Knockdown of the ATR/CHEK1 pathway overcomes resistance to radiation therapy resulting from loss of distal 11q. *S. Gollin[1,2], M. Sankunny[1].* 1) Dept Human Genetics, Univ Pittsburgh GSPH, Pittsburgh, PA; 2) Univ Pittsburgh Cancer Institute, Pittsburgh PA.

One of the most common chromosomal alterations in carcinomas is distal 11q loss, which results from breakage at FRA11F (11q14.2) and/or rearrangement involving segmental duplications on distal 11q. We showed that breakage and rearrangement initiates breakage-fusion-bridge (BFB) cycles that result in 11q13 amplification and overexpression of most of the dozen or so genes in the amplicon, including *CCND1*. Although the literature indicates that 11q13 amplification leads to a poor prognosis, we demonstrated that the first step in the amplification process, distal 11q loss, results in a statistically significantly (p=0.0401) poor prognosis in a series of 42 oral cancer patients with a median followup 6.3 years. The poor outcome may be related to the laboratory observation that head and neck, non-small cell lung, and ovarian carcinoma cell lines with distal 11q loss measured by fluorescence *in situ* hybridization express loss of sensitivity to ionizing radiation (IR) at therapeutic or higher doses as assessed by clonogenic survival assay. Further, we showed that carcinoma cell lines with distal 11q loss have loss or haploinsufficiency for critical DNA damage response genes, including *ATM*, *MRE11A*, and *H2AFX*, a diminished DNA damage response, and overexpression of the ATR/CHEK1 pathway. Knockdown of CHEK1 by siRNA or a targeted CHEK1 small molecule inhibitor (Pfizer PF-00477736) in carcinoma cell lines with distal 11q loss substantially decreased colony formation in response to a single 2.5 Gy fraction of IR. Cell lines without distal 11q loss did not show differential radiosensitivity. These findings led to development of a biomarker for loss of sensitivity to IR (patent pending), to ongoing studies of additional types of carcinomas and investigation of whether these same therapeutically resistant cell lines show decreased sensitivity to other DNA damaging agents, including chemotherapeutic drugs. This biomarker may be useful as a prognostic marker that could be added to predictive personalized cancer genomic assays, some of which are already available, and as a companion diagnostic for CHEK1 small molecule inhibitors under development or in clinical trials.

COPY NUMBER ALTERATIONS IN MYELODYSPLASTIC SYNDROME. *X. Hu[1], D.J. Wolff[5], C. Verghese[2], H. Safah[2], M.M. Li[1,2,3,4].* 1) Louisiana Cancer Research Consortium; 2) Tulane Cancer Center; 3) Hayward Genetics Center; 4) Dept. of Pediatrics; Tulane Univ. Sch. Med, New Orleans, LA; 5) Medical University of South Carolina, Charleston, SC.

Myelodysplastic syndromes (MDS) are a group of heterogeneous myeloid neoplasms that range from indolent conditions with a near-normal life expectancy to acute myeloid leukemia (AML). A few chromosomal rearrangements are known to be associated with disease prognosis. However, 50 to 60% of the cases show normal cytogenetic results but considerably variable outcomes. We hypothesize that cryptic genomic copy number alterations (CNAs) may underlie the prognosis of MDS. We studied 36 patients with newly diagnosed MDS to assay cryptic genomic alterations using a custom designed cancer specific CGH microarray that targets over 400 cancer genes and over 100 cancer-associated genomic regions. We also studied 7 of the 36 cases using a SNP array to evaluate copy neutral loss of heterozygosity (CN-LOH) and cross platform variations. A total of 713 CNAs were detected in the 36 patients, including 413 deletions and 300 duplications. Cryptic deletions (156 kb - 5.9 Mb) were identified at one or both translocation breakpoints in 5 of the 6 cases with apparently balanced rearrangements. Although the CNAs were distributed throughout the whole genome, they were enriched in a few genes: partial or full deletion of the BLM (27.8%, 10/36) and REL (33.3%, 12/36) genes, and partial or full duplication of the PTCH1 (30.6%, 11/36), CSF1R (27.8%, 10/36), and AKT1 (25%, 9/36) genes. The SNP array identified all major cytogenetic alterations but missed some small CNAs. Interestingly, in a patient who showed monosomy 7 at diagnosis and normal karyotype at three-year follow-up, SNP array identified a CN-LOH of 7q at three-year follow-up. Our study demonstrates that cancer-specific microarray analysis in MDS patients reveals unrecognized CNAs that may allow risk stratification of these patients for appropriate therapeutic interventions.

Known and novel copy number alterations in GBM and their patterns of co-occurrence are revealed by GSVD comparison of array CGH data from patient-matched normal and tumor TCGA samples. *C. Lee[1], O. Alter[1,2,3].* 1) Department of Biomedical Engineering, The University of Texas at Austin, Austin, TX; 2) Institute of Cellular and Molecular Biology, The University of Texas at Austin, Austin, TX; 3) Institute of Computational Engineering and Sciences, The University of Texas at Austin, Austin, TX.

Glioblastoma multiforme (GBM) is the most common primary brain tumor in adults and is characterized by rapid growth, treatment resistance, and poor prognosis. Like other cancers, GBM tumors exhibit a range of copy number alterations (CNAs), many of which play roles in the pathogenesis of this disease. Here, we use the generalized singular value decomposition (GSVD) [1,2] to analyze array CGH data from 251 patient-matched normal and tumor samples from The Cancer Genome Atlas (TCGA). The GSVD simultaneously separates the two (normal and tumor) genome-wide copy number datasets into one set of “probelets” and two corresponding sets of “arraylets”. Each probelet represents a pattern of CNAs across the patients, and the two corresponding arraylets describe the corresponding patterns of CNAs in the normal and tumor genomes, respectively. We find that arraylets of significance in the normal datasets identify normal copy number variations (CNVs) in the human genome, and the corresponding probelets describe the distribution of these CNVs in the patients. One of these arraylets captures differences in X chromosome copy number, and the corresponding probelet separates male from female patients. More notably, we find that arraylets of almost exclusive significance in the tumor dataset identify known and novel CNAs prevalent only in tumors and describe their patterns of co-occurrence. The second most tumor-exclusive arraylet identifies most of the important, known CNAs that occur in at least 2% of GBM cases [3], including amplifications of MDM4, AKT3, PDGFRA, EGFR, CDK4, and MDM2, and deletions of CDKN2A/B and PTEN. This arraylet also identifies a frequent pattern of chromosome 7 gain associated with chromosome 9p and 10 loss, as well as several rare (observed in <5% of patients), previously unreported CNAs, including regions of 1p36.21 (containing the tumor suppressor PRDM2), 17q23.2 (containing the histone-associated protein TLK2), and 12p13.33 (containing the Rb-interacting protein KDM5A). Analysis of other tumor-exclusive arraylets reveal common but previously unreported amplifications of regions of 19q12 containing cyclin E1 (CCNE1) and 17q24.1 containing DDX5, which has been implicated in the pathogenesis of other human cancers. A novel complex chromosomal change in a chronic myelomonocytic leukemia with marked ring sideroblasts and normoblastic dysmorphism. *H.O. Shah[1,3], W. Xu[1], A. Yuil[1], A. Pigal[1], M-L. Desormeaux[1], L. Hanna[2], J. Lin[1,3,4,5].* 1) Dept of Pathology, Cytogenetics, Nassau Univ Med Ctr, East Meadow, NY 11554; 2) Dept of Oncology, Nassau Univ Med Ctr, East Meadow, NY 11554; 3) Dept of Pathology, Health Sciences Center, State University of New York at Stony Brook, NY; 4) New York College of Osteopathic Medicine, NY; 5) American University of Caribbean School of Medicine, Netherlands Antilles/Coral Gables, FL.

Chronic myelomonocytic leukemia (CMML) is a clonal hematopoietic malignancy that is characterized by features of both a myeloproliferative neoplasm (MPN) and a myelodysplastic syndrome (MDS). Clonal cytogenetic abnormalities are found in 20-40% CMML, but none is specific. The most frequent recurring abnormalities include +8, -7/del(7q) and structural abnormalities of 12p. Here we report of a case of CMML with novel complex chromosomal changes. A 77 years old female had history of anemia. Peripheral blood (PB) analysis showed WBC 10.2 x 10^9/L with 22%; monocytes (absolute 2.2x10^9/L), 3% myeloblasts, 2.5% promyelocytes, 8% myelocytes, 7% metamyelocytes, 5% bands, 25% neutrophils, 3% eosinophils, 0.5% basophils and 24% lymphocytes, RBC 2.7 x 10^{12}/L, Hb 7.4 g/dL, Hct 22.7%, MCV 84.7 fL, RDW 33.5%, 8 nucleated RBC/100 WBC, and platelet 180x10^9/L. RBC showed marked anisopoikilocytosis and basophilic stippling. Other relevant laboratory assays showed iron 96 ug/dL, total iron binding capacity 268 ug/dL, ferritin 280 ng/mL, vitamin B12 1327 pg/mL and folate 6.7 pg/mL. Bone marrow was hyperplastic with an average of 95% cellularity and the differential revealed 40.0% normoblasts, 3.8% myeloblasts, 0.2% promyelocytes, 32.0% granulocytes, 4% monocytic cells, 18% lymphocytes and 2.0% eosinophils. Iron stain revealed ring sideroblasts in 60% of normoblasts. Flow cytometry analysis of bone marrow aspirates showed approximately 3% blasts expressing CD13, CD 33, CD34, CD117, HLA-DR and CD56. Theses features were consistent with CMML-1 (blasts <5% in PB). The patient died of intracranial hemorrhage one month later after the diagnosis. Cytogenetic study showed a novel complex genotype: 44-45,XX,der(2)t(2;10)(q33;q11.2),del(5)(q13q33),-7,add(10)(q11.2),-12,-13,dic(14;18)(p11.2;p11.2),+mar1[5],+mar2[5],mar3[cp20]. Chromosomal aberrations involving chromosome 2, 5, 7, 10, 12 and 13 have been described in MDS and/or acute myeloid leukemia (AML). The novel complex karyotype in this case might underlie a progression of refractory anemia with marked ring sideroblasts (RARS) to CMML and the poor prognosis.

Frequency, Molecular Pathology and Clinical Significance of Partial Chromosome 3 Alterations in Uveal Melanoma. *M.H. Abdel-Rahman[1, 2], B. Christopher[1], M. Faramawi[3], K. Said-Ahmed[1, 4], C. Cole[5], A. McFaddin[5], A. Ray-Chaudhury[6], N. Heerema[5, 6], F. Davidorf[1].* 1) Ophthalmology, The Ohio State University, Columbus, OH; 2) Clinical Cancer Genetics Program, Department of Internal Medicine, The Ohio State University, Columbus, OH; 3) Department of Epidemiology, School of Public Health, University of North Texas Health Science Center, Fort Worth, Texas; 4) Ophthalmology, Faculty of Medicine, Menoufiya University, Egypt; 5) James Cancer Hospital Cancer Cytogenetics Laboratory, The Ohio State University, Columbus, OH; 6) Pathology. The Ohio State University, Columbus, OH.

Purpose: Uveal melanoma (UM) is the most common primary intraocular tumors in adults. Monosomy of chromosome 3 (M3) is a common somatic alteration in UM. M3 is associated with aggressive disease and is currently used as a prognostic clinical marker. The clinical significance of partial chromosome 3 alterations (P3) is not clear. Also, the frequency of P3 in UM varies considerably in the published literature from 0 to 47%. The aims of the following study were to identify the frequency, molecular pathology and potential clinical significance of P3 in UM. Methods: 47 UMs with an average follow up of 35.3 months were included in the study. Fourteen patients had confirmed metastasis. Allelic imbalance/loss of heterozygosity of chromosome 3 markers was studied using microsatellite genotyping with 16 markers on chromosome 3, eight on each chromosome arm. Chromosomal alterations were assessed by conventional cytogenetics in 11 tumors and by comparative genomic hybridization (CGH) in an additional 13 cases. Results: M3 was detected in 26 (55.3%), P3 in 14 (29.8%) and heterodisomy of chromosome 3 in 7 (14.9%). In the 24 tumors with available cytogenetic/CGH, P3 was detected in 9/24 (37.5%) confirming the high frequency of P3 detected by genotyping. In these 24 tumors P3 was caused by both gains (5/9) and losses (4/9) of chromosome 3. Cytogenetics showed high frequency of complex chromosome 3 aberrations in tumors with P3. Out of the 14 tumors with confirmed metastasis 13 had M3 and only one showed P3. The P3 tumor with confirmed metastasis showed a bi-lobed tumor and a heterogenous genotype profile with part of the tumor showing M3 and other parts showing P3. Genotyping with limiting the assay to M3 was highly sensitive (92.9%) and specific (68.4%) for detection of aggressive UMs. Inclusion of P3 cases increased the sensitivity of the assay to 100% but considerably diminished its specificity. Conclusions: P3 alterations are rather common in UM and are commonly caused by complex chromosome 3 alterations leading to partial gains and/or partial losses of chromosome 3. P3, whether caused by partial gains or losses, is not likely to be associated with aggressive disease. Microsatellite based chromosome 3 genotyping with limiting the aggressive phenotype to M3 tumors is highly sensitive for detection of aggressive UM.

