-/-}$ mice did not restore degeneration rates to that of *Rd1*$^{-/-}$ mice ($n=6$; $p>0.05$). We conclude that 1) the Edn2$^{-/-}$ rescue is one of the largest rescue effects on genetic PR degeneration yet identified; 2) the Edn2$^{-/-}$ rescue appears to be mediated extraocularly; 3) since Edn2$^{-/-}$ mice have lung disease, we examined Epo levels: Epo is 15-fold up-regulated in Edn2$^{-/-}$ mice ($n=5$) suggesting that the Edn2$^{-/-}$ rescue is due either to chronic hypoxia, increased Epo, or both. These results are consistent with a rescue of *Rds*$^{-/-}$ and light damage retinas by Epo (Rex et al Mol Ther 2004), and have therapeutic implications for human IPDs.

Highly punctuate patterns of population structure on the X chromosome. *C. A. Lambert[1], C. Connelly[1], J. Madeoy[1], R. Qiu[2], M. V. Olson[1,2], J. M. Akey[1]* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) University of Washington Genome Center, Seattle, WA.

It is well known that overall levels of population structure are higher for X-linked markers relative to autosomal markers in humans. Because the X chromosome has a smaller effective population size relative to the autosomes, genetic drift is expected to be stronger, resulting in higher levels of population differentiation at X-linked loci. Despite this knowledge, there have been surprisingly few analyses on the spatial distribution of population structure along the X. Using publicly available data from the HapMap Project and Perlegen Sciences, Inc., we show a strikingly punctuate pattern of X chromosome population structure. Specifically, 88% (757) of HapMap SNPs with the top one percent of F_{st} values are clustered in four distinct loci. The largest of these loci spans 5.9 Mb and contains nearly 70% (595) of the most highly differentiated HapMap SNPs on the X chromosome. The clustering we observe does not appear to be an artifact of ascertainment bias present in the HapMap data, nor is it specific to the populations genotyped in the HapMap Project. Additional analyses and resequencing data suggest that these four loci have been substrates of recent, strong, adaptive evolution. Thus, natural selection as well as neutral forces like genetic drift have contributed to the differences in extant patterns of variation between autosomal and X-linked markers.

Genome scan in two large families and 33 medium sized families with childhood absence epilepsies. *M. Tanaka[1, 2], J. Bailey[2, 3], B. Minassian[4], M. E. Alonso[5], I. Martinez-Juarez[2, 5], M. Medina[6], R. Duron[2, 6], J. Machado-Salas[2], D. S. Bai[2], G. Pineda[2], I. Pascual-Castroviejo[7], A. Delgado-Escueta[2]* 1) Dept Pharmacology, UCLA, Los Angeles, CA; 2) Epilepsy Genetics/Genomics Laboratory, Neurology Service, GLAVA &. UCLA Los Angeles, CA; 3) Dept of Epidemiology, UCLA, Los Angeles, CA; 4) Genetics and Genome Biology, Hospital for Sick Children, Toronto, Canada; 5) National Institute of Neurology & Neurosurgery, Mexico City, Mexico; 6) National Autonomous University of Honduras, Tegucigalpa, Honduras; 7) Pediatric Neurology, University Hospital La Paz, Madrid, Spain.

We recently discovered three GABRB3 mutations on chromosome 15q 11-12 in 4 families (8%) out of 48 families with remitting Childhood absence epilepsy (CAE). (2008 Tanaka et al). The aim of the present study is to identify other novel loci for absence epilepsy. Genome scan with 440 microsatellites was performed in (a) 33 medium sized families with 400 members (b) 2 large families, namely, family M-17 (four generations with 58 members of which 9 were clinically and 3 EEG affected) and family LA-40 (four generations with 58 members of which 11 were clinically and 1 EEG affected). Each family was ascertained through a proband with CAE . easy LINKAGE program was used for mathematical analyses using 2 diagnostic models assuming 70% penetrance , disease allele frequency of 0.001 and phenocopy and gene mutation rates of 1%. In family M-17, the highest LOD scores were 3.3 (theta=0m=f) for chromosome 4q13 (D4S409) and 2.08 for chromosome 4q35 (D4S1535). However, haplotypes built around D4S409 and around D4S1535 did not segregate with affecteds in family M-17. Because pooled LOD scores in the 33 medium sized families was 3.3 for D12S1045 in chr.12q24.3 and 2.7 for the same D12S1045 in chr.12q24.3 for family M-17 and because the highest LOD score was 2.7 (theta=0m=f) for chr. 10q11 (D10S1220 and D10S1239) in family LA-40, we are looking for recombinations and building haplotypes around chr.12q24.3 and 10q11 in families M-17 and LA-40 and the 33 medium sized families. Present results indicate locus heterogeneity in CAE and we hope to identify the absence causing genes in chr. 12q24.3 and 10q11.

Identification and validation of novel regions associated with sporadic amyotrophic lateral sclerosis (ALS). *J. Huang*[1], J. Jaworski*[2], Y. Yang[1], W. Chen[1], N. Siddique[1], E. Rampersaud[2], H. Khan[1], E. Liu[1], M. Zheng[1], J. Armstrong[1], R. Sufit[1], S. Heller[1], J. L. Haines[3], M. A. Pericak-Vance[2], T. Siddique[1]* 1) Department of Neurology,Northwestern University; 2) Miami Institute for Human Genomics, Miller School of Medicine, University of Miami; 3) Center for Human Genetics Research, Vanderbilt University.

Sporadic ALS (SALS) is a severe neurodegenerative disorder affecting both the upper and lower motor neurons. The genetic etiology of SALS is unknown but believed to be caused by both genetic and environmental factors. To identify genetic variants that predispose to SALS, we performed a case-control genome-wide association study (GWAS) in a US Caucasian sample. We genotyped 1,045 samples (524 cases and 521 controls) using the Illumina 319K genotyping platform. Following quality control checks (assuming a HWE threshold p>0.0001, MAF threshold> 0.10, sample call rate> 98.5%, and SNP efficiency > 95%), 970 samples (488 cases and 482 controls) and 274,494 SNPs remained for analysis. The mean age at onset for cases (and at ascertainment for controls) was 49 12 yrs. Association analyses were performed using the Armitage Trend test in PLINK. We validated our results using publicly available genotype data for 536 samples from the National Institute of Neurological Disorders and Stroke (NINDS) repository. We identified 2,795 SNPS with a P < 0.01, more than would be expected by chance. Our top 10 hits were observed on chromosomes 16, 10, 11, 3, and 7 with the most significant marker on chromosome16 (rs12446182, P = 7.89 x 10-7). To validate our findings we identified SNPs associated with SALS (P<0.05) in either our GWAS or the independent GWAS performed in the NINDS dataset. We then performed a combined meta-analysis of the 708 analyzable SNPs that overlapped both sets. This analysis revealed one SNP (rs130110) on chromosome 22 that met a Bonferroni-corrected significance threshold (P = 3.66 x 10-7, OR=1.84) in the combined dataset of 1,507 samples from both GWAS. Rs130110 lies in intron 1 of FAM19A5, a gene whose protein is expressed primarily in the brain. These results strongly support the the role for multiple genes of modest effect in SALS.

The contribution of Aneusomy 15q25qter to the Aetiology of the Shprintzen-Goldberg syndrome. *D. Tegay[1], P. Papenhausen[2], J. Tepperberg[2], O. Nahum[3], B. Pletcher[4], A. Shanske[5], B. Levy[3]* 1) Med & Med Gen, NY Col Osteopathic Med at NYIT, Old Westbury, NY; 2) LabCorp Inc. Cytogenetics, RTP, NC; 3) Columbia University, Dept of Pathology, New York, NY; 4) Newark, NJ; 5) Children's Hosp Montefiore, Bronx, NY.

The hallmark of Shprintzen-Goldberg syndrome (SGS) is craniosynostosis & marfanoid habitus. The etiology of SGS is uncertain & a single case report links SGS to a mutation in the fibrillin-1 gene (15q21.1). Tetrasomy 15q in the form of a neocentric marker chromosome (NMC) is a rare disorder with only a handful of reported cases, the majority of which have been mosaic. We have identified 3 patients with a non-mosaic NMC resulting in tetrasomy of the distal region of 15q. CENP proteins, FISH, CGH & microarray analysis were used to characterize the NMCs. Case 1: 37 wk gestation, BW of 2317g & length 47cm. Horseshoe kidney with hydronephrosis, metopic & bilateral coronal craniosynostosis that required craniotomy at 5mnth. Non-verbal at 4½ yrs with Turricephaly, thoracodorsal scoliosis, bilateral contractures of digits 2, 3 & 4. Case 2: Evaluated at 32yrs for overgrowth, marfanoid habitus & mild MR. His BW was 5900g & length 63cm. Surgery for craniosynostosis at 8 mnths & scoliosis at 29yrs. At 32 he was 193.5 cm tall with an HC of 57cm. He had dolicocephaly, malar flattening, low-set ears, a pseudo-cleft palate, retrognathia, pectus deformity & was globally delayed. Case 3: FT pregnancy, BW of 3239g. GR at 6yrs with macrocephaly, turricephaly, & very high vaulted & narrow palate with a bifid uvula, kyphoscoliosis, long extremities, flexion contractures of the digits & was non-verbal. Microarray analysis showed the breakpoints in cases 1-3 to be 15q25.2-qter (17.3Mb), 15q26.1-q26.3 (11.3Mb) and 15q26.1-qter (16Mb) respectively. FISH confirmed the tetrasomic nature of the NMC. The striking phenotypic resemblance in our 3 cases points to a role of genes in distal 15q in the etiology of SGS. The 15q24-26 region is rich in segmental duplications which may promote rearrangements of this area. Future studies will attempt to assess how gene dosage or dysregualtion of genes in 15q25-qter contribute to the SGS phenotype.

Mutational screening of regulatory regions flanking GBA in patients with Gaucher disease. *Y. Blech-Hermoni, E. Barnoy, S. Ziegler, B. Stubblefield, K. Hruska, M. LaMarca, N. Tayebi, E. Sidransky* Medical Genetics Br, NHGRI/NIH, Bethesda, MD 20814.

BACKGROUND: Gaucher disease (GD) is the most common lysosomal storage disorder. Almost 300 mutations have been identified in the gene encoding glucocerebrosidase (GBA), the enzyme deficient in GD, resulting in the accumulation of uncleaved substrate in cells of the reticuloendothelial system. Genotype-phenotype correlation in GD remains limited, encouraging the identification of other modifiers that could underlie the high variability in residual enzyme activity and disease severity in patients with the same genotype. The regulatory architecture of GBA has been investigated previously, identifying functional cis-acting regulatory elements within the proximal promoter region of the human gene locus (Doll et al., 1995; Moran et al., 1997), and c-Myc binding sites within 5kb of the translation initiation site. METHODS: We used computational multispecies comparative approaches to identify evolutionarily conserved sequences in the GBA gene locus. Site-directed mutatgenesis was performed to generate constructs with alterations at these specific sites. We used the dual-luciferase expression assay to validate the functional role of these binding sites in COS-7 cells. Finally, we sequenced predicted and previously reported regulatory sites in patients sharing the same genotypes. RESULTS: Our computational analysis of the locus identified two clusters of predicted transcription factor binding sites. Expression assays revealed that changes in six predicted sequences resulted in dramatic downregulation, whereas changes in two sites resulted in statistically significant increases in reporter gene expression. Each sequence is being examined in patient samples to determine whether alterations at these sites impact phenotype. CONCLUSIONS: Computational multispecies comparative approaches identified potential GBA regulatory regions that appear to impact gene expression, providing sites for further evaluation in phenotypically diverse patients with GD.

Promoter variants of endothelial lipase (*LIPG*) are modulators of *LIPG* gene expression and HDL-C concentration in humans. *S. Khetarpal[1], A. Edmondson[1], H. Neeli[2], S. Kathiresan[3], L. A. Cupples[4], S. Demissie[4], A. Manning[4], S. DerOhannessian[1], M. Wolfe[1], D. Rader[1]* 1) Institute for Translational Medicine and Therapeutics, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Temple University, Department of Hospital Medicine, Philadelphia, PA; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) Boston University and Framingham Heart Study.

Increased blood levels of HDL cholesterol (HDL-C) are associated with decreased risk of developing cardiovascular disease. While few genes have yet been implicated in directly increasing HDL-C concentration, one potential candidate is endothelial lipase (*LIPG*), expression of which in animal models is inversely associated with HDL-C levels. We resequenced the *LIPG* promoter in human subjects from extremes of the HDL phenotypic distribution. We identified an excess of rare promoter variants unique to subjects with elevated HDL-C. We also identified a common promoter haplotype. We hypothesized that promoter variants may alter *LIPG* expression and thus alter HDL-C metabolism. To test this hypothesis, we generated a firefly luciferase reporter construct driven by the *LIPG* promoter. Regulatory variants identified through resequencing were introduced into the luciferase reporter construct via site-directed mutagenesis. Many of the variants identified specifically in high HDL-C subjects were found to significantly decrease gene expression in vitro, consistent with reduced *LIPG* expression leading to elevated HDL-C. Genetic association analysis of the common promoter haplotype in the Framingham Heart Study showed that the common *LIPG* promoter haplotype is significantly associated with decreased HDL-C. The luciferase reporter construct containing the promoter haplotype exhibited increased expression in vitro, as predicted. Subjects with the common *LIPG* promoter haplotype were also found to have significantly increased plasma levels of EL protein, as determined by ELISA. Our results suggest that EL is an important modulator of HDL-C metabolism in humans, with regulatory variation of *LIPG* playing an important role in modulating HDL-C concentration.

The Impact of Small Sample Size on the Robustness of Exploratory Pharmacogenetic Studies. *A. H. Beecham[1], M. R. Nelson[2], G. G. Koch[1]* 1) Biostatistics, University of North Carolina, Chapel Hill, NC; 2) GlaxoSmithKline, Research Triangle Park, NC.

The potential for pharmacogenetics to have an impact on drug development is greatest if its contribution to safety or efficacy can be identified in early phase studies. This requires that statistical analyses of genetic studies be conducted with small sample sizes. However, there have been few efforts to characterize the robustness of statistical methods used for such small samples in early phase trials. To quantify robustness, metrics were used from both quantitative trait (QT) and case-control (CC) endpoints related to idiosyncratic hepatotoxicity on genetic and clinical data from early phase development programs. Sixty genetic markers were analyzed in 195 subjects for the QT analysis and 11 cases and 155 controls in the CC analysis. For the QT analysis, wherein the endpoint was strongly skewed, diagnostics were calculated to test the validity of the homogeneity of variance and normality of residuals assumptions. Violations in these assumptions were found so deviance corrected statistics, GEE based empirical Wald and Score statistics, a gamma model, and proportional hazards regression were investigated to address the violations. For each method the effective type I error was computed using a permutation procedure. For the CC analysis the effective type I errors were calculated for the mid-p, Fishers exact, Pearson chi-square, exact Pearson chi-square, likelihood ratio chi-square, exact likelihood ratio chi-square, and Wald chi-square. In the presence of small sample sizes, the normal and gamma model-based and deviance corrected statistics as well as proportional hazards regression tend to overstate association, while the empirical Wald statistic vastly overstates association and empirical score tends to understate association. For all markers the gamma is a better fit than the normal. For the CC analysis, the mid-p operates at the nominal level, while exact tests tend to understate and approximate tests overstate association. These results provide some guidance on selecting appropriate testing procedures for exploratory pharmacogenetics analyses in small sample sizes.

Introduction of prkar1a -/- Mouse Embryonic Fibroblasts in Nude Mice Leads to Tumor Formation: Gene expression after recombinant mouse growth hormone treatment. *S. Boikos, M. Moschovi, M. Nesterova, E. Bimpaki, K. Tsang, C. Cheadle, T. Watkins, YC. Chen, M. Abu-Asab, AF. Parlow, G. Chrousos, CA. Stratakis* SEGEN DEB NICHD, NIH, Bethesda, MD.

Human growth hormone (GH) therapy in cancer patients is controversial because of its potential effects on tumor growth. Patients with Carney complex and PRKAR1A mutations develop acromegaly and various tumors. We wanted to study the effects of recombinant mouse GH (rmGH) on growth of a tumor grown in nude mice after injection of prkar1a-/- mouse embryonic fibroblasts (MEFs). 20 male and 20 female mice (6 weeks and 6 months old), were used for the experiment: all received injections of immortalized $2x10^6$ prkar1a-/- MEFs after soft agar selection. ; all mice formed tumors. Mice received also either placebo or 50 microg/twice-a-day of rmGH. In the 6 weeks age group, male mice treated with rmGH had greater tumor size (24.51 vs. 19.75 1.71 mm, $p<0.01$) than those that were not treated with rmGH. There were no other statistically significant differences. In order to identify genes regulated by Prkar1a and growth hormone, gene expression was assessed by oligonucleotide microoarrays using the Illumina MouseRef8 V2 Expression BeadChip for microarrays. Z-transformation for normalization was performed on each Illumina sample/array. Using a cut-off of >/=2 times,60 genes were upregulated and 26 were downregulated in the tumors grown in male nude mice with GH injection vs male nude mice w/o GH injection . Most of the upregulated genes (Ecm1, s100a8, s100a9 , Esm1, TM4SF3, Itgr1, Dusp6, KLRA4, KLRA15, KLRA16, KLRA18, KLRA20, KLRA33, SOCS2) have been found to be cancer-related. Mouse Klra receptors inhibit natural killer cell cytotoxic activity which are thought to mediate anti-tumoral immunity. SOCS2 suppresses the cytokine signalling and regulates growth hormone signaling. We conclude that rmGH increased the growth of tumors formed by prkar1a-/- MEFs in male nude mice at a young age. These data suggest an age and gender-specific effect of excess GH in prkar1a-induced tumorigenesis. Ongoing studies aim at further investigating the interaction of these genes with the PKA signaling and related pathways.

Polymorphism associated with ORMDL3 expression Defines Non-Atopic Early Childhood Asthma. *H. Bisgaard[1], P. M. A. Sleiman[3], K. Bonnelykke[1], M. Brasholt[1], B. Chaves[1], E. Kreiner-Moller[1], M. Stage[1], C. E. Kim[1], S. F. A. Grant[1], R. Tavendale[2], C. B. Piper[1], C. N. A. Palmer[2], H. Hakonarson[3]* 1) Copenhagen Studies on Asthma in Childhood; University of Copenhagen; 2) Population Pharmacogenetics Group, University of Dundee; 3) Center for Applied Genomics, The Childrens Hospital of Philadelphia, University of Pennsylvania School of Medicine.

A recent GWA identified an asthma predisposition locus on 17q12-q21. Here, we replicate the reported association in the Danish population and further investigate association between a tagging variant and the development of asthma associated phenotypes, including recurrent wheeze, asthma, acute severe exacerbations, eczema, rhinitis and allergic sensitization as well as lung function and bronchial responsiveness (BH) assessed longitudinally from neonatal age to school age. Case control analysis of the COPSAC mothers identified significant association between rs7216389 and asthma (P=3x10-4). TDT confirmed over-transmission of the risk T allele to the affected offspring. Homozygosity of the risk T allele was significantly associated with the development of recurrent wheeze, asthma and acute severe exacerbations (hazard-ratio 2.15 [1.43-3.21], p=0.0002). Children with the TT-genotype had an increased risk of severe exacerbations that persisted from 1 to 6 years of age (incidence ratio 2.48 [1.42-4.32], p-value=0.001) and a corresponding increase in objective assessment of BH from early infancy to school age. Variation at the chromosome 17q12-q21 locus, tagged in this study by the rs7216389 polymorphism, is associated with approximately 2-fold increased risk of asthma, asthma exacerbations and BH from early infancy to school age. The effect size suggests that this locus is the most important currently identified genetic determinant of preschool asthma. Variation at this locus is associated with specific asthma sub-phenotypes characterized by early onset, persistent risk of severe exacerbations, and bronchial hyperresponsiveness but without conferring risk of eczema, rhinitis or allergic sensitization. As such, this locus is the first to harbour variations that defines a particular non-atopic asthmatic phenotype in early childhood.

Diabetes Genetic Variation Pathway: one step toward the personalized medicine. *B. Oh[1], J. Lim[1], J.-T. Woo[2], H. Park[1]* 1) Medical Engineering, School of Medicine, Kyung Hee University, Seoul, Korea; 2) Endocrinology and Metabolism, School of Medicine, Kyung Hee University, Seoul, Korea.

The prevalence of diabetes mellitus has been epidemic worldwide with the greatest increase in Asia, Africa, and South America. The life-threatening complications of diabetes sometimes devastate patients from the retinopathy, nephropathy, lower-limb amputation caused by the continued exposure of tissues to the high glucose. Since the hyperglycemia could be prevented and reversed greatly by changing the life style including the exercise and nutrition, the diabetes risk tests, such as one provided by American Diabetes Association, have been used to alarm the high risk group. However, the increase of diabetes incidence has not been stopped for the last decade, demanding new approaches. Following the growth of genomics, the disease susceptibility of human genetic variations has successfully been explored to provide the better understanding for the development of diabetes mellitus. Since the discovery of TCF7L2 gene in 2006, more than 15 genes have been confirmed to be replicated from diverse populations and the information grows to contribute their genetic variations as risk factors in the development of diabetes. In order to apply the recent discoveries about genetic risk factors in diabetes mellitus into the personalized medicine, the integration of the genetic variation information into the genetic pathway of diabetes, which so called genetic variation pathway, has been attempted. The diabetes genetic variation pathway will be utilized to provide health care providers with the different susceptibility of individuals in diabetes and will be expanded for the selection of high risk group.

Confirmatory Testing Outcomes Following Newborn Screening for Biotinidase Deficiency. *K. Cusmano-Ozog[1], F. Lorey[2], N. N. Kazerouni[2], M. Roberson[2], T. M. Cowan[3]* 1) Dept Medical Genetics, Stanford Univ, Stanford, CA; 2) Genetic Disease Screening Program, CA Dept of Public Health, Richmond, CA; 3) Dept Pathology, Stanford Univ, Stanford, CA.

Biotinidase deficiency (BD), an autosomal recessive disorder of biotin metabolism, is associated with metabolic acidosis, seizures and other serious sequelae. Symptoms are easily treated with biotin, and BD is included in many newborn screening (NBS) programs via colorimetric testing of biotinidase activity on dried blood spots. Positive screening results are followed up by diagnostic enzyme testing in serum or plasma. Such testing identifies affected individuals with absent or near-absent enzyme activity, and may also reveal partial variants and carriers of BD. Because mishandled samples are prone to enzymatic degradation and artifactually low activity, parental samples are requested to be sent as controls where possible. Since NBS for BD was introduced in California in July 2007, 464,073 newborns have been screened. This report summarizes our experience with confirmatory testing of positive results. Prior to formal implementation of BD screening, testing of newborns and parents during the pilot phase allowed for the establishment of reference ranges for normal activity (nmol/ml/min, meanSD; newborns: 4.40.5; adults: 5.20.7), as well as carriers (newborns: 2.30.2; adults: 3.10.5), partial variants (1.40.2) and profound BD (0.40.2). Following implementation, 21 newborns had positive screens; follow-up testing revealed 10 consistent with profound BD, 5 partial variants, 2 carriers and 2 with normal activity. Two patients had biotinidase activity suggestive of either profound or variant BD, but despite parental testing a definitive diagnostic category could not be assigned. Molecular studies are needed to clarify these cases. Two additional newborns had low biotinidase activity which, upon testing of parents, was shown to be due to a sample handling artifact. Our findings reveal an incidence of BD among California newborns of approximately 1/46,000, and indicate that the screening cutoff (6 ERU or 6-10 on two screens) yields a positive predictive value for profound and variant BD of 81%.

A new strategy using sapropterin and placebo to determine the predictive value of mutation analysis towards identifying BH4 responsive hyperphenylalanemia. *J. R. Utz, K. Bentler, D. Markowitz, C. Pham Lorentz, D. Erickson, B. Diethelm-Okita, C. B. Whitley* Pediatrics, University of Minnesota, 420 Delaware St SE, Minneapolis, MN 55455.

Background: Sapropterin dihydrochloride (SAP), a tetrahydrobiopterin (BH4) analogue, is FDA approved for treatment of BH4 responsive Phenylketonuria (PKU) and is the 1st prescription drug therapy approved for PKU disease. SAP responsive patients typically realize a >20% reduction in serum phenylalanine (PHE), which combined with a low PHE diet minimizes the risk of development/progression of severe neurological damage from hyperphenylalanemia (HPA). SAP responsiveness is reported in 20%-56% of patients and is indicated for indefinite, costly SAP therapy. The cost and chronic nature of SAP therapy make accurate and timely verification of responders/non-responders of utmost importance. The ability to predict the likelihood of SAP response would be advantageous towards justifying trials of SAP in HPA patients. To date, no standard methods exist for predicting SAP response. Mutation analysis (MA) has been considered for this purpose, but usefulness towards this end hasn't been established. Our institution was 1st in North America to offer MA to HPA patients and the mutations of most of our patients are known. **Objective:** We describe "START", a clinical diagnostic test designed to evaluate BH4 response; cumulative results may reveal the predictive value of MA towards determining likelihood of BH4 response. **Methods:** HPA patients are randomized in double blind fashion to SAP 20 mg/kg/day or placebo and alternate SAP with placebo weekly. Weekly PHE levels and food diaries are obtained. Weekly treatments are unblinded after 4 weeks and compared to dietary PHE intake and PHE levels. BH4 response is thereby determined and compared to MA. Finally, correlations between MA and BH4 response are cited. **Conclusion:** The determination of the predictive value of MA towards realizing the likelihood of BH4 response will decide if studies are warranted that further explore specific mutation associations with BH4 response, extent of response, and impact on clinical quality and cost-effectiveness of PKU disease management.

GATA4 Gene Deletions Identified by Clinical aCGH Analysis in Cases with Congenital Heart Defects Observed on Fetal Ultrasound. *S.-H. L. Kang[1], O. Shchelochkov[1], A. N. Pursley[1], A. M. Breman[1], C. Sheppard[2], C. A. Bacino[1], A. Dagli[3], R. T. Zori[3], S. R. Lalani[1], A. Patel[1], S. W. Cheung[1]* 1) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Hill Country Maternal Fetal Medicine, Austin, TX; 3) Dept of Pediatrics-Genetics, University of Florida, Gainesville, FL.

Deletions of chromosome 8p23 have been previously identified and characterized. The sizes are reported to range from large terminal >12Mb deletions to <2Mb interstitial deletions. Recurrent deletions have been observed that are mediated by low copy repeats, with a larger ~6Mb deletion usually detectable by routine chromosome analysis and a smaller ~3Mb deletion requiring high-resolution chromosome analysis. The *GATA4* gene maps to chromosome 8p23.1 and is known to cause congenital heart defects when haploinsufficient. The larger recurrent deletion includes the *GATA4* gene, but smaller deletions sometimes may not. DNA microarrays used for clinical diagnosis are usually enriched for chromosome regions that contain dosage sensitive genes. Although the referral for aCGH testing is now commonplace postnatally when genomic disorders are suspected, it is not often considered in the prenatal period when ultrasound abnormalities are detected. Here, we present four cases where cardiac abnormalities were observed on prenatal ultrasound and the clinical aCGH test detected a recurrent deletion of at least 2.9Mb in size on chromosome 8p23.1 including the *GATA4* gene. Two of these cases were diagnosed prenatally (twins; case 3 and 4) and two in the neonatal period (case 1 and 2). Chromosome analyses were also performed prior to or concurrently with aCGH on all four cases and an interstitial deletion of chromosome 8p23.1 was detected in three of the four cases (1, 3, and 4). Importantly, involvement of the *GATA4* gene is not distinguishable by karyotype analysis alone. In addition, case 2 was also evaluated for possible DiGeorge syndrome by FISH analysis before the aCGH test was ordered. These cases further demonstrate the superior value of aCGH analysis in the prenatal period, particularly when ultrasound abnormalities such as heart defects are observed.

Deep Sequencing of Two Neighboring Autism Candidate Genes: Myo1D and TMEM98. *S. Strom, B. Merriman, S. F. Nelson* Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA.

Linkage analysis has identified chromosome 17q as a region linked to male-specific autism. This linkage signal is derived from a set of 69 affected brothers sharing both alleles (Z2) across this region. Association analysis highlighted several candidates, in this interval, including a locus spanning two known genes Myo1D and TMEM98. To determine if coding variants in these genes are associated with autism, all coding exons in both genes were sequenced one brother from each of the 69 male sib-ships exhibiting Z2 sharing. In total, over 50kb of sequence was generated for each individual, with an average 20x overall coverage. These data are sufficient to rule out the possibility that coding variants in these two genes contribute to autism etiology. However, sufficient coverage of intronic sequence prevents these genes from being eliminated as candidate genes.

Patterns of Genetic Variation at *ICAM-1* in Diverse African Populations. *F. Gomez[1,2], G. Tomas[3], J. Rocha[3], S. A. Tishkoff[1]* 1) The Department of Genetics, The University of Pennsylvania School of Medicine, Philadelphia, PA; 2) The George Washington University, Washington, DC; 3) Instituto de Patologia e Imunologia Molecular da Universidade do Porto, Portugal.

Malaria, resulting from infection by the *Plasmodium falciparum* parasite, causes millions of deaths each year and is one of the strongest selective forces in recent human evolution. ICAM-1 (intercellular adhesion molecule-1) is a major vascular endothelial receptor for *P. falciparum* parasitized erythrocytes, and therefore may affect susceptibility to malaria. Currently, the clinical consequences of nucleotide diversity at *ICAM-1* are not well understood. This study seeks to examine nucleotide variation at *ICAM-1* in diverse African populations to better understand the scope of genetic variation at this locus and to identify variants that may influence susceptibility to malaria. A panel of ~200 individuals originating from Nigeria, Cameroon, Ghana, Tanzania, Kenya, and the Sudan were re-sequenced across a ~7 kb region of *ICAM-1*. Individuals from Thailand and Portugal were also re-sequenced as comparative data. Using these data we have characterized levels of diversity and have used tests of neutrality to identify signatures of natural selection. Initial haplotype analyses suggest that there are more unique haplotypes in Africa than in Europe or Asia. Additionally, a well-studied SNP that may influence susceptibility to severe malaria, called *ICAM-1*$^{\text{Kilifi}}$, was identified at high frequency within Africa and Asia. In Asia *ICAM-1*$^{\text{Kilifi}}$ was identified on a single haplotype background, and in Africa this variant was found on several distinct haplotype backgrounds suggesting that it may have originated in Africa, rather than in Asia.

Prediction of SNPs affecting transcriptional regulation at complex trait susceptibility loci. *K. J. Gaulton[1], C. J. Willer[2], K. L. Mohlke[1]* 1) Dept of Genetics, University of North Carolina, Chapel Hill, NC; 2) Dept of Biostatistics, University of Michigan, Ann Arbor, MI.

Genome-wide association (GWA) studies have successfully identified loci harboring risk variants for numerous traits and common diseases. However, many of these loci have tens to hundreds of associated variants and thus identifying the variant(s) functionally responsible for an association signal often requires prioritizing between SNPs. As many functional variants likely have a regulatory effect on transcription, we developed a naïve Bayesian classifier to predict SNPs in likely regulatory elements. This approach uses a training set to derive the likelihoods that multiple conditionally independent datasets will correctly predict regulatory elements, and uses the joint likelihoods to classify SNPs. We integrated the 12.2 million records in dbSNP with 19 genome-wide datasets characterizing transcriptional regulation, such as DNase hypersensitivity, histone modifications, and transcription factor binding. After training the algorithm with SNPs in genomic regions previously shown to have positive or negative evidence of a regulatory effect, preliminary results suggest that DNase hypersensitivity and H3K4me1 are among the strongest predictors. We tested the classifier on 1,590 SNPs at 60 independent loci associated with type 2 diabetes, body-mass index, triglyceride level, HDL-C level or LDL-C level and without an obvious non-synonymous variant. 188 (11.8%) SNPs were predicted to be located in regulatory elements, an average of 3.1 per locus. Compared to all SNPs in dbSNP, more SNPs than expected by chance were located in TRANSFAC conserved transcription factor binding sites (obs=8, exp=1.6, p=4.2x10-5) and in genomic regions highly conserved across 28 species (obs=11, exp=4.5, p=5.6x10-3). The quality of predictions will continue to improve as additional independent datasets are incorporated. These results suggest that our approach may enrich for SNPs affecting regulation, providing useful information for functional studies at complex trait associated loci.

In Silico fine mapping: The example of gene expression traits in Mouse Liver. *M. A. Rivas[1,2,3], C. Cotsapas[2,3], A. Kirby[2,3], B. M. Neale[2,3], P. Little[4], T. Wiltshire[5], M. J. Daly[2,3]* 1) Dept Mathematics, Massachusetts Inst Technology, Cambridge, MA. USA; 2) Broad Institute of MIT and Harvard, Cambridge, MA. USA; 3) MGH Center for Human Genetic Research Boston, MA. USA; 4) School of Biotechnology and Biomolecular Sciences, University of New South Wales, Randwick, NSW 2052, Australia; 5) Genomics Institute of the Novartis Research Foundation, San Diego, CA. USA.

The genetics of gene expression has been proposed as a way to understand the molecular basis of phenotypes. In this study we demonstrate the power of the Mouse HapMap to perform in silico fine-mapping of eQTLs in mouse liver. We take advantage of the Mouse HapMap, a genome-wide map composed of ~130k SNP variants typed in 94 common inbred lab strains, to enable genotype-phenotype expression correlation analysis. We integrate genotype and phenotype data from 31 BXD strains and 28 classical inbred strains and combine eQTL analysis from these two studies to fine-map loci found in the BXD strains by looking at the added genetic variation captured and shorter LD segments in the classical inbred strain simultaneously. We have implemented an analytic design that addresses biases due to small sample size, over-dispersion effects of statistics, and population substructure. We extend this strategy for analyzing gene expression data to unravel how cis-acting genetic factors influencing gene expression vary from tissue to tissue. Our combined analysis shows at least 25% concordance reached by comparing eQTLs across classical inbred and recombinant inbred strains. We are able to fine-map loci found in the BXD strains by looking at the additional genetic variation and shorter LD segments in the classical inbred strain data. We can resolve eQTL intervals from 10-20 Mb down to 1-5 Mb, and in some cases much smaller intervals. This greatly reduces the burden of subsequent fine mapping to identify the causal variants, and we anticipate that this combined strategy will be applicable for many phenotypes.

Heritability of HCFC1 expression levels from the inactive X chromosome. *J. Stahl, L. Carrel* Penn State College of Medicine, Hershey, PA.

X chromosome inactivation silences one X chromosome in females to equalize X gene dosage between males and females. However, 15% escape X inactivation and are expressed from both the inactive X (Xi) and active X (Xa). An additional 10% are variable and escape in only a subset of Xs tested. How variable Xi expression contributes to normal trait variation amongst females is unknown but of utmost interest. To better understand factors influencing Xi expression, we sought to determine whether variable Xi expression patterns are heritable. We tested Xi expression in clonal lymphoblast lines from three-generation CEPH pedigrees. Using a quantitative allele-specific expression assay, we tested 14 independent Xs and identified five loci with variable Xi expression. We focused on two genes in Xq28, HCFC1 and ARD1A. Xi levels for HCFC1 in nine independent Xs ranged from 0-23% of Xa levels, while ARD1A in five Xs ranged from 0-33% of Xa levels. To determine whether Xi expression levels reflect escape in a subset of cells or low expression in all cells, we tested HCFC1 in 9 independent subclones from one individual. Two distinct patterns emerged; the five subclones carrying an inactive HCFC1 C-allele had no Xi expression, whereas four lines with an Xi T-allele had Xi levels at ~10% of Xa levels. These data suggest Xi levels are not stochastic and reflect reduced Xi expression in all cells. Further, Xi expression differences in clones from a single individual are inconsistent with autosomal inheritance for this locus. To further evaluate Xi heritability, we tested HCFC1 in informative females from one pedigree. Different Xi expression levels were seen for different Xs. One Xi tested in four individuals was 0-4% of Xa levels, whereas another tested in three individuals was 10-22% ($p<0.05$). Xi expression levels for HCFC1 appear heritable and X-linked. However, a maternal Xi allele of ARD1A significantly differed in sisters (0% and 26%), inconsistent with X-linked inheritance. These data illustrate complexity in Xi regulation and suggest both cis and trans factors impact expression. Further, the identification of epigenetic and genetic factors influencing variable escape from Xi will aid in evaluating phenotypic consequences of Xi expression.

The Fanconi anemia pathway plays a critical role in regulating telomeric recombination in ALT-immortalized human cells. *M. Meyn[1,2,3], C. Yeh[1,2], F. Al Murshedi[2,3], H. Root[1,2]* 1) Genetics & Genomic Biology, Hosp Sick Children, Toronto, ON; 2) Molecular Genetics, Univ Toronto, Toronto, ON; 3) Paediatrics, Univ Toronto, Toronto, ON.

To understand how Fanconi anemia (FA) proteins may function in genetic recombination, we are studying the role FA proteins play in the recombination-dependent ALT telomere maintenance pathway. We have found that FANCD2 localizes to telomeric foci in ALT cells, where it interacts with the telomeric protein TRF2 and the BLM helicase. We now report FA pathway proteins upstream (FANCA, FANCG and FANCM) and downstream (BRCA1, FANCJ, and BRCA2/FANCD1) of FANCD2 mono-ubiquitination form nuclear foci that localize to telomeric foci and PML bodies in ALT, but not in telomerase-positive or primary human cells. These FA-related proteins typically associate with telomeric foci containing FANCD2. Depletion of FANCD2 in ALT cells leads to telomeric entanglements, telomere dysfunction-induced foci, rereplicated DNA, mitotic failure and cell death. We now report ALT cells depleted of TRF2 show a similar phenotype. Notably, in telomerase positive cells, TRF2 depletion also results in telomere fusions followed by cell death/senescence, while telomere abnormalities are minimal after FANCD2 depletion.

Our results suggest disruption of the FA pathway causes mitotic catastrophe in ALT cells through effects on telomere homeostasis. Loss of TRF2 uncaps telomeres, leading to their recognition and processing by DNA repair proteins. We find depletion of FANCD2, but not TRF2, causes ALT-specific amplification of telomeric DNA and the appearance of nuclear filaments of the recombination protein RAD51, suggesting that FANCD2 depletion in ALT cells does not simply result in telomere uncapping. Rather, we hypothesize the FA pathway limits telomeric recombination and/or controls resolution of telomeric recombinational events in ALT cells. In the absence of a functional FA pathway, we propose that unregulated recombination causes telomere amplification and entanglement. This leads to continued cell growth without proper segregation of DNA, resulting in multiple secondary abnormalities and mitotic catastrophe.

Mechanistic insights into ring chromosome formation using SNP arrays. *L. K. Conlin[1], B. D. Thiel[1], S. A. Hosain[2], P. S. Munoz[1], J. T. Glessner[1], H. Hakonarson[1], I. D. Krantz[1], N. B. Spinner[1]* 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) UMDNJ Robert Wood Johnson Medical School, New Brunswick, NJ.

Ring chromosomes are associated with varied clinical features depending on the chromosome and the specific sequences involved. We are particularly interested in the ring chromosome 20 (r(20)) syndrome, which is associated with a characteristic form of epilepsy. Several mechanisms for how ring chromosomes impact phenotype have been proposed including deletions at the fusion points, mitotic instability, and gene silencing due to altered chromatin conformation. We studied 16 patients with ring chromosomes to understand their composition and mechanism of formation. We analyzed 9 r(20), 3 r(X), and one each r(3), r(17), r(22), and r(Y) chromosomes by cytogenetics, FISH, and SNP array analysis. SNP array analysis provided both genomic content and inheritance information for the 47,+(r) patients, with two of the three rings showing complex meiotic inheritance. Among the 13 patients with a 46,(r) karyotype, two distinct groups were observed. First, are rings that are present as mosaics with no evidence for genomic loss. All six of these rings were present in conjunction with a normal cell line, consistent with their formation postzygotically. Second, are those that have no evidence for a normal cell line and have loss of material from the ring chromosome. All seven patients with non-mosaic rings had loss of genomic material at one or both telomeres. We propose that these rings occurred during meiosis. Of note, patients with r(20) fall into both groups, indicating the seizures do not result from loss of neurologically relevant genes on chromosome 20. For all autosomal rings, SNP array analysis on peripheral blood DNA showed no evidence for low-level mosaicism for monosomy, or for uniparental isodisomy in the normal cell lines, suggesting these mechanisms do not contribute to the clinical phenotype. Further studies are directed at extending these observations to additional patients, identifying the sequences involved in creation of the ring to understand the mechanism behind the associated clinical features, and elucidating the impact of ring formation on gene expression.

Missense mutations in PDE11A segregate with the disease in kindreds with testicular cancer. *A. Horvath[1], L. Korde[2], R. Libe[3], P. Osorio[1], K. Tsang[1], Y. Patronas[1], L. Tschoukani[1], L. Drori-Herishanu[1], E. Remmers[4], J. Bertherat[3], M. Greene[2], C. Stratakis[1]* 1) NICHD, NIH, Bethesda, MD; 2) NCI, NIH, Bethesda, MD; 3) Institute Cochen, Paris, France; 4) NHGRI, NIH, Bethesda, MD.