Cytogenetics in diagnosing and prognosing in 114 patients with multiple myeloma. *O. Altiok Clark[1], CF. Sargin Ozkaya[2], A. Timuragaoglu[3], B. Akkaya[4], L. Undar[3], I. Karadogan[3], F. Unal[2], F. Asik[2], G. Luleci[2], S. Berker Karauzum[2].* 1) Department of Medical Genetics, Akdeniz University Medical Faculty; 2) Department of Mediacal Biology and Genetics; 3) Department of Hematology; 4) Department of Pathology, Antalya, Turkey.

Recently, there has been a significant increase in patients diagnosed with Multiple Myeloma (MM) in hematology clinics. This increase is due largely to the use of cytogenetic and molecular cytogenetic methods as diagnostic tools which allow us for prognoses to be made for each patient. Between the years 2000-2010, bone marrow samples were collected at the Akdeniz University Medical Faculty Hospital from patients who were suspected of having MM. The patient's karyotypes were assessed using conventional cytogenetic and molecular cytogenetic methods. Of the karyotypes analyzed in 114 patients, 65% were found to be normal, while 32% of the analyzed karyotypes showed either numerical or structural changes, or a combination of the two. Some of these showed expected cytogenetic changes while others were found to contain complex chromosomal rearrangements. A small number of the patients (3%) showed novel, as-yet-unpublished karyotypes. Among the patients for which sufficient metaphases were not obtained, molecular cytogenetic methods allowed for the detection of certain abnormalities which were used to diagnose of MM. The relationship between the cytogenetic results and patient clinical appearance will be discussed in terms of how they relate to prognoses for patients with MM.

A Primate Specific Segmental Duplicated Superstructure and its Assocation with a Cluster of Genetic Diseases and Polymorphisms on Human Chromosome 17q. *D. Chen[1, 2], T. Miettinen[2], V. Leppä[2], O. Choi[3], A. Palotie[2,4, 5, 6], L. Peltonen[2,4, 5, 6], J. Saarela[2].* 1) University of California Irvine, Irvine, CA; 2) Institute for Molecular Medicine, Finland FIMM, Univ of Helsinki, Helsinki, Finland; 3) Dept of Human Genetics, Univ California, Los Angeles, Los Angeles, CA; 4) Dept of Clinical Chemistry, University of Helsinki, Helsinki; 5) Program in Medical and Population Genetics, Broad Instititute of Harvard and Massachusetts Insttitue of Technology, Cambridge, MA; 6) Wellcome Trust Sanger Institue, Wellcome Trust Genome Campus, Cambridge, UK.

Human Chromosome 17 is enriched for a variety of genetic diseases with underlying structural variations and chromosomal abnormalities. We have previously identified a segemental duplicated superstructure on human 17q. This structure appeared to primate specific. The human segmental duplicated superstructure on chromosome 17q contains 13 discrete domains. Corresponding segemntal duplicated superstructures found in genomes of chimpanzee, orangatun and rhesus monkey contain 19, 18 and 13 domains respectively. Each of domains are significantly enriched for homologous sequence fragments. Over 300 fragments pairs with homology greater than 90% and longer than 200bps are found exclusively within human superstructure. These homologous sequence pairs can serve as template sequences for non-allelic homologous recombination (NAHR) thereby contribute to chromosomal structural instability observed in human chromosome 17q. The longest homologous sequence pair is 49.3Kb in lenght with 97.4% homology. Several studies have implicated this particular homologous sequence pair are the template for the partial deletion of NF1 gene. This contribute to the high de novo mutation rate observed in neurofibromatosis type 1 patients. In addition, homologous fragments pairs contributing to the deletions of exone 1&2 of BRCA1 in familial breast cancer, deletion of 17q21.31 in Williams syndrome and inversion of 1Mb sequences in structural polymorphism in 17q are also part this segmental duplicated superstructure. Furthermore, we have also found two homologous and actively expressed retrotransposable elements (AK125814 and AK125932) to be highly associated with segmental duplicated superstructures found in all 4 primate genomes examined. In human chromosome 17, the two retrotransposable element are found to duplicated 34 times--all within the duplicated superstructure. Such association suggest a potential evolutionary relationship between retrotransposable elements and the segmental duplicated superstructure. In addition, we have conducted pair-wise sequence analysis on each of the possible domain pair in all four primate genomes. The results suggest the segmental duplicated superstructures are duplicated in tandem through evolutionary history. In conclusion, a cluster of genetic diseases found on human chromosome 17q appear to have a common evolutionary origin initiated from the transposition of retroelements resulting in the segmental duplicated superstructure.

Monosomy 10 mosaicism as an incidental finding in acute lymphocytic leukemia. *D. Curi[1], C. Stein[2], R. Hurley[1], R. Lebel[3], G. Kennedy[1].* 1) Pediatrics Department, SUNY Upstate Medical University, Syracuse, NY; 2) Pathology Department, SUNY Upstate Medical University, Syracuse, NY; 3) Pediatrics Department, Genetics Section, SUNY Upstate Medical University, Syracuse, NY.

A 3.5 year old previously healthy Caucasian male presented with bone pain, intermittent fever and decreasing appetite. Initial impression of the CBC was pancytopenia due to viral suppression. Bone marrow biopsy revealed a background karyotype of 46,XY with a cell line typical of acute lymphocytic leukemia (translocation 12;21), and another cell line 45,XY,-10 (monosomy 10) in 14% of cells. After treatment to clinical remission, repeat bone marrow study showed persistence of the monosomy 10 cell line (4%). Peripheral lymphocytes showed monosomy 10 in 3% of cells, and a skin biopsy confirmed constitutional mosaicism at a level of 5%. This child was the product of an uncomplicated pregnancy in a 42 year old G6P6->7 Caucasian woman who had one previous set of twins. On evaluation at age 4 years 2 months, the patient was not dysmorphic; he had a Vineland composite score of 96 (components ranging from 88 to 109). We have reviewed the literature and will present a discussion of the significance of these findings. Low-grade constitutional monosomy 10 mosaicism is apparently consistent with normal development, and may be encountered as an incidental finding.

415/W

Secondary Chromosome Aberrations in Non Hodgkin Lymphoma with IG/MYC Rearrangement Defined Burkitt Lymphoma from Diffuse Large B-cell Lymphoma: A Meta-analysis of Cytogenetic Data. *O. Davila, R. Garcia, N. Garay, M. Koller, Z. Lou, J. Liu, B. Elias, F. Valdez, M. Duc, P. Koduru, C.A. Tirado.* The UT Southwestern Medical Center-Department of Pathology Clinical Cytogenetics.

Burkitt lymphoma and diffuse large B-cell lymphoma are categorized as aggressive B-cell non-Hodgkin lymphomas in the WHO classification. The characteristic t(8;14)(q24;q32) of Burkitt lymphoma (BL), which fuses the MYC gene on 8q24 to the IgH loci on 14q32 or its variants, is also detected in up to 10% of diffuse large B-cell lymphoma (DLBCL) cases. Distinction between these two aggressive B-cell lymphomas is critical since they require different treatments. In the present study, we examined the Mitelman database (from 1982-2009) to determine whether additional recurrent chromosome aberrations (RCA) could reliably predict Burkitt lymphoma versus DLBCL. To differentiate BL from DLBCL, we searched for IGH/MYC rearrangement (R) having the following criteria: a defined morphological pattern (i.e., BL or DLBCL) in lymph node tissues with a B-lineage immunophenotype and no previous tumors. Each B-cell non-Hodgkin lymphoma group was assessed for RCA (gains, losses and rearrangements for all band regions). The Fisher Exact Test was used to compare differences in RCA between the two morphological groups, and a p value (2-tail) of less than .05 was considered significant. We identified a total of 151 and 56 unselected cases for BL and DLBCL respectively. Of 151 BL cases, a total of 116, 25 and 10 carried the t(8;14), t(8;22) and t(2;8) respectively. The most frequent events and frequencies in BL included: +7, 4.5% and -X, 3.9%. Likewise, of 56 samples for DLBCL, a total of 45, 8 and 3 cases were detected with t(8;14), t(8;22) and t(2;8) respectively. The most frequent events and frequencies in DLBCL were t(14;18), 26%; +12, 22%; +7 and +18, 18% respectively; +X, 16%; del(6)(q21) and +21, 10% respectively. When comparing between morphological groups, we found the following RCA significantly associated with DLBCL: +X, p = .006; 1p36 L, p = .015; -4, p = .006; 4q L, p = .001; 6q L, p = .0001; 6q21-27 L, p = .00007; +7, p = .001; 7q G, p = .000004; 7p G, p = .001; -9, p = .043; 9p L, p = .015; 9q L, p = .015; 12q G, p = .005; -15, p = .019; 15q15-q22 L, p = .008; 17p L, p = .042; +18, p = .0005; +21, p = .02 and 22q L, p = .007. In summary, our results demonstrate unique RCA in IGH/MYC positive non Hodgkin lymphoma that can be used to clearly defined BL from DLBCL.

"Comparison of Secondary Chromosome Aberrations between Follicular Lymphoma and Diffuse Large B-cell Lymphoma with t(14;18): REVIEW FROM THE MITELMAN DATA BASE". *N. Garay, R. Garcia, P. Koduru, C. Tirado*. UT Southwestern Medical Center, Department of Pathology.

The characteristic t(14;18)(q32;q21) present in up to 90% of follicular lymphoma (FL), also occurs in 20-30% of diffuse large B-cell lymphoma (DLBCL) cases. The translocation juxtaposes the BCL2 gene on 18q21 to the immunoglobulin heavy chain (IGH) on 14q32. The t(14;18) is not commonly present as a sole abnormality and secondary recurrent cytogenetic abnormalities (RCA) are commonly identified, suggesting RCA may play an important role in disease biology. In the present study, we have try to identify differences in RCA between follicular lymphoma and DLBCL with t(14;18). To differentiate FL from DLBCL, we searched the Mitelman database from 1987-2007 for t(14;18) with a defined morphological pattern (i.e., FL or DLBCL). All case karyotypes retrieved from the Mitelman database were previously published. Karyotypes from each morphological group were evaluated for RCA (chromosome gains, losses and rearrangements for all band regions). Results were then compared with the Fisher Exact Test to determine any significant differences in RCA between the two morphological groups. All p values were 2 sided and a p value less than 0.05 was considered significant. We have identified a total of 118 and 30 cases for FL and DLBCL respectively. Among the most frequent events and frequencies in FL included the following: +X (30.5%), +7 (32.2%), loss (L) of chromosome band region 1p36 (24.6%) and i(6)(p10), 8.4%. Whereas gain (G) of chromosome 7 (60%), -15 (26.7%), -4, +8, +11, +5 (20%) respectively, -Y (16.7%), loss of the long arm of chromosome 6 (16.7%) and +12 (13.3%) were more frequent in DLBCL. When comparing between the two morphological groups, the following RCA were significantly associated with DLBCL when compared to FL: 1p12-1p35 L, p = .0005; 1q12-q44 L, p = .017; -3, p = 0.021; 3q27 L, p = .032; -4, p = .0006; 9p22-24 L, .0006; -9, p = .001; +11, p = 0.028; 9q L, 0.027; 11q G, p = .0047; 13q14-34 G, p = .044; 15q L, p = .0068 and 22q13 L, p = .032. In conclusion, taken together, our findings indicate that DLBCL with t(14;18) carried a significantly different RCA profile compared to FL, and may be used to clearly distinguish it from FL with t(14;18). Keywords: FL, DLBCL, t(14;18), recurrent cytogenetic aberrations, RCA profile.

417/W

"Recurrent Aberrations in High Grade B-Cell Lymphomas with Concurrent 8q24/ MYC Rearrangements and t(14;18): REVIEW FROM THE MITELMAN DATA BASE". *R. Garcia, N. Uddin, W. Chen, I. Villalobos, K. Mark, O. Davila, P. Koduru, C. A. Tirado.* UT Southwestern, Dallas, TX 75235.