Inactivating mutations in the phosphodiesterase (PDE) 11A (PDE11A) have been implicated in predisposition to adrenocortical hyperplasia. PDE11A expression in testicular tissue were shown to be the second highest among the studied human tissues - slightly lower than in the prostate and significantly higher than in the adrenal cortex. Male sterility has been seen in the pde11a-/- mouse, and sterility in humans has been linked to TC. In this study, we sequenced the PDE11A gene coding region in 95 patients with testicular cancer (TC) from 40 unrelated families. We identified 8 different non-synonymous substitutions in a total of 23 patients from 13 families. Five of the variations were novel two we have reported before in patients with adrenocortical tumors and one was a common polymorphic variant. With the exception of one patient, all PDE11A missense variants coexisted with the disease status in the affected family members. We compared the frequency of these variants with that in a cohort of 200 unrelated controls who had been screened and found to be negative for adrenocortical diseases: only the two previously reported (R804H and R867G) that are known to be present in the general population were found in this control group. However, R804H and R867G were significantly more frequent among patients with TC than in controls (P=0.012); the combined frequency of nonsynonimous substitutions was significantly higher among TC patients (P=0.0004). Immunohistochemistry studies showed lack of expression of PDE11A protein in the tumor tissues of patients carriers of mutations in PDE11A. Ongoing studies investigate the expression of PDE11A in TC samples from these patients and the gonads of the pde11a-/- mouse. Our data suggest that PDE11A missense changes are perhaps among the many other genetic factors that may confer a predisposition to testicular tumors either within the context of the cAMP-signalling pathway or as players in a multisignaling system that controls germ cell develoment and/or tumorigenesis.

Comparison of Cardiac Pathology in Three Strains of Murine Mucopolysaccharidosis Type I: Considering the Role of Auto-immune Pathogenesis in Hurler Syndrome. *E. A. Braunlin, R. Gunther, S. L. Sandberg, R. D. Cooksley, B. Konair, C. B. Whitley* Pediatrics and Institute of Human Genetics, University of Minnesota, Minneapolis, MN.

BACKGROUND In studies of gene therapy in murine models of Hurler syndrome, we observed much longer, stable expression of -L-iduronidase (IDUA) enzyme activity in the immune-deficient strain of the IDUA knock-out mouse derived by Clarke and colleagues (NOD/SCID) in comparison to the immune-competent mouse derived by Neufeld and colleagues. HYPOTHESIS For ongoing studies that define the therapeutic response to various forms of gene therapy, we sought to characterize the untreated phenotype in both strains, and compare these to the third strain (Clarke mutation in immune-competent B6 mice) for which the cardiac anomalies have already been described (Braunlin et al, Pediatric Research 59:27-32, 2006). This may be particularly important because of the recent hypothesis that some aspects of Hurler syndrome may be auto-immune in nature. MATERIALS AND METHODS Echocardiography and histopathologic analyses of the heart were evaluated in two groups of normal and affected, 7- to 11-month-old male mice from both strains (Neufeld mutation in B6, and Clarke mutation in NOD/SCID), and the findings were compared to the previously-published studies of the Clarke mutation in the B6 background. RESULTS The comparison showed that the Clarke and Neufeld mutations on the B6 background have essentially the same echocardiographic and histopathologic abnormalities with aortic insufficiency being common in both, 10/10 and 9/13, respectively. However, mice with the Clarke mutation on the NOD/SCID background were found to have a much lower 2/12 incidence of aortic insufficiency, despite equal or greater amounts of lysosomal inclusions. CONCLUSIONS These observations in murine Hurler syndrome support the hypothesis that some aspects of the clinical phenotype are auto-immune mediated, an important factor in considering the modalities of treatment, and response to various forms of gene therapy. Comparison of the neuropathology in affected mice is currently in progress. (Supported by P01-HD032652).

Potential utility of germline genetic profiling in colorectal cancer screening: A simulation study. *S. Hawken, J. Little* Epidemiology and Community Medicine, University of Ottawa, Ottawa, Canada.

Genetic variants associated with colorectal cancer(CRC) in candidate gene and GWA studies mostly have low-penetrance. Theoretically, multiple common, low-penetrance variants collectively (not singly) could have utility in triage. Thus, while it is unlikely that a purely genetic test would be used alone, it could identify individuals at elevated genetic risk for enhanced screening surveillance. Canadian and US recommendations are for fecal occult blood (FOB) screening for all individuals 50 years and older. However compliance tends to be very low. Higher uptake rates of CRC screening have been reported in higher risk individuals (e.g.family history of disease). Hence if screening compliance in response to a positive genetic test improved to levels similar to those seen in subjects with elevated familial risk, then a substantial number of additional CRC cases might be detected early, possibly reducing CRC incidence and mortality. Using a representative population age and sex distribution from census data, 10-year age and sex specific CRC incidence rates, and varying test predictive power and compliance rates, we demonstrate that a predictive genomic test could concentrate the subjects at the highest genetic risk into a subset of the population, thus creating an enriched pool of screenees, while also simultaneously enhancing compliance to screening. For example, in the absence of a predictive genetic test, and 25% compliance with conventional screening (the current norm), 2746 cancers would get screened by the FOB test for every 1,000,000 (1M) people referred. If a strongly predictive test that concentrated 80% of cases into the top 50% of the sample were applied (i.e. 2M tests, top 1M referred to screening), and screening compliance remained at 25%, then 4398 cancers would get screened. If in addition to the strongly predictive test, the screening compliance were to improve from 25% to 40% ,7039 CRC cases would get screened, an increase of 4293 CRC cases over the baseline, for every 1M in whom screening is recommended. The majority of these cancers would be detected by the latest screening technologies.

Genome-wide genetic association study of Chronic Obstructive Pulmonary Disorder. *B. T. Webb[1,2], E. J. van den Oord[1,2], T. P. York[1,3], Y. Jia[4], E. L. Murrelle[4]* 1) Center for Biomarker Research and Personalized Medicine; 2) Department of Pharmacy; 3) Department of Human Genetics, Virginia Commonwealth University, Richmond, VA; 4) Philip Morris USA Inc. Research Center, Richmond, VA.

Chronic obstructive pulmonary disease (COPD) is a complex disease characterized clinically by airflow obstruction with cigarette smoking as primary environmental risk factor. To identify genetic risk factors for COPD, a genome-wide association study (GWAS) was performed in a sample of 200 adult smokers with COPD, 100 adult smoker controls without COPD, and 100 non-smoking controls. Using longitudinal spirometric data, basic linear unbiased predictors (BLUPs) that disentangle the pathology of COPD were calculated and analyzed as outcomes in order to increase power. The BLUPs analyzed in the GWAS included baseline lung function (Int), age related decline (AgeDec), cigarette smoke induced decline (CSDec), and an interaction between age and smoke induced decline (Age×CSDec). The minimum SNP association P values observed were 2.33×10^{-7}, 1.90×10^{-6}, 1.90×10^{-6}, and 8.5×10^{-6} for AgeDec, CSDec, Age×CSDec, and Int, respectively. False discovery rate (FDR) analysis showed the AgeDec and CSDec were enriched for significant associations. A minimum SNP specific FDR or q-value of 0.14 was found with AgeDec. A total of 33 SNPs had q-values less than 0.5 with most being associated with CSDec. Clusters of associated SNPs were found in several genes including ones which are strong candidates for COPD. The findings are generally consistent with previous evidence that immune system dysregulation is involved in the pathophysiology of COPD and that genetic differences in regulation of CS-induced inflammatory changes may influence individual disease risk. In summary, we identified several novel COPD associations in genes with functions in known COPD biological processes including cilia function / lung clearance and neutrophil activation and regulation.

Detection of sex chromosomes abnormalities; cytogenetics versus array-CGH. *M. J. Simovich, SH. L. Kang, XY. Lu, T. Sahoo, S. Lalani, C. Bacino, P. Stankewicz, A. Patel, SW. Cheung* Dept of Molecular & Human Genetics, Baylor College of Medicine.

Sex chromosome aneuploidy, microdeletions and microduplications are of specific interest due to their association with a variety of clinical syndromes. We compared the sensitivity of conventional cytogenetics versus array-CGH for detecting abnormalities of the X and Y chromosomes in samples received from January 2005 to December 2007. We identified abnormalities in 312 patients by array-CGH and in 87 by routine karyotype analysis.

	Array-CGH analysis	Karyotype analysis
X/Y aneuploidy	42	40
X/Y duplication	47	3
X/Y deletion	39	1
X/Y derivative	13	12
Multiple cell line	14	31
CNV	123	0
UCS	34	0

Array CGH identified significantly more small deletions and duplications on the X chromosome than standard G- band analysis. Our study shows that array-CGH is more sensitive than conventional chromosome analysis in detecting pathogenic copy number changes on the X chromosome.

Genome-wide map of allelic expression associated SNPs. *T. Pastinen[1,2], B. Ge[2], D. K. Pokholok[3], E. Grundberg[1,2], D. Verlaan[1,2], T. Kwan[2], V. Koka[2], K. Lam[2], L. Morcos[1,2], A. Montpetit[2], M. M. Joly[2], H. H. H. Göring[4], M. Blanchette[5], K. L. Gunderson[3]* 1) Depts of Human and Medical Genetics, McGill Univ, Montreal, Canada; 2) McGill Univ and Genome QC Innov Ctr, Montreal, Canada; 3) Illumina Inc, San Diego, CA; 4) SFBR, San Antonio, TX; 5) Dept of Computer Sci, McGill Univ.

Genetic variants altering gene expression in cis (cis-eSNPs) are an important source of phenotypic differences. We have shown earlier that such variants can be mapped using allelic expression (AE). Differential AE can be thought of as a read-out of cis-acting components of expression variance. AE mapping requires heterozygous sites in transcripts and quantitative detection of differences between heterozygote ratios in paired DNA and RNA samples. Here we have developed a first generation genome-wide map of AE associated SNPs (aeSNPs) in 50 lymphoblastoid cell lines from HapMap, using SNP genotype data from Human 1M BeadChips (Illumina). The AE was measured in unspliced primary trancripts allowing intronic SNPs to be used. Using 2SNPs for each transcript and a normalization algorithm for calculating differences in gDNA/cDNA allele ratios resulted in ~90% concordance in AE calls with Sanger sequencing. To map aeSNPs ~0.9Gb of genome, including 10K RefSeq genes, was partitioned into 80K informative windows - regions with 2 expressed SNPs in at least eight heterozygous individuals. AE was observed in 3 samples in 40% of windows, and we were able to merge 17K windows into longer expressed regions with continuous differential AE. At p<10E-6 we detected aeSNPs for 2052 RefSeqs and 1463 regions outside RefSeq annotations. A 58% overlap was observed between earlier described transcript level cis-eSNPs and aeSNPs. Conversely, aeSNPs showed converging eSNPs in 38% of cases. Complex patterns of heritable AE observed in disease and other loci underscores diversity of functional variation in human genes. Over 20 candidate regions with strong AE but no aeSNPs are candidates for novel imprinted loci. We are now pursuing AE mapping in additional samples, populations and cell types as well as developing new statistical approaches for aeSNP detection.

THE 1000 GENOMES PROJECT. *D. Altshuler[1,2,3] for the 1000 Genomes Project Consortium (www.1000genomes.org)* 1) Massachusetts General Hospital; 2) Harvard University; 3) Broad Institute of Harvard and MIT.

The first generation of genome wide association studies have demonstrated that systematic studies of genetic variation offer a general approach to map novel loci contributing to common human diseases and medical phenotypes. At only a few such loci are causal mutation(s) yet identified, however, and most heritability of common diseases remains unexplained. Thus, the next steps in genetic mapping require a more complete picture of single nucleotide and structural variants across human populations, and methods to discover rare variants with high specificity and accuracy. We have formed an international public-private consortium, The 1000 Genomes Project, to identify and make publicly available all DNA variation in the accessible genome at minor allele frequency (MAF) 1% and above. A variety of next-generation sequencing technologies are being employed and compared. The consortium includes sequencing centres, technology companies, statistical and population geneticists, ethicists, and funders. Data will be released without restriction before publication via sites at the EBI and NCBI. Cell lines are widely available for further study. Our focus in 2008 is three pilot projects: 1) To evaluate strategies to identify variants by combining data across multiple samples: low coverage whole genome sequencing of 180 individuals from the HapMap CEU, YRI and CHB/JPT populations. 2) To obtain high quality reference data for a small number of individuals, and to evaluate the tradeoffs between depth, coverage, sensitivity and accuracy: high coverage whole genome sequencing of two parent-offspring trios. 3) To explore strategies and technologies for capature and deep sequencing of functional gene region: deep sequencing of ~1000 genes in ~1000 samples,. At the time of submission 600 Gb of data (over 200-fold coverage of the human genome) have been deposited and are being processed for public release. We anticipate that data collection for the three pilots will be complete by ASHG, and propose to to present the design, rationale, initial results and analysis of the 1000 Genome Project data.

Development of Methods to Improve Base Calling for DNA Resequencing Arrays. *W. Wang[1], P. Shen[1], M. Yu[1], T. Klopstock[2], R. Horvath[3], C. Palm[1], L. Pique[4], I. Schrijver[4], D. Cutler[5], M. Mindrinos[1], R. Davis[1], T. Speed[6], C. Scharfe[1]* 1) Stanford Genome Technology Center, Stanford U., Palo Alto, CA, USA; 2) Dept of Neurology, Ludwig Maximilians U., Munich, Germany; 3) Friedrich-Baur-Inst, Ludwig Maximilians U., Munich, Germany; 4) Dept of Pathology and Pediatrics, Stanford U., Stanford, CA, USA; 5) Dept of Human Genetics, Emory U., Atlanta, GA, USA; 6) Dept of Statistics, UC Berkeley, Berkeley, CA, USA.

The identification of rare DNA variants (1-3%) in disease candidate genes across many medical cases remains challenging. Medical resequencing (MRS) arrays custom-designed using Affymetrix GeneChip technology provides a strategy for DNA sequencing of up to 300kb per array. For diploid genomes, available base calling tools are limited and based on pixel-level data and likelihood ratio tests. Previous success with RMA (robust multi-array analysis) for gene expression and SNP arrays suggest that the analysis of probe-levels across multiple arrays improves the signal detection. Here we take advantage of these ideas and develop novel methods for MRS array analysis to account for the following: 1) The amplification of individual DNA fragments leads to heterogeneity in data quality; 2) The classification of genotypes is based on query of all four possible nucleotides on both strands; and 3) The probes move along the sequence one base at a time, creating a continuous decrease of the neighboring probe intensities around a SNP location. Our custom-designed MRS arrays contain all exons and intronic splice-sites of 39 nuclear-encoded mitochondrial genes that are candidates for hereditary optic neuropathies. We Sanger-sequenced four genes for reference. Our analysis of 40 MRS samples using established algorithms (i.e. GSEQ, RATools) in comparison to our methods improves the detection of non-variants, homozygote and heterozygote variants with reduction in false positive and false negative base calls. Our efforts lead to improvements of laboratory protocols for array processing and represent steps towards our goal to perform cost-efficient candidate gene resequencing in human disorders.

A genome-wide association study of 1,000 Han-Chinese with Type 2 diabetes mellitus cases vs. 1,000 controls residing in Taiwa. *J. Y. WU[1,2], F. J. TSAI[2], C. C. CHEN[2], P. CHEN[1], C. F. YANG[1], C. H. CHEN[1], Y. M. LIU[1], C. F. SHIU[1], C. S. J. FANN[1], Y. T. CHEN[1]* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) China Medical University Hospital, Taichung, Taiwan.

Background Type 2 diabetes mellitus (T2DM) is the forth leading cause of death in Taiwan. The prevalence of DM in Taiwan increases from 4.63% in 2001 to 4.69% in 2003 and the mortality from diabetes mellitus has almost doubled over the past ten years. This study aims to identify genetic components associated with T2DM, which is significant for the Han-Chinese, account for 98% of the Taiwan population.

Methods A total of 1,000 Han-Chinese T2DM patients and 1,000 random controls were genotyped with the Illumina Hap550duov3 chip as well as the deCode CNV chip. Type II diabetes mellitus was diagnosed using the American Diabetic Association Criteria. All 1000 patients were recruited from the China Medical University Hospital, Taichung, Taiwan. DNA of the 1,000 random controls was selected from the Taiwan Han-Chinese Blood and Cell Bank, Academia Sinica, Taiwan. We excluded SNPs from further analyses by three major criterions: (1) missing data rate>5%, (2) missing data rate>1% for SNPs with a minor allele frequency < 5%, and (3) p-value of Hardy-Weinberg Disequilibrium test <10-7. Haplotpye (multi-point) analyses were applied to summarize regions with multiple significant points.

Results A total of 517,401 SNPs (92.36%) passed the quality control filter with an average call rate of 99.91% and subjected to genome-wide association analysis. None of the SNPs were significant at = 10-7. However, 10 SNPs and 4 regions showed positive association (10-7 < p < 10-5); none of these were located at or near the points previously reported by others.

Summary We have identified novel SNPs/regions associated with Chinese patients with T2DM. Our study indicated the heterogeneity of type 2 diabetes mellitus between the Asian and Caucasian populations.

Association of 9p21 SNPs with premature atherosclerosis in the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study. *T. D. Howard[1], Y. Liu[1], C. D. Langefeld[1], K. Konvicka[2], E. Beilharz[2], C. Johnson[3], J. E. Hixson[4], J. I. Rotter[5], Y.-D. I. Chen[5], D. A. Troxclair[6], G. T. Malcom[6], J. P. Strong[6], D. M. Herrington[1]* 1) Wake Forest Univ Health Sciences, Winston-Salem, NC; 2) Perlegen Sciences, Inc, Mountain View, CA; 3) Univ of Washington, Seattle, WA; 4) Univ of Texas Health Science Center, Houston, TX; 5) Cedars-Sinai Medical Center, Los Angeles, CA; 6) LSU Health Sciences Center, New Orleans, LA.

Several groups have reported an association of SNPs on 9p21 (rs10757274 & rs2383206) with coronary artery disease and MI. This association was replicated in several adult Caucasian populations with coronary disease based on clinical events, angiography or coronary CT. To increase the pathophysiologic specificity of this association and to explore it in other ethnic groups, we evaluated 1065 individuals from PDAY. PDAY consists of individuals ages 15-34 that died of non-cardiovascular causes. A standardized autopsy protocol quantified the percent surface area involvement of raised atherosclerotic lesions in the abdominal aorta, thoracic aorta, and right coronary artery (raised lesion score). 357 cases (166 African-Americans, 191 Caucasians) with the highest total age-adjusted raised lesion scores were frequency matched on age, race, and gender with 708 controls (331 African-Americans, 377 Caucasians) with the lowest total raised lesion scores. Genotypic distributions were consistent with HWE in controls (p=0.21, 0.17), but not cases (p=0.054, 0.0072). In Caucasians the ORs under an additive model for rs10757274 and rs2383206 were 1.27 and 1.29 (nominal p=0.037 & 0.049, respectively), with the G allele for both SNPs associated with increased risk for extensive premature disease. In African-Americans, borderline evidence for association was observed (nominal p=0.052 & 0.067), but the direction of the association was reversed (OR 0.72 & 0.78). **Conclusion:** These data suggest that rs10757274 and rs2383206 are associated with premature and pathologically-defined atherosclerosis in Caucasians, but not African-Americans, and that a genetic predisposition for atherosclerosis may be the underlying pathological determinant of the previously reported associations with CVD.

Genome wide association identifies an asthma susceptibility locus on chromosome 1q31 in both Caucasian and African American children. *P. Sleiman[1], M. Imielinski[1], J. P. Bradfield[1], K. Annaiah[1], S. Willis-Owen[2], N. M. Rafael[3], S. Michel[4], C. E. Kim[1], R. Grundmeier[5], J. Allen[6], J. Spergel[7], J. Christie[8], M. Kabesch[4], M. F. Moffatt[2], M. M. Grunstein[5], K. C. Barnes[3], M. Magnusson[9], S. F. A. Grant[1,9], H. Bisgaard[10], H. Hakonarson[1,6,9]* 1) Center for Applied Genomics, Children's Hospital of Philadelphia; 2) Imperial College London, UK; 3) Johns Hopkins University, Baltimore; 4) Ludwig Maximilian University, Munich, Germany; 5) Dept of Bioinformatics, CHOP; 6) Division of Pulmonary Medicine,CHOP; 7) Division of Allergy and Immunology, CHOP; 8) Division of Pulmonary Medicine, University of PA School of Medicine; 9) Dept of Pediatrics, CHOP; 10) Department of Health Sciences, University of Copenhagen.

Asthma is a heterogeneous disease of complex etiology. We carried out a GWA study utilizing over 545,000 SNPs in 2236 pediatric asthma patients, including 569 North Americans of European ancestry and 1667 African Americans. We describe a locus on chromosome 1q31 containing multiple common variants that are highly and reproducibly associated with pediatric onset asthma in both Caucasians of European ancestry and African Americans. The most highly associated SNP in the Caucasians was rs2134409 (MAF 0.146 cases and 0.22 controls, OR = 0.604 [95% CI 0.47 - 0.78], P-value 7.8x10-8). In African Americans rs2134409 was highly significant (P=3.6x10-05) however, the most significant was rs1747815 (MAF 0.51 cases and 0.28 controls, OR = 1.86 [95% CI 1.46 - 2.37] P-value 2.9 x10-7). In independent replication studies, the 1q31 locus yielded significant association with asthma in 379 North Americans of European ancestry (rs2134409 P=0.032); and an additional 918 pediatric cases of Northern European ancestry (r2 rs2134409-rs2111931 0.83, rs2111931 P=1.94 x10-04). Analysis of the associated interval indicated that all the associated SNPs mapped to a block of high LD encompassing DENND1B and the 3 end of CRB1 in four independent studies of Caucasians of European decent and African Americans. The associated interval contains DENND1B, a natural asthma candidate gene known to interact with the TNF receptor, a well established asthma pathway candidate.

A computational method for predicting the functional effect of missense mutations. *S. Sunyaev[1], S. Schmidt[2], L. Peshkin[3], A. Adzhubei[1], A. Gerasimova[4], A. Kondrashov[4], V. Ramensky[5]* 1) Div Genetics, Dept Medicine, Brigham & Women's Hospital and Harvard Medical School, Boston MA, USA; 2) Steffen Schmidt, Max Planck Institute for Developmental Biology, Tuebingen, Germany; 3) Dept Systems Biology, Harvard Medical School, Boston MA, USA; 4) Life Science Institute, University of Michigan, Ann Arbor MI, USA; 5) Engelhardt Institute of Molecular Biology, Russian Academy of Sciences, Moscow, Russia.

Rapid development of sequencing technology puts to the forefront the need to interpret DNA sequence information. Sequencing of phenotyped clinical populations is widely anticipated to replace genotyping in studies aiming at finding genes underlying human complex diseases. Clinical genetic diagnostics by sequencing is increasingly important in guiding therapeutic intervention and providing counseling to family members of patients with monogenic and oligogenic diseases, although interpretation of results of diagnostic sequencing is sometimes problematic because sequencing of patient cohorts discovers many variants of unknown significance (VUS). These developments create an unprecedented demand for development of computational methods for interpretation of nucleotide and amino acid changes, and for predicting the effect of mutations and polymorphism on molecular function, fitness and phenotype. We developed and extensively tested a new method PolyPhen2 for predicting the functional effect of human missense mutations. The method combines comparative sequence analysis, analysis of protein 3D structure and database annotations. We created a new highly accurate automated multiple sequence alignment pipeline and designed several novel features predictive of the effect of mutations. We employed a number of machine learning techniques to select the best set of features and to generate prediction rules. These developments resulted in a greatly increase sensitivity and specificity of predictions as evident from tests on several datasets. We also analyzed applicability of the method in the setting of a clinical genetic diagnostics lab. The method has been implemented in publicly available software.

ITMAT/Broad/CARE (IBC) candidate gene genotyping platform identifies genes newly associated with HDL cholesterol. *D. J. Rader[1], A. Edmondson[1], I. Stylianou[1], S. DerOhannessian[1], A. Khera[1], M. Wolfe[1], B. Keating[1], M. Reilly[1], M. Li[2]* 1) University of Pennsylvania, School of Medicine, Institute for Translational Medicine and Therapeutics, PA, USA; 2) Department of Biostatistics & Epidemiology, University of Pennsylvania School of Medicine, PA, USA.

High density lipoprotein cholesterol (HDL-C) concentration is inversely associated with coronary artery disease (CAD) and is a highly heritable trait. There are a large number of candidate genes based on biology that have never been tested for genetic association with HDL-C. The ITMAT/Broad/CARE (IBC) candidate gene array is a custom 50K cardiovascular disease SNP array developed in a multi-institutional collaboration. It aims to comprehensively assess the genetic diversity within genes (> 2100) and pathways underpinning primary and secondary vascular disease processes. More than 100 HDL-C candidate genes were chosen for inclusion on this array based on known biology, mouse genetics, and HDL proteomics studies. We used the IBC array to genotype an HDL case-control cohort (600 cases, HDL > 90th percentile; 600 controls, HDL < 30th percentile) to interrogate the association of candidate genes with HDL-C. Many previously validated HDL-C associations appeared very strongly in this study, including CETP (p = 9.4 x 10-14), LPL (p = 5.9 x 10-6), and ABCA1 (p = 1.3 x 10-4). Multiple other HDL candidate genes without prior human association data were found to be significantly associated with HDL-C levels. Replication of HDL-C associations was performed in a separate cohort (PennCATH) also genotyped using the IBC array and significant SNPs were further tested for their association with angiographic CAD. The IBC array will make possible the testing of the association of a large number of candidate genes with relevant cardiovascular phenotypes and has already established the novel association of several genes with variation in HDL-C and the relationship of the same genes to CAD.

Candidate gene association study of *DLGAP3* in Tourette Syndrome patients. *J. M. Scharf[1,2,3,4], J. Fagerness[1,2], B. Gunnell[1,2], S. E. Stewart[1,2], D. L. Pauls[1,2], Tourette Syndrome International Consortium for Genetics* 1) Psychiatric Neurodevelopmental Genetics Unit, Center for Human Genetics Research, Massachusetts General Hospital, Boston, MA; 2) Dept. of Psychiatry, Massachusetts General Hospital, Boston, MA; 3) Dept. of Neurology, Massachusetts General Hospital, Boston, MA; 4) Dept. of Neurology, Brigham and Women's Hospital, Boston, MA.

OBJECTIVE: To test the hypothesis that *DLGAP3* (human ortholog of mouse *Sapap3*) is associated with Tourette Syndrome (TS) using a family-based association approach. BACKGROUND: TS is one of the most heritable non-Mendelian neuropsychiatric disorders, yet no definitive TS susceptibility gene has been identified to date. Recently, a targeted deletion of mouse *Sapap3* (*Sapap3-/-*) was demonstrated to have a compulsive grooming disorder similar to human obsessive-compulsive disorder and trichotillomania, two conditions believed to be genetically related to TS. DESIGN/METHODS: Subjects included 375 complete trios with TS as well as 20 additional affected siblings (395 total affected). Diagnoses were made by DSM-IV-TR criteria and confirmed by a consensus of TS clinical investigators. Common tagSNPs (5% minor allele frequency) were selected from the HapMap Phase II, SNPper and dbSNP databases spanning *DLGAP3* including 40kb of flanking sequence that contained additional highly conserved mammalian sequences. Genotyping of tagSNPs was performed by primer extension and mass spectroscopy detection methods. Family-based association analyses were performed using the program FBAT. RESULTS: Preliminary analysis of a subset of tagSNPs demonstrated no association between *DLGAP3* and TS. Analysis of the complete tagSNP set is currently in progress. CONCLUSIONS: *DLGAP3* remains an intriguing candidate gene for TS. Complete analysis of this sample as well as future genomewide association studies will hopefully provide more definitive evidence for association between *DLGAP3* and TS.

Detection of rare male cells surrounded by female cells using automated slide scanning. *S. Ayub, O. Samassekou, MC. Gregoire, M. Gadji, A. Emad, E. Bouchard, R. Drouin* Genetics, Dep of Pediatrics, Fac Med Health Sci, Univ Sherbrooke, Sherbrooke, Quebec, Canada.

Introduction- Fetal male cells are found in maternal circulation at a rare frequency of 2-6 cells/ml of maternal blood. These male cells that are a source of developing a non-invasive prenatal diagnosis, are identified using a cell-type independent marker (XY). Objectives- To alleviate the burden of manual scanning we are in the process of validating Ikoniscope - an automatic slide scanning apparatus, by diluting XY cells in XX cells in a proportion similar to the number found in the peripheral blood of a female during 18th to 22nd weeks of pregnancy. Methodology- The method involves spreading 1-10 XY cells on clean slides, staining with Giemsa, counting the cells, imaging, then spreading XX cells followed by Fluorescence In Situ Hybridization (FISH) using X and Y probes. The slides are loaded on Ikoniscope and the pictures taken by the machine are compared with the ones taken before FISH. So far, forty slides have been prepared and automatically scanned. Results- For each slide, there were approximately 3000 optical fields at 20X and on an average 5 pictures at high magnification (100X). An analysis of the pictures taken by the Ikoniscope reveals that it is missing around 50% of the cells. Around 90% of the times, cells were missed due to out of focus fields and the rest were missed due to FISH inefficiency. Cells at the edge of two adjacent fields were also missed. Conclusion- Since automatic slide scanning is less cumbersome and less time consuming than manual scanning, we are currently working on optimization of the scanning. Once the validation of automatic scanning is completed it would revolutionize the slide scanning for detection of fetal cells in peripheral blood of pregnant women.

Association of sequence variant rs10757278 on 9p21 with intracranial aneurysm. *R. Deka[1], D. Koller[2], D. Lai[2], S. R. Indugula[1], G. Sun[1], D. Woo[1], L. Sauerbeck[1], R. Hornung[3], E. Sander Connolly[4], C. Anderson[5], G. Rouleau[6], I. Meissner[7], J. Bailey-Wilson[8], J. Huston[7], R. Brown[7], C. Langefeld[9], T. Foroud[2], J. Broderick[1], FIA Investigators* 1) University of Cincinnati School of Medicine, Cincinnati, OH; 2) Indiana University School of Medicine, Indianapolis, IN; 3) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 4) Columbia University, New York, NY; 5) University of Sydney, Sydney, Australia; 6) Notre Dame Hospital, Montreal, Canada; 7) Mayo Clinic, Rochester, MN; 8) Natioanl Human Research Institute, Baltimore, MD; 9) Wake Forest University, Winston-Salem, NC.

Several studies have recently reported association of two common variants on 9p21, rs10757278 and rs10811661, with coronary artery disease (CAD) and type 2 diabetes (T2D). A subsequent study in multiple populations reported that the G allele in rs10757278 was associated with abdominal aortic aneurysm (AAA) and intracranial aneurysm (IA) in addition to CAD (Helgadottir et al. Nat Genet 2008). We typed this variant to test for association with IA in a sample of 270 cases and 281 controls from the Familial Intracranial Aneurysm (FIA; www.FIAStudy.com) study. We found significant association of the G-allele with FIA cases (p=0.0123). We also found significant genotypic association (p=0.0367), with an excess of GG homozygotes and AG heterozygotes as observed previously (Helgadottir et al.). Our results provide nominal replication that a risk factor in the 9p21 region influences the risk of IA. Funded by R01NS039512.

A genome-wide association study of 1,000 Han-Chinese bipolar I cases vs. 1,000 controls residing in Taiwan. *M. T. M. Lee, C. H. Chen, C. H. Lin, C. C. Chang, L. C. Chang, C. F. Li, H. T. Wang, J. Y. Wu, C. S. J. Fann, Y. T. Chen, A. T. A. Cheng, Taiwan Bipolar I Disorder Consortium* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Background Bipolar I disorder is a complex disease with high heritability. Most of the previous gene-mappings were based on small number of families in western populations and their results were not replicated by a large-scale population-based study conducted in UK. Hence, more population-based studies in other populations are in demand. In this study, we conducted a genome-wide association study to detect genes susceptible to bipolar I disorder in the Taiwan Han-Chinese. **Methods** A total of 1,000 Han-Chinese bipolar I patients and 1,000 random controls were genotyped with the Illumina Hap550duov3 chip as well as the deCode CNV chip. The patients were recruited through the Taiwan Bipolar I Disorder Consortium and the DNA of random controls was extracted from the Taiwan Han-Chinese Blood and Cell Bank. Bipolar I phenotype assessment was conducted using a Chinese version of the SCAN (WHO Schedules for Clinical Assessment in Neuropsychiatry). We excluded SNPs from further analyses by three major criterions: (1) missing data rate >5%, (2) missing data rate >1% for SNPs with a minor allele frequency <5%, and (3) p-value of Hardy-Weinberg Disequilibrium test <10-7. Multi-point analyses were applied to summarize regions with multiple significant points. **Results** A total of 517,015 SNPs (92.29%) passed the quality control filter with an average call rate of 99.91% and subjected to genome-wide association analysis. Two SNPs were identified with significant signals ($p < 10\text{-}7$) while 11 SNPs and 3 regions showed positive evidence ($10\text{-}7 < p < 10\text{-}5$); none of these have been reported previously. Furthermore, a few sites have higher frequencies of copy number variations in cases than in controls; additional genotyping using Affymetrix SNP 6.0 chip on 200 cases and 200 controls confirmed the copy number variations. **Summary** We have identified novel SNPs/regions associated with Chinese patients with bipolar I disorder. Our study indicated the heterogeneity of bipolar I between the Asian and Caucasian populations.

A genome-wide association screen for loci influencing homocysteine levels. *L. Almasy[1], M. Carless[1], J. Curran[1], T. D. Dyer[1], H. H. H. Göring[1], M. P. Johnson[1], J. M. Soria[2], J. W. MacCluer[1], E. K. Moses[1], J. Blangero[1]* 1) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Institut de Recerca de l'Hospital de la Santa Creu i Sant Pau, Barcelona, Spain.

Homocysteine (Hcy) levels are a well-known risk factor for venous thrombosis, myocardial infarction, stroke, congestive heart failure, osteoporotic fractures and Alzheimers disease. We performed a genome-wide association (GWA) screen for loci influencing Hcy levels in 858 individuals in extended pedigrees from the San Antonio Family Heart Study. Hcy levels were measured using kits from Genzyme Diagnostics and values were log transformed prior to analyses. SNP genotypes were obtained using the Illumina HumanHap550 BeadChip. Measured genotype association analyses were conducted using SOLAR.

The heritability of Hcy levels in this sample was 0.49 ($p = 1.5 \times 10^{-32}$) and Hcy levels increased with age and were higher in males and in cigarette smokers. One SNP in the methylenetetrahydrofolate reductase (MTHFR) gene, rs1801133, gave genome-wide significant association results ($p = 2.5 \times 10^{-9}$), confirming previous linkage and association studies tying this gene to Hcy levels. Two SNPs in the region of the leucine rich repeat transmembrane neuronal 4 gene (LRRTM4) and one SNP in the region of the mitogen-activated protein kinase kinase kinase 9 gene (MAP3K9) provided suggestive evidence of association ($p < 1.9 \times 10^{-6}$) at levels expected to occur by chance less than once per GWA scan. Nine SNPs in the region of the protocadherin 7 gene (PCDH7) showed association results that just missed this cut-off for suggestive signals ($p = 7.2 \times 10^{-6}$ to 3.5×10^{-6}). We were also able to confirm associations of Hcy levels with the nicotinamide N-methyltransferase gene (NNMT) previously identified through linkage analyses in a Spanish population by the Genetic Analysis of Idiopathic Thrombosis (GAIT) study ($p = 0.005$).

We are currently in the process of expanding the GWA sample size and examining correlations between Hcy levels and RNA expression levels of the genes implicated in the GWA scan.

Seizures in urea cycle disorders (UCDs): an under-recognized symptom in patients outside of the acute metabolic phase. *N. Zecavati, U. Lichter-Konecki, R. Singh, J. Crawford, R. Seltzer, A. Gropman, Children's National Medical Center, George Washington University* Neurology, Children's National Medical Center, Washington, DC.

Objective: To investigate the frequency of seizures in UCDs outside of coma. Methods: We performed a retrospective chart review of patients presenting to our institution over the last 30 years who were ultimately diagnosed as having a UCD and either a single seizure or epilepsy. We identified five patients and queried charts for UCD type, age of diagnosis, timing of first seizure relative to diagnosis, seizure type, EEG pattern, and metabolic studies. Results: There were 2 females and 3 males. Two had ornithine transcarbamylase deficiency (OTC), 3 had arginosuccinic aciduria (ASA), and 4/5 had generalized seizures. In 3/5 cases, seizures occurred after UCD diagnosis but were initially unrecognized. Barriers to diagnosis included behavioral disturbances such as ADHD, OCD, and ODD, which were present in 4/5 patients. Most patients were treated with Keppra or Lamictal with good seizure control. Conclusions: UCDs are a common group of inborn errors of metabolism. In the acute setting, the neurological effects of increasing CNS ammonia include anorexia, vomiting and mental status changes. Progressive CNS dysfunction, reflecting ammonia-induced cell swelling, leads to lethargy, ataxia, seizures, hypothermia and coma. While seizures are known to occur in the acute metabolic phase, the incidence of seizures prior to diagnosis is unknown and thought to be rare. Impediments to diagnosis include comorbid CNS dysfunction accompanying UCDs. Based on this, a low level of suspicion for seizures in children with UCDs should be entertained, especially in the face of changes in behavior or attention without metabolic changes. Use of AEDs may be challenging given underlying metabolic disorder.

In vivo evaluation of chromosomal damage by 4 Gy of ionizing radiation in the presence of curcumin and amifostine. *A. Corona-Rivera, J. E. Franco-Pérez, R. Zepeda-Mora, E. G. Orozco-Arizaga, Y. Martínez-Martínez, C. L. Guzmán-Gutierrez, C. Ortega de la Torre, L. Bobadilla-Morales* Universidad de Guadalajara, Departamento de Biología Molecular y Genómica, Instituto de Genética Humana "Dr. Enrique Corona Rivera", Laboratorio de Citogenética Genotoxicidad y Biomonitoreo.

Ionizing radiations induce chromosome aberrations in a dose dependent manner. In Chinese hamster ovary cell cultures curcumin contributed positively to the gamma-radiation-induced chromosome aberration. A previous study in mice showed radioprotective effect of curcumin evaluated by micronuclei, which was presented 2 hrs before moderate ionizing radiation exposition. Longer exposition curcumin periods may be more effective. Amifostine is a known radioprotector. The aim of this work is to test curcumin and amifostine by chromosome aberrations induced by 4 Gy ionizing radiation in a murine model. We evaluated 30 Balb-C mice, grouped as follows: I, control; II, radiation 4 Gy; III, radiation 4 Gy + curcumin 1%; IV, radiation 4 Gy + amifostine 400 mg/kg (IP, 1 hr before radiation exposure. Mice were fed with curcumin 5 days before radiation exposure. 48 hrs after radiation exposure, the mice were sacrificed to obtain chromosomal preparations. Chromosomal aberrations were scored in around 100 metaphases considering breaks, gaps, rings, dicentrics and acentric fragments. We found that total aberrations and percentage of damaged cells were significantly increased in radiated group versus control, apparently due to an increase of chromatid breaks (Dunetts T3). When curcumin or amiphostine were present in radiated groups, there was no statistical difference versus control (Dunetts T3). Apparently, curcumin and amiphostine were able to diminish the damage due to 4 Gy of radiation exposition.

Variation in the DC-SIGN gene and susceptibility to HHV-8 infection and Kaposi's Sarcoma in HIV-positive men enrolled in the Multicenter AIDS Cohort Study (MACS). *R. S. Bosko, R. E. Ferrell, C. R. Rinaldo, J. J. Martinson, Multicenter AIDS Cohort Study (MACS)* Grad. School of Public Health, University of Pittsburgh, Pittsburgh, PA.

Human Herpesvirus 8 (HHV8) is the causative agent of Kaposi's Sarcoma (KS) in HIV-1 positive individuals. HHV8 is now known to use the C-type lectin molecules DC-SIGN and DC-SIGNR as major receptors in the infection of its target cells, but little is known at present about the extent to which host genetic variation affects virus binding and invasion, and the subsequent progression to KS in HHV8 infected HIV-1 positive individuals.

We determined the extent of sequence variation in the DC-SIGN gene in a sample of 417 men enrolled in the Multicenter AIDS Cohort Study. All men were HIV-1 positive, and were divided into three groups: HHV8+/KS+, HHV8+/KS-, and HHV8-/KS-. Case and control groups were matched based on exposure risk. PCR amplicons containing SNPs were detected by denaturing HPLC, and the SNP was identified by resequencing. The entire coding, promoter, and downstream regulatory regions of DC-SIGN were screened for each individual. A total of 49 SNPs were detected, of which 20 were present with a Minor Allele Frequency (MAF) >5%. Haplotype distributions were obtained using PHASE software.

Few SNPs were found that altered the amino acid sequence of DC-SIGN, and those that were present did not differ in frequency between the case and control groups. Most of the SNPs found were located in promoter and regulatory regions, suggesting that quantitative variation in DC-SIGN levels may be common. Haplotypes based on common SNPs did not vary significantly between the three groups, suggesting that variation in DC-SIGN is not a major determinant of HHV8 infection or disease pathogenesis. Extended haplotypes including rare SNPs were significantly different between the groups (p0.05), but were low in frequency overall and are not a common determinant of KS pathogenesis in the MACS.

The Association between Sequence Variation in the Serotonin Transporter Gene and Obsessive-Compulsive Disorder Symptom Dimensions. *P. D. Arnold[1], J. Beneteau[2], T. Sicard[3], E. Burroughs[4], J. L. Kennedy[3], M. A. Richter[4]* 1) Dept Psychiatry, Hosp Sick Children, Toronto, ON, Canada; 2) Dept Psychology, MacMaster University, Hamilton, ON, Canada; 3) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, ON, Canada; 4) Anxiety Disorders Clinic, Centre for Addiction and Mental Health, Toronto, ON, Canada.