Concurrent 8q24/MYC rearrangements and t(14;18) occur rarely in high grade B-cell lymphomas, and are associated with an aggressive clinical outcome. These dual translocations or double-hit event (DH) in high grade lymphomas have been reported in transformed follicular lymphoma (FL), Burkitt lymphoma (BL), acute lymphoblastic leukemia (ALL), diffuse large B-cell lymphoma (DLBCL) and plasmablastic myeloma. The aim of this study was to determine frequent chromosome alterations with concurrent 8q24/ MYC and t(14;18) rearrangements. Simultaneous 8q24 alterations and t(14;18) with specific morphological patterns (BL, FL and DLBCL) were searched from the Mitelman database (1981-2007). We identified a total of 25, 35 and 39 cases for FL, BL and DLBCL, respectively. Each morphologic entity was first evaluated for frequent alterations. According to the 2008 WHO classification, double-hit BL cases are considered unclassifiable B-cell lymphoma with features intermediate with BL and DLBCL (referred to as INT hereafter). Results were then compared with the Fisher Exact Test and chi square to determine differences in different morphologic groups: In FL, the 9 most frequent alterations were +7, +12, t(2;8), +X, t(8;14), +21, t(8;22),-13 and -X. In DLBCL, the 9 most recurrent alterations included +7, t(8;22), t(8;14), +12, -15, +11, +21, +X and -X. Similarly, t(8;22), +7, +20, t(8;14),+8, +X, +12, t(2;8), +11 were the 9 most frequent aberrations in the INT group. Comparison between morphologic groups showed a higher frequency for t(8;22) in both INT and DLBCL than FL (18 and 15 vs. 4 events respectively); however, only INT showed a statistically significant association ($p < .05$). Other significant findings included the following: a higher frequency for the pair rearrangement +8/+20 in INT compared to both DLBCL and FL (5, 0, 0 respectively; $p < .05$); loss of 10q24-25 in DLBCL compared to FL (8 vs. 0 events respectively; p = .044); loss of Xp10-q28 in DLBCL compared to the INT group (6-7 vs. 0 events respectively; p = .032); loss of 9p11-24 in DLBCL compared to INT (6-11 vs. 0 respectively; p = .032 - .002) and gain of +20 in the INT group compared to DLBCL (6 vs. 0 respectively; p = .032). Taken together, findings in this study help to outline frequent alterations and statistically significant aberrations within specific morphologic groups between double-hit high grade B-cell lymphomas.

418/W

Myeloproliferative disease with cytogenetic biclonality and JAK2 mutation: molecular-cytogenetic characterization of an unusual case. *K. Geiersbach[1], N. Uddin[1], E.C. Kingsley[3], M. Salama[2], S. Shetty[1].* 1) Department of Clinical Cytogenetics, ARUP Laboratories, University of Utah, Salt Lake City, UT; 2) Department of Hematopathology, ARUP Laboratories, University of Utah, Salt Lake City, UT; 3) Comprehensive Cancer Centers of Nevada.

Biclonality in hematopoietic neoplasms is rare. SNP microarray can help to clarify cytogenetic findings and can also unmask genetic abnormalities not detected by traditional molecular cytogenetics. We present a case of essential thrombocytosis (ET) that transformed into a myeloproliferative disorder with myelodysplasia (MPD/MDS). The patient was a 74 year old male with a history of ET with JAK2 V617F mutation, previously treated with hydroxyurea, anagrelide and uracil mustard. He presented with transfusion dependent anemia and progressive splenomegaly. Due to his declining medical condition, aggressive treatment options were avoided and he was discharged on supportive therapy. His bone marrow was hypocellular with dysmyelopoiesis, ringed sideroblasts and 1 percent blasts; the core biopsy showed moderate fibrosis. Flow cytometry showed a left shifted myeloid lineage without increased blasts. Bone marrow and peripheral blood were submitted for cytogenetic evaluation. Both samples showed two separate clones, one with a 20q deletion and one with complex chromosomal rearrangements and clonal evolution. The karyotype was 46,XY,t(4;13;5)(q21;q14;q33)[13]/46,sl,t(2;7)(p13;q36)[2]/46,XY,del(20)(q11.2)[4]/46,XY[1]. FISH with PDGFRB (Veridex and Cytocell), D7S486, and D20S108 (Abbott Molecular) probes confirmed the cytogenetic findings. Deletions at each of the breakpoints of the three way 4;13;5 translocation were confirmed by high resolution CNV/SNP genomic microarray (Illumina OMNI1 Quad). The 5q deletion spanned the PDGFRB gene but did not involve the RPS14 gene. Array also showed copy neutral loss of heterozygosity of 22q12-qter. The chronology and exact significance of these abnormalities are difficult to decipher, but the combination of abnormalities is consistent with this patient's unfavorable outcome. The JAK2 V617F mutation has been shown to promote homologous recombination and mitotic instability, and in this case, JAK2 was likely an influential factor in generating the cytogenetically unrelated clones. Thorough characterization of unusual cases such as this may help elucidate the pathogenesis and natural history of MPD.

419/W

A novel t(9;22)(p24;p11.2) involving the *JAK2* locus in a pediatric case of acute lymphoblastic leukemia. *M. Hiemenz[1], W. Chen[2], L. Huang[4], C. Laborde[3], Z. Lou[1], F. Valdez[1], N. Winick[3], S. Patel[1], R. Smart[1], R. Garcia[1], P. Koduru[1], C. Tirado[1].* 1) Clinical Cytogenetics, Department of Pathology, UT Southwestern; 2) Hematopathology Division, Department of Pathology, UT Southwestern; 3) Hematology/Oncology, Department of Pediatrics, UT Southwestern; 4) Department of Cell Biology, UT Southwestern.

Rearrangements of *JAK2* are rare and have been described in a variety of hematological neoplasms including chronic myelogenous leukemia, acute megakaryoblastic leukemia, CD10+ B-cell acute lymphoblastic leukemia, T-cell ALL and chronic myeloproliferative disorders. Herein, we report a 14-year-old boy who presented to clinic with complaints of increasing weakness over the course of 3 weeks, decreased energy and decreased appetite. His parents also noted 1-2 weeks of pallor. Peripheral blood smear and bone marrow aspirate revealed a predominant population of medium-sized lymphoblasts that had variably irregular nuclei, moderately dispersed chromatin, inconspicuous nucleoli and scant cytoplasm. The marrow core biopsy was populated mainly by lymphoblasts with little normal trilineage hematopoiesis. Immunophenotypic analysis on peripheral blood revealed 80% lymphoblasts that were CD10(bright +), CD13(partial +), CD19(+), CD20(partial +), CD22(+), CD33(partial +), CD34(+), CD36(partial +), CD38(partial +), CD45(partial +), CD79a(+), HLA-DR(+), surface Ig(-), MPO(-), TdT(+). This immunophenotype was consistent with B lymphoblastic leukemia/lymphoma. He was treated with Children's Oncology Group's protocol (AALL0232) but without remission on day 29, and in remission after re-induction (day 36). Conventional cytogenetic studies revealed a t(9;22)(p24;q11.2) balanced translocation. Fluorescence in situ hybridization studies (FISH) using a 172 Kb bacterial artificial chromosome probe RTP1-927116 encompassing the whole Janus kinase 2 (*JAK2*) gene at 9p24, showed a split signal suggesting involvement of the *JAK2* gene with a partner on 22q11.2. To the best of our knowledge, this is one of the few cases with *JAK2* rearrangement in acute lymphoblastic leukemia. The clinical course in this case suggests that this *JAK2* rearrangement may portend an unfavorable prognosis. Ultimately, this patient received a bone marrow transplant as he had a 10/10 HLA matched sibling.

420/W

Genetic imbalances detected by Array CGH in a patient with undifferentiated embryonal sarcoma of the liver. *X. Hu[1,2], H. Chen[1,2], M. Jin[2], X. Wang[1], R. Zhang[1,3], S. Li[1], J. Niu[2].* 1) Department of Pediatrics, the University of Oklahoma Health Sciences Center, OK 73104; 2) Department of Internal Medicine, the First Hospital of Jilin University, Jilin, China 130021; 3) Department of Heamatology, the First Hospital of China Medical University, Shenyang, China 110001.

Undifferentiated embryonal sarcoma (UES) of the liver is an unusual malignancy of childhood. It represents a heterogeneous group of tumors. This group of tumors arises from mesenchymal tissues. In this report, we present a 19-year-old girl with UES of the liver. This patient had an abdominal distension and increasing abdominal girth. Computed tomography showed a massive lesion in the right lobe of the liver. The incision biopsy was performed and pathological findings were consistent with UES. Array comparative genomic hybridization (CGH) analysis was performed in this case to study genetic imbalances. The genomic profiles of this tumor showed significant losses and gains on multiple chromosomal regions. Within these regions, we found that several genes were tumor-related genes, including NIR (1p36.33), PITSLRE (1p36.33), HEN2 (1p13.1), CD9P1 (1p13.1), TRIM45 (1p13.1), B7H4 (1p13.1), HEN1 (1p13.1), PRG2 (2p25.3), TSSC1 (2p25.3), SPAK (2p24.3), AHRR (5p15.3), TCF7 (5q31.1), WNT8A (5q31.2), EGR1 (5q31.2), FGFR4 (5q35.2), HIN1 (5q35.3), MYC (8q24.21), NAIF1 (9q34.11), CIZ1 (9q34.11), IgH (14q32.33) and TP53 (17p13.1). To our knowledge, this is the first array CGH data of UES of the liver. It is unclear whether these regions play roles in tumor initiation or progression. Additional tumor samples have similar pathological features are required to validate our findings, which may provide diagnostic or prognostic values in UES.

421/W

Double hit lymphoma with both a MYC/IgL translocation and an IgH/BCL2 translocation. *J.M. Kogan[1,3], P.A. Kampmeier[2], A.A. Mandernach[1], A.M. Garcia[1], A.H. Sophian[1], D.A. Rita[1,3].* 1) Cytogenetics, ACL Laboratories, Rosemont, IL; 2) Pathology, Condell Medical Center, Libertyville, IL; 3) Clinical Genetics, Lutheran General Hospital, Park Ridge, IL.

"Double hit" lymphomas are rare and aggressive B-cell lymphomas with features of both Burkitt lymphoma and diffuse large B-cell lymphoma. Although these lymphomas often have complex cytogenetic abnormalities, they harbor characteristic chromosome rearrangements that may be readily identified in the cytogenetics laboratory, thus assisting in achieving a pathologic diagnosis. Specifically, they carry rearrangements involving the MYC gene on chromosome 8 as well as translocations between the IgH gene on chromosome 14 and the BCL2 gene on chromosome 18.

We present a patient with a near tetraploid complex karyotype containing both the t(8;22) and t(14;18). A 55 year old male presented with jaundice, weight loss, abdominal pain, and right testicular swelling. Imaging studies revealed a large abdominal and retroperitoneal mass with associated retroperitoneal and iliac chain adenopathy and a right testicular mass. Orchidectomy and biopsies of the bone marrow demonstrated a lymphoid neoplasm comprised of medium to large sized cells with round to oval nuclei, finely dispersed chromatin, prominent nucleoli, and numerous mitotic figures and apoptotic bodies. Immunophenotyping demonstrated a B lineage neoplasm positive for CD19, PAX5, CD10, MUM1 and BCL2 with partial expression of CD20 and TdT and lambda light chain restriction. Final bone marrow karyotype was 86,XXYY,-2,-3,-4,i(6)(p10)x2,der(8)t(8;22)(q24;q11.2),t(8;22)(q24;q11.2)x2,-10,der(13)t(1;13)(q25;q14)x2,t(14;18)(q32;q21.3)x2,-15,-16,-17,+20[4]/86,sl,+7,-20[6]/85,sdl1,-9[9]/46,XY[1]. FISH analysis results for MYC rearrangements and for the IgH/BCL2 rearrangement supported the chromosome findings.

Although morphology and immunophenotyping were indeterminate, chromosome analysis revealed the diagnosis. The near-tetraploid complex karyotype with the classic 8;22 and 14;18 translocations pointed to a diagnosis consistent with the WHO classification of B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma. This entity, also known as a "double hit" lymphoma, is an underrecognized, often puzzling neoplasm with a very poor prognosis. Chromosome and FISH analysis play a very important role in the diagnosis of this rare neoplasm.

422/W

Copy number changes in the patients with the Philadelphia chromosome (Ph+) by using oligoarray CGH. *J. Lee, X. Lu, X. Wang, Y. Kim.* Dept Pediatrics, OUHSC, Oklahoma City, OK.

Chronic myeloid leukemia (CML) is characterized by BCR/ABL fusion gene, usually a consequence of the Philadelphia (Ph+) chromosome due to the t(9;22)(q34;q11.2). However, there is diversity in the clinical course of the disease that may be frequently associated with genetic heterogeneity. Effort has been made to find prognostic genetic marker with limited success. Array CGH technology has been proved to be a powerful tool to identify subtle genomic segmental alterations, either loss or gain of genetic material. These changes may disclose presence of gene or genes that may play very important roles in disease initiation, progression, or treatment outcome. To investigate whether subtle chromosomal changes is commonly present or not in CML patients, a pilot study of 20 Philadelphia chromosome positive (Ph+) patients was carried out using high density whole genome oligoarray CGH analysis. Five out of these 20 cases had copy number changes, including a loss of 9q34, 15q25.3 and 15q13, and a gain of 7p21.1-p15.3, and 22q11.2. The findings demonstrated that the subtle chromosomal changes are relatively common in CML patients with Ph+ chromosome and the clinical significance of these findings need to be determined in the large patient population studies, especially the newly discovered regions.