Obsessive-compulsive disorder (OCD) is a disabling psychiatric condition with strong genetic determinants. Factor analytic studies of OCD symptoms have consistently demonstrated 4 to 5 symptom dimensions which may have distinct genetic risk factors, however most candidate gene studies of OCD have failed to examine symptom dimensions. Purpose: We set out to determine whether OCD symptom dimensions are associated with variants in the serotonin transporter (5-HTT) gene. Methods: A total of 70 parent-proband trios ascertained through an adult with OCD were genotyped for 4 polymorphisms: a promoter insertion/deletion polymorphism (5HTTLPR), rs25531 (a SNP in the long allele of 5HTTLPR), a tandem repeat polymorphism in intron 2 (STin2), and rs1042173 (a SNP in the 3-untranslated region). Analyses were performed using the Family-Based Association Test (FBAT) on the following phenotypes: OCD diagnosis and 5 symptom factor scores derived through principal components analysis of lifetime symptoms collected using the Yale-Brown Obsessive-Compulsive Scale (YBOCS) checklist. Results: No significant associations were found with OCD diagnosis. After correcting for multiple comparisons, the A allele of rs1042173 was associated with higher scores on the contamination symptoms dimension ($z=3.01$, $p=0.003$). The combination of the long allele of 5HTTLPR and the A allele of rs25531, which has been shown to increase gene expression, was significantly associated with higher symmetry scores ($z=3.06$, $p=0.002$). Conclusion: These results provide further evidence that 5-HTT variation may be implicated in OCD, and suggest that quantitative symptom dimensions may be more powerful than qualitative diagnostic categories for detecting susceptibility genes. It is hoped that the identification of susceptibility genes will lead to improved OCD diagnosis and treatment.

Pairing of homologous chromosome regions correlates with the frequency of mitotic recombination. *I. Tereshchenko[1,2], L. Serrano[1,2], Y. Chang[1], N. Goldsmith[1], S. Buyske[1], C. Ayala[1], C. Shao[1], J. Tischfield[1]* 1) Rutgers Univirsity, Piscataway, NJ; 2) equal contributors.

We have developed an in vivo mouse assay for loss of heterozygosity (LOH) and have shown that the major mechanism in somatic cells is mitotic recombination (MR). In interphase cells, chromosomes occupy non-overlapping, discreet areas called territories; the arrangement of territories and specific chromosomal sub-regions has been correlated with DNA replication, transcription and repair. Since MR requires contact between homologous regions of chromosome homologs, we tested the hypothesis that the spatial arrangement of homologous regions regulates the frequency of MR. We analyzed primary fibroblasts of heterozygous Aprt K.O.($Aprt^{+}/Aprt^{neo}$) mice. Physical loss of $Aprt^{+}$ was confirmed by allele-specific PCR. STS and SNP markers mapped the location of MR crossover events. Regions with high and low recombination rates showed marked differences in DNA sequence composition. The high frequency region was enriched with simple repeats, transposable elements, and DNA binding sites for regulatory molecules essential for long-range chromosomal interaction. The spatial organization of chromosome territories and sub-regions was analyzed by FISH and 3D reconstruction techniques. The position of the high recombination region is distinct from the spatial positions of flanking segments, looping out from proximal (<4Kb) chromatin regions, suggesting that its position is locally regulated. Homologous chromosomal regions with high recombination rates were spatially paired (<0.6 m apart) in ~4% of exponentially growing cells. This pairing was significantly higher than that observed for low recombination regions (0.5%). Pairing of homologous regions is distinctly non-random throughout the cell cycle. Our results suggest that the relative physical proximity of homologous chromosomal regions may determine the probability of a mitotic recombination event and support the hypothesis that nuclear architecture regulates the frequency at which a particular chromosomal region undergoes MR leading to LOH.

Differential association of the CYP3A4 alleles and phynotypes with the onset of breast tumors. *D. McDaniel[1,2], T. Thurber[2], A. Lewis[1], X. Zhou[1], S. Bigler[3], R. Vance[2], W. Barber[1,2]* 1) Dept Surgery; 2) School of Medicine; 3) Department of Pathology, Univ Mississippi Medical Ctr, Jackson, MS.

Background: Greater than 50% of breast tumors are hormone-dependent and breast tissue is a local source for both estrogen and estrogen receptors. Estrogens are produced through the activity of Cytochrome P450 aromatase. Particularly, P450 3A enzymes are involved in the metabolism of several drugs, including Tamoxifen, used in breast cancer therapy. Effective treatment of breast tumors depends on identifying the tumor at the earliest stage. We hypothesized that CYP 3A4 allele variant and the amounts of the CYP 3A4 activity might have a potential relationship with the degree of tumor differentiation, histological grading and hormone receptors. Methods: Patients who had undergone biopsy procedures for diagnosis or for partial or radical mastectomy were recruited in this study. Clinical diagnosis was obtained from pathology database. For genotype detection (AG at position -290 of the CYP3A4 gene produce AA, AG and GG genotypes), SNP analysis was used to identify the CYP3A4 gene variants in peripheral blood nucleated cells (PBNCs). Results: Expression levels of mRNA transcripts were determined by RT-PCR. The AA genotype was identified in 47% of patients with malignant tumors as compared with 33% of patients with benign tumors. The GG genotypes were significantly increased in African American patients requiring breast biopsy as compared with healthy controls, and 71.4% patients with benign tumors carrying the GG genotypes had the pathology diagnosis of fibroadenoma. A majority of patients (58%) with stage II tumor diagnosis carried the GG genotype as compared with 20% and 29% for AA and AG genotypes respectively. Estrogen receptors were inversely associated with the GG genotypes, while the HER-2/neu receptors were increased in patients with AG and GG genotypes. The 3A4 mRNA transcript appears to be higher in PBMCs of patients with benign tumors compared to malignant tumors, suggesting that increased hormone metabolism by CYP 3A4 may mean a better prognosis for breast tumors. Conclusion: Genotype analysis may predict likelihood of tumor development and tumor stages.

Identification of two novel sequence variants in two X-linked mental retardation genes: ATRX and RSK2. *O. I. Batista[1,4,5], T. Maher[1], A. Milunsky[1,2], J. M. Milunsky[1,2,3]* 1) Center for Human Genetics; 2) Department of Pediatrics; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA; 4) Obbj Gendiagnostik; 5) Universidad Autónoma de Chiriquí, Provincia de Chiriquí, Panamá.

ATRX and RSK2 are two genes whose mutations cause X-linked mental retardation (XLMR), a common cause of inherited intellectual disability with an estimated prevalence of 1/1000 males. Alpha thalassemia/mental retardation syndrome, X-linked (ATRX), is a severe form of XLMR associated with urogenital abnormalities, facial dysmorphism and mostly with alpha thalassemia. Mutations in the ATRX gene have been shown to underlie this condition. Coffin-Lowry syndrome (CLS) is caused by mutations in the RSK2 gene. CLS affected males show severe MR with characteristic dysmorphism, most notably affecting the face and hands. A 4-year-old boy with a clinical history of mental retardation and microcephaly and a 7-year-old boy with mental retardation and dysmorphic features were referred to our center for sequence evaluation of the genes ATRX and RSK2, respectively. Two sequence variants, previously not reported, were detected. A hemizygous 3 bp deletion (IVS9-3_IVS9-1delAAG) which includes the splice acceptor site, was found in the ATRX gene. This alteration is predicted to cause a frameshift and protein truncation. Protein products of altered size could be determined by further analysis of the probands cDNA. The second variant, identified in the RSK2 gene, is a missense change c.777T>G(p.F259L). This variation results in a non-synonymous substitution of phenylalanine by leucine in the N-terminal kinase domain of the RSK2 protein and, consequently, is likely to produce a deleterious effect. Complementary review of the RSK2 protein sequence using SIFT and PolyPhen tools supports the hypothesis of a deleterious effect caused by the identified F259L change. Further clinical and genetic analysis of the family's probands is recommended in order to clarify the clinical significance of both sequence variants reported here.

Molecular and cytogenetic characterization in a case of terminal deletion 7q36 and literature review. *R. Drouin, S. Ayub, M. Gadji, S. Cote, K. Krabchi* Dept Ped, Fac Med Hlth Sci, Univ Sherbrooke, Sherbrooke, PQ, Canada.

Introduction- Partial monosomy of the long arm of chromosome 7, specifically 7q36 has been associated with holoprosencephaly, microcephaly, facial anomalies, growth and mental retardation and sacral agenesis. Objective- To investigate a 7 yr old girl with microcephaly, moderate hearing problems, partial sacral agenesis and developmental delay and compare the results with other cases of 7q terminal deletion. Materials and Methods- Blood from the child was analyzed cytogenetically by GTG banding in low resolution and then in high resolution. Fluorescent In Situ Hybridization (FISH) using subtelomeric probes and whole chromosome painting probes was performed followed by microsatellite analysis using 16 markers specific for chromosome 7. Result- The child was carrying a de-novo del(7)(q36.3) on the maternally derived chromosome. The deletion was found to be located between the markers D7S550 and D7S2465. It was also observed that out of the two main clinical manifestations associated with terminal 7q deletion, holoprosencephaly and sacral agenesis, the child carried only partial sacral agenesis. Conclusion- Since there is a wide spectrum of phenotypes for the terminal deletions and rearrangements on the long arm of chromosome 7, such cases highlights the significance and role of position effect. Perspectives- We are in the process of cytogenetic investigation of the childs skin cells and buccal smear to rule out the possibility of mosaicism. In order to explain her genotype-phenotype relationship it also becomes essential to look for the possibility of position effect. A microarray analysis is being performed to determine the genes lost and whether this deletion is a simple terminal one or if other cryptic anomalies are associated with it.

An Integrated Informatics Pipeline in support of multiplatform, large-scale genotyping. *G. Grant, J. Carey, P. Lin, E. Winchester, B. Bugalter, B. Handsaker, A. Wysoker, M. Nizzari, D. Mirel, A. Crenshaw, S. Gabriel* Broad Institute of MIT and Harvard, Cambridge, MA.

Genotyping studies today require data to be generated at a range of scales (of both SNPs and samples) and across a variety of platforms. Ideally, genotype data generated on one platform can be easily integrated with that generated on a complementary platform - for example whole genome genotyping data in a given cohort and targeted genotyping performed in follow up in the same cohort. We have developed a robust informatics pipeline to support and integrate whole genome platforms (Affymetrix and Illumina) as well as targeted genotyping (Sequenom and Illumina). At the core of the genotyping platform is the 'experiment packet' an object that allows all relevant aspects of a chip's progress through the lab and informatics workflow to be tracked. These aspects include workflow steps, reagent usage, allocation of resources and user-entered comments. Wherever possible, we have tried to use common steps (i.e. QC and archiving), but in some cases, the nature of the different products require different workflows. Affymetrix-specific steps include submission to GCOS, reading scan data from the scanner, calculation of QC metrics, and running of the Birdseed genotype calling program (developed at the Broad). Illumina-specific steps include supervision of scanning, running of Autocall to generate GTC files from the raw data, parsing of the GTC files to generate call rates and other metrics. Shared steps include several end-stage workflow steps. For instance, once the genotypes files for the chips are generated in their native format (Affymetrix Birdseed and Illumina GTC) the files are parsed into a compact generic binary genotype format (BGT). This file is then stored on a managed file system. Using a software API, the contents of these BGT files can be flexibly interpreted in order to run QC checks (including fingerprint and HapMap concordance verification). In conjunction with mapping information on the chips itself, the BGT files can used to serve up genotypes in a variety of formats for users of the pipeline. We present workflow steps, diagrams, and database schema.

Mutations in *TRIP11* cause neonatal lethal skeletal dysplasias in humans and mice. *P. Smits[1], A. Bolton[2], V. Funari[3], L. Lei[4], M. Hong[1], B. Merriman[3], S. Nelson[3], D. Krakow[3], D. H. Cohn[3], T. Kirchhausen[4], M. L. Warman[1,4,5], D. R. Beier[2,4]* 1) Children's Hospital Boston, Boston, MA; 2) Brigham and Women's Hospital, Boston, MA; 3) Cedars-Sinai Medical Center, Los Angeles, CA; 4) Harvard Medical School, Boston, MA; 5) Howard Hughes Medical Institute, Boston, MA.

Diverse biologic roles for thyroid hormone interacting protein 11 (TRIP11) have been suggested based upon *in vitro* and *ex vivo* biochemical and cell biologic studies. As part of an ENU-induced mutagenesis screen we produced a mouse line segregating an autosomal recessive perinatal lethal skeletal dysplasia. In addition to having short limbs and small thoraces, the newborn mutant mice failed to ossify their vertebral bodies. Chondrocyte proliferation and terminal maturation were abnormal and mutant chondrocytes had markedly elevated rates of apoptosis. At the electron microscopic level, mutant chondrocytes and osteoblasts had swollen endoplasmic reticulum (ER) and a misshapen Golgi apparatus. We identified a nonsense mutation in *Trip11* as the likely cause of the phenotype. The occurrence of dilated ER and misshapen Golgi in the mutant mice is consistent with a previously suggested role for TRIP11 in the Golgi, which was deduced from knock down experiments using RNAi in cultured cell lines. Despite ubiquitous expression of TRIP11, we did not observe ultrastructural evidence of ER swelling in other cells from the mutant mice, including keratinocytes, dermal fibroblasts, myocytes, and pericytes, although most lacked normal appearing Golgi stacks. The human disorder Achondrogenesis type 1A (Houston-Harris type) is characterized by neonatal lethality due to thoracic insufficiency, short-limbed dwarfism, absent vertebral body ossification, and chondrocytes containing swollen ER. DNA from an Achondrogenesis 1A proband, with consanguineous parents, was homozygous for SNPs across the *TRIP11* interval on chromosome 14 and for a 4 bp deletion within the *TRIP11* coding sequence that would frameshift and truncate the protein. These studies illustrate the utility of phenotype-driven genetic studies in model systems for the investigation of human disease and the importance of TRIP11 for skeletal growth in mammals.

Returning Copy Number Variant Findings to Research Participants: A Framework for Understanding Ethical and Clinical Implications. *H. Tabor, M. Cho, The Interdisciplinary Workshop on Returning CNV Results to Research Participants* Ctr Biomedical Ethics, Stanford Univ, Palo Alto, CA.

Rapidly-moving technological changes have allowed for the detection of copy number variants (CNVs), both de novo and inherited, across the entire genome and across hundreds and thousands of samples. Genetic research studies on complex traits are utilizing these new technologies to determine whether CNVs are associated with risk and to infer whether they might play important etiological roles in disease. As increasing numbers of research studies incorporate CNV analysis, many researchers are faced with dilemmas about the clinical implications of CNV findings and determining whether and how to return CNV results to research participants. In part, these concerns are rooted in long-standing controversies surrounding the return of individual genetic results, including debates over ownership of genetic information, interpretation of research results, and obligations of researchers to provide ancillary care, as well as duties emanating from the relationships between researchers and the research participants/disease groups whom they study. In part, however, CNV results present new challenges to researchers because of the impression that they may be more likely to be causal than other kinds of genetic variants. How should rare findings be interpreted, against the backdrop of copy number variation across the genome and populations? How do research participants, those with disease diagnoses, those at risk of disease, and those who are part of healthy normal populations, respond to and interpret CNV findings? An interdisciplinary group of experts met to identify the ethical and clinical challenges posed and develop a framework for deciding whether and how to return copy number variant results to research participants. The group included experts in CNV research, clinical genetics, genetics counseling, bioethics, social science, pediatrics and law. We will present the core challenges we identified and our work on developing a framework for researchers to use in determining whether and how to return CNV results.

The Effects of *ABCB1* Polymorphisms in Perinatal Depression. *A. K. Smith[1], D. J. Newport[2], C. L. DeVane[3], E. Zach[2], E. B. Binder[2], Z. N. Stowe[2], J. F. Cubells[1,2]* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Dept Psychiatry & Behavioral Sciences, Emory Univ, Atlanta, GA; 3) Dept of Psychiatry & Behavioral Sciences, Medical Univ of South Carolina, Charleston, SC.

High levels of maternal depressive symptoms have been widely associated with poor infant outcome and provide compelling evidence to continue antidepressant treatment throughout pregnancy. *ABCB1* encodes P-glycoprotein (P-gp), which is integral in controlling the passage of substances at the blood-brain barrier and between maternal and fetal circulation via the placenta. Emorys Womens Mental Health Program performs longitudinal studies of women with depression throughout the perinatal period. For this study, we recruited 186 women in their 3rd trimester undergoing pharmacotherapy with antidepressants. We then examined the association between maternal polymorphisms in *ABCB1* and the maximum 3rd trimester score on the clinician-administered Hamilton Rating Scale for Depression (HRSD) using linear regression. Associations were observed with 3 exonic SNPs: rs1128503, rs2032582 and rs1045642 ($p < 0.0001$-0.002). Since these SNPs are in linkage disequilibrium, Haplo.Stat was used to examine the association between common haplotypes (>5%) and maximum HRSD score in the 3rd trimester. The G-G-C haplotype (53.9%) was associated with higher maternal depression ($p=6e-05$) while the A-T-C haplotype (28.6%) was associated with lower depression ($p=2e-05$). At delivery, cord blood was collected from the neonates for DNA extraction and to measure the levels of antidepressants in fetal circulation (N=78). Since placental P-gp is of fetal origin, we examined the association between neonatal genotypes and birth weight using a linear regression model that accounted for the level of antidepressant in the cord blood and its relative affinity for the P-gp transporter. Associations between the neonatal genotypes in 3 SNPs (rs2032582, rs2032583 and rs2235040) and high birth weight were observed ($p=0.0021$-0.049). The G allele of rs2032582 was associated with both higher maternal depression and higher neonatal birth weight, which has been associated with poor infant outcome. Though rs2032582 is a silent polymorphism, recent studies suggest that it can alter P-gp conformation and protein activity/substrate specificity. The role of *ABCB1* polymorphisms in antidepressant response, particularly during pregnancy, warrants further investigation. Our results suggest that neonates whose mothers have alleles that influence response to antidepressants may be at higher risk due to both increased maternal depression and antidepressant exposure, both of which may contribute to infant outcome.

A first look at the X chromosome in autism spectrum disorder through GWAS eyes. *E. R. Martin[1], R.-H. Chung[1], D. Q. Ma[1], J. Jaworski[1], J. R. Gilbert[1], D. Hedges[1], R. Abramson[2], H. Wright[2], J. Haines[3], M. L. Cuccaro[1], M. A. Pericak-Vance[1]* 1) Dept Human Genetics, University of Miami, Miami, FL; 2) School of Medicine, University of South Carolina, Columbia, SC; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

The autism spectrum disorders (ASD) are a group of a complex neurodevelopmental disorders with a strong genetic component. The skewed prevalence toward males compared to females and evidence of linkage to the X chromosome in some studies suggests the presence of X-linked susceptibility genes for ASD. We have conducted the first analysis of GWAS data on the X chromosome in ASD families. We analyzed 1497 samples from 488 nuclear families in our Collaborative Autism Project (CAP) database, genotyped using the Illumina Human 1M beadchip. Results were validated in a second independent dataset of 3304 samples from 630 autism families from AGRE 550K SNP dataset. Markers were analyzed using the XAPL, a family-based test of association, in the overall datasets and sex-stratified datasets. Analysis of the overall CAP dataset identified strong association (p0.0001) for several markers in a region from 108.07-108.34 Mb. The AGRE dataset validated these results with peak association in the region at 108.73Mb (p0.0005). Two other markers around 143.88Mb and 144.70 Mb with p0.001 in the CAP dataset were in the region containing SLITRK2 and SLITRK4. This region was also validated with several significant markers in the AGRE dataset, with the most significant (p0.0001) at 143.95Mb. In addition to these findings the CAP dataset showed association (p0.0001) at markers in MAOB around 43.6Mb. Of note in the overall AGRE dataset, 3 SNPs with p0.0001 were in the dystrophin gene (DMD). Of the 22 SNPs with p0.001, a total of 13 were in DMD and 3 in the SLITRK2-4 region. This first GWAS analysis of the X chromosome has indentified and validated two regions, and highlights other putative candidate genes for ASD.

Detecting interacting quantitative traits loci using variance heterogeneity. *A. Skol[1], G. Du[2]* 1) Dept of Medicine, Section of Genetic Med, Univ of Chicago, Chicago, IL; 2) Dept of Statistics, Purdue Univ, Indianapolis, IN.

Genome-wide and candidate gene association studies generally identify disease variants or related quantitative traits using single marker tests. Tests of interaction have been relegated to secondary analyses due to the low power to detect such effects. We present a method to improve the power of interaction tests for quantitative trait loci by restricting tests to those markers that demonstrate unequal variance within each genotype class. Such heteroscedasticity is a natural result of the phenotypes within each genotype being a mixture of three distributions centered on different means (one for each genotype of the interacting locus). Standard tests of interactions are then performed between all pairs of loci showing unequal variances. The detection of heteroscedasticity may also be due to a gene by environment interaction; thus in addition to being an initial screen for interacting loci, our approach may be used as a general test for cryptic interaction, be it genetic, epigenetic, or environmental.

We examined our methods power to detect interacting variants in 3 two-locus interaction models. One with no marginal effects, another with one locus that has a marginal effect and a second that does not, and a third where both markers have marginal effects. We also compare our approach to one that selects markers to test for interaction based on nominally significant marginal effects. We find that when performing a typical candidate gene study in 2000 subjects, we have power of 50% to detect variants that account for > 2% of the phenotypic variability. We would have almost no power to identify such a locus when using marginal effects for initial screening when the model had no marginal effects. In order to have experiment-wise significance to detect unequal variances, such variants would need to account for nearly 10% of the phenotypic variability.

We are now exploring combining marginal effects and heteroscedasticity jointly to select markers for further testing for interaction effects.

Variation of collagen fibrils size by electron microscopy in patients with connective tissue disorders. *D. Babovic-Vuksanovic[1], E. Mihci[1], S. Jenkins[2], N. Lindor[1], J. Tarara[3], J. Parisi[4]* 1) Mayo College of Medicine, Department of Medical Genetics, Rochester, Minnesota; 2) Mayo College of Medicine, Division of Biostatistics, Rochester, Minnesota; 3) Mayo College of Medicine, Biochemistry and Molecular Biology, Rochester, Minnesota; 4) Mayo College of Medicine, Department of Pathology and Laboratory Medicine, Rochester, Minnesota.

Connective tissue dysplasias (CTD) are a clinically and genetically heterogeneous conditions, and for many affected individuals, diagnostic testing is not informative. CTDs are suspected based upon clinical findings of variable combinations and degrees of skin hyperelasticity, joint laxity, tissue fragility and vascular involvement. Ultrastructural studies of collagen fibrils of skin biopsies from patients with CTDs are not diagnostic, but may show heterogenity in collagen fibril diameter and shape. To correlate ultrastuctural findings with the clinical findings in individuals with suspected CTDs, we retrospectively evaluated EM findings in 14 patients, 9 of whom had clinical signs of CTD and 5 without findings suggestive of CTD, but who had skin biopsy for other diagnostic purposes (control group). For each patient, samples of 400-600 individual collagen fibrils (3-5 sets per individual) were examined. The minimum and maximum diameters were measured using semi-automated methods. The coefficient of variation (×100) of fibril diameter was calculated separately for each individual. Variability scores were compared between the groups using linear regression with generalized estimating equations to adjust for within-person correlation. Significantly more variability was found in the group of patients with clinical signs of CTD as compared to the control group ($p=0.004$). Our results suggest that the variation of fibriles size can be an important diagnostic tool in evaluation of patients with CTD. Further research on a larger group is needed to verify this difference.

A full mutation spectrum in Hirschsprung disease: a copy number analysis. *B. Q. Doan[1], C. Stewart[2], C. Kashuk[1], S. M. Arnold[1], A. Chakravarti[1], International HSCR Consortium* 1) IGM, JHMI, Baltimore, MD; 2) Bioinformatics, Boston College, Boston MA.

Multiple genes with rare and common risk variants and gene dosage sensitivity have been identified in Hirschsprung disease (HSCR). To better understand effects of variable gene dosage, we performed a CNV analysis on 233 trios from the International HSCR Consortium. For cost effectiveness, trios were run on either Affymetrix 500K NSP or STY chips. To identify CNVs, we applied two copy number analysis tools, Italics and STEPS, which use different aCGH segmentation algorithms. The 270 HAPMAP samples were also analyzed for an expected level of variation. Using Italics, we identified a total of ~5000 CNVs (72bp-110Mb) in HSCR, with an average length per individual of 500kb/32SNPs (NSP) or 270kb/22SNPs (STY). When affected offspring were analyzed separately, the average length of CNVs detected increased 80kb/5SNPs. Multiple regions were identified that warrant further investigation. A 1.4Mb de novo deletion on 6q25.1 was the most statistically significant variant, although present in only one affected offspring. Corresponding genotype data revealed high proportions of missing data, homozygous calls, and Mendelian errors supporting the presence of a true deletion. Examining all CNVs within this region, five more individuals with 1.3kb-62.9kb deletions were identified, as compared to only one 33kb deletion in HAPMAP. This suggests that although rare, the 6q25.1 region is potentially associated with HSCR. Of great interest is the identification of 665bp-112kb deletions (de novo and segregating) in 29 individuals on 9q31, which resides in the middle of a known linkage peak shown to be a genetic modifier. To understand their role, we are reassessing the CNVs in context of rare and common disease variants identified in our resequencing and genome wide association analysis from the same study population. To minimize follow-up of false positives, we are also developing statistical tests to incorporate copy number data with Mendelian error, homozygosity, missing genotype data rates, and prior genetic evidence to filter the numerous variants identified for those most biologically meaningful.

MicroRNA analysis of formalin fixed paraffin-embedded breast cancer tissues with different stages. *G. Xiao[1], Y. Zhao[1], C. Deng[2], H. Zhang[1], J. Xiao[1], R. Recker[1], Z. Gatalica[2], E. Silva[3]* 1) Genomics & Functional Proteomics Laboratories, Dept Med, Creighton Univ, Omaha, NE; 2) Dept Pathol, Creighton Univ, Omaha, NE; 3) Dept Surgery, Creighton Univ, Omaha, NE.

INTRODUCTION: Breast cancer still has the highest incidence among women in the United States. Our understanding of its molecular and cellular mechanisms is limited. Recently, microRNAs have gained favorable status as upstream regulators of breast cancer progression since then it can posttranscriptionally regulate sets of genes. It is now estimated that there are about 1000 miRNAs in the human genome, but only about 300 miRNAs have been identified in humans now. Much of miRNAs and their roles in cancer formation still await discovery. METHODS: Formalin fixed paraffin-embedded (FFPE) breast tissues from different stages of the cancer were de-waxed before performing total RNA extraction. Tissues, from normal breast, in-situ ductal carcinoma (DCIS), and invasive ductal carcinoma (IDC, stage II), with 15 subjects in each group were analyzed. The total RNA were extracted with acid-phenol: chloroform. MicroRNAs were isolated from total RNA. MicroRNA microarray profiling was performed using LC Sciences technology (LC Sciences, LLC). The Bioconductor implementation of Limma was used to analyze the data. RESULTS: MicroRNA profiling experiments have been performed from 45 FFPE breast tissues of breast cancer subjects. By comparing the endogenous miRNA level in normal to that in DCIS, we found that numbers of miRNAs (e.g. mir-21) were significantly induced, while some of miRNAs (e.g. mir-205) were suppressed, in DCIS stage. In subjects with IDC stage, we observed some up-regulated miRNA species (e.g. mir-21) and more down-regulated miRNA species (e.g. mir-126), indicating that those miRNAs could be important candidate mediators that regulate progressive process of the breast cancer. These findings were confirmed by real time microRNA RT-PCR using breast cancer patient samples. Further functional studies are still under investigation.

Developing and Validating a Breast Cancer Risk Estimator Based on Genetic Polymorphisms and Personal Factors. *J. J. Mulvihill[1], E. R. Jupe[2], N. S. Knowlton[3], L. P. Zhao[4], S. Manjeshwar[2], T. W. Pugh[2], D. C. DeFreese[2], B. A. Gramling[2], C. D. Shimasaki[2]* 1) Department of Pediatrics, OU Medical Center, Children's Hospital, Oklahoma City, OK; 2) InterGenetics Incorporated, Oklahoma City, OK; 3) NSK Statistical Solutions LLC, Choctaw, Oklahoma; 4) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center.

BACKGROUND. Accurately estimating individualized risk of developing breast cancer is useful for early detection and cancer prevention. We hypothesized that combining genetic polymorphisms with clinical and demographic variables could improve estimates of individual breast cancer risk. METHODS. DNAs were genotyped for 117 common functional single nucleotide polymorphisms (SNPs) in candidate genes likely to influence human breast carcinogenesis. They were combined with clinical risk information collected in a large case-control association study from six regions of the United States to develop and validate a novel multifactorial risk estimator (MFRE) for breast cancer. The model-building set consisted of 5022 Caucasian women (1671 breast cancer cases and 3351 cancer-free controls). Two independent sample sets were used to validate MFRE performance: one consisted of 1193 Caucasian women (400 cases and 793 controls) and the other consisted of 581 African American women (164 cases and 417 controls). RESULTS. Application of multivariate logistic regression to the model-building set resulted in a MFRE employing 22 SNPs in 19 genes together with the Gail model risk factors. In the model-building and two validation sets, the MFRE exhibited a 1.7 to 2.2-fold improvement compared to the Gail model by assigning elevated risk estimates more accurately to breast cancer cases than to controls. In each validation group, the performance of the MFRE met or exceeded that of the model-building set. CONCLUSIONS. For the first time genetic information and epidemiological factors have been combined into a single model resulting in improved clinical utility for estimating age-stratified individual breast cancer risk.

Genetics teaching through science fiction: stories of students, appropriating concepts. *A. Ordonez, F. Suarez*
Instituto de Genetica Humana, Pontificia Univ Javeriana, Bogota, DC, Colombia.

The basic concepts of genetics involving the use of complex terminology, as the concepts of transcription, translation, genes regulation, biochemistry, phenotype, genotype and the study of the metabolic pathways have been of inadequate acceptance by the medical students during their early years of training. Similarly evaluating the courses which taught genetics, at medicines schools, has been traditionally based on multiple choice tests, a kind of evaluation that has showed that is not so reliable if the student understood or not the concepts taught. It was presented to medical students who enrolled the second year a new proposal for learning the basics of genetics. Using the concepts developed in the classes, the students were asked to create a fictitious medical history that included the learned concepts but showing their learning through stories of science fiction. The minimum conditions for developing the medical history of science fiction were: correlation phenotype-genotype, explanation of the mutation or polymorphisms, pathophysiology, possible treatments and diagnostic aspects. The students presented a total of 23 medical records where the fictional characters were properly representing the concepts developed at the classroom; students also sustained their ideas in articles of indexed journals to demonstrate the plausibility of certain molecular biology techniques that could eventually give sustenance to the fiction developed by the student. The advantages and future applications of this proposal are discussed.

What Does it Really Take to Re-Sequence a Human? *S. F. Nelson, N. Homer, B. O'connor, D. Skvortsov, H. Lee, Z. Chen, B. Merriman* Dept Human Genetics, UCLA Medical Ctr, Los Angeles, CA.

Rapid advances in massively parallel sequencing technology are bringing us to the era where whole genome re-sequencing will be an important component of biomedical research. This raises the practical question of what it really means to re-sequence a specific individual. Indeed, the only two instances that have been put forth so far, the published genomes of J. Craig Venter and James Watson, actually have rather low coverage and an uncertain level of completeness and accuracy. While these are extremely valuable first efforts, it remains unclear what can be expected from the new technologies, given their limited read length and read accuracy, and the limitations imposed by the large amounts of high-copy number, low-complexity sequence in the real human genome, as well as the degree of variation that exists in the population. To provide a rational framework for planning to re-sequence an individual with high confidence, we instead use large scale simulations to map out the relations between these parameters. Specifically, starting with the Human Genome Project reference as a model human genome, and adding variants drawn from standard variant databases to create a synthetic diploid genome, we then create large-scale (~million to ~billion) read sets drawn from this genome and study the relation between coverage, read length, read accuracy, and end-pairing strategy, and the fraction of the genome that is accurately resequenced. We also estimate the fractions of the genome that cannot be re-sequenced at all, due to their highly repetitive structure, or those that can only be semi-uniquely resequenced, due to large scale repeats within the genome. This systematic survey allows us to set reasonable expectations for what can be accomplished now, to select optimal strategies for doing so, and also allows us to set near-term performance goals that are desirable milestones for the new sequencing technologies.

No Evidence of Differential Gene Expression in Chronic Fatigue Syndrome. *A. Byrnes[1], A. Jacks[2], B. Evangard[2], K. Dahlman-Wright[3], F. Wright[1], N. Pedersen[2], P. Sullivan[2,4]* 1) Dept of Biostatistics, Univ of North Carolina, Chapel Hill, NC; 2) Dept of Medical Epid & Biostatistics, Karolinska Institutet, Stockholm, Sweden; 3) Novum, Karolinska Institutet, Stockholm, Sweden; 4) Dept of Genetics, Univ of North Carolina, Chapel Hill, NC.

Background. Chronic fatigue syndrome (CFS) is defined by idiopathic and debilitating fatigue, and may be caused by immune dysregulation. The goal of this study was to identify transcriptomic biomarkers for CFS by studying MZ twins discordant for CFS. Subjects. We screened 61,000 Swedish twins to identify 44 pairs of proven MZ twins who were rigorously discordant - one twin was currently affected with CFS or the closely related idiopathic chronic fatigue (ICF) and the co-twin had never had chronic fatigue. All subjects were clinically evaluated by experts in CFS on the same day and time. A venous blood sample was collected into RNeasy and Affymetrix HG-U133 Plus 2.0 microarrays (54,675 transcripts) were run per protocol. Intensity values were normalized using the RMA algorithm and analyzed with modified paired t-tests using SAM that contrasted an affected twin with the unaffected co-twin. Results. The primary analysis found that no transcripts showed significantly different expression after correction for multiple comparisons. Secondary analyses consisted of the subset of 37 female twin pairs (i.e., dropping male pairs) and of 28 female twin pairs where the affected twin met the more rigorous criteria for CFS (i.e., dropping pairs where the affected twin had ICF). No transcript showed significant differential expression in either secondary analysis. Conclusions. These results suggest that CFS is not associated with significant differential gene expression in PBLs detectable with this technology. Moreover, prior studies that found differential gene expression in CFS may have been an artifact of inadequate case-control matching. Alternatively, it is possible that there is differential expression, but that these transcripts are expressed at low levels or undetectable with this microarray.

Functionally annotated genomic sequences are enriched for expression trait polymorphisms. *M. Xu[1,2], A. Murphy[1], R. Lazarus[1], S. T. Weiss[1], B. A. Raby[1]* 1) Channing Lab, Harvard Medical School, Boston, MA; 2) Bioinformatics Program, Boston University, Boston, MA.

In contrast to coding variants, distinguishing functional non-coding regulatory single nucleotide polymorphisms (SNPs) from among the millions of known non-genic variants is challenging. Currently available prediction algorithms rely on position weight matrix approaches and sequence conservation. The ever-increasing availability of functional sequence annotation through efforts like the ENCODE project may enable development of more accurate prediction algorithms. However, it is unclear which of the many forms of sequence annotation being generated is most useful for identifying expression trait SNPs. Using results from three genome-wide expression trait mapping studies (Dixon, Stranger, and a third unpublished dataset) and 16 annotation tracks available through the UCSC Genome Browser, we assessed whether functional DNA sequence was enriched for cis-acting expression trait SNPs. In all three datasets, we found significant enrichment for cis-acting expression trait SNPs for most functional tracks. Greatest enrichment (>3 fold increase in all three datasets, p<10-16) was noted for SNP mapping to CpG islands, RNApolII sites, DNase hypersensitivity sites, histone modification sites, and microRNA target sites. In contrast, enrichment was less impressive and was inconsistent when using sequence conservation data (i.e. regPotential 5x and 7x) or transcription factor binding site prediction tracks. These findings were independent of SNP distance from transcription start site. Notably, enrichment of expression trait SNP within functional sequence was greatest for those SNP demonstrating reproducible association with gene expression in two or more studies. These data suggest that available functional sequence annotation databases can be used for classification of SNP for genetic association studies. AN INTRONIC *MEN1* MUTATION IS ASSOCIATED WITH PROLACTINOMA IN A YOUNG BOY, DECREASED PENETRANCE IN HIS LARGE FAMILY, AND VARIABLE EFFECTS ON MENIN mRNA AND PROTEIN. *L. Drori-Herishanu[1], A. Horvath[1], M. Nesterova[1], Y. Patronas[1], M. Lodish[1], N. Patronas[2], S. Agarwal[3], R. Salvatori[4], V. Mericq[5], CA. Stratakis[1]* 1) NICHD, NIH, Bethesda, MD; 2) DDR,NIH,Bethesda,MD; 3) NIDDK,NIH,Bethesda MD; 4) John Hopkins University,Baltimore,MD; 5) University of Chile,Casilla.Chile.

Prolactinomas are extraordinarily rare tumors in prepubertal children. Even in the absence of family history or other symptoms, a prolactinoma in a young child may be due to novel sequence variants of genes that are known to cause these tumors (menin, *PRKAR1A*, *AIP*). We report the case of a 7 year-old boy with a macroprolactinoma who was treated with cabergoline and the tumor receded. We studied him and his family for genetic causes of this tumor. A heterozygous substitution was identified (IVS3-7 c>a) in intron 3 of the *MEN1* gene. There were no mutations in the *PRKAR1A* and *AIP* genes and the defect was not present in an extended set of controls. However, normal individuals did express at low levels the mRNA predicted by lack of splicing of intron 3, incorporating an additional 210 base pairs into the mRNA, which leads to a prematurely terminated protein. The latter, however, was not found in protein lysates of the patients and controls; instead, what was found in the former (but not in the latter) was a longer menin variant which was only present in the cytosol. Menin protein levels were decreased in the carriers of the IVS3-7 c>a defect. We conclude that a novel MEN1 defect was found in a young boy with prolactinoma and his family. It is apparently associated with low penetrance of the disease. The IVS3-7 c>a defect is pathogenic because it leads to lower menin levels in the cells of these patients, but its effects may be mitigated by a variety of factors including changes in transcription and translation of the *MEN1* gene including the cytosolic presence of an unknown menin variant only in carriers.

Frequency of C3435T single nucleotide MDR1 genetic polymorphism in Native and Mestiza Mexican Populations. *L. SANDOVAL-RAMÍREZ[1,2], J. BECERRA-CONTRERAS[1,2], S. G. OROZCO-FLORES[1,2], E. R. OCHOA-MARTÍNEZ[1,2], J. M. OLIVA-ORTIZ[1,2], L. B. LÓPEZ-HERNÁNDEZ[1,2], M. CASAS-CASTAÑEDA[1,2], F. RIVAS[1,2]* 1) DIVISIÓN DE GENÉTICA, CIBO, IMSS, GUADALAJARA, JALISCO, MEXICO; 2) DOCTORADO EN GENÉTICA HUMANA, UNIVERSIDAD DE GUADALAJARA. GUADALAJARA, MEXICO.

BACKGROUND: P-glycoprotein is a membrane protein encoded by the MDR1 gene, which demonstrates functional polymorphism. The MDR1 single nucleotide polymorphism 3435C>T is associated with higher P-glycoprotein expression. OBTECTIVES: To determine allelic and genotype frequencies of C3435T single nucleotide MDR1 genetic polymorphism in Native and Mestizo Mexican populations. METHODS: 415 DNA samples of unrelated individuals were analyzed; 48 Huicholes (North of Jalisco and east of Nayarit), 48 Purepecha (Michoacan state), 60 Tarahumaras (Southeast of Chihuahua) and 215 Mestizos (Oaxaca-Guerrero coast, Chihuahua and Veracruz states). RESULTS: It was found a high percentage of heterozygous in Native and Mestizo populations. The distribution of Huichol population was homozygous for the wild-type allele (CC) was 27.08%, 50% were compound heterozygous with a mutant T-allele (TC), and 22.91% were homozygous for the mutant allele (TT). In Purepecha population the frequencies were: CC (25%), TC (45.83%9 and TT (29.16%), in Tarahumara population: CC (16.66%), TC (63.33%) and TT (20%) and in Mestizos: Oaxaca-Guerrero coast: CC: (27.38%), TC (46.42%) and TT (26.19%), Chihuahua state population: CC (22.22%), TC (44.44%) and TT (33.33%) and Veracruz state population: CC (22.09%), TC (43.02) and TT (34.88%). DISCUSSION: Allelic and genotype frequencies of 3435C>T changed meaningfully in populations with different origins, with a prevalence of the allele C in certain parts of the world (>70% in African populations), on the contrary in Caucasian and Asian populations, where this allele shows frequencies from 30% to 50%. CONCLUSIONS: We found a difference in the distribution of frequencies in the wild-type allele between a Germany population (reference population) and the Native populations (Tarahumara and Purepecha). On the other hand the percentage of heterozygous was high in the other populations (Mestizo and Huichol).

Submicroscopic tandem duplications - unraveling the mechanisms of formation. *P. Stankiewicz[1], K. Derwinska[1,2], Z. Xia[1], M. Nesteruk[1,2], B. Wisniowiecka-Kowalnik[1,2], M. Smyk[1,2], S. W. Cheung[1]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept of Medical Genetics, Institute of Mother and Child, Warsaw, Poland.

Cryptic chromosomal duplications have been long under-ascertained. Using a clinical targeted array CGH CMA-V6 (Agilent, 44K), we have identified seven potentially pathogenic microduplications in patients with normal karyotypes. Application of 385K and 2.1M microarrays (NimbleGen) and long-range PCR determined their tandem orientation in all cases and allowed rapid sequencing of their junction fragments. We have analyzed DNA sequence of 14 breakpoints of: a 280,796 bp duplication encompassing *KCNK16* (epilepsy), a 363,599 bp duplication harboring *PTCH1* (microcephaly), an intragenic 46,451 bp duplication in *DMD* (learning difficulties), a 120,772 bp duplication 7,326 bp 5 to *DAX1*, a 8,846,307 bp duplication in 1p32.3-p31.3 (dysmorphic features, failure to thrive, and autistic behavior), an intragenic 184,260 bp duplication in *NRXN1* (autism), and a 524,226 bp duplication involving *GALNT*. The duplication of exons 17 and 18 in *DMD* led to a 100 amino acids insertion in the dystrophin protein, and the duplication of exons 3-5 in *NRXN1* resulted in a premature protein truncation. Three chromosomal breakpoints mapped within LINEs, one within SINE/MIR and one within DNA/MER1 Charlie2a element. In eight other cases, five LINEs, two SINEs (*Alu* and MIR), and one DNA/MER1 MER5A1 element mapped less than 400 bp from the breakpoint. In two cases (*KCNK16* and *NRXN1*), we have identified TGAAAGTGT and ACCGGG insertions at the breakpoint junctions and microhomology (1-3 bp) between the breakpoints in four microduplications, indicating a nonhomologous end joining mechanism of their formation. In addition, we analyzed DNA sequence of 12 LCR-free breakpoint regions of 6 cryptic likely polymorphic copy-number gains identified using 2.1M microarrays (average resolution ~1.5 kb). We found LINE elements at eight and SINE elements at eight breakpoints. Our data support the results reported recently showing significant (~30%) proportion of retrotransposon elements at the CNV breakpoints.