423/W

Gene Amplification in Acute Myeloid Leukemia - Two Case Reports. *J. Liu[1], K. Vij[1], C.N. Abboud[2,3], G.L. Uy[2,3], D.M. Lenmann[1], J.Y. Bauer[1], S. Kulkarni[1,3]*. 1) Cytoengomics and Molecular Pathology, Department of Pathology and Immunology, Washington University School of Medicine in St. Louis, MO 63108; 2) Division of Oncology, Department of Internal Medicine, Washington University School of Medicine in St. Louis, MO 63108; 3) Siteman Cancer Center at Barnes Jewish Hospital and Washington University School of Medicine.

Gene amplification allows over-expression of oncogenes that presumably confers a growth advantage to the neoplastic cells and is known to be associated with rapid progression and poor prognosis. It is seen frequently in solid tumors but in only 1% of acute myeloid leukemia (AML) with abnormal cytogenetic findings. The most commonly involved genes in AML are *c-MYC* followed by *MLL* and *AML1*. Cytogenetically, gene amplification is manifested as extrachromosomal double minutes (dmin), intrachromosomal homogeneously staining regions (hsr), or marker chromosomes. Here we report the clinical, hematopathologic, molecular genetic, and cytogenetic findings in two cases of newly diagnosed AML with the presence of gene amplification. Patient 1 is a 57-year-old male with blasts in peripheral blood and low hemoglobin, bone marrow biopsy was hypercellular consistent with AML with maturation (FAB M2). Chromosome analysis exhibited complex aberrant karyotype with double minutes. Fluorescence in situ hybridization (FISH) showed amplification of the *c-MYC*. Mutation testing for *JAK2, FLT3, and NPM1* were all negative, qRT-PCR showed no evidence of *BCR/ABL1* or *PML/RARA* fusion. This patient was treated with induction therapy consisting of idarubicin and cytarabin, a follow-up showed a normocellular bone marrow with no increase in blasts, chromosomal abnormalities persisted but without double minutes. Patient 2 is a 47-year old male with pancytopenia, low hemoglobin and platelets, bone marrow biopsy was consistent with AML-M2 based on cell morphology. Chromosome analysis revealed multiple numerical and structural aberrations involving chromosome 11q, and FISH showed amplification of the *MLL* as well as multiple copies of *MYC, BCR, ABL1, PML, RARA*, and *IGH*, indicative of low-level hyperdiploidy. This patient's primary AML never achieved remission after many attempts of various therapies, and bone marrow transplant was finally performed. We propose that gene amplification in hematological malignancies may not be a rare event, identification of target genes, especially unknown genes, of amplification is important for understanding the tumorigenesis and can be useful for selection of individual cancer therapy; however, the frequency and clinical correlations of gene amplification in leukemia require careful investigation, since the cryptic amplification may not generally provoke confirmatory FISH studies.

Identification of chromosome 3 aneuploidy in a rare primary yolk sac tumor of the lung using FISH analysis. *M.J. Macera[1,2], S. Arora[2], W. Thelmo[3], A. Afaf[3], P. Chandra[2], V. Tak[4], A. Babu[1,2]*. 1) Division of Molecular Medicine & Genetics; 2) Department of Medicine; 3) Department of Pathology; 4) Department of Surgery, Wyckoff Heights Medical Center, Brooklyn, NY.

A 48-year-old women with a dry cough and occasional hemoptysis for 3 months arrived at our hospital. She had a 10-pack a year smoking history with no alcohol or drug use. Chest Radiograph and CT with contrast confirmed the presence of a large 10 x 12 cm soft tissue mass in the lower left lobe and a 4 x 6 cm mass in the upper right lobe originally believed to be a cyst. The larger left mass was mostly necrotic and only a few areas demonstrated solid patterns and focal papillary features were seen. One of three lymph nodes showed focus of metastasis. The tumor was negative for TTF-1, Cdx-2, Ck7 and CK20. It was focally positive for Oct3/4, strongly positive for Ki-67 and negative for CD34; thus identifying a primordial germ cell origin. Extragonadal germ cell tumors are rare and it is even more unusual to have a primary tumor in the lung with no evidence of gonadal involvement. The patient was started on platinum based chemotherapy, after which the mass in the right lung began to grow and was removed 8 months later. The more recent tumor showed an organoid to solid and glandular pattern and one fortuitous area demonstrating a Schiller-Duval body, thus re-establishing the yolk sac tumor origin. FISH analysis was done on sections from the initial tumor using the probe set (Abbott Molecular) containing probes for cep 3, cep 7, 9p16, and cep 17. In all cells analyzed, cep 3 was present in at least three copies, with a maxium number of 10 copies and a mean of 4.5 copies. Copies of the other three probes were represented at the same copy number, suggesting probable polyploidy or present in fewer copies, mean of three other probes combined 2.7, suggesting a chromosome 3 aneuploidy. In all cells, chromosome 3 was over represented. It is interesting to note that the Oct3/4 protein, a marker for primordial germ cells, reacts with Sox-2, among others, to form a regulatory complex needed for the pleuripotency of primitive embryonic cells. Sox-2 is located at 3q26.3-q27. A repeat FISH analysis of the second tumor gave similar results that were suggestive of a metastatic origin. The patient is scheduled for additional chemotherapy and is doing remarkably well.

An unusual presentation of an extraskeletal Ewing sarcoma with atypical cytogenetic findings. *J.J.D. Morrissette[1], G.E. Halligan[2], A. McKenzie[2], E. Geller[3], J.P. de Chadarévian[4]*. 1) Dept Pathology, University of Pennsylvania, School of Medicine, Philadelphia, PA; 2) Department of Pediatrics, Section of Oncology, St Christopher's Hospital for Children, Philadelphia, PA; 3) Department of Radiology, St Christopher's Hospital for Children, Philadelphia, PA; 4) Department of Pathology and Laboratory Medicine, St Christopher's Hospital for Children, Philadelphia, PA.

Ewing sarcoma is a soft tissue tumor derived from neural crest cells and is classified as a primative neuroectodermal tumor of the soft tissue. Although most Ewing sarcomas have skelatal involvement, rare presentations of extra-skeletal/extraocceous Ewing sarcoma have been described. Genetically all types of EWS are similar, in that they involve translocations between the EWS gene on 22q12 and various partners. We describe a child with a progressively enlarging scalp lesion that upon resection was identified as an extraosseous Ewing sarcoma by histomorphology. Conventional cytogenetics revealed a deletion of the long arm of chromosome 10 and an apparent deletion of 22q12. FISH studied using the EWSR1 break-apart probe revealed that the 3' region of the EWSR1 locus was deleted in 95% of cells, and that the entire EWSR1 locus was missing in 5% of cells. Array comparative genomic hybridization (aCGH) revealed the deletion on 10q to be interstitial and a mosaic pattern of 22q12 deletion.

426/W

Detection of chromosome abnormalities in Multiple Myeloma using arrayCGH. *A. Patel[1], P. Eng[1], D. Vo[1], J. Taylor[2], J. Chang[2], SW. Cheung[1]*. 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Methodist Hospital, Houston, TX.

Multiple myeloma is presently an incurable disease characterized by a proliferation of malignant plasma cells (PC) and a subsequent overabundance of monoclonal paraprotein. Malignant PCs are characterized by complex genetic aberrations suggesting genomic instability. Several recurrent genetic abnormalities have been identified and a number of these, including t(4;14), 17p13 deletion, 1q amplification, and hypodiploid karyotype, However chromosome abnormalities are only detected in 30-40% of malignant PCs due to a low mitotic index in culture. Recently FISH analysis has allowed for identification of additional submicroscopic abnormalities but there still exists limitations in it use. Array-comparative genomic hybridization (array-CGH) negates many of the limitations of conventional chromosome and FISH analysis. It allows for a genome wide analysis of copy number changes at a high resolution. In this study we compared the standard chromosome and FISH analysis of malignant PC cells to array-CGH using a custom designed 44,000K Agilent array. In a preliminary study, 5 malignant PCs with normal cytogenetics showed copy number abnormalities by array-CGH. Additional data on more samples will be presented.

427/W

Genomic characterization of a recurrent translocation that is associated with myeloproliferative neoplasm (MPN) blast phase progression in a mouse model. *Z. Qi[1], C. Smith[2], M. LeBeau[3], E. Passegue[2], R. Barbeau[4], C. Eisley[4], A. Barczak[4], N. Shah[2], J. Yu[1]*. 1) Department of Laboratory Medicine, University of California San Francisco, San Francisco, CA; 2) Department of Medicine, University of California San Francisco, San Francisco, CA; 3) Section of Hematology/Oncology and the Cancer Research Center, University of Chicago, Chicago, IL; 4) Department of Medicine, Lung Biology Center, University of California San Francisco, San Francisco, CA.

MPN progression from chronic phase to blast phase is believed to involve the accumulation of genomic/genetic alteration(s). The murine MPN associated with JunB-deficiency morphologically resembles chronic phase chronic myeloid leukemia (CML). In contrast to most murine models of CML, blastic phase transformation has been observed in 18% of JunB-deficient mice. Interestingly, leukemic cells from 2/5 JunB-deficient mice that had spectral karyotype analysis performed at the time of blastic phase progression were found to have evolved a clonal translocation between chromosomes 1 and 17. In an effort to characterize the genes located at the sites of the chromosome breakpoints, we first isolated the breakpoint regions of the translocation using chromosome microdissection technology. We further characterized these regions with FISH and mouse chromosomes 1- and 17-specific high-resolution CGH arrays (Roche NimbleGen). We found that the translocation was unbalanced, involving a 1.94Mb and a 1.06Mb deletions on mouse translocation derivative chromosomes 1 and 17, respectively. A total of 16 predicted genes and 5 known genes are involved in the deletion/translocation breakpoint regions. We further identified human homologues of the mouse genes and the human homologous genomic regions of the mouse deletion/translocation breakpoint regions. These findings provide valuable clues for identification of gene(s) and genomic/genetic alteration(s) that are involved in MPN progression in this murine model, and may lead to a better understanding of the pathogenesis of human myeloproliferative neoplasms.

428/W

Investigating genetic abnormalities associated with Y chromosome loss in hematological malignancies by high resolution oligo array CGH. *G. Raca[1,2], X. Xu[1], A. Arthur[1], E. Johnson[1], L. Leverton[1], J. Laffin[1,3].* 1) UW Cytogenetic Services, State Lab Hygiene, Madison, WI; 2) Department of Pathology and Laboratory Medicine, University of Wisconsin-Madison; 3) Department of Pediatrics, University of Wisconsin-Madison.

The goal of our study is to investigate genetic abnormalities associated with Y chromosome loss in hematological malignancies using high resolution oligo array comparative genomic hybridization (aCGH). Y chromosome loss is a common age-related phenomenon in bone marrow of healthy, chromosomally normal males. However, when observed in male patients with hematological malignancies, Y loss can either represent an aging phenomenon or a disease related genetic event in a cell line that has undergone other genetic changes. Previous studies suggest that the loss of Y in a high percentage (>75%) of bone marrow cells rarely occurs in healthy controls, and is more likely to indicate an abnormal clone. We hypothesize that high resolution oligo aCGH could detect disease related genetic abnormalities associated with Y chromosome loss, not detectable by conventional cytogenetics and FISH testing. To test this hypothesis we perform aCGH analysis on genomic DNA isolated from residual bone marrow or peripheral blood specimens from patients with hematological malignancies, where the loss of chromosome Y was the sole abnormality in >75% of bone marrow cells. To date data from ten samples have not detected significant copy number abnormalities and testing of additional specimens is in progress. Discovery of genetic abnormalities associated with loss of the Y chromosome would contribute to better understanding of the biological and clinical significance of this cytogenetic change.

Validation of home-brew probes for Fluorescence in situ Hybridyzation (FISH) in breast cancer samples. *R.M. Rodrigues-Peres, J.K. Heinrich, K.P. Serra, J. Vassallo, L.O.Z. Sarian.* State Univ Campinas, Campinas, Brazil.

Introduction: The Fluorescence in situ Hybridization (FISH) has become popular in the last decades as a rapid and sensitive technique for evaluation of chromosomes and genes, especially in the detection of amplifications, deletions and aneuploidy in tumors. A variety of commercial probes for FISH is currently available in the market although home-brew probes constitute a much more affordable alternative for laboratories pursuing to establish novel tumor marker targets. Objective: To develop and validate a protocol for the establishment of home-brew probes in the context of a cytogenetics laboratory. Materials and Methods: Sequences corresponding to the ERBB2, AURKB and CCND1 genes were selected from the UCSC Genome Bioinformatics Site. After microbiological cloning and purification, the sequences were amplified, labeled and hybridized onto 10 paraffin-embedded sections of selected ductal or lobular breast tumors. The same samples were also hybridized with commercial gene-specific probes for the same targets to validate the hybridization efficiency. Clinicopathological data were obtained from the clinical records. The study protocol has been fully approved by the institution's ethics review board (CEP #705/2007). Results: The hybridization profile of all the studied genes were found to be similar considering both types of probes, in paired breast tumors samples. Discussion: The use of home-brew probes for FISH may bring many advantages as costs reduction, hybridization of multiple targets using different colors when labeling probes and availability of probes for specific markers that have not been produced commercially. The applicability of these probes in tumor diagnosis should bring benefits not only for the FISH technique itself, but mainly for decisions in the disease management and treatment.