Theoretical Investigation of the Polymorphism Pattern Since a Selective Sweep. *H. Chen[1], K. Chen[2]* 1) Department of Genetics, Harvard Medical School, Boston, MA.02115; 2) Department of Statistics, University of California, Davis, CA 95616.

The fixation of an advantageous allele in a population can affect the polymorphism pattern of the nearby neutral loci, which is called a selective sweep. This kind of data pattern can be informative for both detecting selection and inferring the selection intensity and the time since the sweep. Previous work either infers the selection intensity by assuming data is observed right after the selection, or by using simulations lack of theoretical foundations. We analytically investigate the decaying of the skewed pattern with time. The approximate sampling formula by Etheridge et al(2006) is adopted to model the effect of a sweep on a linked neutral locus. Using both the coalescent model and the diffusion equation, different aspects of the polymorphism pattern, including the frequency spectra of the segregating sites, the polymorphism heterozygosity and the number of alleles are derived as a function of the selection intensity and the time of the sweep. Based on our theoretical results, we draw conclusions on the decay of the skewed pattern. As one application of the results, we develop a likelihood method for jointly estimating the selection intensity and the time since the sweep. The method is applied to the real data FOXP2 to demonstrate its performance.

Clinical and biochemical characterization of a chromosome Xq28 microdeletion encompassing at least 9 genes including *ABCD1* and *SLC6A8*. *J. J. Shen[1], J. A. Bernstein[2]* 1) Dept of Medical Genetics & Metabolism, Childrens Hospital Central California, Madera, CA 93636; 2) Division of Medical Genetics, Dept of Pediatrics, Stanford University School of Medicine, Stanford, CA 94305.

The Xq28 genomic region contains several genes known to cause human disease, including *ABCD1* (X-linked adrenoleukodystrophy), *SLC6A8* (X-linked creatine transporter deficiency) and *L1CAM* (L1-spectrum disorders). Deletions affecting these genes individually, as well contiguous gene deletion syndromes involving this region [*e.g.*, CADDS (Contiguous *ABCD1*/*DXS1357E* Deletion Syndrome)] have been described. We report the clinical and biochemical characteristics of a patient with an Xq28 microdeletion encompassing at least 9 genes, including *ABCD1* and *SLC6A8*.

The patient was a former 33 week male infant whose clinical issues included failure to thrive, GI malabsorption, and cholestasis. On exam, he had craniofacial dysmorphisms, slender fingers and toes, and microphallus. Echocardiogram demonstrated two small VSDs, eye exam revealed anterior iris stroma hypoplasia, and liver biopsy showed evidence of cholestasis but no paucity of bile ducts. Head and abdominal ultrasounds as well as plain films of the spine were normal. Endocrinologic evaluation demonstrated normal pituitary function and isolated hypogonadism. Cystic fibrosis and Alagille syndrome were ruled out. Through oligonucleotide array-CGH, a microdeletion in Xq28 was identified. Based on the breakpoints, biochemical studies were performed. VLCFA analysis was consistent with a peroxisomal disorder, and studies of creatine metabolism suggested X-linked creatine transporter deficiency. He passed away at 4 months of age due to liver failure.

The clinical course and biochemical profile seen in this patient with an Xq28 microdeletion was similar to that described in CADDS, and he had further evidence of a defect in creatine transport, consistent with a missing *SLC6A8* gene. He also had hypogonadism, likely because additional genes were affected by the microdeletion. This patients phenotype expands our understanding of the clinical consequences of genomic disorders involving the Xq28 region.

Detection of copy number imbalances in lung adenocarcinoma is enhanced by laser capture microdissection. *A. C. Borczuk, O. Nahum, L. Herlitz, C. A. Powell, B. Levy* Department of Pathology, Columbia University, New York, NY.

Mixed subtype pulmonary adenocarcinomas frequently have an admixture of tumor cells, desmoplastic stroma and inflammation, as well as areas of residual alveolar walls in areas of lepidic growth. Sections that contain over 70% tumor are preferentially used for studies of DNA copy number imbalances. However, many tumor sections have far less representation of tumor cells (<< 70%) or they contain significant numbers of benign inflammatory cells. The net effect is a reduction in the sensitivity of CGH methodologies for detection of copy number gains and losses in the tumor specimen. Frozen sections of mixed subtype adenocarcinoma were either manually needle dissected or laser capture microdissected using a PALM Zeiss Microbeam System to obtain a minimum of 500 ng of genomic DNA for study on Affymetric 6.0 SNP microarrays. Laser capture microdissected material identified all alterations that were detected by needle microdissection, confirming that laser capture did not result in poor DNA quality. Laser capture microdissected tumor allowed for detection of increases and decreases in copy number in multiple chromosomal arms; overall, alterations in 19 chromosomal arms in one pair of samples and 11 chromosomal arms in the other pair were detected in the LCM samples only. The majority of these alterations comprised small deletions that would not be expected to be detected in a specimen of heterogenous cell populations. Laser capture microdissection of mixed subtype lung adenocarcinoma allows for detection of numerous regions of copy number gains and losses that would not be identified by whole section homogenates or manual needle dissection enrichment. This creates the opportunity to study copy number changes in early neoplasia and tumors that contain abundant admixed non-neoplastic stromal or inflammatory cells.

***Caenorhabditis elegans bbs* mutants have body size defects.** *C. A. Mok[1,3], E. Héon[1,2], M. Zhen[3]* 1) Program in Genetics and Genome Biology, Sick Kids Hospital, Toronto, ON, Canada; 2) Department of Ophthalmology and Vision Sciences, Sick Kids Hospital, Toronto, ON, Canada; 3) Mount Sinai Hospital Research Institute, Toronto, ON, Canada.

Bardet-Biedl syndrome (BBS) is an autosomal recessive, genetically heterogeneous, pleiotropic disorder. Cardinal features include photoreceptor degeneration, obesity, digit anomalies, kidney anomalies, cognitive impairment and hypogonadism. BBS genes include ciliary proteins related to the intraflagellar transport (IFT) system. *C. elegans bbs* mutants have defects to ciliary morphology and function (Blacque et al., 2004, Tan et al., 2007). Neurosensory defects in *C. elegans* have been associated with decreased body length (Fujiwara et al., 2002) and increased fat accumulation (Mak et al., 2006). The transforming growth factor beta (TGF-) superfamily of proteins encompasses those in a pathway that also controls body size (Patterson and Padgett, 2000). The vertebrate orthologs of this pathway form the bone-morphogenic proteins (BMPs) and are important to early embryonic development, patterning, and skeletal formation. We hypothesize that *C. elegans bbs* mutants will share specific phenotypes related to various ciliated-neurons. We examined *C. elegans bbs* mutants, and indeed, body length measurements showed a statistically significant loss of 15-20% in mean body length with no increase in body width. DAPI nuclei staining of *bbs* mutants indicate no gross defects in cell number. Analysis of TGF- mutants (*dbl-1* and *lon-2*) showed that *bbs* body size defects are not epistatic to this pathway. In conclusion, *bbs* body length defects are likely due to decreased cell volume in a pathway separate from that of the TGF- body length pathway. The non-cell autonomous control of body size through a subset of ciliated neurons identifies an interesting pathway for further study in *C. elegans* and later study of our human BBS cohorts.

SNP genotyping in large sample sets using a miniaturized PCR array platform. *S. Liu-Cordero[1], H. Ranu[2], E. Ortenberg[1], A. Bond[1], K. Munnelly[1], D. Hunter[2]* 1) BioTrove Inc., 12 Gill St., Suite 4000, Woburn, MA 01801; 2) Brigham and Woman's Hospital - Channing Laboratory 181 Longwood Ave Boston, MA 02115.

Robust genotyping technologies and the availability of the International HapMap Project data have made genome-wide association studies possible. The number significant results coming from these studies are rapidly increasing and have highlighted the next challenge of validating these results in larger sample sets with a smaller and more refined set of assays. In this study we test the utility of a high density and low-volume PCR array for mid-range genotyping applications. The array consists of 3072 holes that can be loaded with reagents to perform individual 33 nL reactions. The surfaces of the array are treated to have hydrophilic coatings on the interior of each hole and hydrophobic coatings on the exterior. This enables solutions to be accurately loaded in the holes via capillary action. The unique configuration of the holes in the array allowed for the interrogation of a large number of DNA samples against a large number of assays in a flexible, configurable format. We tested a number of assay configurations, including sets of 16, 32 and 64 SNPs within candidate regions. These assay sets were tested on sample populations from a variety of genetic epidemiological studies such as diabetes, skin, colon, and endometrial cancers. The data showed high quality genotype cluster data and high genotype call rates. This platform provided an efficient and robust solution for completing a large number of projects each consisting of thousands of samples.

Biological properties of a novel AML1 mutation in a family with Familial platelet Disorder/Acute Myeloid Leukemia Syndrome. *A. Sorrell[1], W. Wang (Co-author)[2], J. Weitzel[1], P. Parker[3], R. Bhatia[3]* 1) Clinical Cancer Gen, City Hope National Medical Center, Duarte, CA; 2) Div. of Population Sciences; 3) Div. of Hematology and Transplantation.

AML1/RUNX1 mutations (linked to 21q22.1-22.2) are associated with a rare form of Autosomal Dominant, familial thrombocytopenia, with a predisposition to adult-onset myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML). At least 10 different causative AML1 gene mutations have been described in families with Familial platelet Disorder/Acute Myeloid Leukemia Syndrome (FPD/AML). Families carrying mutations that retain greater degrees of biological activity (e.g. deletions and frameshift mutations that act via haploinsufficiency) have a ~ 20% risk of MDS/AML as compared to a ~ 60% risk in families that carry mutations with little residual activity (e.g. dominant negative or biallelic nonsense mutations). The functional significance of AML1 mutations can provide valuable information needed for cancer risk assessment of FPD/AML families. We have identified a novel AML1 gene mutation that tracks with disease in an American family of Western/Northern European descent. Genomic DNA from our proband (37-year old with thrombocytopenia and eczema) and his mother (68-year old with MDS, thrombocytopenia, and eczema) were analyzed using PCR amplification and bidirectional sequencing of all 8 exons of the AML1 gene. They each carry one copy of a frameshift mutation (nc1413_1414 insGC) at the 3 end of exon 8, which is predicted to bypass the normal stop codon and produce a run-on RNA product. If stable, this run-on RNA product could be translated into a substantially extended protein product (p.Leu472fsX123). The biological characteristics and functional significance of this mutation are not known. The aims of this study are to 1) characterize the genotype-phenotype associations within this family and to 2) use immunoblotting and functional assays to determine the biological significance of this novel mutation. We are currently performing segregation analyses, further characterization of the phenotype, and confirmatory studies using hematopoietic samples from additional family members.

Confirmation of Dynapsin Association in Alzheimer Disease. *P. L. Whitehead[1], J. R. Gilbert[1], S. Züchner[1], G. Wang[1], C. Kroner[1], C. Lu[1], P. Bronson[2], P. Gallins[1], M. A. Slifer[1], D. D. Vance[1], S. M. Garvey[2], P. Xu[2], W. K. Scott[1], Y. Li[2], J. M. Vance[1], J. L. Haines[3], E. R. Martin[1], M. A. Pericak-Vance[1]* 1) Miami Inst Human Genetics, Univ Miami , Miami, FL; 2) Duke University Medical Center, Durham, NC; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Unraveling the complex genetics underlying Alzheimer disease (AD) is critical for understanding this devastating condition. Previously, through linkage, and association analyses, we identified 3 key SNPs (rs12622006, rs10932212, and rs13432421) on the q arm of chromosome 2 that showed significant association with intermediate-onset familial AD (IOAD) (p=.002). IOAD encompasses AD families with a mean age-at-onset > 60 yrs that have at least one early-onset individual (< 60 years). Through the convergence of our statistical results and Serial Gene Expression Analysis(SAGE) we implicated LOC389072/dynapsin as a novel IOAD risk gene. Dynapsin is expressed in neurons of AD neuritic plaques and neurofibrillary tangles and interacts with the dynein-dynactin motor complex. In order to validate our previous significant association results,18 SNPs in and surrounding dynapsin were further interrogated in a second independent non-Hispanic Caucasian cases (N=74)/cognitively normal controls (N=108) IOAD dataset. Analysis of the new independent dataset of IOAD patients confirmed a risk effect (p=0.02) for the dynapsin SNPs and alleles. Joint analysis of the combined discovery and validation datasets further strengthened the risk effect (p=0.001), with the odds ratio for SNPs rs12622006, rs10932212, rs13432421 being OR 2.59, 95% Cl[1.4, 4.7], OR 2.68, 95% Cl[1.4,4.9], OR 2.81, 95% Cl[1.4, 5.2], respectively. Our results strongly support that variation in the region of the dynapsin gene contributes to the risk of familial AD.

***NF1* exon23a alternative splicing in neurofibromas and MPNSTs.** *R. Loda, H. Li, M. Wallace* Dept Molec Genetics/Microbiol, Univ Florida, Gainesville, FL.

Three well-characterized alternatively spliced exons have been identified in the *NF1* gene. Mutations in this gene cause neurofibromatosis 1 (NF1), a common autosomal dominant disorder in which individuals are predisposed to neurofibromas and other tumor types. Inclusion of alternately spliced exon23a inserts 21 amino acids in the GTPase activating protein (GAP)-related domain of the encoded protein, neurofibromin. This insertion reduces the proteins ability to down-regulate Ras, currently neurofibromins major known function in the cell. *NF1* mRNA containing exon23a (Type II mRNA) is present at equal or slightly greater levels than Type I mRNA (no exon23a) in the majority of adult tissues reported, and has been reported at aberrantly high levels in some non-NF1 related cancers. We have analyzed the relative levels of Type I/Type II mRNA in blood (non-NF1 patients), in primary dermal and plexiform tumors (NF1-derived), as well as neurofibroma and malignant peripheral nerve sheath tumor (MPNST) Schwann cell cultures. We found Type I transcript levels in blood to be greater than or equal to Type II. However, dermal and plexiform tumors and cultures had Type II mRNA as the predominant transcript, with some tumors having very little or no Type I transcript present. These samples were of interest based on a previous report of MPNSTs with high levels of Type II mRNA exhibiting RNA editing, leading to a premature stop codon. However, analysis of several of our tumors (including an MPNST) with little or no Type I transcript found no evidence of RNA editing. Of interest, an MPNST with no Type I transcript has a classic microdeletion of the *NF1* gene and flanking sequences as its germline mutation, but no somatic *NF1* mutation has been found in the entire open reading frame of the remaining allele (at the DNA or RNA level). This raises the question of whether the Type II transcript could be a hypomorph, which could be contributing to tumorigenesis by virtue of reduced Ras-GAP activity.

Promoter methylation patterns of ATM, ATR, BRCA1, BRCA2 and P53 as putative cancer risk modifiers in Jewish BRCA1/ BRCA2 mutation carriers. *E. Friedman[1], T. Kontorovich[1], Y. Cohen[2], U. Nir[3]* 1) Oncogenetics Unit, Inst Gen, Chaim Sheba Medical Ctr, Tel Hashomer, Israel; 2) Dept. of Gyneco-Oncology, Sheba Medical Center, Tel-Hashomer, Israel; 3) Mina and Everard Goodman Faculty of Life Sciences, Bar-Ilan University, Israel.

Background: BRCA1/BRCA2 germline mutations substantially increase breast and ovarian cancer risk, yet penetrance is incomplete. Genetic and environmental factors putatively modify penetrance. We hypothesized that germline epigenetic gene silencing may also affect penetrance. To test this notion, we determined the methylation status of the promoter in several candidate modifier genes in Jewish BRCA1/BRCA2 mutation carriers Methods: Asymptomatic (n=41) and breast cancer affected (n=48) BRCA1/2 mutation carriers, breast cancer non-carriers (n=52), and healthy controls (n=89), were all genotyped. Real-time, methylation-specific PCR was used for detection and quantitation of promoter hypermethylation in the BRCA1, BRCA2, ATM, ATR and P53 genes. Results: Promoter hypermethylation was detected only for BRCA1, noted in 14 of 230 samples analyzed. There were no differences in the rate of BRCA1 promoter hypermethylation between the study groups: BRCA1/2 mutation carrier breast cancer patients: 6.25% methylated, BRCA1/2 mutation carrier asymptomatic: 7.31% methylated, sporadic breast cancer: 5.76% methylated and controls: 5.62% methylated. Conclusions: Although methylation of the promoter region of BRCA 1, BRCA2, ATM, ATR and P53 genes does not substantially contribute to phenotypic expression of mutant BRCA1/BRCA2 alleles, germline promoter hypermethylation in the BRCA1 gene can be detected in about 5% of the female population, regardless of the BRCA1/2 status. The significance of this observation is yet to be determined.

The association of AVPR1A with addiction is mediated by spousal relationship quality. *B. S. Maher[1], S. J. Latendresse[1], M. Kang[1], B. Devlin[2], R. E. Ferrell[2], G. P. Kirillova[2], L. Kirisci[2], R. E. Tarter[2], K. S. Kendler[1], M. M. Vanyukov[2]* 1) VIPBG,Virginia Commonwealth Univ, Richmond, VA; 2) Univ Pittsburgh, Pittsburgh, PA.

The risk for addictions is largely non-specific to particular drugs and is highly genetically correlated with premorbid traits reflecting regulation of social behavior/antisociality. Involvement with illicit drugs by definition requires violation of social norms. An important role in social behavior has been attributed to the neuropeptide arginine-vasopressin (AVP), shown to be involved in mate and social relations and aggression. We hypothesized that variation in a vasopressin receptor gene, AVPR1A, influences the risk for addiction to illicit drugs, and that this association is mediated by the characteristics of mate/spousal relations. In a sample of 398 individuals diagnosed with a drug use disorder and 359 controls we performed association analysis between 1536 SNPs in 106 candidate genes and a dichotomous diagnosis of drug use disorder (DUD). The quality of mate relations was evaluated by the Dyadic Relationship Scale of the Family Assessment Measure (FAM). Two SNPs in the AVPR1A gene demonstrated the strongest association with DUD risk, rs1587097 (p=0.0003, OR=2.02 [1.37-3.00]) and rs10784339 (p=0.0008, OR = 1.72 [1.25-2.36]); gene-wise permuted p=3x10-5. The FAM score was significantly associated with DUD in males (p<0.0001), but not females (p=0.09). The AVPR1A SNPs were significantly associated with FAM factor score in males (p=0.007), but not females (p=0.74). The mediation hypothesis was further tested using structural equation modeling. All direct paths - AVPR1A and FAM, FAM and DUD, and AVPR1a and DUD - were significant (p=0.006, p<0.001, and p=0.006, respectively). Most importantly, the indirect (mediated) path was also significant (p=0.013), supporting mediation of the association between AVPR1A and addiction risk by the FAM. (R01DA011922, K02DA018701, P50DA005605, K02DA017822, and R01DA01957).

Distinct patterns of gene expression in complex disease genes. *D. Torgerson, C. Ober* Department of Human Genetics, University of Chicago, Chicago, IL.

Identifying genes that contribute to human disease is an important step towards understanding disease etiology, and can facilitate the development of diagnostic tools, preventive medicine, and novel treatments. Previous studies have suggested that evolutionary signatures of natural selection can facilitate the identification of disease genes, as they tend to show stronger signatures of positive and negative selection. We identified complex disease genes from the Genetic Association Database, and Mendelian dominant and recessive disease genes from OMIM in order to identify additional characteristics of disease genes that could be used in the same way. Using the results from a genomic scan for natural selection, we find that complex disease genes have only moderately higher probabilities of negative selection than non-disease genes (Mann-Whitney U-test, p=0.04). However, a more striking pattern was observed in gene expression profiles from 71 normal human tissues using the geneAtlas2 data. We find that complex and Mendelian disease genes have a significantly higher index of tissue specificity () than other genes (MWU-test, p0.001), suggesting that disease genes are more tissue specific in their expression. We also find that mean expression level is significantly higher in disease genes (MWU-test, p0.001), despite their being expressed in fewer tissues. This results from disease genes having a significantly higher absolute level of gene expression in their tissue of maximum expression (MWU-test, p0.001), suggesting that disease genes are more likely to be highly expressed, tissue-specific genes. Our results suggest that both complex and Mendelian disease genes exhibit distinct patterns of gene expression, and identify an additional biological characteristic that may facilitate the identification of novel disease genes.

Evaluation of DNA damage in bone marrow of acute lymphoblastic leukemia patients by comet assay and blood reference group. *L. Bobadilla-Morales[1,2], C. E. Monterrubio-Ledezma[1], R. Silva-Cruz[1], M. A. Orozco-Martín[1], A. L. Fletes-Rayas[1], A. R. Hernández-Robles[1], A. Márquez-Mora[1], F. Sánchez-Zubieta[2], V. Soto-Chávez[2], A. Corona-Rivera[1,2]* 1) Universidad de Guadalajara, Departamento de Biología Molecular y Genómica, Instituto de Genética Humana "Dr. Enrique Corona Rivera", Laboratorio de Citogenética Genotoxicidad y Biomonitoreo; 2) Unidad de Citogenética, Servicio de Hemato Oncología Pediátrica, Hospital Civil Dr. Juan I. Menchaca.

Cancer consists of uncontrolled cellular clonal proliferation and genetic instability. The most frequent cancer in children is leukemia. It consists of an irregular clonal expansion of immature lymphoid or myeloid stem cells. The X-ray treatment of this disease shows mutagenic effects including breaking in the DNA. The comet assay is a standard method to evaluate damage to DNA. Since there might be differences in the response of ALL cells to radiation exposition, we want to test DNA damage in ALL patients before treatment onset, measured by comet assay. We considered bone marrow from 10 patients. We included also a reference group composed of 10 peripheral blood samples from 10 healthy controls matched by age and sex (ages, between 3 ms to 16 yrs). Comet assay was performed in each sample as follows: basal, 0, 30 and 60 min. of culture after exposition to 2Gy of radiation as well as 30 and 60 min. without radiation exposition. 50 cells were analyzed per condition, measuring tail, nucleus and total length as well as qualitative measures as Urbina et al. 2006. There were no statistical differences between patient cell tested conditions, nor reference cell conditions. DNA damage was increased in patient cell conditions versus reference blood cell conditions. Variances were greater in patients. Patient cells exhibited more damage than blood reference group in all experimental conditions. Besides, greater variances in patients indicate that individual variation was present. Sensibility of Comet assay was able to detect DNA damage and to distinguish between patient damage values.

Genetic risk factors for Post-Infectious IBS in the Walkerton outbreak of waterborne gastroenteritis. *AC. Villani[1], M. Lemire[2], M. Thabane[3], SM. Collins[3], D. Franchimont[1], JK. Marshall[3]* 1) McGill University, Canada; 2) Ontario Institute for Cancer Research, Canada; 3) McMaster University, Canada.

In May 2000, heavy rainfall washed livestock fecal residue from nearby farms into inadequately chlorinated water of Walkerton, a small Canadian rural town. Municipal water was contaminated with E. coli 0157:H7 and Campylobacter species, and over 2300 residents developed acute gastroenteritis (GE) with some describing post-infectious irritable bowel syndrome (PI-IBS) symptoms. Although family and twin studies support a genetic basis for IBS, no susceptibility loci have yet been identified. Method: We selected 78 reported functional variants for screening on the Walkerton cohort (*Gastroenterology* 2006;131:445-50), a well characterized longitudinal study. Candidates were classified into 3 categories:1) serotoninergic pathway; 2) intestinal epithelial barrier; and 3) innate immunity risk variants. Variants were genotyped using Sequenom hME or Taqman assays. Analysis consisted at comparing Walkerton residents who experienced GE and reported PI-IBS 2-3 years after the outbreak (220 cases) to those with GE who did not develop PI-IBS (874 controls). A quasi-likelihood association test for cases and controls that accounts for known relatedness within the sample was used. Results: Four candidates show association with PI-IBS. Two are located in TLR9: rs352139 (coding, P545P) (p=0.0135) and rs5743836 (promoter,-T1237C) (p=0.0324) (r^2<0.14); one in CDH1: rs16260 (promoter,-C160A) (p=0.0352); and one in IL-6: rs1800795 (promoter,-G174C) (p=0.0489). Denser mapping was conducted in these 3 regions. We observed two novel associations in IL-6 (p=0.0012) and 14 additional associations that can be explained by LD with the 4 original variants. All SNPs were more significantly associated in the clinically confirmed GE subgroup (p as low as 4.7×10^{-5}), suggesting a clinical gradient. Conclusion: This is the first population study of its kind studying genetic risk factors for PI-IBS. These results indicate abnormalities in genes encoding epithelial barrier functions and innate immune responses to enteric bacteria, and suggest a genetic predisposition to the development of IBS following acute GE.

A community-based participatory approach to developing genetics education materials for Hispanic/Latino students and families and the Pacific Islander community. *L. Stark[1], R. Giles[2], J. Johnson[2], S. Eddings[3]* 1) Genetic Science Learning Center, University of Utah, Salt Lake City, UT; 2) Chronic Disease Genomics Program, Utah Department of Health, Salt Lake City, UT; 3) Bach-Harrison, LLC, Salt Lake City, UT.

The Family Genetics Education Through School and Community Partnerships project seeks to develop culturally-appropriate materials. We first worked with the teacher community to develop genetics curriculum materials for fifth grade (inherited traits) and high school (polygenic, multifactorial chronic diseases and family health history). This ensured that the materials addressed the science and/or health Standards teachers are required to teach. We then worked with a Hispanic/Latino Community Advisory Community to adapt these curricula so that they were culturally-appropriate. The Committee also developed ideas for take-home family materials, and multi-country consensus Spanish translations. The materials have been tested with teachers, students and their families from urban Utah schools with high Hispanic/Latino enrollment. Students completed pre/post knowledge tests, as well as feedback surveys about their reactions to the materials and their familys engagement with the take-home materials; teachers completed more detailed feedback surveys. Fifth grade results: Students showed a significant knowledge gain as a result of using the curriculum. Teachers reported that the materials were very effective, and that the Spanish-language family materials led to students and families as well as parents and teachers having conversations about science - and genetics - that had previously not occurred. High school results: Preliminary data indicate high teacher satisfaction with the curriculum but some challenges for students in collecting family health histories. We are working with a Tongan/Samoan Community Advisory Committee to adapt several of the classroom and family activities for use in community education classes. This project is supported by grant U33MC00157 from the Health Resources and Services Administration, Maternal and Child Health Bureau, Genetic Services Branch and the March of Dimes.

Association between FOXE1 and cleft palate. *M. A. Mansilla[1], L. M. Moreno[1], T. Busch[1], S. A. Bullard[1], J. Machida[1], M. E. Cooper[2], A. Jugessur[3], R. T. Lie[3], A. Wilcox[4], K. Christensen[5], P. Chines[6], A. C. Lidral[1], M. L. Marazita[2], J. C. Murray[1]* 1) Univ Iowa, Iowa City, IA; 2) Univ of Pittsburgh, Pittsburgh, PA; 3) Univ of Bergen, Bergen, Norway; 4) NIEHS, Durham, NC; 5) Univ of Southern Denmark, Odense C, Denmark; 6) NHGRI, NIH, Bethesda, MD.

Non syndromic cleft palate (NSCP) is a complex birth defect caused by genetic and environmental factors. It involves the secondary palate and occurs in 1/2000 live births. Previously we reported a major role for FOXE1 in non syndromic cleft lip with or without cleft palate (NSCL/P). Although NSCP and NSCLP have been described as etiologically separate they share some common genetic and environmental contributors. We investigated the role of FOXE1 in the etiology of NSCP. Our study included 476 families with NSCP from Philippines, USA, Denmark and Norway. Twelve SNPs surrounding and in the FOXE1 gene were tested for association. All populations but those from USA showed significant p values in almost all the SNPs tested. A SNP in the FOXE1 gene, rs1867278, showed the most significant p value of 1E-04, when combining the significant populations. Estimates of the attributable risk for this marker ranged from 29 to 34% depending on the population. The most significant haplotype for this data set was rs1867280-rs3021523 that showed a p value of 9E-04. Foxe1 expression was observed at E10.5 and E11.5 in mouse epithelium involved in the fusion between the medial nasal and maxillary processes. Previous reports have shown that mutations in FOXE1 cause the Bamforth-Lazarus syndrome that includes cleft palate. Altogether these evidence shows that FOXE1 is another transcription factor that plays a role in facial morphogenesis and specifically in both NSCL/P and NSCP.

Ongoing Genomewide Association in Familial Intracranial Aneurysm. *T. Foroud[1], D. L. Koller[1], R. Deka[2], D. Lai[1], D. Woo[2], L. Sauerbeck[2], R. Hornung[2], E. S. Connolly[3], C. Anderson[3], G. Rouleau[3], I. Meissner[2], C. Langefeld[3], J. E. Bailey-Wilson[3], J. Huston[3], R. Brown[3], J. P. Broderick[2]* 1) Indiana Univ Sch Medicine, Indianapolis, IN; 2) Univ Cincinnati, Cincinnati, OH; 3) FIA Study Group.

Subarachnoid hemorrhage due to the rupture of an intracranial aneurysm (IA) occurs in 16,000 to 17,000 persons in the U.S. annually and nearly half of affected persons are dead within the first 30 days. Individuals with 1st degree relatives harboring an intracranial aneurysm (IA) are at an increased risk (GRR=2-4) of IA. Families with multiple members having ruptured or unruptured IA were recruited and all available medical records and imaging data were reviewed to classify possible IA subjects. One definite or probable IA subject from each of 270 Caucasian families were selected for genotyping as cases. Genotyping was performed using the Affymetrix 6.0 in a sample of 270 cases and 281 controls. Quality assessment removed SNPs and samples with call rates below 95%, SNPs with deviation in controls of Hardy-Weinberg equilibrium ($p<.0001$), and minor allele frequency below 0.01; the data set retained 742,338 SNPs. The MDS algorithm implemented in PLINK was performed using HapMap samples to identify and exclude individuals with substantial non-Caucasian admixture. The final analytical sample consisted of 250 FIA cases and 278 controls. The test of allelic association in the FIA case-control cohort for the SNP panel resulted in the detection of several SNPs providing strong evidence of association with FIA, which were supported by additional SNPs in the same gene or chromosomal region. These included the *DHCR24* gene region on chromosome 1p32.3 ($p<2x10^{-6}$), the *HNT* gene region at chromosome 11q25 ($p<3x10^{-6}$), and the *ZEB2* gene region at chromosome 2q22.3 ($p<5x10^{-6}$). We also detected multiple SNPs with evidence of association with FIA in intergenic regions at 4q28.3 and 2q35 (both $p<3x10^{-6}$). Additional case and control samples are currently being genotyped, which will enable us to confirm the evidence of association with FIA in these chromosomal regions and pursue additional genotyping and functional studies of these loci.

Global Changes in DNA methylation in Melanoma. *Y. Koga[1], M. Pelizzola[2], AE. Urban[3], A. Molinaro[2], M. Krauthammer[4], S. Ariyan[5], D. Narayan[5], R. Halaban[6], S. Weissman[1]* 1) Genetics; 2) Epidemiology; 3) Cellular and Developmental Biology; 4) Pathology; 5) Surgery; 6) Dermatology, Yale University, New Haven, CT.

DNA methylation is an important component of epigenetic modifications that influences the transcriptional machinery and is aberrant in many human diseases. Several methods have been developed to map DNA methylation for either limited regions or genome-wide. In particular, antibodies specific for methylated CpG have been successfully applied in genome-wide studies. However, despite the relevance of the obtained results, the interpretation of antibody enrichment is not trivial. Of greatest importance, the coupling of antibody-enriched methylated fragments with microarrays generates DNA methylation estimates that are not linearly related to the true methylation level. Here, we present an experimental and analytical methodology to obtain enhanced estimates which better describe the true values of DNA methylation level throughout the genome. We propose an experimental scenario for evaluating the true relationship in a high-throughput setting and a model-based analysis to predict the absolute and relative DNA methylation levels. We successfully applied this model to evaluate DNA methylation status of normal human melanocytes compared to several melanoma cell strains. Despite the low resolution typical of methods based on immunoprecipitation, we show that model-derived estimates of DNA methylation provide relatively high correlation with measured absolute and relative levels, as validated by bisulfite genomic DNA sequencing. Importantly, the model-derived DNA methylation estimates simplify the interpretation of the results both at single-loci and at chromosome-wide levels.

Common deletions of non-coding regions are strongly associated with Crohns disease and body mass index. *S. McCarroll[1,2], A. Elliott[1,2], A. Huett[2], P. Kuballa[2], S. Chilewski[1], A. Landry[2], M. Zody[1], P. Goyette[3], E. Speliotes[1,4], J. Hirschhorn[1,4], J. Rioux[1,3], D. Altshuler[1,2], R. Xavier[1,2], M. Daly[1,2], NIDDK IBD Genetics Consortium, GIANT Consortium* 1) Broad Institute, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Université de Montréal and Montreal Heart Institute, Montreal, Canada; 4) Children's Hospital, Boston, MA.

Human genome structural polymorphism is common and extensive, but its contribution to phenotypes is not yet defined.

Data from genome-wide association studies (GWAS) may contain more information about CNVs than is appreciated. We typed >1,000 common CNVs in HapMap, found most to be in LD with SNPs, identified tagSNPs, and are using these relationships to assess the extent to which CNVs might explain GWAS signals.

Crohn's disease is associated ($p < 10^{-10}$) with SNPs around the autophagy gene *IRGM*, but *IRGM* lacks explanatory coding-sequence variation. We found a common, 20-kilobase deletion polymorphism, immediately upstream of *IRGM* and in perfect LD with the most strongly Crohns-associated SNP. As a result of this deletion, *IRGM* segregates in the population with two distinct upstream sequences. The deletion (Crohns risk) and reference (Crohn's protective) haplotypes of *IRGM* showed distinct expression patterns across tissues and cell lines. Expression levels of *IRGM* regulated autophagy of intracellular bacteria, a physiological process implicated in Crohns.

Meta-analysis of body-mass index (BMI) across GWAS data by the GIANT Consortium identified novel genomic loci associated with BMI. We found that one strong, replicated association ($p < 10^{-8}$) arises from SNPs that tag a common, 45-kilobase deletion of non-coding sequence; the two strongest BMI-associated SNPs immediately flank this 45-kb deletion on both sides and are in perfect LD with it.

These results identify strong candidate causal polymorphisms at two genomic loci implicated in GWAS and suggest that CNVs influence human phenotypes by regulatory mechanisms.

A Novel Deletion Associated with Anophthalmia and Diaphragm Hernia. *R. T. Chao[1], A. Delaney[2], P. Agarwal[3], L. Nevin[4], M. Akana[3], D. FitzPatrick[5], B. L. Black[3], P. Kwok[3], H. Baier[4], A. M. Slavotinek[1]* 1) Department of Pediatrics, UCSF, San Francisco, CA; 2) University of British Columbia, Canada; 3) Cardiovascular Reseach Institute, UCSF, San Francisco, CA; 4) Department of Physiology, UCSF, San Francisco, CA; 5) MRC Human Genetics Unit, Edinburgh, U.K.

Array comparative genomic hybridization is now standard of care in the investigation of idiopathic mental retardation, and its use is becoming widespread in patients with birth defects. We used Affymetrix 100K SNP arrays to examine 15 patients with congenital diaphragmatic hernia (CDH) or Fryns syndrome for copy number variations (CNVs). Using stringent criteria selecting CNVs with a SNP count of 20 or more and a p-value < 1x10-8, we found 8 regions of CNV suggestive of either a deletion or a duplication that had not been previously described. One patient with a p-value of 0 had tetrasomy 12p, an aberration known to cause CDH. A second patient with a p-value of 0 had unilateral right anophthalmia/microphthalmia, R-sided CDH and mild developmental delay. This male had a novel 2.7 Mb deletion at chromosome 18q22.1 which was verified by FISH, but parental studies showed that the deletion was inherited from his normal mother. *In situ* hybridization studies using murine sections showed that one of the deleted genes, *Txndc10*, was expressed in the developing eye, brain, lung, and kidney. We re-sequenced this gene in 66 anophthalmia/microphthalmia patients, and found c.G260A, predicting p.R39Q, in a patient with microphthalmia and retinal coloboma. The sequence alteration was absent in more than 200 control chromosomes. We are currently testing the hypothesis that *Txndc10* is important in eye development using morpholinos to knock down a zebrafish ortholog of *Txndc10*. Taken together, our results suggest that haploinsufficiency for *Txndc10* may perturb eye development because of the anophthalmia in the patient with the deletion, the conserved expression data, and the presence of a second gene alteration in an unrelated patient with microphthalmia. Our results also emphasize the established utility of array methodology for candidate gene investigation.

Microarray based capturing of human genomic loci for high-throughput re-sequencing and application to cancer genome study. *H. Lee, B. O'Connor, B. Merriman, S. Nelson* Dept Human Gen, Gonda 5554, Univ California, Los Angeles, Los Angeles, CA.

We are approaching a new era in the field of Human Genetics equipped with high-throughput sequencing technique which is opening a new venue to personal genomics and accelerating the discovery of new rare variants in different human disorders. However, even though it is not impossible to sequence the 3-billion-base human genome, it is not very practical yet. This imposes on us a need to develop new methodologies to more effectively utilize the high-throughput sequencers. Thus, we are developing a technology using microarrays to capture specific genomic loci that could be re-sequenced through high-throughput sequencers. Currently, using Agilent custom arrays, we are reaching ~60% enrichment which is comparable to the reported results (Hodges et al. 2007; Albert et al. 2007). However, further refinement of the protocol should improve the enrichment and reduce the cost of sequencing by significant factor. As an application of our developing capture technique, we have designed custom arrays targeting ~3,000 cancerous genes retrieved from the Wellcome Trust Sanger Institute Catalogue of Somatic Mutations in Cancer (COSMIC). By re-sequencing paired samples of normal genomic DNA and tumor genomic DNA within an individual, we hope to identify rare mutations that occurred in the individuals normal genomic DNA in the process of initiating the cancer. This study will not only give us new insights in understanding the cancer development by providing deeper mutational landscape of individual cancer samples, but also show the significance of the capture methodology that could be applied to any human disorders.

Mitochondrial gene set analysis of genome-wide association studies of type 2 diabetes and related clinical traits.

A. V. Segrè[1,2,3], R. Saxena[1,2,3], S. Calvo[1,2,3], V. K. Mootha[1,2,3], L. Groop[4], M. J. Daly[1,2,3], D. Altshuler[1,2,3] 1) Broad Institute of Harvard and MIT, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) Lund University, Malm;ö, Sweden.

Mitochondrial dysfunction is observed in diabetic patients, and mtDNA mutations are linked to a rare form of diabetes, however no common DNA variants (SNPs) linked to mitochondrial genes have yet been robustly associated with T2D in genome-wide association studies (GWAS). While replication is typically done for the top ranked SNPs (p<~1e-4), it is feasible that there are SNPs linked to mitochondrial genes that lie below the top ranked SNPs that are truly associated with T2D. By jointly analyzing a set of SNPs linked to functionally related genes, true associations may be detected that on a single SNP level failed to achieve genome-wide significance. Hence, we tested whether mitochondrial genes or the oxidative phosphorylation (OXPHOS) subset are statistically enriched for genes modestly associated with T2D or related clinical traits. We developed a gene set enrichment method for analyzing GWAS, based on similar approaches for expression data. The method involves: (i) assigning to each gene in the genome the highest score among the GWAS scores of all SNPs in a region around the gene, (ii) normalizing the gene scores according to confounders (e.g. gene size), (iii) defining the sets of functionally related genes to be tested, (iv) testing statistically whether any of the gene sets is enriched for high scores, and (v) estimating statistical significance by permutation analysis. We applied our method to a meta-analysis of three GWAS of T2D, using 933 mitochondrial genes and 86 OXPHOS genes. No significant enrichment of gene associations to T2D was found for the mitochondrial or OXPHOS gene sets using an enrichment cutoff of the top 1% or 5% of all ranked genes (p>0.2). Simulations used to assess the power of our method suggest that at least 50 mitochondrial genes need to lie in the top 5% of ranked genes (38 observed) or 8 OXPHOS genes (1 observed) for collective association to be identified at a 0.05 false positive rate.

Scanning for gene-gene interactions involving known type 2 diabetes genes and the genome in 2335 Finnish cases and controls. *T. Hu[1], L. J. Scott[1], L. Bonnycastle[2], N. Narisu[2], M. A. Morken[2], P. A. Deodhar[2], T. T. Valle[3], J. Tuomilehto[3], R. N. Bergman[4], K. L. Mohlke[5], F. S. Collins[2], M. Boehnke[1]* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) National Human Genome Research Institute, Bethesda, MD; 3) National Public Health Institute, Helsinki, Finland; 4) University of Southern California, Los Angeles, CA; 5) University of North Carolina, Chapel Hill, NC.

~20 loci have been identified as convincingly associated with the risk of type 2 diabetes (T2D). However, little is known about the interactions among these loci or with other variants across the genome. Since gene-gene interaction may play an important role in determining disease risk, we set out to test the interactions of T2D associated variants in and around identified regions in genome-wide association (GWA) data from the Finland-United States Investigation of NIDDM Genetics (FUSION) study. Based on a sample of 1161 T2D cases and 1174 normal glucose tolerant controls genotyped for >300,000 SNPs, we tested for two-way interactions among the following loci: *IGF2BP2* (rs4402960), *CDKAL1* (rs7754840), *CDKN2A/B* (rs10811661), rs9300039, *FTO* (rs8050136), *PPARG* (rs1801282), *SLC30A8* (rs13266634), *HHEX* (rs1111875),*TCF7L2* (rs7903146), *KCNJ11* (rs5219), *JAZF1* (rs864745), *CDC123* (rs12779790), *TSPAN8* (rs7961581), *THADA* (rs7578597), *ADAMTS9* (rs4607103), and *NOTCH2* (rs10923931), using logistic regression and controlling for age, sex, and birthplace. None of these two-way interactions gave results sufficiently significant to survive correction for the 120 correlated tests. We currently are using this same strategy to test for interaction between the T2D-associated loci and the >300,000 SNPs genotyped in our FUSION GWA.

Cross-species targeted DNA sequencing: New methods for exploring diversity and evolution. *M. Lovett* Dept Genetics, Washington Univ Sch Med, St Louis, MO.

Cross-species DNA sequencing presents particular technological challenges. PCR primers designed from a reference sequence frequently do not amplify DNA from other species. We have developed methods to achieve large-scale, cross-species sequence comparisons and have applied these to regions within the genomes of six Darwins finch species plus out groups. Up regulation of *BMP4* gene expression is the only difference discovered to date correlated with large beak morphology in these birds. It is possible that differences in a trans-regulator of *BMP4*, or different cis-regulatory sequences between the species, account for these differences. To test the latter we targeted the 500kb region surrounding the *BMP4* gene for DNA sequencing in the finch species. This was achieved by direct genomic selection (DIGS) using a biotinylated *Gallus gallus* BAC contig. The published DNA sequence over this region has many gaps, including the putative *BMP4* promoter. We therefore also sequenced the entire region in leghorn chicken DNA to fill these gaps. Genomic DNAs were modified by shearing and the addition of Illumina/Solexa sequencing linkers. Hybridization selections were conducted in solution and captured and eluted DNAs were directly sequenced. Approximately 20% of chicken reads mapped to the reference and these provided close to 100% coverage of single copy sequences in the contig at 100X coverage. This filled in the missing gaps in the *Gallus gallus* sequence including the putative *BMP4* promoter. Assembly of the finch DNA sequences readily identified 20% of the contig as having high levels of sequence conservation between chickens and finches, with the remainder of the contig showing much higher conservation within the finches than with the chicken. Within the assembled contigs are numerous examples of conserved elements, including the promoter of the *BMP4* gene and many other more distal elements, some of which differ between finch species. These are being functionally assessed. This is the first example of any large- scale DNA sequence comparison between Darwins finches and has applications for DNA sequencing of large regions within many other species.

DNA damage produced following UV radiation in combination with hydrogen peroxide in skin cells. *J. Perron, N. Bastien, JF. Millau, R. Drouin* Genetics, Dept Pediatrics,, Fac Med Health Sci, Univ Sherbrooke, Sherbrooke, Quebec, Canada.

The main etiological factors responsible for skin cancer are the ultraviolet radiations emitted by the sun. Indeed, long wavelength UVB (295-320 nm) and UVA (320-400 nm) reach the skin surface and cause DNA damage like cyclobutane pyrimidine dimers (CPD) and oxidized bases. These damage lead to mutations and ultimately to cancer. In addition, other cellular molecules can also interfere within this process such as hydrogen peroxide (H2O2) produced during skin inflammation. The objective of this study was to compare the formation of damage in human fibroblasts following UV irradiation, hydrogen peroxide treatment or a combination of both. Methods- We irradiated fibroblasts with UVA, UVB or solar simulated light (SSL) with or without different concentrations of H2O2. DNA damage were converted in single-strand breaks using the T4 endonuclease V to study CPD and the Endonuclease III or Formamidopyrimidine DNA glycosylase to study oxidative damage. Then, glyoxal gels were performed to assess the global frequency of DNA damage. Finally using LMPCR technique (ligation-mediated PCR) on the p53 gene we mapped DNA damage formation at the level of nucleotide resolution. Results- In fibroblasts, the combination of UVB and H2O2 did not induce a higher frequency of damage than UVB and H2O2 alone but a combination of UVA and H2O2 led to increased levels of oxidative damage comparatively to UVA or H2O2 alone. The CPD were the most important photoproducts following UVA irradiation. The CPD were mapped at the dipyrimidine sites, mainly the TT sites. The oxidative damage were mapped mainly at the G residues suggesting the formation of 8-oxo-guanine. Conclusion- UVB are known to be implicated in skin cancer but the contribution of UVA in the sun induced carcinogenesis process is still unclear. These results show that UVA could play an important role in the formation of mutations, particularly if their effect is combined with the H2O2 produced during the sunburn inflammatory response. Moreover we also showed that UVA produced CPD, reinforcing the potential role of UVA in skin cancer genesis.

Loss-of-function mutations in endothelial lipase are associated with elevated HDL cholesterol in humans. *A. Edmondson[1], R. Brown[1], S. Kathiresan[2], L. A. Cupples[3], S. Demissie[3], A. Manning[3], E. Rimm[4], J. Wang[5], M. Wolfe[1], S. DerOhannessian[1], D. Evans[6], R. Hegele[6], D. J. Rader[1]* 1) Institute for Translational Medicine and Therapeutics, University of Pennsylvania School of Medicine, Philadelphia, PA, USA; 2) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 3) Boston University and Framingham Heart Study; 4) Department of Epidemiology, Harvard School of Public Health, Boston, MA, USA; 5) Robarts Research Institute and Schulich School of Medicine and Dentistry, University of Western Ontario, London, Ontario, Canada; 6) Endokrinologie und Stoffwechsel, Medizinische Klinik III, Zentrum für Innere Medizin, Universitätsklinikum Hamburg-Eppendorf, Hamburg, Germany.

Elevated plasma levels of high density lipoprotein cholesterol (HDL-C) are associated with protection from cardiovascular disease. Animal models indicate that increased expression of endothelial lipase (*LIPG*) is inversely associated with HDL-C levels, and genome-wide association studies have identified *LIPG* as being associated with human HDL-C. We hypothesized that loss-of-function mutations in *LIPG* are a cause of elevated HDL-C and performed medical resequencing of *LIPG* in cases with HDL-C > 95th percentile and controls with HDL-C < 25th percentile. We identified an excess of nonsynonymous *LIPG* variants in cases with elevated HDL-C. Functional analysis using in vitro lipase activity assays demonstrated that the unique nonsynonymous *LIPG* variants identified in cases with elevated HDL-C exhibited significantly decreased lipase activity. The association of two more common nonsynonymous *LIPG* variants, T111I and N396S, with HDL-C levels in the Framingham Heart Study was studied and indicated that N396S was significantly associated with increased HDL-C (p=0.00004), while T111I was not associated with HDL-C. Functional analysis demonstrated that N396S has significantly decreased in vitro lipase activity, while T111I has normal in vitro lipase activity. Our results establish that loss-of-function mutations in *LIPG* lead to increased HDL-C levels and support the concept that endothelial lipase is an attractive candidate for inhibition to raise HDL-C.

The DISC1 locus - A circumscribed intron 9-interval associates with disease risk in females affected by schizophrenia. *J. Schumacher[1, 2], G. Laje[2], R. Abou Jamra[1], T. Becker[3], T. W. Muehleisen[4], C. Vasilescu[4], M. Mattheisen[4], S. Herms[4], P. Hoffmann[4], A. M. Hillmer[4], A. Georgi[5], C. Herold[3], T. G. Schulze[2, 5], F. J. McMahon[2], P. Propping[1], M. Rietschel[5], M. M. Noethen[1, 4], S. Cichon[1, 4]* 1) Institute of Human Genetics, University of Bonn, Germany; 2) National Institute of Mental Health (NIMH), National Institutes of Health (NIH), Bethesda, USA; 3) Institute for Medical Biometry, Informatics and Epidemiology, University of Bonn, Germany; 4) Department of Genomics, Life & Brain Center, University of Bonn, Germany; 5) Division of Genetic Epidemiology in Psychiatry, Central Institute of Mental Health, Mannheim, Germany.

The gene Disrupted-In-Schizophrenia-1 (DISC1) has been reported as a risk factor for schizophrenia by association studies. It encodes a multifunctional scaffold protein involved in neuronal migration, cortical layering, and hippocampal formation; all processes implicated by the neurodevelopmental hypothesis of schizophrenia. We conducted a systematic LD mapping at the DISC1 locus using 556 polymorphisms (121 genotyped, 435 imputed SNP markers) in a case-control-sample from the German population (N=1,621, cases=782, controls=839). To protect from type-I error we performed 10,000 permutations. A circumscribed DISC1 intron 9-interval was significantly overrepresented in schizophrenia female patients (38% vs. 28% in controls, p=4x10-5), spans between 27.5-28.8 kb at the genomic level, and is associated to early onset (< 21 years) (44% vs. 28%, p=9x10-5). The corresponding ORs are in the range of 1.46 to 1.88. Our results point to a so far undescribed DISC1 susceptibility interval that may contribute to the disease risk in the German (or mid-European) population. However, other DISC1 intron 9 associations with schizophrenia have already been reported. This, together with the high cross-species conservation and the exceptionally large size of intron 9 suggest that this interval might be of functional importance in the disease process. Furthermore, based on present and previous findings, the consideration of allelic heterogeneity and gender-specific effects seems to be crucial in genetic studies of schizophrenia.

Isolating genetic causes of familial lung cancer. *C. I. Amos[1], J. E. Bailey-Wilson[2], S. M. Pinney[3], A. G. Schwartz[4], M. You[5], P. Yang[6], G. Gaba[7], D. Mandal[8], P. Fain[9], Y. Li[1], J. Minna[10], E. Kupert[3], M. deAndrade[6], M. W. Anderson[3]* 1) Dept Epidemiology, MD Anderson Cancer Ctr, Houston, TX; 2) National Human Genome Research Institute; 3) University of Cincinnati, Cincinnati; 4) Karmanos Cancer Institute, Detroit; 5) Washington University, St. Louis; 6) Mayo Clinic College of Medicine, Rochester, MN; 7) Medical College of Ohio, Toledo; 8) Louisiana State University Health Sciences Center, New Orleans; 9) University of Colorado, Denver; 10) U.T. Southwestern Medical Center, Dallas.

Individuals with a first degree relative with lung cancer are at approximately a 2.5 fold higher risk for lung cancer compared with population rates that allow for smoking behaviors. We previously identified in 2004 by linkage analysis a region of chromosome 6q that harbors a susceptibility locus for lung cancer using data from 52 families with at least three relatives who had lung cancer. Previously we found that families with 5 or more affected relatives showed the strongest evidence for linkage, yielding a heterogeneity LOD (HLOD) score of 4.26. Our current studies expand to 92 the number of families that we have studied to identify a strongly familial cause for lung cancer, and increase the time of observation and number of cases with lung cancer. Evidence for a lung cancer susceptibility locus on chromosome 6q is strongly supported in families that include 5 or more affected relatives in 2 or more generations, yielding an HLOD score of 4.57 at 158 cM. Genetic linkage analysis of other chromosomes provided weaker evidence for linkage. Evidence for linkage is also provided in these families to chromosomes 6p (HLOD score of 1.72 at 63 cM), 4p (HLOD score of 1.3at 4cM) and chromosome 12 (HLOD score of 0.97 at 146 cM). Further analyses of the risk for lung cancer from the chromosome 6q locus show a dramatic increase in risk among carriers who smoke any amount, compared with nonsmokers. These results strongly support evidence for at least one locus on chromosome 6q that greatly increases risk for lung cancer particulary in response to smoking, and suggest that additional loci contribute to lung cancer risk.

Deep sequencing of genes associated with type 2 diabetes and Crohn's disease. *M. Daly[1,2,3], F. Kuruvilla[1,2], N. Burtt[2], C. Stevens[2], C. Guiducci[2], G. Crawford[2], J. Maguire[2], K. Cibulskis[2], T. Green[1,2], M. Rivas[1,2], B. Voight[1,2], E. Lander[1,2,3], S. Gabriel[2], D. Altshuler[1,2,3], NIDDK IBD Genetics Consortium; Diabetes Genetics Initiative* 1) CHGR, Massachusetts General Hospital, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) Harvard Medical School, Boston, MA.

Genome-wide association studies have identified more than 100 unequivocally significant associations to complex diseases. In most cases, specific causal variants have yet to be pinpointed, limiting follow-up functional studies and even recognition of which nearby gene is involved. Moreover, since the proportion of disease risk explained is generally quite modest, deeper assessment of variation is further motivated by observations of multiple independent risk alleles at many susceptibility loci (e.g., IRF5, IL23R, NOD2) and particularly the observation of both rare variants of large effect and common variants of modest effect at many genes conclusively linked to lipid levels. Thus we have undertaken deep sequencing of coding regions of 50 genes near SNPs identified and replicated beyond genome-wide significance in Type II Diabetes and Crohns Disease using Solexa/Illumina technology. Since the PCR-targeted exons are small relative to the capacity of a lane of Solexa, we sequenced 500 cases and controls in pools of 50 individuals. To identify SNPs we implemented a likelihood-based estimate of p(data | genotype) with population genetics priors on polymorphism rates informed by HapMap and dbSNP variant locations. By targeting a set of previously typed rare variants, we observed 90% sensitivity to detect rare variants carried by 1 of 100 chromosomes, suggesting pooling and rare SNP detection were successful. Validation genotyping identified a modest but inflated number of false positives - automated analysis of neighborhood quality further refined SNP discovery. We present here the experimental and analytic strategy and apply it to summarize rare coding variation and aggregate excesses in cases versus controls - providing an overall assessment of the role of rare variation in genes identified through common SNP association.

High Resolution Comparative Genomic Hybridization of pre-invasive laser-capture microdissected lung adenocarcinoma. *L. Herlitz, A. C. Borczuk, O. Nahum, C. A. Powell, B. Levy* Department of Pathology, Columbia University, New York, NY.

Non-mucinous bronchioloalveolar carcinoma (BAC) is pre-invasive lung adenocarcinoma characterized by tumor growth along benign alveolar walls. DNA derived from homogenized tumor sections contains a large proportion of non-tumoral cells. Laser capture microdissection (LCM) allows for significant enrichment of tumor cells improving detection of small copy number changes and deletions. LCM of tumor cells from frozen sections of 7 cases of non-mucinous BAC was performed using the PALM-Zeiss Microbeam System. Whole genome amplified DNA was used for metaphase spread comparative genomic hybridization. Increases in DNA copy number were observed in chromosomes 1q32, 5p, 7p, 8q24 and losses in 9p13-21, 11q13 in at least 5 of the 7 cases. Known cancer genes in these regions include KIF4, CENPF, KCNH1, EGFR,RECQL4, RNF139 and tumor suppressor genes p16 and MEN1. LCM allows for the detection of copy number alterations in tumors in which less than 50% of the cut surface represents tumor cells. This creates the opportunity for uncovering genes that play a role in the etiology of early neoplasia and pre-invasive lesions.

Lysosomal Disease Network, and *WORLD Symposium 2009*. *C. Whitley[1], J. Barranger[2], J. Muenzer[3], C. Eng[4], G. Grabowski[5], M. Patterson[6], S. Walkley[7], B. Davidson[8], R. Steiner[9], W. Wilcox[10], E. Shapiro[1], . other LDN members[11]*
1) University of Minnesota, Minneapolis, MN; 2) University of Pittsburgh, Pittsburgh, PA; 3) University of North Carolina; 4) Baylor College of Medicine, Houston, TX; 5) Children's Hospital Research Foundation, Cincinnati, OH; 6) Mayo Clinic, Rochester, MN; 7) New York University, New York, NY; 8) University of Iowa, Iowa City, IA; 9) Oregon Health & Science University, Portland, OR; 10) Cedars-Sinai Medical Center, Los Angeles, CA; 11) other LDN institutions.

The Lysosomal Disease Network (LDN) is a consortium of basic researchers, clinicians, pharmaceutical industry professionals, and patient advocates devoted to promote and facilitate basic, translational and clinical research in lysosomal diseases. The network is a scalable multi-center consortium of geographically distributed expert medical centers, patient support and corporate partners. The infrastructure, mission and charter were developed through organizational committees; the collaborating medical centers, pharmaceutical and patient support organizations will direct the activities of the network through participation in the Steering Committee. Toward meeting its goals, the LDN has launched its web site **www.LysosomalDiseaseNetwork.org** to facilitate professional and public education, timely network communication, and develop a data entry mechanism for research projects. The web site has announced its 5th annual scientific meeting, the **WORLD Symposium** (February 18-20, 2009) in San Diego, CA, USA. Through the web site, participants are able to submit abstracts, register for the meeting, and join the growing membership list to receive regular communications. The Network is currently developing longitudinal studies to understand the natural history of lysosomal diseases and treatment outcomes. Long term network goals include: 1) development of an information management infrastructure to encourage integration of shared clinical experience and relevant longitudinal studies, 2) investigator training, and 3) public education. Organizational and symposium support has been provided by NIH, NINDS, NIDDK, and ORD.

THE HUMAN VARIOME PROJECT - Collection of variation causing human disease: Progress Pilots and Plans. *J. T. Den Dunnen[1], F. A. Macrae[2], R. G. H. Cotton[3], Collaborators of the HVP, HGVS and InSiGHT* 1) Human Genetics, S4-030, Leiden Univ Medical Ctr, Leiden, Netherlands; LOVD; 2) Department of Colorectal Medicine and Genetics, The Royal Melbourne Hospital, Parkville, Australia; InSiGHT; 3) Genomic Disorders Research Centre, Melbourne, Australia; Human Variome Project; Department of Medicine, The University of Melbourne.

Lack of up-to-date, complete, electronically accessible and correctly curated information on gene sequence variants leads to excessive web searching, wastes valuable healthcare funds and may lead to incorrect clinical diagnosis. The Human Variome Project (HVP; www.humanvariomeproject.org) was created to coordinate the curation and collection of all genetic variation, its phenotype and associated disease(s). A planning meeting was held in Spain (May 2008) to focus the task. A number of projects are planned or underway under the HVP or related and/or collaborator activities. These include: 1. The HVP InSiGHT colon cancer pilot study to set up a trial system in inherited colon cancer genes (HNPCC) to be later applied to all genes in all countries. 2. The microattribution initiative initiated by Myles Axton, Nature Genetics. 3. Ethics of curation of gene or locus specific databases (LSDBs). 4. GEN2PHEN, a European initiative to rationalize and harmonize databases. 5. Development of systems to collect data from hospitals and diagnostic labs. Country-specific efforts are underway in the UK and Germany and planned in Japan and the Arab countries. 6. Establishing data exchange between LSDBs and central repositories like NCBI and EBI. 7. Locus specific database hosting, registering and software are all available.

Clinical Ascertainment of Patients with Muir-Torre Syndrome by Dermatologists and Pathologists within a Large HMO. *K. Wendt[1], S. A. Ahmed[1], F. Eggerding[2], A. Thomas[1], M. Jamehdor[1]* 1) Regional Gen Testing Lab, Kaiser Permanente SCPMG, Los Angeles, CA; 2) HMRI, Pasadena, CA.

Muir-Torre syndrome (MTS) is characterized by sebaceous skin lesions (adenomas, epitheliomas, basaliomas and carcinomas) and one or more visceral malignancies (colorectal, endometrial, ovarian, stomach) within the spectrum of hereditary nonpolyposis colorectal cancer (HNPCC). A subtype of MTS allelic to HNPCC is caused by germline mutations in the DNA mismatch repair (MMR) genes, leading to early onset colorectal cancer and other tumors. Both microsatellite instability (MSI) testing and immunohistochemical examination of MMR protein expression in MTS-associated skin tumors can be used as a diagnostic screening tool to identify patients with MMR germline mutations. During a 3 yr period (2/2005-6/2008), the SCPMG Genetic Testing Laboratory received 23 samples (6 blood samples, 17 paraffin-embedded sebaceous adenoma tumors) from 22 patients (age 45-87y; 13M: 9F) at risk for MTS. Each of the 6 blood samples for MMR germline testing was submitted by one of our Medical Geneticists based upon their patients personal history of sebaceous adenoma and family history of colon or other HNPCC-related malignancy. Of the 17 paraffin-embedded sebaceous adenoma tumor samples received, 14 were submitted by Pathologists and Dermatologists within our HMO. In 6 of 14 cases, absent immunostaining for MSH2/MSH6 was noted. Microsatellite instability (MSI-H) was noted in 5 of the 6 cases with absent MSH2/MSH6 immunostaining. Although most HNPCC cases are ascertained through Medical Geneticists and/or Gastroenterologists, our report acknowledges the role of Dermatologists and Pathologists in raising the suspicion of HNPCC and initiating MSI/IHC testing following diagnosis of a sebaceous neoplasm. The unique structure within our HMO allows us to review abnormal MSI/IHC results with referring Dermatologists and Pathologists and re-integrate those patients into our genetic service. Patients are referred to their local Medical Geneticist and Genetic Counselor for evaluation of the extended pedigree, consideration of germline testing and coordination of surveillance for MTS-associated visceral and skin neoplasms.

Genome-wide association study reveals *ADIPOQ* variation as strongest genetic influence on circulating adiponectin levels in the Old Order Amish. *T. I. Pollin[1], H. Ling[1,2], P. F. McArdle[1], Q. Gibson[1], B. D. Mitchell[1], J. R. O'Connell[1], A. R. Shuldiner[1]* 1) University of Maryland School of Medicine, Baltimore, MD; 2) Center for Inherited Disease Research, Baltimore, MD.

Adiponectin is a fat-secreted hormone that enhances insulin sensitivity and free fatty acid oxidation and inhibits inflammation. Reduced levels are associated with obesity and increased risk of type 2 diabetes and cardiovascular disease. We measured adiponectin levels in 689 Old Order Amish participants of the Heredity and Phenotype Intervention (HAPI) Heart Study and performed a genome-wide association study using the Affymetrix GeneChip Human Mapping 500K Array. The greatest evidence for association with ln-transformed adiponectin levels occurred at three SNPs on chromosome 3q27 in or near *ADIPOQ*, the adiponectin structural gene, including rs3774261 in intron 2 and rs6773957 in the 3' UTR (minor allele frequency [MAF] = 0.31, additive $p = 8.1 \times 10^{-8}$ for both, adjusted for sex and sex-specific age and age^2 as well as residual covariance between relatives), and rs698092, 393 kb downstream (MAF = 0.33, $p = 1.6 \times 10^{-8}$). The two *ADIPOQ* SNPs (both C>T) were in complete LD (D' = 1, $r^2 = 1$), and adiponectin levels (geometric mean [95% CI]) were 9.7 [9.4 - 10.1], 10.4 [10.1 - 10.8] and 12.1 [11.4 - 13.0] mg/dl for the CC, CT and TT genotypes respectively. Either SNP accounted for 5.0% of trait variation. Rs698092 was in low LD with the two *ADIPOQ* SNPs (D' = 0.16, $r^2 = 0.03$), explained 4.2% of the trait variance and may tag a distinct causal variant in *ADIPOQ*. A prior genome-wide linkage study in the Amish Family Diabetes Study (AFDS) also identified the *ADIPOQ* locus as the greatest genetic predictor of adiponectin levels (LOD = 2.13). Five additional regions contained SNPs associated at $p 10^{-5}$: rs1290894 at 3q13 (MAF = 0.05), rs1380722 at 4q32 (MAF = 0.05), rs996825 at 8q12 (MAF = 0.16), rs1857471 at 9q21 (MAF = 0.05), and rs2420941 at 10q26 (MAF = 0.46). These findings confirm the key influence of *ADIPOQ* variation on adiponectin levels and provide opportunities for elucidating additional genetic influences on adiponectin levels and associated diseases.

Association of the Monoamine oxidase gene A and autism spectrum disorder. *L. Qi[1,6], F. Tassone[2], W. Zhang[1], P. Krakowiak[4,6], R. Hansen[3,6], I. Hertz-Picciotto[4,6], I. Pessah[5,6]* 1) Program Human Gen, Univ California, Davis, Davis, CA; 2) Department of Biochemistry and Molecular Medicine, School of Medicine, Univ California, Davis, CA; 3) Dept of Pediatrics, School of Medicine, Univ California, Davis, CA; 4) Dept of Public Health, School of Medicine, Univ California, Davis, CA; 5) Dept of Molecular Biosciences, School of Medicine, Univ California, Davis, CA; 6) M.I.N.D. Institute, UCD Medical Center, Sacramento, California.

We have studied three polymorphisms, the serotonin transporter promoter region polymorphism (5-HTTLPR), the dopamine hydroxylase (DBH) and the Monoamine Oxidase A (MAOA) in families participating in the CHARGE (Childhood Autism Risks from Genetics and the Environment) Study. The CHARGE study is a large ongoing case-control investigation which recruits families with a child aged 2-5 years from three groups: autism, ASD, and the general population. A total of 359 AU, ASD and TD families were genotyped to investigate whether allelic variations in the candidate genes are associated with higher risk of autism and whether transmission differed by autism case status. Case-control association analysis shows that allele 4 in MAOA doubled the risk for AU or AU +ASD among White and Hispanic boys (95% CI = 1.10, 3.59, p = 0.02 for AU and 95% CI = 1.18, 3.49, p = 0.01 for AU+ASD), with or without adjusting for other covariates. Family-based association analysis does not show significant transmission disequilibrium for HTT, DBH, and MAOA. However, more mothers had the 44 genotype among AU (49%;) and AU&+ASD (45%) boys than among TD boys (31%, p = 0.005 for AU vs TD and p = 0.01 for AU+ASD vs TD, using White and Hispanic subjects). Moreover, mothers MAOA genotype is significantly associated with risk for AU or AU+ASD ($p < 0.05$). Adjusted for race, mothers and fathers age at delivery, mother having the 34 or 44 genotype is associated with 2 to 4.7-fold increase in the risk of AU or AU+ASD compared with the genotype 33. These results provide more evidence that allele 4 in MAOA may be a risk allele for Autism Spectrum Disorders.

Plasma Peptide Tyrosine Tyrosine Levels are Increased in Urea Cycle Disorder Patients. *S. Mitchell, D. Murdock, M. Summar* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Peptide tyrosine tyrosine (PYY) and N-acetylglutamate synthase (NAGS) are divergently transcribed and separated by less than 200 base pairs in humans; an arrangement that is consistent with coordinate regulation. PYY inhibits gut motility and is a key component in the regulation of appetite, inducing feelings of satiety postprandially. NAGS plays an important role in ureagenesis providing the necessary co-factor for carbamoyl phosphate synthetase 1, which catalyzes the first step of the urea cycle. In the urea cycle, ammonia is converted to urea and is excreted as waste through the kidneys. Inherited metabolic disorders resulting in deficiencies in any of the urea cycle enzymes result in aberrant nitrogen clearance and elevated ammonia levels. Additionally, anorexia is well-documented in patients with urea cycle disorders (UCDs). Decreased appetite is normally attributed to cerebral edema and dysregulation of neurotransmitters resulting from the elevations in ammonia levels. However, if PYY and NAGS are regulated in a coordinate manner due to their arrangement and physical proximity, then increased levels of PYY may underlie a significant part of the anorexia observed in hyperammonemic patients. We hypothesize that patients with UCDs and an upregulation of NAGS will show increases in PYY production. Using an ELISA, we measured plasma PYY levels in a group of UCD patients (n = 37). The levels ranged from 10.5 pmol/L to 249.5 pmol/L, and the average level was 48.8 pmol/L. The upper end of this range is dramatically higher than ranges reported for normal fasting and postprandial plasma PYY levels, 12.1 pmol/L and 29.9 pmol/L, respectively. We plan to further investigate these preliminary results; as the increased expression of PYY may result in appetite suppression in these patients leading to catabolism, and an increase in ammonia levels. If clinical observations in UCD patients are directly relevant to the transcriptional regulation of this gene pair, then PYY becomes a potential therapeutic target in the management of patients suffering from UCDs and other diseases involving disrupted nitrogen metabolism.

Validation of the manual scanning process to detect rare events using FISH technique. *A. Emad, S. Ayub, MC. Gregoire, O. Samassekou, M. Gadji, F. Hemmings, K. Krabchi, R. Drouin* Genetics, Dept Pediatrics,, Fac Med Health Sci, Univ Sherbrooke, Sherbrooke, Quebec, Canada.

Introduction- Fetal cells are found in the maternal circulation at a rare frequency of 2-6 cells/ml. The male fetal cells by serving as markers XY are a potential source of developing non-invasive prenatal diagnosis. Techniques like Fluorescence In Situ Hybridization (FISH) and Primed In Situ labeling (PRINS) have been used before for retrieval of these cells. To our knowledge, the efficiency of the manual scanning using either of these techniques has never been evaluated. Objectives- For the purpose of developing non-invasive prenatal diagnosis, we are in the process of determining the efficiency of the manual scanning by the FISH technique to detect rare XY cells amongst thousands of XX cells. Hybridization efficiency is also determined. Methodology- The methodology involves spreading of 1-10 XY cells on pre-cleaned slides, staining with Giemsa, imaging of these cells then spreading around 100,000 XX cells, followed by FISH using XY probes. This was followed by blind manual scanning with the Y chromosome serving as marker. Pictures taken of XY cells are compared with the ones taken initially following Giemsa staining. Results- A total number of 76 XY cells were distributed on 17 slides processed by manual scanning using FISH technique. The scanner was able to detect 66 of these XY cells. By evaluation of the hybridization of the 10 missed cells, it was found that 20%; (2/10) were not hybridized for the Y chromosome, 30%; (3/10) were poorly hybridized and the hybridization was adequate at the remaining 50%; (5/10). The overall detection rate after exclusion of the cells with defective hybridization was 92.9%; (66/71). Conclusion- Manual scanning of the slides processed by FISH can lead to underestimation of the real number of cells by about 13.1%; (10/76). FISH technique is responsible for missing of 2.6%; (2/76) while 6.6%; (5/76) is missed in the process of the manual scanning itself. The rest 3.9%; (3/76) is in a gray zone in-between. This data is mandatory for later comparison between different techniques on one hand and manual and automatic scanning on the other hand.

Haplotype analysis enabled the dissection of two chromosome 2 variants with major effect on plasma plant sterol levels on the Pacific Island of Kosrae. *E. Kenny[1,2], A. Gusev[2], D. Lütjohann[3], J. Lowe[1,4,5], J. Salit[1], J. Maller[4,5,6], M. Stoffel[1], M. Daly[4,5,7], D. Altshuler[4,5,7], J. Friedman[1,8], I. Pe'er[2], J. Breslow[1], E. Sehayek[9]* 1) Div Biol, 156-29, Rockefeller Univ, New York, NY; 2) Columbia University, New York, NY; 3) University of Bonn, Germany; 4) Broad Institute of Harvard & MIT, Cambridge, MA; 5) Massachusetts General Hospital, Boston, MA; 6) University of Oxford, Oxford, UK; 7) Harvard Medical School, Boston, MA; 8) Howard Hughes Medical Institute; 9) Cleveland Clinic, Cleveland, OH.

Plasma plant sterol levels (PPS) serve as a surrogate measure of cholesterol absorption from the intestine. Measurement of PPS on the Pacific Island of Kosrae previously identified five -sitosterolemic patients homozygous for a frame shift mutation in ABCG8 on chr2p21 and 11% of the islanders who are heterozygous for the ABCG8 mutation and have 30-50% increased PPS. To characterize this and other genetic determinants of PPS, we performed a genome-wide association study in 1,429 related individuals. As expected, a very strong association of PPS with SNPs was detected on chr2p21 ($p<10^{-40}$). Association analysis that has been conditioned on the ABCG8 mutation disclosed a second strong signal that maps ~250kb downstream of the ABCG8 locus ($p<10^{-35}$). Identity-by-descent analysis of the population (using the GERMLINE software) revealed that the entire downstream signal was captured by a 525kb haplotype (chr2:43.8-44.3MB) that harbors the ABCG8 locus but was completely unlinked to the ABCG8 mutation. The novel haplotype is carried by ~2% of the population, and segregates in two large kindreds of the same Kosraean village. Carriers show >90% increase in PPS ($p<10^{-69}$) which exceeds the ABCG8 mutation effect. Carriers of the novel haplotype are characterized by 50% decrease in cholesterol synthesis, as reflected by a decrease in plasma lathosterol levels ($p<10^{-11}$). We are currently resequencing search for the causative genetic variant on this haplotype. These findings exemplify the power of haplotype analysis in dissecting the effect of multiple variants of the same locus.

HEMIZYG: Detects Novel SNP in Bipolar Linkage Region And Uncovers Evidence for Genetic Heterogeneity.

W. C. L. Stewart[1], N. Xiang[3], S. Villafuerte[3], S. Zoellner[1,2], M. G. McInnis[2], M. Burmeister[3] 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Dept Psychiatry, Univ Michigan, Ann Arbor, MI; 3) Dept Human Genetics, Univ Michigan, Ann Arbor, MI.

The impact of novel genetic variants (e.g. rare alleles and/or deletions) on common, complex disesaes is largely unknown as these variants are often missed by genome-wide discovery efforts. To increase the rate at which novel variants are discovered, we exploit the fact that these variants tend to have large effects on marker-specific traits (e.g. genotype signal intensities) to confirm the existence of a novel SNP in a 20 Mb region of 8q24. This region was recently identified in a meta-analysis of 11 bipolar (BP) studies as a candidate region for BP disorder. In our data, which consist of 737 multiplex BP families genotyped at 1536 SNPs using Illumina Bead Array technology, we hypothesized the existence of a novel variant that negatively affects the genotyping assay at SNP rs2978607. We used the deletion detection program HEMIZYG to impute the genotypes at the novel SNP from the genotype signal intensities at the known SNP (rs2978607), which led to the successful identification of 100 true carriers of the novel allele (confirmation obtained via pyrosequencing). We find insufficient evidence to reject the null hypothesis of no association between the novel SNP and BP disorder; however, there is evidence to support the presence of a second novel variant, and this variant may increase risk for BP disorder ($p \sim 0.001$). We examined this possibility by selecting only those families that did not segregate for the apparent second novel variant. Consistent with a pattern of genetic heterogeneity, the maximum nonparametric LOD (NPL) score increased from 0.63 in the original 737 families to 1.17 in the selected set. By contrast, random subsets of the same size yield, on average, a decrease in the NPL score. Further, the proportion of segregating families (72.2 %) is close to an independent estimate of Ott's heterogeneity parameter (72.4 %). In summary, this work highlights the ability of HEMIZYG to detect novel, potential risk variants from genotype signal intensity data of related individuals.

Optimizing Measured Genotype Genome-wide Association Analysis for Quantitative Traits in Pedigrees. *J. R. O'Connell* Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD.

The measured genotype (MG) model is a flexible regression framework for quantitative trait SNP association analysis in pedigree data. The model treats SNP genotypes as fixed effects while controlling for residual familial correlation through a polygenic variance component. The standard genetic models are implemented by coding SNP genotypes as categorical covariates, with natural extensions to multilocus SNPs and haplotypes. Additional covariates such a age, sex, environmental factors, gene-by-gene and gene-environment interactions and population structure are easily incorporated.

The limiting computational step in maximizing the MG likelihood is inverting the variance-covariance matrix, which has order n^3, where n is the dimension of the pedigree kinship matrix. Thus, the computing time to analyze a single SNP quickly increases from seconds to minutes as n increase to from tens to hundreds to thousands, making genome-wide analysis at current SNP chip densities intractable for larger pedigrees. A standard solution is to break up the pedigree into smaller subpedigrees, thus partitioning the variance-covariance matrix into smaller matrices, but at the cost of increased Type I error due to ignored familial correlation.

We present a novel approach based on diagonalizing the variance-covariance matrix to reduce the complexity the likelihood calculation from n^3 to pn^2, where p is the number of covariates. Since the kinship matrix is independent of the SNP, the diagonalization is required only once for the entire genome-wide scan if genotype data is complete, providing significant computational gains. For example, we analyzed 350K SNPs genotyped in 860 Amish subjects within an 8100 pedigree in 70 minutes, compared to an estimated 583 days for SOLAR, a 12,000-fold speed up. To fill in missing genotypes, we have developed an algorithm optimized to compute the posterior probability distribution for untyped subjects.

Our methods have been implemented into user-friendly Open Source software.

Establishment of the pathogenic potential of nonsynonymous variants informs causal relationships in oligogenic disease. *N. Zaghloul[1], J. Gerdes[1], J. Binkley[3], Y. Bromberg[4], Y. Liu[1], L. Davey[1], C. Leitch[1], R. Karchin[2], R. Leibel[5], A. Sidow[3], N. Katsanis[1]* 1) Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Department of Biomedical Engineering, Johns Hopkins Univ., Baltimore, MD; 3) Departments of Genetics and Pathology, Stanford University Medical Center, Stanford, CA; 4) Columbia University Center for Computational Biology and Bioinformatics (C2B2), New York, NY; 5) Division of Molecular Genetics, Columbia University, New York, NY.

A major challenge in human and medical genetics is the assignment of pathogenicity to alleles, with potentially profound consequences on the interpretation of patient data and management of genetic disorders. This problem is particularly poignant in oligogenic and complex traits, where the phenotype is the result of the combined effect of numerous alleles across several genes. Bardet-Biedl Syndrome represents a useful oligogenic model, where mutations at a second locus have been found in as many as 30% of patients. Numerous mutations in 14 genes have been identified, including 97 missense variants, some of which do not segregate with the disorder in the traditional Mendelian sense. To determine the potential pathogenicity of each known variant and to understand how total mutational load in a functional system modulates penetrance and expressivity, we capitalized on our recent development of in vivo and in vitro assays of ciliary function to assess the functionality of mutant protein. Through an analysis of all missense variants, we show that both loss of function and dominant-negative mutations contribute to the disorder; and a subset of common alleles considered previously to represent benign polymorphisms are in fact detrimental to protein function; in several families, combinations of rare, strong alleles and common, milder alleles, interact to cause the phenotype. Our data represent the first comprehensive modeling of epistatic interactions in human genetic disease and are likely to inform human genetic disorders in which the genotype at a single locus is insufficient to explain phenotypic variability.

Genome-wide analysis of clinical phenotypes in multiple sclerosis (MS). *L. F. Barcellos, International Multiple Sclerosis Genetics Consortium* Div Epidemiology-SPH, Univ California, Berkeley, Berkeley, CA.

Multiple sclerosis (MS) is a chronic inflammatory disorder of the central nervous system (CNS) with a strong genetic component. Variation within the major histocompatibility complex (MHC) region genes on chromosome 6p21, specifically the *HLA-DRB1*15* haplotype, is the strongest genetic risk factor for MS, yet it is estimated to account for only a portion of disease risk. A role for genetic factors influencing clinical outcome in MS is also favorably supported by several lines of evidence. Identification of genetic variants that distinguish particular disease subgroups and/or predict a severe clinical outcome is critical to further our understanding of disease mechanisms and guide development of therapeutic approaches. The Affymetrix GeneChip Human Mapping 500K array was used to examine common genetic variation in 931 MS cases (and trio family members) fully characterized for several clinical phenotypes including age of disease onset, disease subtype, and disease severity. SNPs within two genes (*PHYHIPL* on 10q21 and *CADPS2* on 7q31) were strongly associated with primary progressive MS (PPMS) (OR=3.5, 95% CI: 2.1-5.9; $p=4.1 \times 10^{-7}$, and OR=2.7, 95% CI: 1.7-4.1; $p=4.1 \times 10^{-6}$, respectively). Disease severity was measured using the MS severity score or MSSS (Roxburgh et al. *Neurology* 64:1144-51, 2005) and MS cases were categorized into high (MSSS > 6.0) and low (MSSS < 6.0) groups for comparison. Results showed that SNPs within *RAB40C* and *PIGQ* on 16p13 significantly increased risk for severe disease (OR=1.7, 95% CI: 1.4-2.2; $p=2.1 \times 10^{-6}$) and SNPs within *SDCCAG10* on 5q12 were strong predictors of a more mild disease course (OR=0.6, 95% CI: 0.5- 0.8; $p=8.9 \times 10^{-6}$). Additional genetic variants were also observed to distinguish male and female MS case groups or predict age of symptom onset. The combined results from the very first comprehensive genome-wide association scan of MS clinical outcomes provides an important framework for mapping variants with strong prognostic implications.

PCM1 is recruited to the centrosome by the cooperative action of DISC1 and BBS4 and is mutated in schizophrenia. *N. Katsanis[1], A. Kamyia[2], P. L. Tan[1], K. Kubo[3], C. Engelhard[2], K. Ishizuka[2], A. Kubo[4,5], S. Tsukita[4,5], A. E. Pulver[2], K. Nakajima[3], N. G. Cascella[2], A. Sawa[2]* 1) Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Departments of Psychiatry and Behavioral Sciences, and Neuroscience, Johns Hopkins University, Baltimore, MD; 3) Department of Anatomy, Keio University School of Medicine, Tokyo, Japan; 4) Department of Cell Biology, School of Health Sciences Faculty of Medicine, Kyoto University; 5) Solution Oriented Research for Science and Technology, Japan Science Technology Corporation, Kyoto, Japan.