430/W

Sequential retrospective microarray analysis of CLL patients over a period of 14 years. *S. Shetty[1], R. Toydemir[1], N. Uddin[1], Y. Zhang[2], L. Rowe[3], A. Brothman[1,4], J. Johnston[2,5].* 1) University of Utah, Department of Pathology ,School of Medicine and Cytogenetics/Molecular Cytogenetics, ARUP Laboratories, Salt Lake City, UT; 2) Manitoba Institute of Cell Biology, and The Genomic Centre for Cancer Research and Diagnosis (GCCRD)[Clinical Research] Winnipeg, ManitobaWinnipeg, Manitoba, Canada; 3) ARUP Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 4) University of Utah, Department of Pediatrics, Salt Lake City, UT; 5) Internal Medicine, University of Manitoba, Winnipeg, Manitoba, Canada.

INTRODUCTION AND GOALS: Chronic lymphocytic leukemia (CLL) is a heterogeneous disease with variable clinical course. Genetic characterization has played a pivotal role in the clinical classification and treatment of this disease. The aim of this study was to ascertain whether genetic markers play an important role during the course of the disease and to analyze its possible correlation with disease progression. Thirty sequential peripheral blood samples (taken at initial diagnosis and then again at the latest interval post therapy) from patients with CLL over a period of 14 years are being evaluated retrospectively using the high resolution CNV/SNP microarray platform (Illumina OMNI1 Quad). All results are correlated with other clinical and laboratory information including IgVH mutation status, ZAP-70, CD38, telomeric length, lymphocyte doubling time, response to therapy and survival time. RESULTS: Examples of some of the findings in the first five patient's sequential samples include three patients with at least two genetic abnormalities. In the two samples from each patient, expansion of the clonal population was seen and correlated with disease progression. Genetic abnormalities such as 6q del, 11q del and 13q del with established prognostic clinical value were found in three patients. Other abnormalities detected were loss or gain of regions on 4p, 7p, 7q, 8p, 8q, 10q, 11p. One patient with an unmutated IgVH status (poor prognostic marker) showed no copy number changes (CNC) or loss of heterozygosity (LOH) in sequential samples and is doing well without any treatment for the past nine years since diagnosis. LOH was seen in one patient without any copy number changes and interestingly, this patient partially responded to therapy and showed a decrease in the abnormal clone followed by progression of the disease. INTERPRETATION AND CONCLUSIONS: Preliminary results indicate that sequential samples provide insight into the cytogenetic clonal evolution and clinical implications associated with CNC and LOH information in CLL patients. Additional sequential samples with well characterized genetic abnormalities including 6q, 11q, 13q, 17p and normal karyotype are being evaluated and correlation of findings with clinical outcome will be discussed.

431/W

Extensive whole-chromosome aberrations detected by SNP array in a neurofibromatosis type 1-associated glomus tumor. *D. Stewart[1], A. Pemov[1], E. Beert[2], H. Brems[2], E. Legius[2].* 1) Genetic Disease Research Branch, NHGRI/NIH, Bethesda, MD; 2) Department of Human Genetics, Catholic University Leuven, Leuven, Belgium.

Introduction. Glomus tumors are painful benign tumors of the glomus body, a thermoregulatory shunt located in the fingertips. We recently reported that NF1-associated glomus tumors arise from bi-allelic inactivation of the gene *NF1*. We performed analysis of the genomic architecture in two sporadic and four NF1-associated glomus neoplasms using high-resolution Illumina SNP arrays. **Methods**. DNA was collected from primary cell cultures (except for one case, when DNA was also extracted directly from tumor tissue) that were established from dissected glomus tumors. Comprehensive *NF1* sequencing was performed on DNA from NF1-associated tumors. DNA samples were processed and hybridized to the Illumina HumanOmni1-Quad microarrays. White blood cell DNA was used as germline control in NF1-associated glomus tumors (germline DNA for the patients with sporadic glomus tumors was unavailable). Analyses of copy number variants (CNV) and loss of heterozygosity (LOH) regions was performed using GenomeStudio (Illumina). Every putative CNV or LOH region from NF1-associated tumors was compared to its matching germline DNA sample. For the sporadic tumors, where control germline DNA was unavailable, normal copy number for each region was assumed to be 2 and deviation from that was considered as copy number loss or gain. **Results**. We hybridized DNA from the genomes of four NF1-associated and two sporadic glomus tumors. We found germline mutations of *NF1* in all 4 tumors and a somatic mutation in *NF1* in three of the four NF1-associated tumors. In the fourth tumor there were multiple large-scale chromosomal aberrations, including evidence of likely mitotic recombination of chromosome 17q. Across the entirety of chromosomes 2, 3, 4, 5, 6, 8, 9, 13, 18, 19 and 21, we observed B allele frequencies of 0%, ~33%, ~67% and 100% in conjunction with a log R ratio of ~0. We also found evidence of a large number of smaller CNVs shared by multiple tumors. **Conclusions**. This is the first report of bi-allelic inactivation of *NF1* arising from mitotic recombination of chromosome 17q in an NF1-associated glomus tumor. The multiple large-scale chromosomal aberrations in 1/4 NF1-associated glomus tumors may be due to chromosomal trisomy or, less likely, mosaic whole-chromosome uniparental disomy (UPD). Somatic aneuploidy (and/or UPD) may be more common than expected in NF1-associated glomus tumors.

432/W

Cryptic BCR/ABL1 fusion in a Philadelphia chromosome negative patient, resulting in a 9;22 insertion. *P.D. Storto, G.R. Diggans, D.R. Halinka.* Pathology, The Western Pennsylvania Hospital, Pittsburgh, PA.

A 48 year-old female patient presented with an increased WBC count and nose-bleeding, and cytogenetic testing was ordered. A routine cytogenetic analysis detected mosaicism for both trisomy 8 and trisomy 9, and the karyotype was described as 47,+8,+9[2]/ 46,XX[18]. Subsequently, FISH analysis for the 9;22 translocation was requested. The Extra Signal Dual-Color (ES-DC) BCR/ABL1 probe developed by Abbott Molecular, Inc. was used. This probe is designed to differentiate between the major and minor breakpoints in the BCR region. We examined 218 interphase nuclei and 215 (98.6%) had abnormal hybridization patterns. The majority of cells (200) contained one orange, one large green, one small green, and one fusion signal, indicating an intact ABL1 copy, an intact BCR copy, a deleted BCR copy, and a single BCR/ABL1 fusion. Fifteen interphase cells contained this abnormal pattern plus an additional fusion signal. In the case of the common 9;22 translocation involving the major breakpoint, the expected pattern with this probe would be one large orange, one small orange, one green and one fusion signal. A translocation involving the minor breakpoint would result in one orange, one green, and two fusion signals. Analysis of metaphase cells treated with the FISH probe showed that the fusion signal was located on one copy of chromosome 9. This probe was specifically designed to detect the 5'BCR/3'ABL1 fusion gene, (which is typically located on the derivative chromosome 22). We interpret these results to indicate that the abnormal karyotype is most likely the result of a direct insertion involving chromosome 22 material, with breaks proximal to the 5' BCR region and at the minor BCR breakpoint. The material is inserted into a break within the ABL region, resulting in the 5'BCR/3'ABL1 fusion gene located within the derivative chromosome 9, and no material from chromosome 9 translocated onto the deleted chromosome 22. Cells with an additional fusion signal reflect the trisomy 8 and trisomy 9 clone; as FISH analysis of metaphase cells shows that the additional chromosome 9 contains the fusion gene. Note that the homologs of chromosomes 9 and 22 appeared normal in the G-banded karyotypes. The final karyotype was reported as 47,+8,+9[2]/ 46,XX[18].ish ins(9;22) (q34;q11.2q11.2)(ABL1+,BCR+;BCR+,ABL1-).nuc ish (ABL1x2,BCRx3) (ABL1 con BCRx1) [200/218]/(ABL1x3,BCRx4)(ABL1 con BCRx2)[15/218].

Recurrent Cytogenetic Abnormalities in Fanconi Anemia Patients with MDS/AML. *L. Wang[1], F. Boulad[2], A. Auerbach[3], S. Jhanwar[1].* 1) Department of Pathology, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Department of Pediatrics, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) The Rockefeller University, New York, NY.

Fanconi Anemia (FA) is a rare inherited disease characterized by physical abnormalities, bone marrow failure, and increased risk of MDS/AML, head/neck squamous carcinomas and some other malignancies. Genetically, FA is associated with high spontaneous mutation rate and chromosomal instability. Interestingly, the non-random cytogenetic abnormalities seen in FA with MDS/AML are similar to that identified in secondary MDS/AML. We reviewed cytogenetics findings in bone marrow samples from 55 Fanconi Anemia patients who had either Aplastic Anemia, or MDS/AML. The main objective of such an analysis was to identify chromosomal sites of tumor suppressor genes associated with malignant transformation in cells with underlining germline mutation related to genomic instability. Clonal abnormalities were detected in 32 patients, majority of which were characterized by unbalanced chromosome rearrangements (only three balanced chromosome translocations were identified). In addition, clonal evolution was evident in 12 patients. Recurrent abnormalities identified in this study included gain of 1q (entire 1q or partial segments of 1q) [23/32]; -7/del(7q) [10/32]; gain of 3q specifically 3q26qter [6/32]; loss of 6p with 6p21pter as the commonly involved region[7/32]; and del(11)(q23) [4/32]. Clonal abnormalities, such as gain of 1q, -7/del(7q), gain of 3q26qter, and del(11)(q23) in FA with AA/MDS-AML are well demonstrated by other studies. We present here a significant number of cases with loss of 6p21pter. Moreover, in most of the cases [5/7], the loss of 6p21pter was due to unbalanced translocations between 6p and either chromosome 1 or chromosome 3, which also resulted in partial trisomy of 1q or 3q, respectively. In our study, the loss of 6p21pter was highly associated with clonal evolution in FA patients with AA/MDS-AML, which indicated the presence of tumor suppressor gene(s) and the loss of which may play an important role in the development/progression of hematological malignancies in FA patients. While the nature of genes located at 11q23 (ATM, MLL) and 3q26(EVI1) has been well recognized, the nature of genes located on 1q and 6p21 remain unknown. It is interesting to note that one of the FA genes, FANCE, is mapped to 6p22-21. Further molecular studies are likely to provide information related to nature of genes at these sites.

Acute leukemia of ambiguous lineage associated with t(4;11). *S.L. Wenger[1], R. Livengood[1], S. Paul[2], J.A. Vos[1].* 1) Dept Pathology, West Virginia Univ, Morgantown, WV; 2) Dept Pediatrics, West Virginia Univ, Morgantown, WV.

We report on a 16 year old girl with acute leukemia of ambiguous lineage. The patient presented with pallor, petechiae, dyspnea and menorrhagia of approximately 10 days. Initial CBC revealed a white blood cell count of 43,000/mm3, hemoglobin of 6.4 g/dl and platelet count of 17,000/mm3. The bone marrow aspirate showed 80% blasts comprised of two distinct populations. Approximately 75% of blasts had an immunophenotype positive for CD19, HLA-DR, CD38 and CD79a with block positivity for PAS, consistent with B-lymphoblasts with a primitive phenotype. The second population, representing 25% of blasts, was positive for CD33, HLA-DR, CD38, CD11b as well as nonspecific esterase and lysozyme, consistent with myeloblasts with possible monocytic differentiation. Overall, the diagnosis was consistent with acute leukemia of ambiguous lineage. FISH for ALL panel was negative for trisomy 4, 10 and 17, t(8;21) and t(9;22), but was positive for MLL translocation in 88% of interphase cells. The karyotype showed a t(4;11)(q21;q23) in 50% of metaphase cells. The patient initially received myeloid induction chemotherapy, became pancytopenic and recovered counts by day 30 of treatment. Peripheral blasts were present at this time and a bone marrow biopsy revealed persistent bi-lineal acute leukemia. She was re-induced with lymphoid therapy with remission pattern seen on day 28. Five months from diagnosis, the patient received an allogenic matched related donor transplant, resulting in 100% donor cells one month post-transplant consistent with engraftment. She was admitted to the hospital 2 weeks later with an RSV infection. She received treatment and was released. Despite a relatively uncomplicated post-transplant course, the patient relapsed and died of her disease 5 months following her transplant. Acute leukemia of ambiguous lineage is rare, occurring in less than 4% of all acute leukemia cases, with poor prognosis. The most common rearrangement associated with 11q23 is a translocation involving 4q21.