Recent genetic studies have suggested that centrosomal dysfunction underlies risk for various neuropsychiatric disorders, because variants in some genes that encode centrosomal proteins have been associated with schizophrenia (SZ) and bipolar disorder (BP). These genes include pericentriolar material 1 (PCM1) and Disrupted-In-Schizophrenia 1 (DISC1). We have reported previously that DISC1, a major susceptibility factor for SZ and BP, plays a crucial role at the centrosome, where it is required for neurite outgrowth and proper development of the cerebral cortex. Therefore, we hypothesized that PCM1, DISC1, and their interacting partners that include the BBS proteins may play a coordinate role in the centrosome and that such interactions might be relevant both to the etiopathology of SZ. Here, we provide biological and genetic evidence that PCM1-DISC1-BBS proteins function in a common centrosomal pathway, associating with SZ. We show that these proteins form a complex at the centrosome through discrete binding domains and that DISC1 and BBS4 act synergistically to recruit PCM1 to the centrosome. Disruption of any of these proteins leads to profound defects in neuronal migration during cortical development, a phenotype accentuated by the coordinate suppression of multiple complex subunits. Finally, we report a pedigree in which a nonsense mutation in PCM1 segregates with SZ spectrum psychosis, suggesting that haploinsufficiency at this locus likely contributes to the development of SZ and highlighting further the critical role of the centrosome in neurodevelopment.

Whole Genome Oligonucleotide Array Comparative Genomic Hybridization (oaCGH) for Clinical Diagnosis: The Line between Call In and Cut Off. *K. Lu[1], B. Xiang[1, 2], M. R. Rossi[1], B. Renu[1], P. Li[1]* 1) Department of Genetics, Yale School of Medicine, New Haven, CT; 2) Department of Human Genetics, University of Miami, Miller School of Medicine, Miami, FL.

Whole genome oaCGH has become the standard of care of most genetic clinics. However, due to the differences in the technical platforms and array designs, there is no consensus as to the analytical validity of these assays. We applied receiver operating characteristic (ROC) statistics to evaluate the sensitivity, specificity, and analytical resolution of oaCGH using Agilents 44K oligonucleotide array (CGH4410B). With specificity preset at 99% and a resolution based on average $\log_2$ ratio of 1, 2, 3, 5 and 7 contiguous probes, the oaCGH showed a sensitivity of 85%, 95%, 96.7%, 98% and 100% for deletion detection and 5%, 40%, 74%, 98% and 99% for duplication detection, respectively. These results indicated that the oaCGH can achieve 99% specificity and 99% sensitivity with an average resolution of 300-500 Kb (5-7 contiguous probes). Using a known deletion in a dilution series of 50%, 33% and 25% mosaicism, the oaCGH showed 85% sensitivity and 95% specificity in detecting 50% mosaicism; however, increased test-to-test variations and reduced sensitivity were noted as the mosaic percentage decreased. To further enhance the diagnostic accuracy, sex-matched alternate referred dye-swap (SMARDS) design was introduced. Each sample was labeled as test by Cy5 and as reference by Cy3 in alternate pairs, allowing for dye-swap analysis by joining the test and reference readouts. The SMARDS method has increased the average analytical resolution to 150-250 Kb (3 contiguous probes in a dye-swap pattern) and detected significantly ($p<0.001$) more copy number variants (CNVs) (CNVs/case: 1.4921.286, n=242) than the widely used method of single test labeling and pooled controls (0.4690.683, n=175). FISH analysis using targeted BAC clones was performed to confirm these genomic imbalances and to assess suspected mosaic patterns. These data suggest that the 44K oaCGH could make correct calls for genomic imbalances in a resolution of >150 Kb (3-7 contiguous probes) with 99% sensitivity and 99% specificity.

Variation near Complement Factor I is associated with risk of Advanced Age-Related Macular Degeneration. *J. A. Fagerness[1,2], J. B. Maller[1,2,4], B. M. Neale[1,2,3], R. C. Reynolds[5], M. J. Daly[1,2], J. M. Seddon[5]* 1) CHGR, Massachusetts General Hospital, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT; 3) SGDP Centre, Institute of Psychiatry, Kings College London; 4) Department of Statistics, University of Oxford, Oxford UK; 5) Ophthalmic Epidemiology and Genetics Service, New England Eye Center, Tufts-Medical Center.

Age-related macular degeneration (AMD) is the leading cause of irreversible blindness in older adults and has become a model for the genetics of complex disease. AMD has been shown to be associated with variants on chromosome 1 (CFH), chromosome 6 (CFB; C2), chromosome 10 (LOC387715/ARMS2), and chromosome 19 (C3) and has clearly identified the primary role of the complement pathway in disease pathogenesis. We tested 29 SNPs across a region spanning complement factor I (CFI) and phospholipase A(2) Group 12A (PLA2G12A) for association with AMD in 1228 cases of both neovascular (wet) and geographic atrophy (dry) advanced AMD and 825 age and sex matched controls. Conditioning on our most associated SNP, rs10033900 (p-value = 6.46×10^{-8} with an OR = 0.7056), we observed no further significant independent associations. We did, however, observe modest residual association at two neighboring, highly correlated SNPs. This result suggests that rs10033900 may not be the causal variant but may be highly correlated with said variant. Therefore, we applied multi-marker haplotype tests in an attempt to refine and isolate the association signal. We tested the two-marker haplotype of the two closest SNPs to rs10033900, both 5 (rs13117504) and 3 (rs11726949). The two-marker haplotype between rs13117504 and rs10033900 shows a somewhat stronger association to AMD than either SNP alone with a p-value = 1.18×10^{-8}. All exons were sequenced across the block of linkage disequilibrium (LD) where the associated SNPs were found. This block of LD contained all four exons of PLA2G12A and the last two exons of CFI, but none of the variation discovered could explain the observed association.

Assessing Response of Hunter Syndrome to Idursulfase (Elaprase) Enzyme Replacement Therapy. *B. Najafian, A. Van Heest, C. Whitley* University of Minnesota, Minneapolis, MN.

We examined the outcome of the severe form of Hunter syndrome after treatment with idursulfatase (Elaprase) enzyme replacement therapy (ERT). Proband C presented in October, 2005 with a murmur and was referred to a geneticist. High urine glycosaminoglycan (GAG) was found. When several lysosomal enzymes were reported normal, it was concluded that C did not have a mucopolysaccharidosis condition. The diagnosis was made in May, 2006 at 5 years of age when the father reviewed the medical record, and challenged the specialists conclusions. With additional testing, C was found to have deficient iduronate-2-sulfatase (IDS) activity. This motivated the parents to relocate for ongoing care. Upon presentation to our clinic, C was having episodic chest pain thought by his parents to be life-threatening heart disease. Gastro-esophageal reflux was found, and responded dramatically to medical management. Molecular analysis identified the 1449delA mutation of the IDS gene associated with severe neuropathologic Hunter syndrome. Brother Ms diagnosis was made in May, 2006. After starting on idursulfase ERT urine GAG levels declined, neuropsychometric scores remained unchanged, but orthopedic problems have progressed. Carpal tunnel syndrome and finger contractures have motivated surgical procedures. Both have hearing loss, hand and finger contractures, and umbilical hernia. The excellent learning progress of these children led the parents to ask two important questions: (1) Does reduction of urine GAG reflect a systemic halt, or reversal of pathology? (2) With a systemic response, what is the long-term neurologic prognosis for these children with severe mutations associated with mental retardation? Close monitoring is being done to answer these questions: Tenosynovial and liver biopsies were performed before idursulfase therapy was started. Electron microscopy showed lysosomal inclusions in fibroblasts of tenosynovium, but not in the liver. Quantitation of these inclusions using unbiased stereology will be used to assess possible reversal of pathology in the follow-up biopsies.

RPGRIP1L interacts biochemically with a diverse ciliary protein complex and contributes causal and modifying alleles across all ciliopathies. *E. E. Davis[1], H. Khanna[2], A. Estrada[2], Z. M. Zamalloa[2], I. Lopez[3], A. I. den Hollander[4], M. N. Zonneveld[4], L. M. Davey[1], M. I. Othman[2], N. Waseem[5], C. Maubaret[5], I. MacDonald[6], D. M. Muzny[7], T. Attie-Bitach[8], C. A. Johnson[9], R. K. Koenekoop[3], F. Hildebrandt[10], R. A. Gibbs[7], A. Swaroop[2,10,11], N. Katsanis[1]* 1) Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Department of Ophthalmology and Visual Sciences, University of Michigan, Ann Arbor, Michigan; 3) McGill Ocular Genetics Laboratory, McGill University, Canada; 4) Department of Human Genetics, Nijmegen Centre for Molecular Life Sciences, The Netherlands; 5) Institute of Ophthalmology, UCL, London, UK; 6) Ophthalmic Genetics and Visual Function Branch, National Eye Institute, USA; 7) Human Genome Sequencing Center, Baylor College of Medicine, USA; 8) Département de Génétique, Paris Cedex 15, France; 9) Section of Ophthalmology and Neurosciences, Leeds Institute of Molecular Medicine, United Kingdom; 10) Department of Human Genetics, University of Michigan, USA; 11) National Eye Institute, Bethesda, Maryland, USA.

Loss of function mutations in RPGRIP1L, a ciliary protein, cause Meckel-Gruber (MKS) and Joubert (JBTS) Syndromes, two traits at the extreme severity of the ciliopathy spectrum. Here we demonstrate that RPGRIP1L interacts directly with RPGR, encoded by the locus mutated most frequently in RP, as well as with a multitude of BBS and NPHP proteins. Prompted by these data, we interrogated the potential mutational load of RPGRIP1L in a ciliopathy cohort comprised of >500 patients spanning the phenotypic spectrum of severity, including LCA, Senior-Loken Syndrome (SLS), NPHP, BBS, JBTS, and MKS. We identified a large allelic series of missense variants, which occur in concert with null genetic lesions at other ciliary protein encoding loci. We also demonstrate that these variants either attenuate or completely abrogate the biochemical interaction between RPGRIP1L and RPGR, data substantiated further by in vivo testing of each allele in a zebrafish ciliopathy model. Taken together, our data suggest that RPGRIP1L is a pan-ciliopathy gene and highlight the emerging utility for medical resequencing in dissecting total mutational load.

Van Allen-Myhre Syndrome and Goltz Syndrome are allelic. Report of two cases with PORCN gene mutations.

S. Parkash[1,2], S. Keating[3], I. Van den Veyver[4], K. Siriwardena[5], E. Kolomietz[2], A. Toi[6], C. Zaitsoff[7], D. Purvis[8], A. Patel[4], X. Wang[4], D. Chitayat[1, 2] 1) Dept Clinical/Metabolic Gen, Hosp Sick Children, Toronto, ON, Canada; 2) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Canada; 3) Department of Laboratory Medicine and Pathobiology, Mount Sinai Hospital, Toronto, Canada; 4) Department of Obstetrics and Gynecology and Molecular and Human Genetics, Baylor College of Medicine, Houston, USA; 5) Clinical Genetics NZ, Auckland, New Zealand; 6) Department of Diagnostic Imaging, Mount Sinai Hospital, Toronto, Canada; 7) Northern Regional Genetic Service, Auckland Hospital, New Zealand; 8) Department of Dermatology, Auckland City Hospital, New Zealand.

Van Allen-Myhre Syndrome (VAMS) is a rare condition consisting of ectopia cordis, omphalocele, ectrodactyly, absent sacrum, radial hypoplasia, microphthalmia, hemifacial microsomia and cutis aplasia, among other findings (Van Allen and Myhre, 1991). Some of these features overlap with findings in Goltz syndrome (GS), which suggest that they are allelic. The finding that GS is caused by mutations in the PORCN gene enabled us to test this possibility. We report two cases with VAMS, one of which supports the assumption that VAM and GS are allelic. Case 1 - A fetus with absent and possibly bifid sternum, omphalocele, hyperlordosis, scoliosis, and bilateral ectrodactyly consistent with VAMS. Karyotype and microarray analysis were normal, with no deletion in the Xp22 region. A deletion in the PORCN gene was detected by qPCR. Case 2 - A male with an antenatal diagnosis of Klinefelter syndrome, bladder extrophy, ectrodactyly, symmetrical IUGR, hypoplastic nails, linear skin lesions, right hemifacial microsomia, and bilateral microphthalmia consistent with VAMS. No mutation in the PORCN gene was found. The finding of mutations in the PORCN gene in our patients supports the assumption that VAMS is the same condition as GS.

The power of the allele-based N-Test in linkage analysis. *S. Khan[1, 3], S. Shah[3], D. E. Weeks[1,2]* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA 15261, USA; 2) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA 15261, USA; 3) Department of Statistics, University of Peshawar, Peshawar, NWFP, Pakistan.

There are many tests of inheritance based upon sibling information for diseases that have late onset. The N-test (Green et al. 1983) is one of these tests, which utilizes information from affected siblings. The N-test is the count in affected siblings of the most frequently occurring haplotype from the father plus the analogous count from the mother. When applied to haplotypes, the N-test excludes recombinant families from the analysis. In this study we modified the N-test to be based on alleles instead of haplotypes. This modified allele-based N-test can include all families (recombinant as well as non-recombinant). We carried out a simulation study to compare the power of the allele-based N-test with the powers of the Sall and Spairs non-parametric statistics as computed by Merlin. The powers of the allele-based N-test, Sall and Spairs statistics are identical to each other for affected sibships of size 2 and 3. For affected sibships of larger sizes, the powers of the Sall and Spairs statistics are larger than the power of allele-based N-test. These simulation-based results are consistent with earlier results based on analytical computations.

GRM7 variants confer susceptibility to age-related hearing impairment. *J. Ohmen[1], R. Friedman[1], L. Van Laer[2], M. Huentelman[3], E. Van Eyken[2], J. Corneveaux[3], W. Tembe[3], S. Thys[2], E. Fransen[2], J. Huyghe[2], J. Pearson[3], D. Craig[3], D. Stephan[3], G. Van Camp[2], additional member of the European Presbycusis Genetic Study* 1) House Ear Institute, Gonda Research Center for Cell and Molecular Biology, Los Angeles, California, USA, 90057; 2) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium, B-2610; 3) The Translational Genomics Research Institute, Phoenix, Arizona, USA, 80054.

Age-Related Hearing Impairment (ARHI) is a complex disease resulting from the interaction between environmental and genetic factors and is the most prevalent sensory impairment in the elderly. While the environmental factors conferring altered risk for ARHI have been extensively studied, the genetic risk factors are unknown. Here we describe the results of a whole genome association study with 1,692 ARHI samples. Using an age- and sex-independent measure of hearing loss, the samples from individual centers were combined into good and bad hearing pools and assayed in triplicate on the Affymetrix 500K GeneChip. The highest ranked SNPs identified in the initial pooling experiment were confirmed by genotyping individual samples in the primary cohort. Subsequently, the 23 most interesting SNPs were individually genotyped in a second cohort with the same phenotypic criteria. This resulted in the identification of a highly significant replicated SNP located in GRM7, the gene encoding the type 7 metabotropic glutamate receptor (mGluR7). We performed functional studies and show that mGluR7 is expressed in the inner ear hair cells and in the spiral ganglion nerve cell bodies of the inner ear. Together these data indicate that common alleles of GRM7 contribute to an individuals risk of developing ARHI and suggest a possible functional role for mGluR7 in hair and spiral ganglion cells of the ear. Our central hypothesis is that common variation within GRM7 gene may lead to altered levels of GRM7 protein in the afferent auditory synapse, resulting in perturbations of glutamate metabolism.

Building, mining, and managing array CGH databases define a new paradigm for the identification of clinically significant cytogenetic aberrations. *B. C. Ballif, J. Coppinger, B. A. Torchia, B. A. Bejjani, L. G. Shaffer* Signature Genomic Laboratories LLC, Spokane, WA.

The use of microarray-based copy-number screening methods such as array CGH have revolutionized cytogenetic diagnostics by facilitating the identification of previously unrecognized chromosomal syndromes, refining critical regions for established genetic disorders, and broadening our view of the normal diploid genome. However, these high-resolution whole genome screens generate a wealth of genomic information which can be difficult to interpret in a clinical cytogenetics setting. Indeed, the prevalence of copy-number variants of unclear clinical significance underscores the need for the development of readily accessible diagnostic tools and databases of documented chromosome abnormalities to distinguish between benign copy-number variants and those of clear clinical significance. The utility of building, mining and managing an array CGH database is illustrated through the identification of three rare chromosome abnormalities that may not have been recognized otherwise. First, we have refined the microcephaly locus on 1q44 by characterizing the deletion sizes of three patients with interstitial deletions surrounding the *AKT3* gene. Second, we report the identification of three additional cases of microdeletions encompassing *TCF4* on 18q21.2 recently reported to result in Pitt-Hopkins syndrome. The identification of these patients will aid in the further delineation of the phenotype associated with this deletion. Third, we have identified a previously unrecognized putative microdeletion syndrome on 17q23.2. This region is flanked by low-copy repeats and may be a recurrent novel microdeletion syndrome. We anticipate that array CGH databases will have a profound impact on our ability to understand the clinical significance of chromosome abnormalities identified by high-resolution copy-number analysis.

Do Biobank Regulations Parallel Recommendations and Guidelines Presented in the Literature? *I. T. Gordon, T. Caulfield* Health Law Institute, University of Alberta, Edmonton, Alberta, Canada.

Large genetic repositories, often referred to as biobanks, present an important platform for genetic research. Many scientists believe the genetic study of large population cohorts is the next logical step towards understanding and treating a variety of diseases. It is therefore unsurprising that large, often national, biobanking projects are already underway in countries such as the United Kingdom, Canada, Latvia, Estonia, Iceland and are being considered by others. While these biobanks may be a welcome aide to researchers, they are not without their difficulties. Indeed, a number of important issues must be dealt with by the governance structures seeking to establish these databases. This study investigates how recent major policy documents address five of the major governance issues facing biobanks. These issues include the informed consent of participants, the right of participants to withdraw from the study, how the database will protect the privacy of participants including who will be allowed access to the database, the ownership of samples and study results as well as the need for an independent ethics review board in governing the biobank. This comparative analysis looks for consensus and divergence of views within major policy documents and compares them to themes in the recent, relevant, academic literature. The study found a variety of common themes, particularly around the need for governance, consent and the right to withdraw. However, a comparison with the academic literature reveals that broad, principled based, consensus has yet to be achieved.

The spectrum of BCSIL related conditions. *N. Longo[1], M.-A. Abbott[4], A. Yatsenko[2], D. Dimmock[3], L.-J. C. Wong[2]* 1) Dept Peds, Div Med Genetics, Univ Utah, Salt Lake City, UT; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston Texas; 3) Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 4) Pediatric Genetics, Baystate Medical Center, Springfield,MA.

Background Specific autosomal recessive mutations in *BCS1L* have recently been described to cause GRACILE syndrome. This is a disorder of people of Finnish heritage associated with a prenatal onset disease of Growth Retardation, Aminoaciduria, hepatic Cholestasis, Iron overload and Lactic acidosis and Early death. It is not associated with classical hair changes. Similar presentations have been described in 3 British kindreds with the addition of mitochondrial complex 3 deficiency. Turkish patients with mutations in *BCS1L* have a slightly different phenotype of tubulopathy, encephalopathy, and liver failure due to complex III deficiency. Bjornstad syndrome is a clinically distinct disorder of Pili torti, and deafness, it is caused by milder mutations in *BCS1L* and is not associated with complex 3 deficiency **Cases** The 1st patient failed her newborn hearing screen but otherwise had a normal early infancy. At 3m of age she started to failure to thrive with poor feeding, by 6m of age she had significant developmental delay. At this point she had a normal brain MRI but significant lactic acidosis. At 7m of age, when referred to genetics, she had sparse abnormal scalp hair, mild liver dysfunction and renal Fanconi syndrome. Subsequently her MRI developed changes suggestive of Leigh syndrome. ETC showed profound deficiency of complex III, sequencing revealed 2 mutations in *BCS1L*. The 2nd case presented with Infantile spasms at 6m of age. She was noted at this point to have significant failure to thrive, renal Fanconi syndrome, Cholestatic jaundice and lactic acidosis. She died at 7 months of age. Postmortem ETC studies revealed profound complex III deficiency and sequencing revealed mutations in *BCS1L*. **Conclusions** These reports suggest that Bjornstad syndrome and GRACILE are ends of a phenotypic spectrum and not discrete disorders. The also suggest that mutations in *BCS1L* should be considered in children with renal Fanconi syndrome especially when associated with hearing loss or hepatic disease.

MicroRNA-Mediated Cardiac Dysfunction and Myosin Regulation. *J. T. C. Shieh[1], D. Srivastava[2]* 1) University of California San Francisco; 2) Gladstone Institute for Cardiovascular Disease, San Francisco, CA.

Background: Heart failure is common in patients with congenital heart disease and with cardiomyopathies, yet our understanding of the basis of disease is limited to a few genes. Since gene dysregulation can lead to cardiac failure, we hypothesized that microRNAs, small non-coding RNAs that regulate other genes, could be important in disease. **Purpose:** We sought to identify novel, tissue specific microRNAs from the human heart and determine their role in cardiac function using model organisms. **Methods:** We performed a screen of over 295 microRNAs to detect those expressed preferentially in the human heart using microRNA microarrays. Cardiac-specific microRNA expression was confirmed using qPCR and Northern blotting on human and mouse tissues. To mimic states where microRNAs are elevated, we generated cardiac-specific transgenic mice to overexpress the microRNA. We assessed cardiac function in transgenic mice using echocardiogram and performed histology. In vitro microRNA-mRNA experiments were used to establish potential gene expression pathways regulated by the microRNA. **Results:** We found a previously uncharacterized microRNA that demonstrates strong expression in human heart. This non-coding RNA is sufficient to cause cardiomyopathy in mice, and the conservation in the microRNA sequence from fish to humans supports a key gene regulatory role. Interestingly, myogenesis is accompanied by increased levels of the microRNA while inhibition of the microRNA in vitro reduces myosin expression, suggesting a direct role in regulating muscle. When we overexpressed the microRNA in mouse hearts, we found myosin upregulation in transgenic lines. Interestingly, microRNA-overexpressing mice developed cardiomyopathy. We have identified a potential mechanism of disease since the microRNA appears to affect target mRNAs important in myosin regulation. **Conclusions:** These studies demonstrate that expression of a single microRNA is sufficient to cause cardiomyopathy and suggest the importance of microRNA gene regulation during cardiac disease. These data suggest the need for more widespread analysis of non-coding transcripts in unexplained cardiac disorders.

Germline missense mutations in a DNA glycosylase gene, NEIL2 is associated with lung cancer. *A. Maiti[1], M. Hegde[1], G. Wang[3], N. He[1], D. Bannerjee[1], X. Xie[1], Y. Lee[3], B. Shen[2], S. Mitra[1], T. Hazra[1]* 1) Dept Biochem & Molecular Biol, Univ Texas Medical Branch, Galveston, TX.USA; 2) City of Hope Medical Center, California, USA; 3) Chinese Academy of Sciences, Beijing, China.

Genetic predispositions along with environmental factors including genotoxic agents have critical etiologic roles in developing lung cancers and a handful of genes are identified for lung cancer. We identified several missense mutations in the coding regions of a DNA glycosylase gene, NEIL2 and studied their association with lung cell carcinoma. Analyzing 170 lung cancer patients with equal number of healthy control, we identified 4 misense mutations. Among them two are rare polymorphism and in an extended study with large population size, other two shows ethnic specific associations. Two SNPs are associated in caucasian lung cancer patients (rs8191664 p=0.028, OR=3.42, 95% CI 1.12-10.2, n=case:control-112:188) and (rs8191613, p=0.008, OR=5.76, 95%CI 1.15-21.4, n=case:control=112:188). In chinese population, rs8191664 (OR= 1.31, 95%CI 1.03,1.66 p=0.002, n=case : control=670:666) is moderately associated. It appears that risk factor for lung cancer of rs8191664 is much more higher in caucasian population than chinese population. A large number of caucasian patient analysis is in progress. However, purified mutant proteins for these SNPs have lower glycosylase activities, lower overall repair activities in compare to wild type NEIL2 protein in vitro. These mutant proteins also show less interaction with DNA polymerase and ligase3, prerequisites for DNA repair activity in vivo. These results suggest that these SNPs may impair DNA repair activity in vivo and contribute to the development of lung cell carcinoma.

High Reslolution microarray analysis of CpG island methylation. *D. Roberts[1], A. Wong[1], R. Straussman[2], B. Curry[1], Z. Yakhini[1], I. Steinfield[2], A. Ashutosh[1], R. Saxena[1], H. Cedar[2], D. Roberts[1]* 1) Dept Research & Development, Agilent Technologies, Santa Clara, CA; 2) Dept. of Cellular Biochemistry and Human Genetics, Hebrew University, Jerusalem, Israel.

CpG islands are stretches of high GC content DNA containing multiple CpG dinucleotides. When CpG dinucleotides within these islands are methylated, especially in promoter regions, expression of the corresponding downstream genes is most often repressed. Aberrant CpG island methylation is implicated in genetic diseases and especially cancer. We have developed a microarray based solution for determination of methylated and unmethylated CpG islands in the human genome. This microarray contains ~200,000 oligo probes tiling the 21 megabases of ~25,000 unique CpG islands, with an average spacing between probes of ~95 base pairs. Methylated DNA is immunoprecipitated (mDIP), fluorescently labeled, and competitively hybridized to the array against differentially labeled pre-immunopreciptiated DNA. We have developed a methylation calling algorithm to accurately determine methylated and unmethylated regions. We describe the application of this method and algorithm in a normal adult liver DNA model system. We demonstrate the ability of the assay to discriminate between regions confirmed to be methylated or unmethylated by bisulfite sequencing. We then apply the whole-genome assay to colon and colon carcinoma tissue DNA. We describe differential methylation between normal and cancer tissues.

Array CGH detects tetrasomy 12p in blood from Pallister-Killian syndrome cases without invasive skin biopsy. *J. A. Rosenfeld, B. A. Torchia, B. C. Ballif, L. G. Shaffer* Signature Genomic Laboratories, Spokane, WA.

Pallister-Killian syndrome (PKS) is a genetic disorder characterized by mental retardation, seizures, streaks of hypo- or hyperpigmentation and dysmorphic features. PKS is associated with tissue-limited mosaic tetrasomy 12p, usually caused by an isochromosome 12p. The mosaicism is usually detected in cultured skin fibroblasts or amniotic cells and rarely in PHA stimulated lymphocytes, which suggests stimulation of T-lymphocytes may distort the percentage of abnormal cells. We recently reported the identification by microarray-based comparative genomic hybridization (aCGH) of a previously unsuspected case of tetrasomy 12p caused by an isochromosome 12p. Here we report six additional individuals with tetrasomy 12p characterized by our laboratory. All six individuals were referred for mental retardation/developmental delay and/or dysmorphic features. In each case, aCGH using genomic DNA extracted from whole peripheral blood detected copy-number gain for all clones for the short arm of chromosome 12. In all but one case, FISH on metaphases from cultured lymphocytes did not detect the copy-number gain; in the remaining case, metaphase FISH on cultured lymphocytes showed an isochromosome in 10% of cells. However, interphase FISH using probes to 12p on peripheral blood smears showed additional signals in 28-50% of cells. Microarray and FISH analysis on cultured skin biopsies from two individuals confirmed the presence of an isochromosome 12p. Our results demonstrate aCGH using genomic DNA from whole peripheral blood can detect chromosome abnormalities that are not present in stimulated blood cultures and would otherwise require invasive skin biopsies for identification.

Metabolic syndrome gene network and its association with factors of metabolic syndrome. *A. T. Kraja[1], Y. M. Park[2], I. B. Borecki[1], H. K. Tiwari[3], J. S. Pankow[4], S. C. Hunt[5], U. Broeckel[6], D. K. Arnett[7], D. C. Rao[2], M. A. Province[1]* 1) Div. Statist. Genomics, Washington U., MO; 2) Div. of Biostat. Washington U., MO; 3) Dep. of Biostat. U. of Alabama at Birmingham; 4) Dep. of Epi, U. of Minnesota; 5) Cardiovasc. Gen. U of Utah; 6) Hum. Mol. Gen. Ct., Med. Coll. of Wisconsin; 7) Dep. of Epi, U. of Alabama at Birmingham.

We performed an extended review of the curated literature to identify genes that influence metabolic syndrome (MetS). From 1,188 unique genes that contributed to 1 or more MetS domains, 123 genes were identified as candidate contributors to MetS because each was connected to 3 or more domains. The domains selected were obesity, dyslipidemia, glucose intolerance, insulin resistance, and high blood pressure. As a result of these gene findings, a gene network of 123 genes was built where 60 genes connect to 3 domains, 39 others to 4 domains, and 24 to 5 domains. Of these candidate genes, 40 were also classified as candidate contributors to inflammation. We tested association of SNPs across these candidate genes with each of the 4 MetS-factor-domain scores. This examination was based on factor analysis on 11 MetS risk factors using 1,470 white subjects of the Hypertension Genetic Epidemiology Network Study. From the list of 123 genes, 63 of them had at least one SNP associated significantly with the MetS factor scores. The most SNPs associated with one or more MetS-factor-domains belonged to genes ABCA1 (14 SNPs), ALMS1 (14), CYP19A1 (9), FTO (24), LIPC (21), and SELE (9 SNPs). We are currently carrying out replication of the significant associations in the Family Heart Study involving ~1,000 subjects with measurements at two time points. The MetS gene network helped to indentify hypothesis-driven focused associations to better understand the MetS genetic mechanisms. Such an approach has the advantage of protection from multiple testing problems.

Single Nucleotide Polymorphisms of *TNF, TNFR1* and *TNFR2* genes in Mexican lepromatous leprosy patients.

M. Montoya-Buelna[1], M. Fafutis-Morris[2], JF. Muñoz-Valle[3], LE. Figuera-Villanueva[1] 1) CIBO, Instituto Mexicano del Seguro Social, Guadalajara, Jalisco, México; 2) Centro de Investigación en Inmunología y Dermatología. Guadalajara, Jalisco, México; 3) Instituto de Investigación en Reumatología y del Sistema Músculo Esquelético. Guadalajara, Jalisco, México.

Leprosy is a chronic infectious disease caused by *Mycobacterium leprae*, where tumor necrosis factor-alpha (TNF-) activates several effector mechanisms against this infection binding to its receptors (TNFR1 and TNFR2). The TNF- promoter polymorphism at position -308 (named TNF2) has been extensively associated with a variety of autoimmune and infectious diseases, such as leprosy. In addition, polymorphic variants in both TNFR genes are associated with several disorders, although in leprosy patients have not been yet explored. OBJECTIVES: To analyze the association between SNPs at positions -308 in TNF, -383 TNFR1 and +196 TNFR2 in Mexican leprosy patients. DESIGN AND METHODS: Genomic DNA was extracted from peripheral blood cells from 42 lepromatous leprosy (LL) and 5 tuberculoid leprosy (TT) patients. As a control group, 42 healthy subjects (HS) were included. TNF-, TNFR1 and TNFR2 gene polymorphisms were analyzed by PCR and restriction fragment length polymorphism (PCR-RFLP). RESULTS: TNFR2 196 R/M polymorphism was statistically different ($p<0.05$) in the genotypes frequencies between LL and TT patients which lead to increase the susceptibility to develop TT leprosy. TNFR2 196R allele, TNF -308 G/A and -383 TNFR1A/C polymorphisms were not statistically different when compared to LL, TT and HS groups. CONCLUSIONS: Our study suggests that TNFR2 196 R/M genotype is associated with the susceptibility to develop TT leprosy. Polymorphisms in TNF promoter region and TNFR1 receptor genes are not associated with any pole in Mexican leprosy patients. Further studies are needed to elucidate the role of other polymorphisms that increase susceptibility to develop some leprosy pole.

Bayesian inference of fine-scale recombination rates and hotspots using population genomic data. *Y. Wang, B. Rannala* Genome Center and Department of Evolution and Ecology, University of California Davis.

Inferring how recombination rates vary and how recombination hotspots are distributed across genomes is a fundamental problem in population genetics. As more large-scale human genomic data become available, a picture of how recombination rates vary on a genome-wide scale can be inferred using statistical models. Recently, several statistical methods for estimating fine-scale recombination rates using population samples have been developed. However, currently available methods that can be applied to large-scale data are limited to approximated-likelihoods. We developed a full-likelihood Markov Chain Monte Carlo (MCMC) method for estimating recombination rate under a Bayesian framework. In our method, genealogies underlying a sampling of chromosomes are effectively modeled by using marginal individual SNP genealogies related through an ancestral recombination graph. Based on the observed patterns of recombination rates and hotspots obtained from sperm-typing studies, we designed a new model for the distribution of background recombination rates and hotspots. A geometric Brownian motion model is used to account for the random changes in background recombination rates. A Markov process was used to model the distribution of the intervals between hotspots and the duration of hotspots. A reversible jump MCMC scheme is used to estimate the posterior distributions of parameters of interest. The posterior probability that a chromosomal interval contains a hotspot is inferred and plotted along a chromosome. Simulation studies show that the method performs well, and if the hotspot signal from a locus is strongly supported by the data, it is highly likely that the locus is on a hotspot. The method was applied to two human population genetic variation data sets that have been studied previously by sperm-typing. Our results are consistent with estimated hotspot locations from sperm crossover analysis. We also applied our method to a population genetic data set of SNPs spanning chromosome 19 that were sampled from three populations. The biological properties of chromosomal regions with a high probability of containing hotspots were investigated.

Prevalence of Consanguinity in Yazd Province of Iran and It's Role in RPL. *S. Seyedhassani[1,2], A. Aflatoonian[1], N. Tabibnejad[1], G. Modabber[2], R. Mirfakhrai[2], S. Kalantar[1], M. Houshmand[2]* 1) Medical Genetics Dept, Res/Clinical Ctr Infertility, Yazd, Iran; 2) National Institute of Genetic Engineering and Biotechnology, Tehran, Iran.

Introduction: A consanguineous relationship is one between blood relatives who have at least one common ancestor no more remote than a great-great grandparent. While relatively rare in western populations, consanguinity is common in many populations of the world. pregnancy loss is the most common complication of pregnancy. About 1% to 2% of couples experience three or more consecutive spontaneous pregnancy loss, suggesting some underlying operative mechanisms. Many studies have shown that among the offspring of consanguineous marriages there is an increased incidence of both congenital malformations and other conditions which will present in fetal life and later. Material and methods: We studied 5200 married defined couples in 260 randomized clusters that were divided in ten different rural and urban areas. These couples were interviewed based on using a structured questionnaire to ascertain the prevalence of consanguinity and related epidemiological findings. On the other hand, we assess the consanguinity in 261 couples were involved with repeated pregnancy loss. Results: There were consanguineous marriages in 2153 cases (41.1%)(CI 95% from 41.2% to 42.7%) in different degrees including degree 2 (0.04%), degree 3(27.3%), degree 4 (7.4%), degree 5(6.7%). Thus, 58.9% of population had nonfamilial or more remote than five degree marriages. There were 261 cases of RPL that were encountered and referred to our center. In these couples 142 had consanguineous marriage (54.4%) in degree2 (2.3%), degree3 (37.5%), degree4 (7.7%), degree5 (6.9%). Conclusion: In Iran, there was an incidence of high consanguineous marriage near to neighboring countries such as Pakistan, Kuwait and Saudi Arabia. Consanguinity was related to in expression of RPL (p 0.00 and Odds Ratio= 1.69, 1.31< OR< 2.18). These findings can implicate the probability of bilateral recessive genetic effects leading to repeated abortion in encountered couples and thus, avoidance of familial marriage is suggested .

Epigenetic mechanisms and autoimmunity: a pilot study testing DNA methylation profiles in multiple sclerosis cases and controls. *F. B. S. Briggs[1], S. Clark[1], J. Oksenberg[2], C. Schaefer[3], L. F. Barcellos[1,3]* 1) Univ of California, Berkeley, CA; 2) Univ of California, San Francisco, CA; 3) Div of Research, Kaiser Permanente, CA.

Multiple sclerosis (MS), a chronic inflammatory autoimmune disease (AD) of the central nervous system, is characterized by incomplete concordance in monozygotic twins, female preponderance, the presence of other co-morbid autoimmune conditions, and variable patterns of symptoms and disease progression. A large number of MS studies have consistently shown strong associations with *HLA-DRB1*15*; however, the identification of additional disease loci is critical to fully understand pathogenesis. Previous studies support a role for aberrant DNA methylation (heritable and stable methylation of DNA CpG loci that alters gene expression) in autoimmunity. To identify novel epigenetic loci in MS, we conducted a pilot study testing the DNA methylation patterns of 807 candidate genes (1,505 CpG loci) in 109 Caucasian female MS cases and 61 female controls. Two-sided t-tests were used to compare methylation profiles at each locus in a two-stage approach which allowed for replication of promising results, (Stage I: MS=47, controls=36; Stage II: MS=62, controls=25). We identified a CpG locus within *TJP2* as being significantly unmethylated in MS cases (p1=0.03; p2=0.007) when compared to controls. When analyses were restricted to primary progressive MS (PPMS) cases only (PPMS=24; controls=25), the *TJP2* locus remained the most significant result (p=0.001). We also compared cases with particular co-morbid AD conditions known to cluster with MS (Hashimotos thyroiditis, inflammatory bowel disease and psoriasis; Stage I: MS/AD=22, controls=36; Stage II: MS/AD=29, controls=25). A total of 16 genes emerged as differentially methylated in cases when compared to controls ($p1<0.05$; $p2<0.05$). The two most promising candidates were *HLA-DOA*, which participates in the presentation of peptides bound to MHC class II molecules, and *CDK6*, which is involved in CD8 memory T cell division. Several potential epigenetic candidates that may contribute to MS etiology were identified. Further research in this important area is needed.

Genome-Tissue Expression Analysis (GTEx), Digital Transcript Expression (DTE) and Genomic Congruence Analysis of the Cerebellar Cortex in Schizophrenia: A Model for Analysis of Complex Traits with Massively Parallel mRNA Sequencing. *S. Kingsmore[1], J. Mudge[1], N. Miller[1], G. May[1], J. Huntley[1], A. Farmer[1], R. Langley[1], J. van Velkingburgh[1], D. Gessler[1], G. Schroth[2], I. Khrebtukova[2], S. Luo[2], L. Zhang[2], M. Garcia[3], R. Harlan[3], S. Khalsa[3], R. Wolfinger[4], S. Martin[4], R. Roberts[5], N. Perrone-Bizzozero[6]* 1) Natl Ctr Genome Resources, Santa Fe, NM; 2) Illumina Inc., Hayward, CA; 3) Northern New Mexico College, Española, NM; 4) SAS Institute, Cary, NC; 5) Department of Psychiatry, University of Alabama at Birmingham, AL; 6) Department of Neurosciences, University of New Mexico, Albuquerque, NM.

Purpose: Massively parallel mRNA sequencing was performed to assist in characterization of a prototypic complex trait, schizophrenia (SCZD). Methods: 16.7 GB of mRNA sequence was generated from 20 cerebellar cortices (14 with SCZD and 6 controls) using Illumina sequencing-by-synthesis. Sequences were aligned to reference databases, gene abundances were determined by aligned read frequency and nucleotide variants identified using trained bioinformatic filters. Gene expression differences were identified by analysis of variance; cis-acting eSNPs were identified by Infinium genotyping of samples and assessment of significant deviations in read-count-based allele frequency at heterozygote loci; Variant associations with SCZD were identified. Results: Of 33,200±1,000 expressed transcripts, 204 differed significantly between SCZD and controls. GO annotation showed significant SCZD associations with Golgi apparatus and vesicle-mediated transport. DTE was more sensitive and accurate than array hybridization. 10,022 genes contained novel splice isoforms. Of 453,555 single nucleotide variants identified, 56 were eSNPs and 113 showed significant associations with SCZD, including rs4894 in ATF4, a DISC1-interactant that maps within an SCZD QTL. Conclusion: Massively parallel mRNA sequencing appears to have utility for Genome-Tissue Expression Analysis, Digital Transcript Expression and Genomic Congruence Analysis of complex traits, and appears to be effective for integration of genetic and genomic information.

Catechol-O-Methyltransferase (COMT) Polymorphism and response to Cognitive Remediation in Schizophrenia.

S. Kaushik[2], H. Lachman[4], J. P. Lindenmayer[1,2,3], S. Kaushik[1], A. Khan[1,5] 1) Psychopharmacology Research Un, Nathan Kline Institue, New York, NY; 2) Department of Psychiatry, Manhattan Psychiatric Center, New York, NY; 3) Department of Psychiatry, NYU School of Medince, New York, NY; 4) Department of Neuroscience, Albert Einstine College of Medicine, Bronx, NY; 5) Fordham University, Fordham, NY.

Background: Studies have indicated COMT val108/158met polymorphism associations with impairments in specific cognitive functions, in particular dorsolateral PFC dependent working memory and attention. Methods: 38 patients with schizophrenia were enrolled in a 12 week computerized neurocognitive rehabilitation treatment (CRT) program to evaluate the association of COMT genotype with the response to CRT. PANSS and Neurocognitive assessment using MATRICS Consensus Cognitive Battery were done at baseline and at end point. Analysis: 19 patients(3 males, 16 females) had Val/Val and 19 (1 male, 18 females) had Val/Met or Met/Met (Val+Met) genotype. Mean age for the whole cohort was 43.49 (SD=9.55) and mean length of illness was 18.38 months (SD=11.79). 58% were african americans, 24% caucasians, 35% hispanic and 2% asian. No significant differences were observed in demographic characteristics between Val/Val and Val+Met groups. RM ANOVA analysis showed significantly greater improvement in Global cognitive index (GCI)($p=0.05$) and Trail making test A (processing speed, $p=0.011$ and working memory, $p=0.049$) for the Val+Met group. Higher PANSS score were significantly correlated with Val/Val genotype ($p=0.044$). The correlation between effect sizes of improvement (higher GCI score and lower PANSS) was significant at $p=0.038$. Conclusion: The presence of Met allele was associated with significantly greater improvements in overall neurocognitive functioning after 12-weeks of CRT and indicates COMT polymorphism influences improvement of cognitive function after CRT. Due to the small sample size, the positive findings could be due to Type I Error. Therefore as we accrue a larger sample size we will be able to validate these findings and be able to determine if the two effects (i.e. improvement from CRT and COMT polymorphism) act at different levels.

Association analysis of seven tagSNPs in the endothelial nitric oxide synthase gene and acute mountain sickness.
P. Wang, MS. Koehle, JL. Rupert The University of British Columbia, Vancouver, BC, Canada.