435/W

A rare case having t(8;22) and t(14;18) double hit with up to 3 copies of t(8;22) and morphologic and immunophenotypic features of large B cell lymphoma of possible follicular origin. *J. Xu[1], C. Hamm[2], P. Allevato[3].* 1) Cytogenetics, London Health Sciences Centre and University of Western Ontario, London, ON, Canada; 2) Oncology, University of Western Ontario, Windsor, ON, Canada; 3) Pathology, University of Western Ontario, Windsor, ON, Canada.

A 43 year old female had 1 week long history of fatigue, easy bruising and persistent nosebleed. WBC was 22.7x109/L (neutrophils 9.4; lymphocytes 8.5; monocytes 2.5; eosinophils 1.1; basophils 0.3), platelets, 22x109/L. LDH was > 2400u/L(177-217). CT scan showed moderate splenomegaly (14.8cm), 3.4cm axillary and retroperitoneal adenopathy. Bone marrow (BM) biopsy showed a diffuse infiltration of large atypical blast-like cells with moderate amounts of basophilic cytoplasm and irregular, somewhat coarse nuclear chromatin with several nucleoli. These atypical cells strongly expressed CD45 and were positive for CD10 and bcl-2 with weak positivist CD79a and were negative for CD20, Tat, CD99, CD34, CD117, CD30, CD3, CD5, CD23, bcl-6 and cyclin D1. several lymphoid nodules had B cells (CD20, CD79a), which were bcl-2 and focally bcl-6 positive. Ki67 staining showed a high proliferate rate of ~90%. Megakaryocytogenesis was only slightly decreased. Flow cytometry showed 2 monoclonal B cell populations: the 1st represented ~33% of the leukocyte population and was CD19/CD10, dim to negative CD20, kappa light chain restricted. The 2nd represented 6% of the leucocyte population and was CD19, CD 20, and CD23 positive and CD 10 and CD 5 negative with kappa light chain restriction. G-banding of cultured BM showed a complex karyotype: 68-83,XXXX,+X,+X,+X,+X, del(1)(p36)x2,-4,-5, del(6)(q15q23)x2,der(6)t(6;17)(q13;q11.2)x2,-7,-8, t(8;22)(q24;q11),t(8;22)x2,t(8;22)x3,-9,add(9)(p22),-10,del(10)(q24),-11,+12,-13, -14, t(14;18)(q32;q21),-15,-16,-17,-18, add(18)(q11.2),-19, +r(cp22)/46,XY[3]. FISH showed fusion of IGH/BCL2 and split signal of CMYC in 69% and 42% of 200 cells, respectively, confirming the presence of t(14;18) and t(8;22). Both t(8;22) and t(14;18), "a double-hit" were found in all 21 G-banded cells. Notably t(8;22) was seen in 1 copy in 1/21 cells, 2 copies in 18/21 cells, and 3 copies of t(8;22) in 2/21 cells. In contrast, only 1 copy of t(14;18) was detected in all 21 cells. t(8;22) is commonly associated with Burkitt lymphoma (BL) whereas t(14;18) and deletions in 1p36, 6q, 9p and 10q24, with follicular or diffuse large B-cell lymphomas (DLBCL). This is likely the 1st reported case with a double hit with up to 3 copies of t(8:22) and probably is best classified as a B cell lymphoma, unclassifiable, with features intermediate between DLBCL and BL (2008 WHO classification). This cytogenetic finding indicates an aggressive disease and poor prognosis.

436/W

Utility of High Resolution Oligo Array CGH in Clinical Testing for Hematological Malignancies. *X. Xu[1], A. Arthur[1], E. Johnson[1], L. Leverton[1], J. Laffin[1,3], G. Raca[1,2].* 1) UW Cytogenetics Services, State Laboratory of Hygiene, Madison, WI; 2) Department of Pathology and Laboratory Medicine, University of Wisconsin-Madison; 3) Department of Pediatrics, University of Wisconsin-Madison.

Our study compares the ability of array Comparative Genomic Hybridization (aCGH) and conventional cytogenetic methods -G-banded analysis and Fluorescence In Situ Hybridization (FISH)- to detect chromosomal abnormalities in patients with hematological malignancies. Our goal is to investigate the suitability of using aCGH as a routine diagnostic test for hematological disorders. DNA samples are isolated from residual bone marrow or peripheral blood specimens from clinical testing. aCGH analysis is performed using a custom 2x105k whole genome oligo array designed by the Cancer Cytogenetics Microarray Consortium (CCMC) and manufactured by Agilent (Agilent Technologies, Inc., Santa Clara, CA). This array has over 105,000 probes targeting 500 cancer genes and more than 130 cancer-associated genomic regions. Prior to aCGH testing the samples are analyzed by conventional cytogenetics and FISH, as a part of routine diagnostic evaluation. Comparison of the aCGH results with the results of the conventional testing methods allows to determine whether: 1) aCGH can detect all the gains and losses of chromosome regions which were detected by cytogenetic and FISH studies, and 2) aCGH can detect additional chromosome abnormalities which were not detected by traditional testing. Our results to date illustrate the specific advantage of aCGH methodology to aid in characterization of complex karyotypes. We tested a subset of specimens where multiple numerical and structural abnormalities were observed by G-banded analysis, but could not be fully characterized by conventional methods. We show two cases (one case of acute lymphoblastic leukemia and one case of multiple myeloma) where aCGH successfully determined the origins of marker chromosomes and characterized complex derivative chromosomes. In both cases aCGH helped to clearly identify recurrent disease associated abnormalities with diagnostic and prognostic significance. Although the inability to detect balanced rearrangements remains a serious disadvantage for application of aCGH, this study shows how aCGH provides useful clinical information both by detecting submicroscopic deletions and duplications as well as by allowing accurate characterization of gross unbalanced rearrangements.

New genomic profile signatures revealed in Western World adult T-cell leukemia/lymphoma patients by 244K array CGH. *S. Xu, R. Lima, J. Ramos, Y. Fan.* University of Miami Miller School of Medicine.

Adult T-cell leukemia/lymphoma (ATLL) is a peripheral T-lymphocytic malignant disease caused by human T-lymphotropic virus type 1 (HTLV-1). ATLL is endemic in several regions of the world, including Japan and the Caribbean region. We performed aCGH analysis in 50 ATLL patients from Brazil and the USA, which were most of Caribbean origin, using a high density oligo array 244K platform (Agilent). All patients presented copy number changes (CNCs) with variable sizes and complexity. The common CNCs were gains at 1q21-q44, 3, 3p, 7q22-q36, 8, 18, 19p13.1-p13.3, 21q21.1-q22.3, 22q12-q13 and losses at 5q13.2-q32, 6q11-q15, 9q13-q21. Gains in the 14 q32 (IGH) regions and losses in the 7p14.1 (TCRG), 7q34 (TCRB) and 14q11.2 (TCRA) regions involving small DNA segments were frequently observed. We compared the CNCs observed in two subgroups of patients, one with acute T-cell leukemia (n=34) and the other with T-cell lymphoma (n=8). We found that the acute leukemia group showed a high frequency of loss of tumor suppressor gene CDKN2a/2b (50% in leukemia group vs. 12.5% in lymphoma group). On the other hand, the lymphoma group showed high frequency of TP53 loss in comparison with the leukemia group (75% vs. 11.8%). As expected, patients with chronic leukemia (n=8) showed a lower frequency of CNCs. Two genes, LATS2, a tumor suppressor gene, and BAGE which encodes a tumor antigen recognized by autologous cytolytic lymphocytes were frequently deleted in lymphoma type. We also observed frequent gain of CCNL2 in acute leukemia type (41.2%) and gain of PDCD6IP in lymphoma type (62.5%) while gain of IFRD2 and RASSF commonly occurred in all types (avg. 40%). Our studies have revealed genomic profile signatures in the two subtypes of ATLL. Our results have shown that CNCs of specific genes may have contributed to tumorigenesis and progression of ATLL and these CNCs may be used as biomarkers to predict patient survival and treatment outcome.

Myeloid malignancies with acquired trisomy 21 exhibit a heterogeneous pattern of mutations and copy number alterations. *N. Larsson, H. Lilljebjörn, C. Lassen, B. Johansson, T. Fioretos.* Department of Clinical Genetics, Univeristy and Regional Laboratories, Skåne University Hospital, Lund University, Lund, Sweden.

Acquired trisomy 21 is a recurring cytogenetic aberration in myeloid malignancies that is present in about 5% of all cytogenetically abnormal acute myeloid leukemias (AML) and in 3-4% of myelodysplastic syndromes (MDS). Clinically, the prognostic value of this cytogenetic change is debatable, although most often it has been associated with intermediate prognosis. To investigate the role of trisomy 21 in myeloid malignancies, we studied a cohort of 11 such cases with trisomy 21 as the sole acquired cytogenetic aberration. We looked for a possible association between trisomy 21 and mutations in eight genes known to be important in differentiation, proliferation or survival of early hematopoietic cells (NPM1, TET2, FGFR1, FLT3, NRAS, KRAS, KIT, JAK2).Our results showed that the highest frequency (3/11, 27%) of mutations were found in the RUNX1 transcription factor, frequently known to be mutated or rearranged in both AML and MDS. The mutations included two missense mutations and one frameshift mutation, all located in the Runt domain of the gene. Apart from RUNX1, single mutations were detected in the TET2 and NPM1 genes. We also performed SNP array analysis using Affymetrix 500 K arrays on all cases to look for copy number alterations (CNA) and patterns of uniparental disomy (UPD) that could be common to these patients. Although CNAs and areas of UDP were observed, no recurrent genetic alterations were detected.

Prognostic and predictive impact of cytogenetic changes in relapsed multiple myeloma patients treated with bortezomib or thalidomide based regiments: a Czech group experience. *J. Smetana[1,2], P. Kuglik[2], H. Greslikova[1], R. Kupska[1], P. Nemec[1,2], R. Zaoralova[1,2], E. Braggio[3], L. Pour[1,4], L. Zahradova[1,4], M. Holanek[4], Z. Adam[4], R. Hajek[1,4].* 1) Babak Research Institute, Brno, Czech Republic; 2) Masaryk University, Faculty Of Science, Brno, Czech Republic; 3) Mayo Clinic Scottsdale, Collaborative Research Building, Scottsdale, Arizona, USA; 4) Department of Internal Medicine - Hemato-oncology, Brno University Hospital, Brno, Czech Republic.

Multiple myeloma (MM) is a hematological disease characterized by high clinical and genetic heterogeneity. There are two major genetic entities of MM: a hypediploid MM (H-MM), associated with the incidence of trisomies of chromosomes 3,5,7,9,11,15,19 and 21, and a non-hyperdiploid variant (NH-MM) associated with high incidence of IgH translocations (t(4;14)(p16.3;q32); t(14;16)(q32;q23)) and thus usually worse prognosis of disease. In this paper, we present pilot results of our study focuisng on utilization of modern cytogenetic and genomic techniques for finding new prognostic and predictive markers in MM. The main aim of this work was to evaluate predictive and prognostic significance of hyperdiploidy / non-hyperdiploidy in relapsed MM patients treated with bortezomib (median follow-up 18,3 months) or thalidomide-based regiments (median follow-up 21.5 months) by interphase FISH. 57 samples were investigated for H-MM / NH-MM by using LSI D5S23 /D5S721, CEP 9, CEP 15 Multi-Color Probe Panel and for other chromosomal abnormalities with prognostic value in MM as t(4;14)(p16.3;q32), del(13)(q14), del(17)(p13) and gain(1)(q21). At least 100 cells per slide were scored, 20% cut-off level was used. Prognostic impact of hyperdiploidy / non-hyperdiploidy was evaluated using Kaplan-Mayer surviving curves and treatment intervals. Hyperdiploidy was found in 25 of 53 patients (47%), non-hyperdiploidy in 28 of 53 patients (53%). Although no significant correlation between incidence of structural aberrations and hyperdiploid / non-hyperdiploid groups was found, our data suggest that t(4;14)(p16.3;q32) and del(13)(q14) are associated with NH-MM group (P=0.065 and P=0.10), similarly as described in literature in studies with newly diagnosed patients. Neither for bortezomib, nor for thalidomide treated patients, any statistically significant difference was observed between treatment responses and treatment intervals between hyperdiploid (median OS 87.1 vs. 72.2 months, P=0.27) and non-hyperdiploid group (113.6 vs. 84.6 months, P=0.49) According to our hypothesis, bortezomib or thalidomide-based regiments are able to overcome negative prognostic impact of non-hyperdiploidy in relapsed multiple myeloma patients. However, confirmation will require analysis of a larger cohort of patients with a longer monitoring period. Supported by VZ LC06027, MšMT ČR (MSM0021622415, MSM0021622434) and IGA NS10207.

Simultaneous measurement of copy number and copy-neutral genome alterations in cancer on CGH+SNP microarrays. *P. Anderson, B. Curry, B. Peter, N. Sampas, P. Costa, L. Bruhn.* Agilent Technologies, Inc., Santa Clara, CA.