BACKGROUND: Acute mountain sickness (AMS) frequently occurs in individuals who ascend to altitudes above 2500m. The recurrence rates of AMS in individuals suggest a genetic contribution to susceptibility to the condition. Nitric oxide (NO) is important in regulation of pulmonary vascular tone and may play a role in acclimatization to high altitude. Lower levels of exhaled NO have been demonstrated in individuals who adapt poorly to high altitude. There are a number of polymorphisms in the endothelial nitric oxide synthase (eNOS) gene which may affect NO levels. This study investigated the impact of variants in the eNOS gene on the susceptibility to AMS. METHODS AND STUDY DESIGN: 103 (80 male, 23 female) subjects were recruited at the 2005 Janai Purnima Festival at Lake Gosain Kunda at 4380 m in Lang Tang, Nepal. Seven tagSNPs in the eNOS gene (identified by HapMap) were investigated including the polymorphism Glu298Asp that previously has been associated with eNOS activity. AMS and non-AMS groups were determined both by Lake Louis Score (LLS) and by the more stringent criteria of clinical evaluation. DNA was prepared from buccal (cheek) cells, genotyped, and allele frequencies were compared between the AMS and non-AMS groups by Chi-Square analysis. RESULTS: The tagSNPs, rs1799983 (G/T; Glu298Asp)and rs1808593 (T/G), are associated with AMS when diagnosed by clinical evaluation. No association was found between AMS and alleles at other three tagSNPs (rs743507, A/G; rs3918188, C/A; rs7830, C/A. Genotyping SNPs rs1800781 and rs3918186 is ongoing. CONCLUSIONS: Our data suggest that the T (Asp) and G alleles at rs1799983 (Glu298Asp) and rs1808593 respectively may contribute to AMS susceptibility in the Nepalese.

Decreased expression of Hsp60 and Hsp70 by Caffeic acid phenethyl ester and induction of apoptosis in human oral cancer cells. *H. Tsai[1], T. Chen[2]* 1) Sch Medical Technology, Chung Shan Medical Univ, Taichung, Taiwan; 2) National Taichung Institute of Technology, Taichung, Taiwan.

Oral cancer is one of the ten most common cancers worldwide with a high morbidity and mortality. It is currently consider that dysregulated cell proliferation and apoptosis leads to the development of cancer. Heat shock proteins (Hsps) are overexpressed in various human cancers and involved in tumor cell proliferation and metastasis. To understand the role of Hsp in the pathogenesis of oral cancer, its expression was studied in oral squamous cell carcinoma. An oral cancer cell line, SCC4, was treated with caffeic acid phenethyl ester (CAPE) for 24 hours and then subjected to Hotech33258 staining, DNA fragmentation assay, RT-PCR and Western blot analysis for apoptosis. Results showed that SCC4 cells exhibited apoptotic features and fragmentation of DNA after a 24-hour treatment with CAPE. Furthermore, such CAPE-induced apoptosis was proved to be through an increased expression of proapoptotic protein Bax together with a decreased expression of antiapoptotic protein Bcl-2. In addition, CAPE reduced the heat shock response, leading to decreased levels of Hsp60 and Hsp70. Taken together, these data suggested that CAPE specifically suppresses Hsp60 and Hsp70 expression in oral SCC4 cells and blocks the inhibitory effects of this molecular chaperone on apoptotic cell death, indicating that Hsp60 and Hsp70 may participate in the CAPE-induced sensitization of oral cancer cells to anticancer drugs, which warrants further studies.

Systematic deep sequencing to identfy variants in GRM7 associated with age related hearing impairment. *A. F. Zebboudj[1], J. Ohmen[1], S. Bonneax[2], L. Van Laer[2], G. Van Camp[2], R. Friedman[1]* 1) House Ear Institute, Gonda Center for Cell and Molecular Biology, Los Angeles, CA, 90057; 2) Department of Medical Genetics, University of Antwerp, Antwerp, B-6210, Belgium.

Abstract: Studies employing whole genome genotyping are now routinely and reproducibly making positive associations between genetic variants (typically SNPS) and specific diseases and/or traits. Surrogate markers that "tag" individual haplotype blocks reduce the number of SNPs needed to capture genome-wide genetic variation from millions, to just a few hundred thousand. Haplotype blocks range in size from less than a kilobase to many hundreds of kilobases. While the identification of blocks associated with a given disease is important, the causal variant, and thus the true basis for the pathogenic condition, remains unknown. Identification of causal variants in these genome intervals will be an important next step for many of the studies currently in progress. We recently completed a genome-wide association study (GWAS) for genes associated with Age Related Hearing Impairment (ARHI). One of the most prominent genes identified in our analysis was GRM7. We fine mapped this association signal, and identified a significant stretch of genomic DNA sequence that appears to contain the ARHI association signal. To identify the mutation responsible for some part of ARHI pathogenesis, we have undertaken a strategy to sequence all the different haplotypes in this region to identify SNPs with minor allele frequencies as low as 1%. Once we have cataloged the different variants present in the individual haplotypes, we will genotype these variants in individual DNA samples, to accurately identify causal variants. Our strategy to sequence this region is to design overlapping 11kb amplicons, which can then be combined in equal molar amounts to provide complete coverage of this genomic region. We will then PCR amplify the entire genomic contig from each haplotype. Due to the enormous capacity of these next generation technologies, along with single molecule analysis, we can pool 50 to 100 DNAs representing each haplotype. The results of this strategy and effort will be presented.

Accurate discovery of expression quantitative trait loci under the presence of technical confounding factors. *C. Ye[1], H. Kang[2], E. Eskin[3,4]* 1) Bioinformatics Program, Univ California San Diego, San Diego, CA; 2) Department of Computer Science and Engineering, Univ California San Diego, San Diego, CA; 3) Department of Computer Science, Univ California Los Angeles, Los Angeles, CA; 4) Department of Human Genetics, Univ California Los Angeles, Los Angeles, CA.

Genome wide mapping of expression quantitative loci (eQTL) has successfully identified a large number of cis and trans associations. However, as several recent studies have demonstrated, technical confounding factors such as batch effects can complicate eQTL analysis by causing many spurious associations. Yet little is understood how these technical confounding factors affect eQTL analyses and how to correct for these factors. Through analysis of datasets with biological replicates we can motivate a statistical basis for the observation of spurious associations. We observe that pairs of expression arrays are often highly correlated due to technical confounding factors. Our analysis suggests that it is this inter-sample correlation structure inherent in expression data that leads to spurious associations. We propose a statistical method that corrects for the spurious associations caused by complex inter-sample correlation of expression measurements in eQTL mapping. Applying our Inter-sample Correlation Emended (ICE) eQTL mapping method to mouse, yeast, and human identifies many more cis associations while eliminating most of the spurious trans associations. The concordance of cis and trans associations has consistently increased between different replicates, tissues, and populations; demonstrating the higher accuracy of our method to identify real genetic effects.

Investigation of the colorectal cancer susceptibility region on chromosome 8q24.21 in a large German case-control sample. *J. Hampe[1], S. Buch[1], H. Völzke[7], W. von Schönfels[1], J. H. Egberts[2], B. Schniewind[2], M. Brosch[1], A. Ruether[4], A. Franke[4], M. Mathiak[5], B. Sipos[5], T. Henopp[5], S. Hellmig[1], M. Lerch[1], U. John[8], U. R. Fölsch[1], F. Fändrich[2], S. Schreiber[4,1], M. Krawczak[6], C. Schafmayer[2,3]* 1) General Internal Med, Univ Kiel, Kiel, Germany; 2) Departent of Surgery, UKSH Kiel, Germany; 3) POPGEN Biobank, UKSH Kiel, Germany; 4) Insitute of Clinical Molecular Biology, UKSH Kiel; 5) Insitute of Pathology, UKSH Kiel, Germany; 6) Institute of Medical Informatics and Statistics, UKSH Kiel, Germany; 7) Institute of Community Medicine, University Greifswald, Germany; 8) Deptartment of Medicine A, Universitiy Greifswald, Germany.

Background: Human chromosome 8q24.21 has been implicated as a susceptibility region for colorectal cancer (CRC) as a result of genome-wide association and candidate gene studies. Aims: To assess the impact of molecular variants at 8q24.21 upon the CRC risk of German individuals and to refine the disease-associated region. Patients and Methods: A total of 2713 patients with operated CRC (median age at diagnosis: 63 years) were compared to 2718 sex-matched control individuals (median age at inclusion: 65 years). Information on microsatellite instability in tumors was available for 901 patients. Results: Association analysis of SNPs rs10505477 and rs6983267 yielded allelic p-values of $1.42'10^{-7}$ and $2.57'10^{-7}$, respectively. For both polymorphisms, the odds ratio was estimated to be 1.50 (95% CI: 1.29-1.75) under a recessive disease model. The strongest candidate interval, outside of which significance dropped by more than four orders of magnitude, was delineated by SNPs rs10505477 and rs7014346 and comprised 17 kb. In a subgroup analysis, the disease association was found to be more pronounced in MSI-stable tumors (odds ratio: 1.71). Conclusion: Our study confirms the role of genetic variation at 8q24.21 as a risk factor for CRC and localizes the corresponding susceptibility gene to a 17 kb candidate region.

Identification of human and mouse alternative splicing of functional significance. *T. Imanishi[1], J. Takeda[1], Y. Suzuki[2], S. Sugano[2], T. Gojobori[1,3]* 1) BIRC, AIST, Tokyo, Japan; 2) Univ. Tokyo, Tokyo, Japan; 3) Natl. Inst. Genet., Mishima, Japan.

As a part of the project for developing an integrated database of human genes and transcripts, H-Invitational Database (H-InvDB; http://www.h-invitational.jp/), we analyzed comprehensive sets of human and mouse transcripts for alternative splicing variants of functional significance. As a result, we identified many human genes in which two or more alternative splicing variants are structurally conserved in mouse at the transcript level. This suggests that these alternative splicing variants are functionally important and contribute to the diversification of human and mouse proteome. On the other hand, there are more species-specific alternative splicing variants in human and mouse transcripts, implying that alternative splicing greatly serves evolutionary changes in gene structure. These results are made public in our database of human alternative splicing, H-DBAS (http://www.h-invitational.jp/h-dbas/).

Familial amyloid polyneuropathy (ATTR V30M): a monogenic disorder with an unusual large variability. *A. Sousa[1,2], A. Martins da Silva[3], L. Maia[3], T. Coelho[3]* 1) Dept Population Studies, ICBAS, Porto, Portugal; 2) UnIGENe, IBMC, Porto, Portugal; 3) Unidade Clínica de Paramiloidose, HGSA, Porto, Portugal.

Andrade first described FAP (1952) as a disease occurring between 25 and 35 yrs. He reported 64 patients, 13 of which had no family history of the disease. Later PE Becker established its AD mode of inheritance and interpreted isolated cases not as a de novo mutation but as the expression of incomplete penetrance of the gene in one of the parents. This hypothesis could only be tested after the finding of the mutation in 1985. Our aims were: 1) to estimate the number of probands with no affected parent at time of diagnosis; 2) to study age at onset of proband and its changes over time. Between 1939 and 2005, 2075 patients (525 families) were diagnosed at HGSA, all with V30M mutation. Families were classified as new when the proband reported no similar disease in earlier generations. 3) To assess the number of late-onset cases (o. 50y, thought to be so rare in earlier descriptions. Age-at-onset varied from 20-80 yrs (mean 37.1 in women, 32.4 in men). 209 probands (40%) had no affected parent at time of diagnosis. This type of family represented 68% of those diagnosed in last decade (only 27% before 1985). Mean age-at-onset of probands of new families was 46.0 yrs (vs. 32.3 yrs for classical families) and it has increased over time, being 49.5 yrs in last decade. Also, cases with late-onset are not rare: they represent 13% of all cases; also they aggregate in families and often descend from old asymptomatic carriers, what raises the hypothesis of genetic modifiers. Regarding FAP two realities coexist in Portugal: families with several generations of affected (where probands have classical onset) and probands with late-onset who report no similar disease in previous generations. The mutation may cross generations without clinical manifestations, then expresses as late-onset and later anticipation occurs, giving origin to families with classical onset of the disease.Since anticipation seems not to be due to TNR expansions, the question remains as how to explain anticipation in a disease due to a point mutation.

Dissection of optimal DNA dyes and amplicon length for high throughput mutation screening by real time PCR/high resolution melting analysis using the LightCycler480 System. *K. Naritomi[1,2], K. Yanagi[1], T. Kaname[1,2]*
1) Dept Medical Genetics, Univ Ryukyus Sch Medicine, Okinawa, Japan; 2) SORST, JST, Saitama, Janan.

We describe the optimal condition of DNA dyes for High-Resolution Melting (HRM) analysis using the LightCycler480 (LC480) System (Roche Diagnostics) with conventional Taq DNA polymerase. PCR was performed in presence of dyes, SYTO9, LCGreen Plus or EvaGreen. ***Background:*** LC480 System enable us to perform HRM analysis which could scan genetic variations such as single-nucleotide polymorphisms (SNPs) or mutations in PCR amplicons prior to sequencing by searching differences of thermal denaturation of a double strand DNA. As the optimal PCR condition for first step of genetic testing has been settled in most diagnostic laboratories, we tried to join the settled conditions to the new system. ***Methods:*** A 384-well plate was used to scan amplicons of the *Faciogenital dysplasia 1* (*FGD1*) gene. PCR was performed in the presence of double-strand DNA saturating dyes, SYTO9, LCGreen Plus and EvaGreen. Melting curves were analyzed with the LC480 Gene Scanning Software and reconfirmed sequences of DNA variants. ***Results:*** We show SYTO9 was most suitable for PCR-HRM analysis among them because of minimal affects on PCR amplification. The optimal concentration of SYTO9 was much less than previous reports. No clear relation was found in amplicon length and positions of mutations or SNPs in an Amplicon. Methods of DNA extraction dose not affect on HRM analysis. Amplicons included DNA dyes could be direct sequenced after purification using commercially available clean-up columns for PCR products. ***Conclusions:*** We concluded that SYTO9 is the most applicable for PCR-HRM analysis. No much effort was needed to adapt conventional PCR conditions to the new system.

A Genome wide association study of antioxidant vitamin levels identifies variants in the BCMO1 gene that alter vitamin A levels. *J. Perry[1], N. Rice[1], A. Matteini[2], M. N. Weedon[1], H. Lango[1], D. Hernandez[3], A. Singleton[3], A.-M. Corsi[4], J. Guralnik[3], S. Bandenelli[5], A. Cherubini[6], R. Semba[2], J. Walston[2], D. Melzer[1], L. Ferrucci[3], T. M. Frayling[1]*
1) Peninsula Medical Sch, Exeter, United Kingdom; 2) Johns Hopkins University, USA; 3) National Institute of Ageing, USA; 4) Tuscany Regional Health Agency, Italy; 5) Azienda Sanitaria di Firenze, Italy; 6) University of Perugia Medical School, Italy.

The role of oxidative stress and antioxidants in health, disease and ageing, is controversial. To improve the understanding of the control of antioxidant levels we performed a genome wide association study of 1200 individuals from the population based InCHIANTI study. We tested associations between 496,032 SNPs and eight anti-oxidant vitamin measures; alpha-tocopherol, gamma-tocopherol, lycopene, and alpha-carotene, beta-carotene, Zeaxanthin, lutein, and Beta-cryptoxanthin. We followed up SNPs reaching p<5x10-7 using 601 individuals from the WHAS study. We identified two associations that exceeded genome wide significance in a joint analysis. A cluster of SNPs, situated 5 of the BCMO gene, were associated with beta-carotene levels (p=1x10-10 in InCHIANTI, p=3x10-6 in WHAS, joint p=1x10-15) and other carotinoids (e.g. joint p=6x10-13 for lutein levels). The strongest association with vitamin E related measures was between a variant in the APOAV gene (S19W), known to alter triglyceride levels, and alpha-tocopherol levels (p=2x10-8 in InCHIANTI, p=0.006 in WHAS). This finding is consistent with the fact that vitamin E is a fat-soluble micronutrient carried by plasma lipoproteins, but shows that genetically determined lipid levels impact on vitamin levels. There were no associations between these variants and vitamin intake or secondary phenotypes including diseases analysed as part of the WTCCC. Our results provide the first evidence for common genetic variants that alter circulating levels of antioxidants. Understanding the genetic basis of vitamin levels should help clarify the role of antioxidants in health.

Genotyping Oculocutaneous Albinism -- a Case Report from an Ongoing Project. *D. Adams, M. Huizing, W. Gahl*
NHGRI, NIH, Bethesda, MD.

Objective: We are evaluating a cohort of patients with clinical evidence of oculocutaneous albinism (OCA), but no definitive molecular diagnosis. The cohort includes individuals who have unusual presentations, and who have been evaluated for other albinism-related disorders. We describe a pair of siblings for whom our ongoing project has yielded a new, definitive diagnosis. **Methods:** DNA sequence was obtained from PCR amplicons using custom primers. A known pseudogene complicates the sequencing of the TYR gene. TYR encodes the melanogenic enzyme tyrosinase. Allele-specific primers were used to differentiate TYR from the TYR pseudogene. **Results:** The two sisters were ages 2 y/o and 9 m/o at the time of presentation. The initial evaluation was conducted under a protocol for Hermansky-Pudlak Syndrome (HPS). HPS combines OCA with platelet dysfunction and the potential for pulmonary fibrosis and chronic colitis. In addition to OCA, both children had intermittent abdominal pain and easy bruising. Gastroenterological, pulmonary, hematological and ophthalmological evaluations were performed, greatly reducing the suspicion for HPS. Molecular analysis of the OCA2 (P) gene, associated with OCA, type 2 (OCA-2), revealed heterozygosity for p.S736L, a mutation previously described in OCA-2 patients. A tentative diagnosis of OCA-2 was assigned. Given the lack of a second OCA2 mutation, we added the siblings to our re-analysis project, revealing a homozygous p.G190fs mutation in the tyrosinase gene, associated with OCA, type 1. **Conclusion:** Technical progress has dramatically reduced the cost of DNA sequencing, allowing for more liberal use of sequencing in the search for definitive diagnoses. By sequencing all known OCA genes in our undiagnosed cohort, we hope to both assign additional diagnoses and discover candidates for new OCA-related genes. Clinical sequencing will allow rapid screening for common causes of OCA to confirm clinical diagnoses and to exclude more severe conditions. Future areas of research include characterization of pathogenicity for known variants and discovery of variants outside the coding sequence of OCA-related genes.

Evaluation of germline genomic profiling for colorectal cancer screening and risk prediction in data from the Assessment of Risk for Colorectal Tumors in Canada (ARCTIC) study. *J. Little, S. Hawken* Epidemiology and Community Medicine, University of Ottawa, Ottawa, Canada.

The genetic variants associated with colorectal cancer(CRC) in candidate gene and GWA studies mostly have low-penetrance. Collectively but not singly, multiple common,low-penetrance variants have potential utility in triage to alternative prevention strategies. For example, genetic information could be used in targeting individuals at elevated genetic risk for enhanced screening surveillance. Using a candidate gene approach, we identified a panel of common, polymorphic germline variants associated with CRC with some consistency, based on original research articles, meta-analyses and systematic reviews. This list of variants was then used to develop and test risk prediction models in a population-based case control study with genotyping of over 600,000 SNPs in 1200 CRC cases, and 1200 controls (the ARCTIC study). Approximately 80 variants were identified for evaluation in ARCTIC, but only about 1/3 were adequately captured in the data due to: low minor allele frequency, lack of coverage in the SNP panels, and the fact that a number of variants were not simple SNPs (e.g. microsatellites, deletions/ insertions). Model building proceeded in the ~20-30 SNPs available. Univariate odds ratios (OR) for homozygotes for uncommon variants versus homozygotes for common variants ranged from 0.67-2.16, and ORs for heterozygotes versus homozygotes for common variants ranged from 0.67-1.22. Minor allele frequency ranged from 1-50%. Although the genotype call rate was high for individual SNPs, missing data became an important issue in multivariable models, and hence we employed data-imputation techniques. Multivariate logistic regression analysis was used, with cross-validation techniques employed to address overfittingan important issue given our goal of developing generally applicable risk prediction models. Results showing promising predictive utility in the reduced set of available SNPs will be discussed. Next steps involve genotyping the variants not available in ARCTIC, and accessing additional data sources through collaborators, both for pooled analyses and for risk model validation.

Identification of biological targets for a microRNA molecule, miR-145 in prostate cancer cell lines. *M. Ozen[1,2], A. Uzumcu[1], O. F. Bayrak[1]* 1) Dept of Medical Genetics, Yeditepe University Medical School and Yeditepe University Hospital System, Istanbul, Turkey; 2) Dept Pathology, Baylor College of Medicine, Houston, TX.

MicroRNAs (miRNAs) are small (20-22 nucleotide) regulatory RNAs which might regulate gene expression transcriptionally or translationally. There is emerging evidence that miRNAs are involved in cancer pathogenesis. A number of studies have detected frequent alterations of miRNA expression in a variety of human malignancies including prostate cancer. We have recently demonstrated a widespread deregulation of miRNA expression in human prostate cancer. In this study, we have analyzed the status of one of the selected miRNAs, miR-145 in human prostate cancer cell lines DU-145, LNCaP and PC3. We have transfected these cell lines with precursor miR-145 and anti miR-145 molecules and compared the gene expression profiles by using Agilent whole genome expression arrays. Data analysis is carried out by the help of Agilent Gene Spring GX software package. We have also compared the targets for miR-145 identified biologically in prostate cancer cells and in three different databases. Experiments on verification of select targets and the biological effects of these targets on prostate cancer cell lines are in progress. The results obtained in these studies might identify new markers that can be used for prostate cancer progression and as new targets for prostate cancer therapy.

Significant association of MECP2 alleles with autism. *R. D. Delahanty, E. Crawford, D. G. Hwang, L. Jiang, K. Luci, J. S. Sutcliffe* Ctr for Human Genetics Res, Vanderbilt Univ, Nashville, TN.

Mutations in the methyl CpG binding protein 2 (MECP2) gene cause Rett syndrome (RTT; OMIM 312750), accounting for up to 95% of cases. Animal studies have demonstrated that MeCP2 is essential for normal brain development. While RTT has a distinct, known etiology, it has nevertheless been categorized as a Pervasive Developmental Disorder, as has autism and its spectrum diagnoses; this reflects the shared phenotypic features of these two disorders, and has fostered speculation that they may also share biological connections as well. Autism, like RTT, is a neurodevelopmental disorder. Narrowly defined autism affects ~1 in 500 individuals, while the broader autism spectrum disorders (ASDs) affect ~1 in 150 individuals. Key clinical features of autism include deficits in reciprocal social interaction, communication and patterns of repetitive behaviors and restricted interests. Autism affects males more commonly than females at a ratio of 4:1. In contrast, the vast majority of RTT cases are female, owing to lethality in males fully deficient for MECP2. To ask whether common alleles of MECP2 might contribute to autism, we conducted an association study using SNP markers to index common haplotypes across the MECP2 locus. These SNPs were genotyped in a group of 962 combined simplex and multiplex families ascertained for idiopathic autism. FBAT and x-APL application were used to conduct a family-based test to evaluate our hypothesis. We found that multiple SNPs in a block of linkage disequilibrium showed strong association using both narrow (e.g. P=0.0007) and broad (e.g. P=0.0054) diagnostic criteria. These associations remain significant even after a conservative Bonferroni correction. A more in depth, albeit preliminary analysis of these data indicate an ancestry effect, with the association driven by a non-European subset of families. Resequencing of MECP2 exons in a set of 192 unrelated cases and 192 controls does not indicate a burden of rare mutations in the autism sample. To our knowledge, this is the first report suggesting that common alleles in MECP2 may confer susceptibility to autism.

Generation of a Human miRNA Tissue Atlas. *B. B. Gardiner[1], G. Kolle[1], N. Cloonan[1], J. Gu[2], E. Nourbakhsh[1], K. Lea[2], S. Heater[2], S. Kuersten[2], S. M. Grimmond[1]* 1) Institute for Molecular Bioscience, University of Queensland, Brisbane, Queensland, Australia; 2) Ambion, Inc. - An Applied Biosystems Business, Austin, TX 78744.

The involvement of miRNAs in many cellular and developmental processes is well established and the elucidation of their roles depends on a complete catalog of miRNAs and a more thorough understanding of their expression patterns. To address these issues a robust method for expression profiling and novel miRNA discovery is required. We have previously used a shot-gun sequencing approach in conjunction with the Applied Biosystems SOLiD technology to assess gene activity and transcriptional complexity (Cloonan et al., 2008). In contrast to array based approaches direct sequencing of RNA populations does not suffer from the issues of cross-hybridization, and can be utilized for the discovery of novel sequences. Further, short read sequence approaches are especially suited to the discovery and analysis of miRNA sequences. We have generated a sequence based expression atlas by surveying the miRNA fraction across nine human tissue samples (heart, brain, liver, testes, spleen, kidney, thymus, lung and ovary). Individual barcoded libraries were prepared using an RNA ligation based approach and pooled for SOLiD sequencing. Our sequence data reveals that tissue restricted miRNA expression can be detected and quantified by this approach, which also allows for the identification of variations in the mature miRNAs as well as the identification of novel miRNAs.

Development of a national certification program for hemoglobinopathy service counselors Joseph Telfair*, Sonya Ross **, Nancy Callanan*, Eileen Miller,* UNCG* , SCDAA.** *J. Telfair* Public Health, University of North Carolina at Greensboro, Greensboro, NC.

In Fall 2004, the Sickle Cell Disease Association of America (SCDAA) engaged Professional Examination Service (PES) to perform consulting services with regard to the development of a national certification program for hemoglobinopathy service counselors. An overall description of a hemoglobinopathy service counselor, and a description of the domains and tasks performed by such counselors as well as the knowledge required was crafted and subsequently validated via electronic survey disseminated to subject-matter experts nationwide. A review of the quantitative results from the survey indicates that the domains of practice are important areas of practice that comprise the work time of hemoglobinopathy counselors. Moreover, the topic areas comprise knowledge and skills that are required in practice and that make a very important contribution to protecting the client/public from health-related harm. Accordingly, The domains and tasks identified in connection with the profile of the hemoglobinopathy service counselor provide a valid and comprehensive description of the work of such practitioners. The knowledge base identified in connection with the topic areas can be used as the basis of both curriculum development and review initiatives and test development initiatives. The skill based identified in connection with the topic areas can be used as the basis for evaluating the competencies of hemoglobinopathy service counselors during training and as a pre-condition for certification. The validated description of practice, including domains, task, topics, and knowledge and skills provides a reasonable basis for related accreditation and certification initiatives, should the SCDAA elect to move forward in either direction.

Sepsis in premature infants: investigation of candidate genes. *M. E. Cooper[1], A. S. Abu-Maziad[2], K. L. Schaa[2], M. L. Marazita[1], J. M. Dagle[2], J. C. Murray[2]* 1) University of Pittsburgh, Pittsburgh, PA; 2) University of Iowa, Iowa City, IA.

Sepsis is a serious bacterial infection that is a significant cause of morbidity and mortality in neonates. In this study we examined 48 SNPs in 16 candidate genes on 12 autosomal chromosomes. The sample is 644 nuclear families, with 82 premature infants diagnosed with sepsis, 261 with suspected sepsis and 216 with no sepsis. Birth weight, gestational age, delivery type, race/ethnicity, number of days on oxygen/ventilator, rupture of membranes details, bacterial gram positive/negative episodic details and chorioamnionitis status were collected. **Methods**: Allelic, genotypic and haplotypic transmission disequilibrium tests (TDT) were performed. Within the set of premature infants, various tests (Chi Square, ANOVA, correlations, regression) were used to assess association between covariates and sepsis defined as definite sepsis with/without suspected sepsis. **Results**: All biological measures are highly correlated (all p0.0001) and vary significantly between the 3 sepsis groups (ANOVA p0.0001). A model with gestational age and gender as main effects is the best predictor of definite sepsis diagnosis. TDT analysis reveals that definite sepsis is associated with PLA2G2Ars1891320s common C allele (p=0.04) and C/C genotype (p=0.08) but that suspected sepsis is associated with the rare T allele and the C/C genotype is protective (p=0.02). Definite sepsis is associated with TLR5rs5744105s C allele (p=0.05) and the G/G genotype is protective (p=0.07); the no sepsis group is associated with the G allele (p=0.02) and the C/G genotype (p=0.04) but the C/C genotype is protective (p=0.004). Two SNPs in the IL10 and TLR2 genes are associated with definite sepsis (p=0.05) and 3 other SNPs are associated with suspected sepsis group but not in the other groups. Conclusions: Although the p-values are only minimally significant even without multiple test adjustment, the results are intriguing. It appears that the C allele in SNPs from the PLA2G2A and TLR5 genes are relevant to sepsis and the opposite allele are associated with non-sepsis. Further studies are needed to explore the role of these genes in the occurrence of sepsis in premature neonates. Grant:#HD52953.

Rapid Screening of genetic factors associated with warfarin dosage using a nanofluidic system. *R. Ramakrishnan[1], A. Mir[1], H. Sagreiya[2], R. D. Altman[3]* 1) R&D, Fluidigm Corp, S San Francisco, CA; 2) Stanford Medical School, Stanford CA; 3) Department of Bioengineering, Stanford University, Stanford, CA.

There is a need for systems allowing medium multiplexing platforms with high throughput, excellent call rates, high concordance and low cost. In the current study we demonstrate the use of one such system, utilizing unique nanofluidic products in a clinical research study that analyzed the genetic and clinical determinants of warfarin dose. We demonstrate the use of Integrated Fluidic Circuits (IFCs), called dynamic arrays, in a study to genotype unique human DNA samples on 28 different SNP assays, covering the VKORC, CYP2C9 and the CYP4F2 genes, using nanoliter volumes of reagents. The DNA samples screened included DNA case control samples extracted from saliva of patients currently undergoing warfarin therapy, at the Stanford Oral Anticoagulation Clinic (OAC) and the Stanford Hematology Clinic. Each dynamic array IFC systematically combines samples and assays into 9216 reactions in a single chip run. Each chip was thermocycled, imaged and analyzed using a BioMarkTm system. Call rates of greater than 99.5% and high concordance values were achieved. Calls were validated by selected genotyping of the same samples on the ABI 7900. We have also determined copy number variation changes associated with these patients on the BioMark system using a second different IFC, known as the digital array. Each digital array is capable of reliably discriminating between copy numbers which are only 15% different. The excellent call rates and high concordance, combined with the combination of samples and reagents in nanofluidic chips, provides a formidable screening tool. It is possible that this research could lead to improved warfarin dosing policies at Stanford Hospital and Clinics in the future.

Dysfunctional MeCP2 causes microtubule defects. *S. Alka[1], R. Scaife[1], J. Christodoulou[2], P. Zhang[1], G. Pelka[3], P. Tam[3], H. Leonard[4], G. Matthijs[5], M. Kavallaris[6], D. Ravine[1,7]* 1) Western Australian Institute for Medical Research, Perth , Western Australia, Australia; 2) Western Sydney Genetics Program, Childrens Hospital at Westmead, Sydney, NSW, Australia; 3) Children's Medical Research Institute, 214 Hawkesbury Rd, Westmead NSW 2145 Australia; 4) Telethon Institute for Child Health Research, Centre for Child Health Research, University of Western Australia, 100 Roberts Road, Subiaco, Perth, WA 6008, Australia; 5) Laboratory for Molecular Diagnostics, Center for Human Genetics, University of Leuven, Herestraat 49, B-3000 Leuven, Belgium; 6) Children's Cancer Institute Australia for Medical Research, High Street, Randwick, Sydney, NSW 2031, Australia; 7) School of Medicine and Pharmacology, University of Western Australia, Level 5/6, MRF building, Rear 50 Murray Street, Perth WA 6000, Australia.

Methyl CpG binding protein 2 (MeCP2) is known to mediate gene expression by several mechanisms within the nucleus. MeCP2 also has a recently recognised cytoplasmic distribution, which is of unknown functional significance. Here, we report that MeCP2 maintains microtubule stability via the tubulin de-acetylation pathway. We show that MeCP2 associates with microtubules in the cytoplasm as well as on the mitotic spindle and within the midbody remnant. We have found that microtubule inhibitors alter the cytoplasmic distribution of MeCP2 in wild type cells. In a MECP2 mutant cell line, we have detected impaired microtubule stability and dynamics together with reduced amounts of acetylated tubulin. siRNA knockdown of MeCP2 in wild type cells is associated with reduced amounts of acetylated tubulin, whereas MeCP2 overexpression heralds a rise in the level of acetylated tubulin. We have since identified an interaction between MeCP2 and the microtubule deacetylase histone deacetylase 6. We propose that that MeCP2 maintains microtubule stability by inhibiting the tubulin deacetylase activity of HDAC6.

Skewed X-inactivation in Female Carriers of Menkes Disease Associated with Neuropsychiatric Abnormalities.

V. Desai[1], A. Donsante[1], M. Martensen[2], K. Swoboda[2], S. G. Kaler[1] 1) Unit on Pediatric Genetics, NICHD, NIH, Bethesda, MD; 2) Pediatric Motor Disorders Research Program, University of Utah School of Medicine, Salt Lake City, UT.

Menkes disease is an X-linked recessive neurogenetic disorder caused by mutations in a gene, ATP7A, located at Xq13, that encodes a copper-transporting P-type ATPase. Deficiency of the gene product causes abnormal cellular copper transport and decreased activities of copper-dependent enzymes. ATP7A plays a significant role in the development and maintenance of the central nervous system (CNS), as evidenced by the marked neurodevelopmental abnormalities in affected patients. Female carriers of this condition are typically healthy and do not manifest clinical or biochemical phenotypes. We studied a large Utah family in which an ATP7A mutation (del exon 13-14) segregates. We identified a 5,557 base deletion in the proband and mapped the breakpoint using long polymerase chain reaction (long-PCR) and stepwise sequencing. We developed an assay to amplify a 684 bp junction fragment in the proband, his mother, and maternal grandmother (obligate carriers). We then applied this assay to evaluate six other at-risk females in the family, as well as a newborn male. In addition to the two obligate carriers, we detected the junction fragment in four of the other six at-risk females. The newborn male, born to one of the identified carriers, did not show the fragment, ruling out Menkes disease. X-inactivation studies showed moderately skewed (n=2) to highly skewed (n=4, 100:0 in 3) patterns among the six carriers, and random X-inactivation in two non-carriers. Serial neurocognitive evaluations during childhood and early adulthood revealed significant abnormalities in several females with del exon 13-14. Our results provide evidence that heterozygosity for a severe ATP7A mutation, in conjunction with nonrandom X-inactivation, may be associated with significant clinical abnormalities in females. We speculate that the 5.5 kb deletion in ATP7A interferes with cis-limited silencing by Xist RNA, or is genetically linked with a second mutation at Xq13, viz., in the Xic locus, accounting for the marked skewing observed.

Community Centered Family Health History: A model and a resource. *J. O'Leary, V. Edelson, S. Terry* Genetic Alliance, Washington, DC.

Significant stigma exists in communities and families surrounding health information. Privacy concerns and fears of discrimination can make it difficult to discuss health within the family, let alone with a healthcare provider. Yet the family plays an important role in shaping a person's habits and encouraging healthy behaviors, and a provider can recommend lifestyle modifications based on family risk. Community Centered Family Health History models how adaptation of resources and a broad definition of community can produce infinite individualized access points to health information. The Does It Run In the Family? health history toolkit addresses common, complex conditions alongside single gene disorders to foster the understanding that all people are affected by their genetics, in ways that might be surprising. Communities in the project customized family health history materials and translated community experiences into a customizable online version of the Does It Run In the Family? toolkit. The online tool allows users to input personal stories, photographs, quotes, resources, and health condition descriptions and statistics - or choose from libraries of such information - to easily create community-specific resources.

Technical variation and whole genome data quality: A systematic approach to "cleaning" genotype data for analysis. *R. Lazarus, B. Raby, E. K. Silverman, B. Klanderman, C. Hersh, S. T. Weiss* Channing Laboratory, Brigham and Women's Hospital; Center for Genomic Medicine, Brigham and Womens Hospital; Harvard Medical School, Boston, MA.

Genotype measurement error is a potential source of bias in genetic association studies. From sample collection to assay, every step in high throughput genotyping is highly optimized, so even minor departures from optimal conditions are likely to decrease genotype quality, and some kind of data cleaning is nearly always performed before analysis. Subjects and markers lying at the extremes of the distributions of technical measures, including missingness rates, departures from Hardy-Weinberg equilibrium (HWE), Mendelian error rates and duplicate genotyping discordance rates, are candidates for removal as part of a quality control process, because these characteristics suggest non-optimal technical conditions associated with process control variation and increased genotype error rates. These candidates can easily be identified with *in-silico* methods, but guidance on optimal strategies for data cleaning is lacking. We evaluated and compared measures of technical quality variation in whole genome data from 1200 subjects in the CAMP study, and explored their potential contribution to systematic data cleaning strategies, using departure from the expected uniform distribution of p-values under the null, as a figure of merit for a range of thresholds for each measure. In a principal components analysis (PCA) of markers, ¾ of the total variance was explained by the first 2 components. The proportion of Mendelian errors, the missing fraction and discordance rates for duplicate measurements loaded heavily onto the first component, the logarithm of the Hardy-Weinberg p-value in founders loaded equally onto both, while the minor allele frequency (MAF) loaded mostly onto the second component. MAF affects power to detect departures from HWE but appears not to affect the other commonly used measures of technical variation. We conclude that PCA may be used to identify outlier markers in technical variation PCA space for removal during quality control before analysis. Support: HG003646, HL065899, HL083069.

Genomic profiling of high grade primary brain tumor, the Gliomas: A cytogenomic study by FISH. *P. Singh-Kahlon, L. Montella* Cytogenetics, Genzyme Genetics, 521 W. 57th St, #5, New York, NY 10019.

Diffuse gliomas are the primary brain tumor, graded as per WHO classification (in high grade category), as oligodendrogliomas, asrocytomas, anaplastic oligodendrogliomas & mixed oligoastrocytomas. Genomic profiling of these tumors has prognostic significance. It has been shown that loss of heterozygosity (LOH) by the codeletion of two gene regions, EGLF and TP73 located at 1p36 and GLTSCR1, GLTSCR2, CRX on 19q13, results in improved prognosis for the above mentioned high grade diffuse gliomas. FISH based cytogenomic studies with 1p36 and 19q13 probe sets were conducted on over 150 samples of paraffin block specimens. Standard FISH hybridization methodology (Vysis) used for block tissue samples and modified in our Genzyme laboratory was employed. FISH data analysis showed nearly 76% of the total samples as abnormal. Amongst the abnormals, 55.3% had loss of heterozygosity (LOH) for both 1p and 19q i.e concurrent codeletion, 5.3% showed deletion of 1p alone, and 1% deletion of 19q only. Multisomy of 1p and 19q was present in 24.4% cases, while 13.8% showed complex abnormal FISH patterns. Correlation of the observed genomic aberrations with clinical subtypes and prognostic implications for high grade gliomas shall be elucidated.

PCR/high-resolution melting analysis for rapid and sensitive gene scanning of the faciogenital dysplasia gene, FGD1. *T. Kaname[1,2], K. Yanagi[1], Y. Chinen[3], K. Naritomi[1,2]* 1) Dept Medical Genetics, Univ Ryukyus, Nishihara, Japan; 2) SORST, JST, Kawaguchi, Japan; 3) Dept Pediatrics, Univ Ryukyus, Nishihara, Japan.

It is important to establish an easy and reliable system to detect mutations or variations for genetic testing. High-resolution melting analysis (HRM analysis) is a method, which allows simple and rapid detection of gene variations. We constructed a sensitive system for detecting gene variations in *FGD1*. The *FGD1* gene is a responsible gene for Aarskog-Scott syndrome (AAS), which is an X-linked disorder characterized by short stature, dysmorphic facial appearance, brachydactyly, shawl scrotum, and sometimes neurobehavioral impairment. We set up PCR/HRM system for all the exons of *FGD1* using LightCycler 480 Instrument (Roche). Then we evaluated the PCR/HRM in the screening seven mutations of *FGD1*, which we found in AAS patients previously, plus variations of *FGD1* in five sporadic patients, two families, and 48 controls. The PCR/HRM discriminated all the *FGD1* mutations studied from wild-type DNA. In control individuals, four polymorphisms and three unknown variations were found in the *FGD1* gene. Besides, the PCR/HRM discriminated not only four haplotypes in exon 14, but also between heterozygous and hemizygous or homozygous of those haplotypes. The system is a valuable method for rapid and reliable scanning of *FGD1* gene variations and is applicable to high-throughput genetic testing.

A novel cassette exon flanked by schizophrenia-associated SNPs in the dopamine transporter gene. *M.Y-M. Chen[1], K. McCann[1], P. Papasaikas[1], M. E. Talkowski[3,4], M. Bamne[3], L. McClain[3], D. Lewis[3], V. L. Nimgaonkar[3,4], A. J. Lopez[1,2]* 1) Dept Biological Sciences, Carnegie Mellon University, Pittsburgh, PA; 2) Lane Center for Computational Biology, Carnegie Mellon University; 3) Dept Psychiatry, Univ Pittsburgh, Pittsburgh, PA; 4) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

The dopamine transporter (*SLC6A3*, DAT) is a critical gene involved in the re-uptake of dopamine from the synapse. Previous studies identified statistical associations between common intronic sequence polymorphisms in *SLC6A3* and schizophrenia in two large Caucasian samples (see Talkowski et al. abstract and Talkowski et al 2008). This prompted us to examine the *SLC6A3* sequence for possible alternative exons or recursive splicing elements that might have been missed by previous molecular analyses. Using a primate-specific computational model, we predicted a novel 108 nt cassette exon that is defined by a potential recursive splice site and a standard 5 splice site motif within intron 3. This exon was flanked within 600 nucleotides by four schizophrenia-associated SNPs, three of which fell within computationally predicted splicing regulatory signals. We verified alternative splicing of the cassette exon (E3b) in cell transfection experiments in both its normal intron context and in a heterologous splicing reporter system. Results of mutagenesis tests are consistent with a recursive splicing mechanism for E3b. We also verified alternative splicing of exon E3b in endogenous *SLC6A3* transcripts from adult human brain and lymphocytes using RT-PCR assays. Because E3b introduces multiple in-frame stop codons into the mRNA, it truncates the DAT protein and may serve a negative regulatory function. This might also explain why inclusion of E3b had not been detected previously, since it might trigger nonsense-mediated decay of the corresponding mRNA. A potential exon E3b is conserved among primates and many other placental mammals but it appears to have been lost in the Glires. Experiments are under way to test whether the frequency of inclusion of exon E3b is altered by alleles associated with schizophrenia risk at the flanking SNP positions.