For the characterization of genomic copy number changes that occur in the development and progression of cancer, oligonucleotide array comparative genomic hybridization (aCGH) offers high-resolution and precise determination of chromosomal copy number and genome-wide aberrations. We have developed a new method for making simultaneous measurements of Single Nucleotide Polymorphism (SNP) genotypes and copy number alterations in the same microarray assay to provide detection of copy-number neutral events, such as acquired loss of heterozygosity (LOH), as well as allelic imbalance in and around amplified regions. We profiled genomic DNA isolated from cancer cell lines, blood samples, and solid tumors on CGH+SNP arrays to measure chromosomal copy number at >200,000 loci and genotypes for >50,000 SNPs. DNA was digested with AluI and RsaI restriction enzymes and labeled with a standard enzymatic labeling protocol. In a two color assay, the sample was hybridized against a known genotyped reference to the CGH+SNP arrays. Copy number, SNP and aberration calls, including copy-neutral LOH, were generated using novel algorithms implemented in Agilent's Genomic Workbench software and Matlab. We detected copy number alterations and copy neutral LOH in many samples. For example, we found several focal amplifications contained within larger regions of copy-neutral LOH in a model Burkitt's lymphoma cell line (Raji). In a chronic lymphocytic leukemia sample, we measured a single copy deletion of 18p as well as copy-neutral LOH at 18q22.3-qter. Tumor heterogeneity and variable sample quality create significant challenges for accurate determination of SNP genotypes and copy number in both solid and liquid tumors. In paired tumor/normal tissues, we determined SNP genotypes and were able to calculate the fractional clonality of the tumor and detected copy number aberrations in samples with as little as 20% tumor cell content. In regards to sample variability we found that inaccurate quantitation of DNA input to the labeling reaction is a significant contributing factor to noise in the CGH and SNP measurements. To further decrease assay noise, a GC correction algorithm was used to improve the overall data quality for some cancer samples. Low noise assays with accurate measurements of both copy number and SNP genotypes will enable a deeper understanding of the alterations related to tumor development and progression.

441/W

Cell Line Identification by SNP: an Emerging Need in Cell Biology. *R. Fang, J. Shewale, M. Furtado.* Life Technologies, 850 Lincoln Centre Drive, Foster City CA 94404, USA.

Cancer cell lines are used worldwide in biological research for applications like cancer studies, genetics, and drug screening. Data misinterpretation due to incorrectly identified cell lines is a growing concern. Identification of human cell lines, therefore, has become a focus area. NIH has issued a guideline for mandatory identification of human cell lines used for drug screening. Short tandem repeat (STR) profiling is being used for cell line authentication. It is observed that the STR profile of some cell lines drift over the passages. In this study, we proposed to use the single nucleotide polymorphism (SNP) markers for this application because of its high genetic stability. To prove the concept, a PCR-OLA based SNP profiling system developed for human identification was evaluated for this application. This system enables to genotype 48 SNPs simultaneously in single reaction and provides accurate results. In this study, we profiled DNA preparations from 60 cell lines from National Cancer Institute (NCI) and 50 cell lines from American Type Culture Collection (ATCC) using the 48-Plex SNP detection system. Our results show that each human cell line typed has its own unique SNP profile. Three mislabeled cell lines were identified during the study. Our study demonstrates that the SNP based DNA profiling can be used for human cell authentication. This approach is more robust than the method using the genomic length polymorphism which may get altered under various cell culture conditions and the number of cell line passes. In addition, our study would enable researchers to authenticate the human cell line and monitor the contamination of cell lines in the laboratory.

Hemihypertrophy, Bilateral Pheochromocytomas, and Subtle Somatic Mosaicism: the Utility of SNP Array Analysis. *J.M. Kalish[1], L.K. Conlin[2], A.B. Wilkens[1], S. Mulchandani[2], M. Kowalski[3], K.E. Nichols[3], J.A. Biegel[1,2], N.B. Spinner[2], M.A. Deardorff[1].* 1) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pathology, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Division of Oncology, Children's Hospital of Philadelphia, Philadelphia, PA.

We report a case of a girl with hemihypertrophy, bilateral pheochromocytomas, and 11p15 mosaic uniparental disomy (UPD). Hemihypertrophy of the upper arms was diagnosed at 4 months with a 7.5% difference in girth. Clinical methylation testing for 11p15 in the blood was normal with a reported detection threshold of 20%. SNP array analysis (610K) performed on the blood secondary to additional minor facial dysmorphia was normal. She was subsequently diagnosed at 18 months with bilateral, non-secreting, non-metastatic adrenal masses. Following surgical resection, her tumor histology demonstrated eccentric round nuclei, eosinophilic cytoplasm that was diffusely positive for neuron-specific enolase, with some nodules positive for synaptophysin, all findings consistent with pheochromocytoma. Mutation analysis of genes known to cause pheochromocytoma (*VHL*, *SDHB/SDHD*, and *RET*) was negative. SNP array analysis of the pheochromocytoma tissue demonstrated mosaic deletions of chromosome regions common to pheochromocytomas (8p12pter, 21q21.1qter, and 22q11.23qter) and a novel finding of homozygosity for 11p15.3pter. The presence of 11p15 homozygosity suggested that it could be the primary event. To pursue a definitive diagnosis, SNP array analysis of skin fibroblasts from the hypertrophied side was performed and demonstrated <5% mosaic paternal uniparental isodisomy for this same region. Two cases of isolated hemihypertrophy and two cases of Beckwith-Wiedemann syndrome (BWS) have been reported with pheochromocytoma. Molecular testing was reported in only one case. This patient had a normal karyotype, and no detectable mutations in *RET* and *NF* in peripheral blood, or *VHL* and *RET* in the tumor, and normal methylation studies of *LIT1* and *H19* genes. We feel our case is unique, given the young age of this patient, the use of SNP array analysis, and the demonstration of a definitive molecular diagnosis. Given our experience, we feel that SNP array analysis is more sensitive in detecting UPD than MLPA due to the larger number of data points available for evaluation. This case underscores the utility of SNP analysis in rapidly identifying low levels of mosaicism and also suggests that 11p15 paternal UPD may be a general mechanism of pheochromocytoma in the pediatric population. Furthermore, we suspect that silencing of *CDKN1C* and segmental loss of growth inhibition likely led to further chromosomal changes that developed in the pheochromocytoma.

The role of Flt3 in a murine model of B-precursor Acute Lymphoblastic Leukemia. *R.M. Johnson[1, 2], E. Papp[3, 4], I. Grandal[2], J. Danska[3, 4], C. Guidos[1, 2].* 1) Developmental & Stem Cell, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Immunology, University of Toronto, ON, Canada; 3) Genetics & Genome Biology, The Hospital for Sick Children Research Institute, Toronto, ON, Canada; 4) Department of Medical Biophysics, University of Toronto, ON, Canada.

Acute lymphoblastic leukemia (ALL) is the most common childhood malignancy characterized by abnormal survival and proliferation of precursor-B lymphocytes. To identify dysregulated developmental pathways in ALL, our laboratory has generated Rag-2$^{-/-}$p53$^{-/-}$Prkdc$^{scid/scid}$ triple mutant (TM) mice, which develop B-precursor ALL. Using a genome-wide approach to uncover genetic alterations, we showed that TM leukemic blasts over-express FMS-like tyrosine kinase 3 (Flt3) relative to normal early B cell progenitors. FLT3 is a class III receptor tyrosine kinase (RTK), which is expressed on early hematopoietic progenitors and on B cell and macrophage precursors. Activation of Flt3 results in autophosphorylation of specific tyrosine residues and activation of signaling intermediates to promote cell survival and proliferation. FLT3 is normally expressed in two forms: a 160kDa membrane-bound fully glycosylated form and a 130kDa immature form. Two types of FLT3 mutations have been characterized in acute leukemias: (1) internal tandem duplications (ITD) in the juxtamembrane domain, and (2) kinase domain (KD) point mutations. Although FLT3 is expressed in most human B-lineage ALLs, ITD and KD mutations occur in only 3% of cases. We examined FLT3 expression on CD19^{+} leukemic blasts from TM mice and found variable surface expression of FLT3 despite high levels of Flt3 transcript. Culturing TM leukemic cells in the presence of class III RTK inhibitor, AGL 2043, revealed that FLT3, and potentially other class III RTKs, are necessary for the proliferation of these cells. Moreover, TM leukemic cells were able to proliferate in vitro in the absence of FLT3 ligand suggesting that ligand-independent activation is responsible for the growth of TM leukemic cells. Immunoblotting studies revealed that all TM ALLs over-expressed a truncated form of FLT3. Further biochemical studies revealed that this truncated FLT3 is constitutively phosphorylated in TM ALLs. Taken together, our studies have identified a novel type of FLT3 alteration in a murine model of B-precursor ALL resulting in a constitutively activated truncated form of the protein. We hypothesize that this aberrant FLT3 activation is responsible for the abnormal proliferation of TM leukemic cells. These findings suggest that aberrant activation of FLT3 plays an important role in the pathogenesis of B-precursor ALL. Future studies are needed to determine whether similar FLT3 alterations are present in human ALL.

444/T

Mapping Transitional Cell Carcinoma of the Bladder in the Dog. *H.G. Parker[1], E.M. Kwon[1,4], D.W. Knapp[2], P. Bonney[2], E. McNiel[3], E.A. Ostrander[1].* 1) Comparative Genomics Section, Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Purdue Comparative Oncology Program, Dept. of Veterinary Clinical Sciences, Purdue University, West Lafayette, IN; 3) Dept. of Veterinary Clinical Sciences, University of Minnesota, Minneapolis, MN; 4) Program in Human Genetics and Molecular Biology, Johns Hopkins University School of Medicine, Baltimore, MD.

Transitional cell carcinoma (TCC) of the bladder in the domestic dog is an ideal model of invasive bladder cancer in humans, which takes the lives of more than 14,000 people each year. Both diseases develop spontaneously, respond similarly to drug treatments, and have nearly identical histopathology. TCC is the most common cancer of the urinary bladder in pet dogs. It is an aggressive disease resulting in metastasis in approximately 50% of all dogs diagnosed. Currently little is known about the genetic basis of human bladder cancer. Recent GWAS studies identified two risk loci in both European and Asian populations, however, they account for only a small fraction of the overall risk of developing the disease. In comparison, our group has identified a small number of dog breeds that show a greatly increased risk of bladder cancer, as much as 20 fold higher than average, indicating a strong inherited component to the disease. In order to find mutations that increase susceptibility to TCC of the bladder, we have conducted a genome-wide association study using the Affymetrix canine v2 SNP chip on 122 Scottish terriers (ST), West Highland White terriers (WHWT), and Shetland Sheepdogs (SSD) with confirmed diagnoses of TCC compared to 135 dogs of the same breeds that are nine years or older and have never been diagnosed with cancer of any form. After correcting for both population structure and kinship, we have identified two primary susceptibility loci within the three breeds with $p<1x10^{-6}$. The association at locus1 is driven primarily by the ST and is increased with the addition of WHWT but not with SSD. Locus2 is associated with the TCC in the WHWT and SSD when analyzed apart from the ST and does not show association with the disease in the ST. We hypothesize based on allele frequencies within the region that the ST are nearing fixation at locus2, explaining the 20-fold increased risk in this breed. We have designed and run a Goldengate assay of 768 SNPs covering both loci at ~15kb density in order to fine map the region and assess gross copy number within the germline and within tumor DNA at both loci. We expect to find overlapping regions between the three breeds that contain causal mutations that increase overall risk of bladder cancer. The identification of genetic risk factors for TCC will allow selection of molecular targets for early detection and treatment in both humans and dogs.

Canine Gastric Cancer GWAS Identifies a Single Locus in the Chow Chow. *D.M. Karyadi[1], E.A. McNiel[2], E. Karlins[1], N. Madrill[2], E.A. Ostrander[1].* 1) Cancer Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Dept. of Small Animal Clinical Services, Michigan State University, East Lancing, MI.

The role of predisposition genes in human gastric cancer (GC) is not well understood. However, strong associations between specific dog breeds and GC risk have been reported, suggesting a mechanism for identifying genes important in GC susceptibility. Breeds at increased risk of GC include the Chow Chow, Belgian Sheepdog, Belgian Tervuren, and Keeshond. Of note, Chow Chows have striking 10-20-fold increased risk of developing GC compared to other breeds. GC in Chow Chows is clinically and morphologically similar to familial forms of the disease described in humans and, like human GC, has a grave prognosis. Diagnosis is usually made late in the course of the disease when effective treatment is rarely feasible. In humans mutations in limited number of genes have been suggested to increase risk, such as the *CDH1* gene and genes in the DNA mismatch repair pathway. However, these genes explain only a portion of familial human disease, little if any sporadic disease, and none of the canine disease. We hypothesize that a more global evaluation of the canine genome is likely to reveal genes of interest for both human and canine GC susceptibility. We conducted a genome-wide association study with Chow Chow cases, and unrelated and related controls using the Illumina CanineHD BeadChip with 170,000 SNPs. The final data set consisted of 125,713 SNPs informative in Chow Chows. Using the single-locus chi-squared test of significance, we calculated the allelic association of each SNP with the disease phenotype. In the analysis of cases and unrelated controls, the top 4 most significant SNPs were all at the same genomic locus ($P_{raw} = 6.83x10^{-5}$ - $1.09x10^{-5}$), creating a double peak spaced 20 Mb apart. Chromosome-wide permutations (n=100,000) were performed to test for significance of this locus. For the SNP with the best disease association, the chromosome-wide empirical P value is significant at P = 0.021. Analysis of the Chow Chow cases and entire set of controls (unrelated plus related) identified the same locus. Chromosome-wide permutations (n=100,000) were also significant for the top SNP (P_{emp} = 0.033). None of the peaks in other genomic regions are significant at the chromosome-wide level in either analysis. We are in the process of fine-mapping this region and using haplotype analysis in order to identify the causal variant. Our findings would likely highlight genes and biological pathways important for future studies of both human and canine GC.

Comprehensive resequence analysis of a 123kb region of chromosome 11q13 associated with prostate cancer. *C. Chung[1,2], Z. Deng[2,3], J. Boland[2,3], C. Matthews[2,3], M. Yeager[2,3], K. Jacobs[2,3,4], A. Hutchinson[2,3], R. Hoover[2], J. Fraumeni[2], D. Hunter[2,5,6,7], G. Thomas[2], S. Chanock[1,2].* 1) Laboratory of Translational Genomics/DCEG, NCI/NIH, Bethesda, MD; 2) Division of Cancer Epidemiology and Genetics, NCI/NIH, Department of Health and Human Services, Bethesda, MD; 3) Core Genotyping Facility, Advanced Technology Program, SAIC-Frederick Inc., NCI-Frederick, Frederick, MD; 4) Bioinformed Consulting Services, Gaithersburg, MD; 5) Program in Molecular and Genetic Epidemiology, Department of Epidemiology, Harvard School of Public Health, Boston, MA; 6) Department of Nutrition, Harvard School of Public Health, Boston, MA; 7) Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Recent genome-wide association studies of prostate cancer have identified single nucleotide polymorphism (SNP) markers in a region of chromosome 11q13. A subsequent fine-mapping in the Cancer Genetic Markers of Susceptibility (CGEMS) initiative identified at least three independent SNPs (rs10896438, rs12793759, and rs10896449) that contribute to prostate cancer risk. A comprehensive cataloging of variants by resequencing and refinement of linkage disequilibrium (LD) structure is essential steps to prioritize SNPs for further fine-mapping and functional studies. Therefore, we conducted a resequence analysis of 123kb region of chromosome 11q13 (68,642,755-68,765,690), which encompasses all three independent signals, in 78 individuals of European ancestry using next-generation sequencing technology. We identified a total of 549 polymorphic loci, of which 243 variants (187 SNPs and 56 insertion-deletion polymorphisms (indels)) were novel. We identified 18, 26, and 6 variants strongly correlated ($r^2 > 0.8$) with rs10896438, rs10896449, and rs12793759, respectively. The HapMap genotyped SNPs could interrogate 47%, 59%, and 71% of SNPs from each rs10896438, rs10896449, and rs12793759 bin, respectively. Our comprehensive resequencing results extended list of high correlation variants of priority for follow-up functional studies.

447/T

Mutations in Fanconi Anemia Genes and the Risk of Esophageal Cancer. *M.R. Akbari[1,2], R. Malekzadeh[2], P. Lepage[3], D. Roquis[3], A.R. Sadjadi[2], K. Aghcheli[2], A. Yazdanbod[4], R. Shakeri[2], J. Bashiri[2], M. Sotoudeh[2], A. Pourshams[2], P. Ghadirian[5], S.A. Narod[1].* 1) Women's College Research Institute, University of Toronto, Toronto, Canada; 2) Digestive Disease Research Center, Tehran University of Medical Sciences, Tehran, Iran; 3) Genome Quebec Innovation Centre, McGill University, Montreal, Canada; 4) Department of Internal Medicine, Ardabil University of Medical Science, Ardabil, Iran; 5) Epidemiology Research Unit Research Centre, CHUM-Hôtel-Dieu, University of Montreal, Montreal, Canada.

The incidence of esophageal squamous cell carcinoma (ESCC) is very high in northeastern Iran. Previously, we reported a strong familial component of ESCC among Turkmens, who constitute approximately one-half of the population of this region. Based on different lines of evidence, we hypothesized that the genes for Fanconi anemia may be candidate genes for ESCC. We sequenced the entire coding regions of 12 Fanconi anemia genes in the germline DNA of 190 Turkmen ESCC cases. We identified three heterozygote insertion/deletions; one in FANCD2 (p.Val1233del), one in FANCE (p.Val311SerfsX2) and one in FANCL (p.Thr367AsnfsX13). All three patients had a strong family history of ESCC. None of 811 Turkmen controls carried any of these three insertion/deletions. In addition, we found two homozygote patients for the deleterious FANCA p.858Ser>Arg mutation. We found two more homozygotes in another set of 556 ESCC patients. Four FANCA p.858Ser>Arg homozygotes were identified in total number of 746 ESCC patients, but in none of 1373 matched controls (P = 0.01). The p.3326Lys>X mutation in BRCA2 (Fanconi anemia gene FANCD1) was present in 27 of 746 ESCC cases and 16 of 1373 controls (OR = 3.38; 95% CI: 1.97 - 6.91; P=0.0002). In summary, both heterozygote and homozygote mutations in a number of Fanconi anemia genes are associated with an increased risk of ESCC.

448/T

Association of *CDKN1B* gene (polymorphism c.326T>G) with sporadic prostate cancer in Southern Brazilian Population. *R.B. Alexandre[1], A. Horvath[2], G.P.C. Silva[1], F.R. Faucz[1,2].* 1) Laboratory of Molecular Genetics, Core for Advanced Molecular Investigation (NIMA), Center for Health and Biological Sciences (CCBS), Pontificia Universidade Católica do Paraná (PUCPR), Curitiba - PR - Brazil; 2) Section of Endocrinology and Genetics, Program on Developmental Endocrinology & Genetics (PDEGEN), Eunice Kennedy Shriver National Institute of Child Health & Human Development (NICHD), National Institutes of Health (NIH), Bethesda, MD, USA.

A multigenic model of prostate cancer susceptibility has been proposed, in which common polymorphic variants of genes, such as the androgen and vitamin D receptor, contribute to tumorigenesis. The discovery of additional genetic factors involved in the prostate cancer predisposition is essential for the development of new diagnostic and therapeutic molecular tools. We examined a single nucleotide polymorphic variants in codon 109 of *CDKN1B* [c.326T>G (p.V109G) rs2066827] for association with sporadic prostate cancer in a Southern Brazilian population. Fifty-two cases and 110 controls were analyzed using PCR amplification and Single Strand Conformation Polimorphysm (SSCP) analysis; to characterize the patterns initially, a direct sequencing was applied on 15%; of the samples. The *CDKN1B* genotype was scored as T/T, T/G, or G/G. The T allele showed association with an increased risk of sporadic prostate carcinoma (p=0.015, OR 1.84, 95%; confidence interval, 1.09-3.09). An association between *CDKN1B* T/T genotype and advanced prostate carcinoma has been reported in the context of androgen-independent disease, suggesting that a restricted group of advanced cases might be informative to explore the above association (ongoing research).

Molecular screening of CDKN2A and CDK4 genes in Spanish Melanoma prone families. *C. Badenas[1,2], J.A. Puig-Butille[1,2], Z. Ogbah[3], C. Carrera[2,3], P. Aguilera[2,3], J. Malvehy[2,3], M. Mila[1,2], S. Puig[2,3].* 1) Biochemistry and Molecular Genetics Service, Hospital Clinic, Barcelona, Spain; 2) Centro Investigacion Biomedica en Enfermedades Raras (CIBERER), ISCIII. Barcelona, Spain; 3) Dermatology Department. Melanoma Unit. Hospital Clinic and IDIBAPS (Institut d'Investigacions Biomediques August Pi i Sunyer), Barcelona, Spain.

Introduction: Melanoma is a multifactorial and polygenic disease. The main risk factors are number of nevi, familial predisposition and skin phototype related to ultraviolet radiation exposition. Ten percent of cases are detected in a familial setting, being then inherited as an autosomal dominant trait. Two high susceptibility genes have been implicated: CDKN2A/p14ARF and CDK4. Mutations are detected in up to 40% of families. Objectives: To describe the prevalence of germ line mutations in CDKN2A and CDK4 in Spanish melanoma families and evaluate differences in clinical variables between carriers and non carriers. Subjects and Methods: we included 255 Melanoma affected patients from 201 Spanish families with at least two melanoma and 100 controls from Spanish population. CKN2A and CDK4 mutational screening was performed by PCR-SSCP and sequencing. Results: Mutations in CDKN2A were present in 12.4% of families (25/201). No mutation was detected in CDK4. We detected 16 different mutations, most of them being located in CDKN2A exon 2 (13/16). Mutation G101W accounts for 40% of mutated families (10 cases). CDKN2A alteration in the family was correlated with: the number of cases in the pedigree (p=0.001) and presence of patients with more than one primary tumor (OR: 3.77 IC 95%: 1.32-10.72). Regarding melanoma patients, mean age of onset for CDKN2A mutation carriers was 35 years while it was 43.5 years for non carriers. Dysplasic nevi were present in 30.6% of cases, although no association between dysplasic nevi and presence of CDKN2A mutation or number of patient melanomas was detected. Furthermore, a non statistically significant trend was observed between presence of A148T polymorhism in non mutation carriers and age of onset. Polymorhism A148T was found more frequently in melanoma cases than Spanish control population (9% vs 4.6%) being higher in subgroup of cases with multiple primary melanomas (17.4%). Conclusion: the frequency of CDKN2A Spanish melanoma families is similar to currently reported frequencies in other populations. Mutations in CDKN2A are implicated in age of onset and in the risk to develop more than one melanoma. The presence of CDKN2A mutation and of dysplasic nevi decreases the age of onset. Our results support the hypothesis that A148T variant is associated with an increased risk to develop melanoma in the Spanish population. More studies should be carried out to elucidate the effect of A148T variant on the age of onset.

Gastrointestinal stromal tumors (GISTs) are a rare mesenchymal neoplasm originating from the pacemaker cells of the GI tract known as the interstitial cells of Cajal. The identification of activating mutations in the tyrosine kinase receptors KIT and PDGFRA in approximately 80 % of GISTs led to the classification of GISTs that do not harbor these mutations, termed "wild-type" (WT) GISTs. WT GISTs can occur (1) sporadically, or (2) as a component of the familial GIST and paraganglioma (PGL) syndrome, (Carney-Stratakis syndrome (CSS) OMIM #606864) or (3) the Carney triad (CT) (OMIM #604287). Recently, inherited germ line mutations in SDHB,-C, and -D and mitochondrial oxidation defects have been implicated in approximately 15 %; of WT GISTs; thus additional genes are likely involved in WT GIST pathogenesis. Using a novel genome wide association study (SOMATICS), somatic deletions at the 1p31 locus were detected in 6/22 tumors from patients with the Carney triad, representing the most frequently deleted region. The 1p31 locus harbors the embryonic stem cell factor FOXD3 (genesis). Western blots and immunohistochemistry revealed a decrease in FOXD3 protein expression in tumors harboring deletions compared to PDGFRA mutant GIST and WT GISTs not harboring 1p31 defects. Somatic methylation in the promoter region of FOXD3 was also observed in at least two tumors from CT patients. FOXD3 mutations were not found in either tumor or germ line DNA from CT patients, however two novel variants were found in two unrelated patients affected by sporadic WT GIST (c.161G>A/p.R54H and c.255_266del12). When compared to wild-type FOXD3, R54H and del12 expressing vectors showed decreased DNA binding and decreased activation of a target luciferase promoter. siRNA knockdown of FOXD3 in embryonic cell lines resulted in an increase in c-KIT expression, and conversely, ectopic expression of FOXD3 downregulated c-KIT. Foxd3 mutant animal models including mice and zebrafish showed abnormalities in the Cajal cell phenotype and GI tract neural networks. Foxd3 mutant zebrafish also showed a hyperpigmented phenotype. Both melanocytes and Cajal cells require c-KIT for normal development and increased c-KIT activity can lead to both hyperpigmentation and GISTs. FOXD3 is expressed in neural crest cells and represses melanocyte development. These data indicate FOXD3 may act as a contributing factor in WT GISTs, possibly through upregulation of c-KIT.

451/T

Association analysis of candidate genes in childhood acute lymphoblastic leukemia. *J. Beuten[1,2], D. Piwkham[1,4], J.A.L Gelfond[3], A. Collier III[5,6], S. Pakakasama[4], B.H. Pollock[3], G.E. Tomlinson[1,2].* 1) Greehey Children's Cancer Research Institute; 2) Department of Pediatrics; 3) Department of Epidemiology and Biostatistics, UTHSCSA, San