PhenX: Consensus Measures to Facilitate Cross-Study Analysis for Genome-wide Association Studies. *C. M. Hamilton[1], E. Ramos[2], R. Kwok[1], D. Maiese[1], D. Wagener[1], W. R. Harlan[3], J. Haines[4]* 1) RTI International, Research Triangle Park, NC; 2) National Human Genome Research Institute, Bethesda, MD; 3) National Library of Medicine, Chevy Chase, MD; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Genome-wide association studies (GWAS) measure hundreds of thousands of single nucleotide polymorphisms (SNPs) across the genome and relate them to common diseases and traits. Once an individuals genome has been comprehensively characterized, it can potentially be related to any trait, not just the trait that was initially investigated. Despite the vast potential of GWAS, opportunities for cross-study comparisons have been severely restricted by the lack of standardized phenotypic and environmental measures, even though many risk factors (e.g., obesity, smoking, low socioeconomic status) are common to multiple diseases. PhenX (consensus measures for Phenotypes and eXposures) was initiated to enhance cross-study analyses of GWAS and other large-scale genomic research efforts. The PhenX Steering Committee has identified 20 high priority research domains. Over the course of the three year project, experts from across the scientific community will participate as members of Working Groups (WGs) to address these research domains. Each WG will propose a set of high-priority measures that will be vetted with the larger research community through web-based surveys. Ultimately, the PhenX Toolkit will make the selected measures available to the scientific community. The PhenX Toolkit will make it easy for researchers to incorporate the recommended measures in proposed or ongoing genome-wide studies. To date, five PhenX WGs are in progress: Demographics, Anthropometrics, Alcohol, Tobacco and Other Substances, Cardiovascular, and Diet and Nutrition. The input of the scientific community is needed to ensure that the measures included in the PhenX Toolkit will be widely accepted and readily incorporated into ongoing and future research efforts. Investigators are encouraged to find out more details about PhenX and to participate in the web-based surveys at www.PhenX.org. Supported by: NHGRI, Award No. 1U01 HG004597-01.

Etiology of 200 infertility cases. *C. Trujillo[1,2], S. Ashour[1,3], S. B. El Badawi[1]* 1) Dept Genetics Erfan & Bagedo Hospital, Jeddah, Saudi Arabia; 2) Dept Genetics, CES Inst, Medellin, Colombia; 3) Andrology Department, Cairo University, Egypt.

Objectives: According to the WHO 15% of all couples attempting to have children are infertile. The male factor alone explains 30% and a combination of male and female factors is 20%. Genetic factors clearly contribute a big portion of the infertility etiology. Methods:Clinical evaluation included, detailed medical history and physical examination.Testicular volume was measured by orchidometer.Semen analysis was performed according to the WHO guidelines.The diagnosis of azoospermia was established after centrifugation.LH,FSH and Testosterone were measured by immunometric assays with commercial kits.Chromosomal analysis was performed using G banding;FISH studies was used in all cases of mosaicism and in 46,XX males, using centromeric probes for the X and Y chromosomes and SRY probe.Molecular testing for Y chromosome microdeletion of the AZF regions were evaluated by PCR using the European Academy of Andrology (EAA) and (EMQN)laboratory guidelines. Results:Total of 200 patients were studied, 121 were oligospermic, 79 Azoospermic.Chromosome abnormalities found in 30 azoospermic and in 7 oligospermic; including 47,XXY 20 cases, 4 mosaic cases (47,XXY/46,XY/45X, 47,XXY/46,XY and 46,XY/45,XY).Two patients had a karyotype 46,XX and The SRY was detected by FISH.One patient had a karyotype 46,XY with absence of the SRY gene.Y microdeletion were found in 4 cases of azoospermia, two in the AZFc, and one in both the AZFb-c region. In two cases of oligospermia AZFc mutation were found. Three patients with obstructive azoospermia one was heterozygous for the 508 mutation, and one was compound heterozygous compound heterozygous. Other causes of infertility in our patients were Werner Syndrome (one patient), del 19ptet. Conclusion:The overall rate of genetic abnormalities found in this study was 30%.Infertile men with a normal karyotype have an increased risk of chromosomally abnormal sperm and children.New techniques may help to identify this cases.Whether this further will help our patients to be included in assisted reproductive programs will be worth to consider in future studies.

PhenX: Demographic Measures for Cross-study Analyses. *M. Cockburn[1], V. Bonham[2], O. Carter-Pokras[3], G. Gee[4], R. Kington[5], N. Lange[6], D. Makuc[7], P. Kraft[8], M. Phillips[9], R. Kwok[9], D. Maiese[9], D. Wagener[9], E. Ramos[2], C. M. Hamilton[9]* 1) Department of Preventive Medicine, USC, Los Angeles, CA; 2) NHGRI, Bethesda, MD; 3) University of Maryland, College Park, MD; 4) UCLA School of Public Health, Los Angeles, CA; 5) NIH, Bethesda, MD; 6) Schools of Medicine and Public Health, Harvard University, Belmont, MA; 7) National Center for Health Statistics, CDC, Hyattsville, MD; 8) Harvard School of Public Health, Boston, MA; 9) RTI International, RTP, NC.

The potential for cross-study comparisons in genome-wide association studies (GWAS) is severely restricted by the lack of standardized or comparable phenotypic and environmental measures. PhenX (consensus measures for Phenotypes and eXposures) is a consensus-building effort to choose high-priority phenotypic and environmental exposure measures which are of public health significance and suitable for GWAS. The goal of PhenX is to improve the ability of research groups to combine their data, thus increasing statistical power and the ability to detect genes associated with common complex diseases. The selected high-priority measures will be made available to the scientific community via the PhenX Toolkit. The PhenX Steering Committee selected Demographics as the first domain to be addressed by a Working Group (WG). The PhenX Demographics WG is composed of researchers whose expertise represents the wide breadth of the field. The selected demographics domain measures assess fifteen elements including: age; race; ethnicity; gender and ancestry. The Demographics WG recommended a set of measures and associated measurement protocols. Opinions on the proposed measures were sought from the research community through a web-based survey, the results of which were then used to define a small set of high priority measures. Measures were chosen on the basis of several criteria including: clearly defined; well established; broadly applicable; and a low burden to participants and investigators. The PhenX Steering Committee has identified 19 additional research domains to be addressed by PhenX Working Groups over the course of the three-year project. Supported by: NHGRI, Award No. 1U01 HG004597-01.

Bipolar disorder as presenting clinical feature associated with the 3243 AG mutation in the mitochondrial tRNA Leu(UUR) gene. *F. Scaglia[1], C. W. Brown[1], R. Diaz Millan[2], L. J. Wong[1]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) University of Guatemala School of Medicine, Guatemala City, Guatemala.

Mitochondrial cytopathies are a genetically, biochemically, and clinically heterogeneous group of disorders associated with abnormalities of oxidative phosphorylation that affect organs and tissues highly dependent on energy metabolism such as the central nervous system, the skeletal muscle and the heart. These disorders demonstrate a wide range of central nervous system involvement and may be accompanied by focal brain necrosis, dementia or static encephalopathy; however, it is increasingly recognized that they may be associated with psychiatric illness and in particular affective disorders. The 3243 AG mutation in the mitochondrial tRNALeu(UUR) gene has been associated with several clinical phenotypes including mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS), Leigh syndrome, progressive external ophthalmoplegia, and diabetes and deafness. Here we report a family carrying the common 3243 AG mutation and whose main presenting clinical feature was unusual behavior later characterized as bipolar disorder. The proband first presented at age 16 years with unusual behavior that was diagnosed as bipolar disorder. Subsequently, he developed multiorgan dysfunction that included seizure disorder, sensorineural hearing loss, short stature, and dilated cardiomyopathy and was found to harbor the 3243 AG mutation. His family history was relevant for bipolar disorder as the presenting clinical feature on his mother, maternal aunt and maternal grandmother who were also found to harbor this mutation. The atypical clinical presentation in this family illustrates that psychiatric illness may be associated with mitochondrial dysfunction expanding the clinical spectrum of mitochondrial cytopathies.

Estimate of the local FDR in genome-wide association studies. *J. Bukszar, E. J. van den Oord* Virginia Commonwealth University/ Medical College of Virginia Campus 410 North 12th Street Richmond, VA. 23298.

We present a method that estimates the individual effect sizes (IES) in genome-wide association studies. A novel and key element is that we use the real likelihood function of the multiple tests rather the one based on the frequently used mixture model. Interestingly enough, this latter one would result in fairly inaccurate estimate even for arbitrarily high sample size. Our IES estimates enable us to estimate the posterior probability that a marker has no effect, i.e. the local FDR, accurately. Further applications of IES, such as the estimate of Storeys q-values, will also be discussed.

Newborn screening in Fragile X syndrome. *F. Tassone[1,2], P. J. Hagerman[1,2], R. J. Hagerman[2,3]* 1) Department of Biochemistry and Molecular Medicine, University of California, School of Medicine, Davis, California, USA; 2) M.I.N.D. Institute, University of California Davis Medical Center, Sacramento, California, USA; 3) Department of Pediatrics, University of California, School of Medicine, Davis, California, USA.

Screening for the FMR1 mutations has been a topic of considerable discussion since the FMR1 gene was identified. However, Fragile X has not been recommended for newborn screening mainly because of the lack of an accurate screening test and of data on potential benefits. We have recently developed an improved PCR method for the identification of premutation and full mutation alleles for the FMR1 gene. The method is an inexpensive, accurate, and quick and can be performed on a number of sample templates including, and more importantly, blood spots. We have applied this method for international screening. Specifically, we have screened 5267 anonymous blood spot samples from newborn males from the center-northwest region of Spain. One important outcome from this study is that the frequency of premutation alleles (1 per 250) appears to be higher than previously reported. This is of importance, especially in view of the different phenotypic involvement observed in carriers of premutation alleles, including neurological problems such as FXTAS. Here, we present data on the frequency of premutation/full alleles found in this population and their size distribution. We have also used this technology to a pilot high risk screening program of individuals with autism and/ or intellectual disabilities and family members of a proband with fragile X initiated in Guatemala. This project is a prototype for future screening endeavors. Results from our pilot program in both Spain and Guatemala will lend strong support for implementing this technology for rapid screening to a much larger scale population screening.

L1c2a, the (African) Haplogroup With The Longest Mitochondrial Genome! *K. Ritchie[1], U. A. Perego[1,2], A. Achilli[2,3], N. Angerhofer[1], N. M. Myres[1], A. Torroni[2], S. R. Woodward[1]* 1) Sorenson Molec Genealogy Fndn, Salt Lake City, UT; 2) Dip. di Genetica e Microbiologia, Università di Pavia, Pavia, Italy; 3) Dip. di Biologia Cellulare e Ambientale, Università di Perugia, Perugia, Italy.

Haplotypes derived from the maternally-inherited mitochondrial DNA (mtDNA) control region are often employed as a first step in determining phylogenetic-relevant samples that could be selected for additional coding region testing. Using the currently defined world mtDNA haplogroup tree, researchers can assign these haplotypes to specific branches, paying particular attention to novel mutations that could assist in identifying new subclades. During a recent survey of the nearly 58000 mtDNA control region haplotypes currently present in the publicly accessible Sorenson Molecular Genealogy Foundation database, we observed a small number of mtDNAs (n=16) characterized by the presence of unusually long insertions of up to 200 bases. A small subset of these particularly long mtDNA haplotypes shared an identical insertion of 15 bases. Genealogical analysis combined with haplogroup prediction confirmed that these haplotypes shared a common African origin. Additionally, based on the pedigree data gathered, we determine the donors were not closely related. Moreover, through the analysis of complete mtDNA sequences, we conclude that the newly defined haplogroup is most likely of recent origin. As reported in this study, insertions of more than 10 bps are quite rare in the general population and in the published literature, thus providing an interesting case work in population and possibly future disease studies.

Comperhensive approach to autosomal recessive non-syndromic hearing loss in Iranian Population. *H. Najmabadi[1], C. Nishimura[2], N. Meyer[2], T. Yang[2], K. Kahrizi[1], N. Bazazzadegan[1], M. Mohseni[1], Y. Riazalhoseini[1], G. Asaadi Tehrani[1], A. Daneshi[3], M. Farhadi[3], S. Yahyavi[3], E. Taherzadeh[1], P. Imani[1], A. Anousheh[1], A. Nazeri[1], S. Abedini[1], N. Nikzat[1], S. Arzhangi[1], R. J. H. Smith[2]* 1) Gen Res Ctr, Univ Soc welfare & Rehab Sc, Tehran, Iran; 2) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa, IA, United States; 3) Research Center of Ear, Nose, Throat, and Head and Neck Surgery, Iran university of Medical sciences, Tehran, Iran.

Genetic testing for deafness in Iran is well established. The population is extremely heterogeneous, which means that ethnic-specific data are required. We have generated much of these data by screening over 2000 families segregating autosomal recessive non-syndromic deafness (ARNSD). All patients were screened for mutations in GJB2 and GJB6 (DFNB1), and if no mutations were identified, haplotypes were reconstructed by typing three short tandem repeat polymorphisms flanking 22 known ARNSD loci. In a subset of families, genome-wide linkage analysis was completed. Our data show that 16.7% of the Iranian population with ARNSHL segregates mutations in GJB2. The most prevalent mutation in this gene was 35delG, although more than 20 mutations have been identified, five of which are unique to the Iranian population. We also identified novel GJB2 mutation in an endogenous population segregating ADNSHL in village north of Iran. For approximately 30% of families, we have been able to establish a genetic cause for deafness. Over half have mutations in GJB2, and after GJB2, mutations in SLC26A4 and TECTA are most commonly detected. We have also found mutations in PJVK , TMC1 and USH1C, OTOF, MYOVIIA, VLGR1 and genes in our families. In addition, we have described a new syndrome, a contiguous gene deletion syndrome that involves both deafness and infertility in males. The data from the Iranian population attest to its diversity and contribute to the current body of knowledge regarding the deafness of genetics.

Genetic analysis of Iranian families with usher syndrome type 1, 2, 3. *K. Kahrizi[1], G. Asaadi Tehrani[2], S. Saketkhoo[2], N. Bazzazadegan[1], M. Mohseni[1], S. Arzhangi[1], R. J. H. Smith[3], H. Najmabadi[1]* 1) Genetics Research Ctr, GRC, USWR, Tehran, Iran; 2) Genetic Department, Science and Research Branch , Islamic Azad University; 3) Molecular Otolaryngology Research Laboratories , Department of Otolaryngology Head and Neck Surgery , University of Lowa , IA , United States.

Usher syndrome (USH) is an autosomal recessive hereditary disorder characterized by the association of sensorineural hearing loss, retinitis pigmentosa and vestibular dysfunction. It is clinically and genetically heterogeneous and at least 13 chromosomal loci are assigned to three clinical USH typed, namely USH1A-H, USH2A-H and USH3A. There are five known USH1 molecules, in addition, three USH2 genes and one USH3A gene have been identified. Worldwide USH1 and USH2 account for most of the usher syndrome cases with rare occurrence of USH3. In the present study, we performed linkage analysis using STR polymorphic markers for 33 consanguineous Iranian families to examine , all identified loci for USH1 (USH1A, USH1B, USH1C,USH1D,USH1E,USH1F,USH1G and USH1H) , all loci for USH2 (USH2A, USH2B, USH2C,USH2D) and USH3A . Our results showed that ten families linked to one of the loci related to USH1 or USH2: three families linked to DFNB12, two families linked to DFNB2, one family linked to DFNB23 and one family showed linkage for USH1C, also linkage analysis for USH2 loci showed that one family linked to USH2A, and two families linked to USH2C, in which concludes USH1D, USH1B, USH1F, USH1C, USH2A and USH2C. Mutation analysis for MYO7A gene in one family showed R150X: 444 C>T in all affected , also one deletion mutation identified in VLGR1b gene , furthermore mutation in exon 5, 463C>T, Arg155X for USH1C detected , and sequencing mutation analysis for other CDH23, PCDH15 and USH2A genes is performing. The present study suggests that mutations in CDH23 , MYO7A , causing non syndromic autosomal recessive deafness DFNB12 , DFNB2 and USH1D, are the two major components of causes for USH1, while USH1C, and SANS are less frequent causes, also VLGR1b should have more prevalent from other USH2 genes .

Carrier Frequency of SMA by Quantitative Analysis of the SMN1 deletion in the Iranian Population. *M. Hasanzad[1,2], M. Azad[3], K. Kahrizi[1], S. H. Tonekaboni[4], S. Nafisi[5], Z. Keyhanidoust[6], B. Shoja Saffar[1], A. Aghajani[1], S. H. Jamaldini[1], H. Najmabadi[1,3]* 1) Genetics Research Center, University of Social , Tehran, Tehran, Iran; 2) Islamic Azad University, Tehran Medical Branch, Tehran, Iran; 3) Kariminejad-Najmabadi Pathology & Genetics Center, Tehran, Iran; 4) Mofid Hospital,Tehran,Iran; 5) Shariati Hospital,Tehran, Iran; 6) Imam Khomeini Hospital, Tehran, Iran.

Spinal muscular atrophy (SMA) is a common neuromuscular disorder. The survival motor neuron (SMN) protein is encoded by two genes, the telomeric and centromeric SMN. This disease is caused by mutation in the telomeric copy of the SMN gene. Carrier frequency studies of SMA have been reported for various populations. Although no large-scale population-based studies of SMA have been performed in Iran, previous estimates have indicated that the incidence is much higher in the Iranian population compared to that of other populations, partly because of the high prevalence of consanguineous marriage. In this study, we use a reliable and highly sensitive quantitative real-time PCR assay with SYBR green I dye to detect the copy number of the SMN1 gene to determine the carrier frequency of SMA in 200 Iranians. The homozygous SMN1 deletion ratio among the patients was 0.00 and the hemizygous SMN1 deletion ratio among the parents of the patients ranged from 0.29 to 0.55. The Ct ratios of 46 persons among 200 normal individuals were within the carrier range of 0.31-0.57, revealing a carrier frequency of 20% in the Iranian population. Our data confirms that the SMA carrier frequency is much higher in the Iranian population compared to that reported for many other countries.

De novo copy number variations in children with sudden infant death. *G. A. Toruner[1,2], R. Kurvathi[2], R. Sugalski[2], L. Shulman[2], S. Twersky[2], P. Goldblatt Pearson[2], R. Tozzi[3], M. Schwalb[1,2], R. Wallerstein[2]* 1) The Genetics and Genetics Counseling Program,Dept of Pediatrics at The Joseph M. Sanzari Childrens Hospital,Hackensack University Medical Center, Hacksensack, NJ; 2) Institute of Genomic Medicine, Dept of Pediartics, UMDNJ - NJ Medical Sch, Newark, NJ; 3) Pediatric Center for Heart Disease ,Dept of Pediatrics at The Joseph M. Sanzari Childrens Hospital,Hackensack University Medical Center, Hackensack, NJ.

Background: Sudden death of an infant is a devastating event that needs an explanation. When an explanation cannot be found, the case is labeled as Sudden Infant Death Syndrome (SIDS) or Unclassified Infant Death (USID). The influence of genetic factors has been recognized for sudden infant death, but copy number variations (CNVs) as potential risk factors have not been evaluated yet. Methods: Twenty-seven families were enrolled in this study. The tissue specimens from deceased children were obtained and array based comparative genomic hybridization experiments (array-CGH) were performed on the genomic DNA isolated from these specimens using custom Agilent 4x44K arrays. Q-PCR experiments were performed to confirm the overlapping duplication and deletion region in two different cases. Results: A de-novo CNV is detected in three of twenty-seven cases (11%). In case 1, a ~3 Mb (chr8: 143,211,215- qter) duplication on 8q24.3-qter and a 4.4 Mb deletion on the 22q13.3-qter (chr 22: 45,047,068- qter) were detected. Subtelomeric chromosome analysis of the father and the surviving sibling of case 1 showed a balanced reciprocal translocation, 46,XY t(8;22)(q24.3;q13.3). A 240kb (chr 6: 26,139,810-26,380,787) duplication and a 1.9 Mb deletion (chr 6: 26,085,971-27,966,150) at chromosome 6p22 were found in cases 2 and 3 respectively. Array-CGH and conventional cytogenetic studies did not reveal the observed CNVs in the parents and the siblings of the cases 2 and 3. The detected CNVs in cases 2 and 3 encompassed several genes including the major histone cluster genes. Conclusion: Array-CGH analysis may be beneficial during the investigations after sudden infant death.

Polymorphism in Cyclooxygenases-2 (COX-2 / PTGS-2) and liver cancer in Chinese. *N. Tang[1,2], J. Y. Jiang[1], W. Yeo[3], P. S. Lai[4]* 1) Dept Chemical Pathology, Chinese Univ Hong Kong, Hong Kong, SAR, China; 2) Laboratory of Genetics of Disease Susceptibility, Li Ka Shing Institute of Health Sciences, Prince of Wales hospital, Hong Kong, SAR, China; 3) Dept of Clinical Oncology, The Chinese University of Hong Kong, Hong Kong, SAR, China; 4) Dept of Surgery, The Chinese University of Hong Kong, Hong Kong, SAR, China.

Hepatocellular carcinoma (HCC) is an important cancer in the Southern Chinese population and many are related to chronic HBV hepatitis and cirrhosis. The importance of the prostaglandin pathway in the carcinogenesis of HCC has been implicated by treatment of COX-2 inhibitors in animal models of HCC, where COX-2 inhibitor was protective against development of HCC. COX-2 is the inducible isoenzyme and we previously identified a putative functional SNP in the coding gene for COX-2, PTGS-2. Here we examined the association between this 3-UTR SNP and HCC in a Chinese patient sample. Genomic DNA was extracted from peripheral blood collected from 388 Chinese HBV-related HCC patients and 152 sex-matched controls (HBV carriers). This 3-UTR SNP (rs5275, Ex10+837 T/C) represents one of the 4 tagging SNPs we identified from the Han HapMap data. Genotyping was performed by PCR-RFLP as described in the references. There was a borderline association between rs5275 and HCC(p value of genotypic association=0.07 and allelic association = 0.04). The T allele was more prevalence among HCC patients (0.84 vs 0.78 in control). Previous studies of polymorphisms in PTGS-2 were largely confined to a promoter SNP -765G/C (rs20417), however this SNP was not polymorphic in Chinese with MAF less than 0.05. Therefore, we investigated other potential functional or tagging SNPs of this inducible COX gene. The 3-UTR SNP was a potential functional SNP located within a region which had been shown to influence mRNA stability. Furthermore, it had been associated with risk of lung cancer recently. We are expanding our sample size to further validate this association.

Molecular Mechanism and Characterization of Maternally Inherited Essential Hypertension. *S. W. Wang[1], Z. B. Li[1], Y. Q. Liu[1], H. Y. Zhu[1], Y. S. Zhao[1], C. Y. Lu[1], Y. H. Li[1], Y. Wen[1], M. X. Guan[2, 3]* 1) Geriatric Cardiology, Institute of Geriatric Cardiology, Chinese PLA General Hospital, Beijing, China; 2) Division of Human Genetics, Cincinnati Childrens Hospital Medical Center, 3333 Burnet Avenue, Cincinnati, OH 45229-3039, USA; 3) Deparment of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH, USA.

Objective:We aimed to observe the relationship between the mitochondrial tRNA mutation and the essential hypertension by examining the mutation of tRNA. We also wanted to explore the inherited signs and clinical characters of maternally inherited essential hypertension. Methods: We collected the clinical data subjects. We extracted DNA from subjects white blood cell, and amplificated the target fragment using the special primers. We then purified the PCR products, and then we directly sequenced them. We also made a comparative analysis of the collected data of the essential hypertension subjects who carried tRNA mutation and those who did not. Results: From the mutation analysis of mitochondrial DNA of 2,000 essential hypertensive subjects, we totally found 26 mutation sites in 57 subjects, in which 22 mutation sites were new. The most frequently occurrence of the mutation site was A4386G in tRNAGln gene. The onset ages of the individuals carrying the mutation were earlier than those who did not bear them. tRNA mutations significantly affected serum lipids, blood electrolyte, blood creatinine, blood urea nitrogen and heart structure and function. Most essential hypertensive patients had maternally inherited history, which fulfilled the feature of mitochondrial hereditary. Conclusion: Mitochondrial tRNA mutations might result in the change of their structure and function, and then damaged the blood metabolism, the balance of the blood electrolyte, the steady-state of the blood cells and the heart structure and function, which were involved in the progress of the essential hypertension. Part of the essential hypertension patients clinically presented the characters of maternal inheritance, which might be associated with the tRNA mutation.

Maternally inherited hypertension is associated with the mitochondrial tRNAIle A4295G mutation in a Chinese family. *Z. B. Li[1], S. W. Wang[1], Y. Q. Liu[1], L. Yang[2], M. X. Guan[2,3]* 1) Institute of Geriatric Cardiology, Chinese PLA General Hospital, Beijing, China; 2) Division of Human Genetics, Cincinnati Childrens Hospital Medical Center; 3) Deparment of Pediatrics, University of Cincinnati College of Medicine.

Objective: Mutations in mitochondrial DNA have been associated with cardiovascular disease. We report here the clinical, genetic, and molecular characterization of one three-generation Han Chinese family with maternally transmitted hypertension. Methods: Members of this Chinese family underwent a physical examination, laboratory assessment of cardiovascular disease risk factors, and routine electrocardiography. Genomic DNA was isolated from whole blood and the entire mitochondrial gene was amplified by PCR. PCR fragments were purified and subsequently analyzed by direct sequencing analysis. Results: Sequence analysis of the complete mitochondrial DNA in this pedigree revealed the presence of the known hypertension-associated tRNAIle A4295G mutation and 33 other variants, belonging to the Asian haplogroup D4j. The A4295G mutation, which is extraordinarily conserved from bacteria to human mitochondria, is located at immediately 30 end to the anticodon, corresponding to conventional position 37 of tRNAIle. The occurrence of the A4295G mutation in several genetically unrelated pedigrees affected by cardiovascular disease but the absence of 242 Chinese controls strongly indicates that this mutation is involved in the pathogenesis of cardiovascular disease. Of other variants, the tRNAGlu A14693G and ND1 G11696A mutations were implicated to be associated with other mitochondrial disorders. The A14693G mutation, which is a highly conserved nucleoside at the TwC-loop of tRNAGlu, has been implicated to be important for tRNA structure and function. Furthermore, the ND4 G11696A mutation was associated with Leber s hereditary optic neuropathy. Conclusion: The combination of the A4295G mutation in the tRNAIle gene with the ND4 G11696A mutation and tRNAGlu A14693G mutation may contribute to the high penetrance of hypertension in this Chinese family.

Effect of voltage-dependent anion channel on the apoptosis of cell lines carrying mitochondrial DNA A4263G mutation. *S. Wang[1], Y. Q. Liu[1], Z. B. Li[1], Y. li[1], H. Xu[2], Y. Wen[1], L. Wang[1], R. Chen[1], M. H. Liu[1], M. X. Guan[3]* 1) Institute of Geriatric Cardiology, Chinese PLA General Hospital, Beijing, China; 2) Military Medical Science Academy of the Chinese PLA; 3) Cincinnati Childrens Hospital Medical Center, Division of Human Genetics.

Objective: In this report, we studied the effect of voltage-dependent anion channel (VDAC) on the apoptosis of the cell lines carrying mitochondrial DNA A4263G mutation. Methods: We established lymphoblastoid cell lines from 3 symptomatic and 1 aymptomatic hypertension individuals in the family carrying A4263G mutation compared with 3 control cell lines. The mitochondrial potential was detected by flow cytometry and the co-localization of VDAC and Bax was evaluated by confocal microscopy. Results: The results showed that the expression of VDAC and Bax in individuals carrying mtDNA A4263G mutation increased compared with control group, while the expression of small conductance calcium dependant potassium (sKCa) had no change. Flow cytometry showed mitochondrial potential (m) of cell lines from individuals carrying mtDNA A4263G mutation decreased 32% compared with control group (P0.05) and this difference was attenuated by Cyclosporin A (CsA), which was a blocker of VDAC. The confocal scanning showed co-localization of VDAC/Bax on the membrane of mitochondrial in individuals carrying mtDNA A4263G mutation, while the combination was not seen on control group. Conclusion: In conclusion, the change of expression of mitochondrial VDAC and subcellular localization of VDAC/Bax leads to the significant increase of mitochondrial permeability and apoptosis of cell lines carrying mtDNA A4263G mutations.

P-values may not provide optimal ranks of true associations in whole-genome scans. *D. V. Zaykin[1], L. A. Zhivotovsky[2], W. Czika[3], S. Shao[3], R. D. Wolfinger[3]* 1) Dept Biostatistics, NIEHS/NIH, Res Triangle Park, NC; 2) Vavilov Institute of General Genetics, Moscow, Russia; 3) SAS Institute, Inc., NC.

In the context of a large collection of statistical genetics tests in which the number of true associations (TAs) is small, we study the distribution of the ranks of TAs among the false associations (FAs). We investigate the relative efficiency of ranking measures and how many "best" results need to be screened to cover TAs with high probability, using a few different ways of assessing significance and adjusting for multiple testing. This way of looking at the problem can aid in optimally following up on initial significant findings and in planning of future large scale experiments. Genome-wide expression studies and whole-genome association scans are prominent examples where the number of tests can range from tens to hundreds of thousands. The measure of association with a trait of interest could be a p-value, possibly weighted towards the effect size. Under a wide set of conditions, we study rank distribution of the TA p-values amongst a large number of FAs, while taking into account the impact of multiple testing adjustments. We demonstrate theoretically, and confirm by simulations, that there are situations where sorting results by the effect size produces better ranks of TAs than the usual sorting by a test statistic value, or by a p-value.

Replication of candidate genes, locus-wide association study for IQ. *T. S. Rizzi[1], A. Arias-Vásquez[2], B. Neale[3], J. Lasky-Su[12], R. Anney[4], P. Asherson[3], E. Sonuga-Barke[5], M. During the past decades, a handful of candidate gene association and genome-wide studies of specific and general cognitive abilities have been reported for human intelligence. We therefore decided to conduct a replication effort of all currently reported genomic regions of interest for general intelligence. Participants were 947 families from the International Multi-center ADHD Genetics(IMAGE) project. 13.290 SNPs within previously reported candidate genes and genomic regions for human intelligence were analyzed. Six associations yielded $p10^{-5}$ and are located in chromosome 6. Most of the candidate genes did not present significant p-values with the exception of DTNBP1 and APOE ($p10^{-3}$). The function of the most significant genes is not completely clear, yet, and additional studies are needed to validate these results.

Genetic variations of CYP2C9 in 724 Japanese individuals and their impacts on the antihypertensive effects of losartan. *T. Yin[1 2], K. Maekawa[3], K. Kamide[4], Y. Saito[3], H. Hanada[2], K. Miyashita[5], Y. Kokubo[6], Y. Akaiwa[5], R. Otsubo[5], K. Nagatsuka[5], T. Otsuki[5], T. Horio[4], S. Takiuchi[4], Y. Kawano[4], K. Minematsu[5], H. Naritomi[5], H. Tomoike[6], J. Sawada[3], T. Miyata[2]* 1) Institute of Geriatric Cardiology, General Hospital of People's Liberation Army, Beijing, China; 2) Research Institute, National Cardiovascular Center, Osaka, Japan; 3) Division of Functional Biochemistry and Genomics, National Institute of Health Sciences, Tokyo, Japan; 4) Division of Hypertension and Nephrology, Department of Medicine, National Cardiovascular Center, Osaka, Japan; 5) Cerebrovascular Division, Department of Medicine, National Cardiovascular Center, Osaka, Japan; 6) Department of Preventive Cardiology, National Cardiovascular Center, Osaka, Japan.

CYP2C9, a drug-metabolizing enzyme, converts losartan, an angiotensin II receptor blocker, to its active form for the antihypertensive effect. We resequenced CYP2C9 in 724 Japanese individuals including 39 hypertensive patients under the treatment of losartan. Of two novel missense mutations identified, the Arg132Gln variant showed a five-fold lower intrinsic clearance toward diclofenac when expressed in a baculovirus-insect cell system, while the Arg335Gln variant had no substantial effect. Several known missense variations were also found, and approximately 7% of the Japanese individuals (53 out of 724) carried either one of the deleterious alleles (CYP2C9*3, *13, *14, *30, and Arg132Gln) as heterozygotes. After 3 months of losartan treatment, the systolic blood pressure was not lowered in two patients with CYP2C9*1/*30, suggesting their impaired in vivo CYP2C9 activity. CYP2C9*30 might be associated with the diminished response to antihypertensive effects of losartan.

New Mutations Identified in Hermansky Pudlak Syndrome, Subtype 3 and Case Reports of Two Children With This Subtype. *G. A. Golas, R. Hess, A. Helip-Wooley, M. Huizing, R. Fischer, K. O'Brien, T. Markello, W. Westbroek, W. A. Gahl* Medical Genetics Branch NHGRI/NIH 10 Center Drive Bethesda, Md 20892.

Hermansky Pudlak Syndrome (HPS) is an autosomal recessive disdorder exhibiting both genetic and clinical heterogeneity with 8 distinct subtypes identified at specific loci, and characterized by oculocutaneous albinism, a bleeding diathesis, and variably, in some subtypes, pulmonary fibrosis and granulomatous colitis. We have diagnosed and described the clinical and molecular findings of 29 patients with HPS 3 in a cohort of 232 individuals with HPS studied in the NIH protocol 95-HG-0093. Analysis of gene map locus 3q24 is reported here and revealed 19 different mutations: 5 with an Ashkenazi Jewish mutation in the homozygous state; 9 with the central Puerto Rican HPS mutation in a homozygous state; and 15 others carrying 17 varied mutations, 12 of which are novel and unpublished. Two unrelated children, ages 7 and 10, diagnosed with HPS 3, confirm the previously-documented milder clinical phenotype of HPS 3, reflecting near normal skin/hair hypopigmentation, typical ocular findings, and only a very mild bleeding tendency. Neither had any significant gastrointestinal involvement and both are too young to exhibit the pulmonary fibrosis which characterizes subtypes 1 and 4, not HPS 3. Patient 1, of consanguineous French Canadian parents, has blonde hair, blue eyes, pale skin, visual acuity 20/160-250, nystagmus, photophobia, easy bruisability and a history of one minor nosebleed. A chin laceration requiring sutures had no prolonged bleeding. Patient 2, of nonconsanguineous Jewish and Irish/French/German parents, has brown eyes, brown hair, olive skin, nystagmus, visual acuity of 20/60-80, easy bruisability, and a history of two episodes of epistaxis controlled with intranasal DDAVP. Identification of a milder subtype of HPS without the prognosis of fatal pulmonary fibrosis in early adulthood can give enormous relief to parents of these children and guide management of their milder bleeding manifestations.

Histone Deacetylase Inhibitors Differ in Regulating Cardiac Dysfunction in Response to Pressure Overloaded. *J. Ma[1,2], T. Minamino[2], Y. Asano[2], Y. Liao[2], M. Kitakaze[3], S. Wang[1]* 1) Institute of Geriatric Cardiology, Chinese People's Liberation Army General Hospital, Beijing, China; 2) Department of Cardiovascular Medicine , Osaka University Graduate School of Medicine, Osaka, Japan; 3) Department of Cardiovascular Medicine , National Cardiovascular Center, Osaka, Japan.

Recent work has uncovered that histone acetylation might work as a nodal point in the signal network for gene regulation in hypertrophic myocardium, moreover, histone deacetylase(HDAC) inhibitors might hold promise as potential therapeutic agents in hypertrophic heart disease. However differential class effects of HDAC inhibitors on cardiac dysfunction in response to pressure overload have not been fully elucidated. In this study, we tested the effects of 4 types of HDAC inhibitors, trichostatin A (TSA) ,valproic acid (VPA), 4-Sodium phenylbutyrate (PBA), and butyrate acid (BS). All the 4 inhibitors successfully inhibited HDAC total activity both in vivo and in vitro. Individual HDAC activity assay showed rather than class IIa members (HDAC 4 and 7), PBA and BS predominantly inhibit classIHDACs (HDAC2 and 8), whereas VPA and TSA inhibit them all to a similar extent. To investigate their effects on cardiac function, transverse aortic constriction (TAC) operation was performed on C57BL mice. Cardiac hypertrophy and dysfunction induced by TAC for 6 weeks were significantly blunted by administrations of TSA and VPA, as reported previously. In contrast, PBA and BS treatments unexpectedly exaggerated cardiac remodeling and dysfunction indicated by histological and echocardiogram results. Invasive hemodynamic measurements demonstrated higher LV end diastolic pressure (PBA:31.0, BS: 29.9, vehicle: 15.5 mmHg, $p<0.001$) and lower contractivity index (PBA:120.8, BS: 118.7, vehicle:160.4, $p<0.01$). Kaplan-Meier analysis also revealed significantly lower survival rate (PBA: 32.7%, BS: 30.8%, vehicle: 66.7%, $p<0.001$). Together, these data suggest that PBA and BS accelerate load-induced hypertrophy and cardiac dysfunction and increase mortality, whereas VPA and TSA hold opposing effects. The differential regulation pattern on HDACs might account for this.

JAZF1 is a novel risk gene for type 2 diabetes: the DiaGen consortium. *J. T. Salonen[1], O. Kontkanen[1], P. Uimari[1], M. Pirskanen[1], J. Hyppönen[1], T.-P. Tuomainen[2], J. Luedemann[3], W. Kerner[4], U. Kowalik[5], D. Meyre[6], J. Delplanque[6], P. Froguel[6]* 1) Oy Jurilab Ltd, Kuopio, Finland; 2) University of Kuopio, Kuopio, Finland; 3) Ernst Moritz Arndt University, Greifswald, Germany; 4) Center of Cardiology and Diabetes, Karlsburg, Germany; 5) Grochowski Hospital, Warsaw, Poland; 6) Institut Pasteur de Lille, Lille, France.

Progress in the development of genotyping technologies has resulted in a burst of genome wide association (GWA) studies identifying multiple new genetic loci associated with type 2 diabetes (T2D). Subsequent meta-analysis of the three GWAs followed by a large replication has brought our attention to at least six new gene regions having a modest effect on susceptibility to T2D. Following our GWA study DiaGen, we carried out a replication study of almost 1400 single nucleotide polymorphisms (SNPs) in 2706 individuals from France, Germany and Poland. The strongest evidence for association was detected in the previously identified TCF7L2, CDKAL1 and EXT2 loci, and in the CDKN2A - CDKN2B and HHEX - IDE regions. SNPs flanking the JAZF1 gene, the strongest new locus in the recent meta-analysis, showed a significant association with T2D (P = 2.24×10-8) after Bonferroni correction. Our present study provides further support for an association of the JAZF1 intron 1 region with T2D, and further elaborates the association of the JAZF1 upstream regulatory region with T2D. Our present results, together with the meta-analysis by Zeggini and co-workers suggest that JAZF1 is a gene that contributes to the predisposition and most likely to the etiology of T2D.

Replication study for the Wellcome Trust Case Control Consortium data in large-scaled Japanese rheumatoid arthritis case-control populations. *S. Tsukahara[1], K. Ikari[1], Y. Kochi[2], K. Yamamoto[2], N. Yasui[3], H. Inoue[4], M. Itakura[4], M. Hara[1], H. Yamanaka[1], N. Kamatani[1], S. Momohara[1]* 1) Inst of Rheumatology, Tokyo Women's Med Univ, Tokyo, Japan; 2) Dept of Allergy and Rheumatology, Graduate School of Medicine, the University of Tokyo, Tokyo, Japan; 3) Dept of Orthopedics, Inst of Health Biosciences, The University of Tokushima Graduate School, Tokushima, Japan; 4) Inst for Genome Research, The University of Tokushima, Tokushima, Japan.

INTRODUCTION. Rheumatoid arthritis (RA) is believed to be a complex disease that is influenced by both genetic and environmental factors. Recently, the Wellcome Trust Case Control Consortium (WTCCC) published the result of GWAS in a British population. In addition to SNPs within HLA region and PTPN22, nine SNPs were found to be associated with RA. Moreover, another SNP at 6q23, rs10499194, was reported to be associated with RA using GWAS in U.S., which is located 3.8kb from rs6920220, one of the nine associated SNPs. To replicate these findings in Japanese, we performed an association study using three independent cohort.

METHODS. Genotyping was performed using the TaqMan method. IORRA cohort, which included 1504 cases with 752 controls, was used for the first stage of the association study. When an association was found, two other cohort were used to evaluate the result; RIKEN/BioBank (1113 cases and 940 controls) and Tokushima (950 cases with 507 controls). Associations of the SNPs with RA were estimated by Chi-squared test and the results among independent cohort were combined with the use of the Mantel-Haenszel method.

RESULTS. We could not support the evidence of association between the nine WTCCC SNPs and RA (P= 0.09-0.77, rs6920220 was not polymorphic in a Japanese population). Though we found an association between rs10499194 at 6q23 and RA in the IORRA cohort (P= 0.039), the latter stage of the study revealed no association between them (combined P= 0.08).

CONCLUSION. We conclude that the nine WTCCC SNPs do not have big impact on RA susceptibility in Japanese.
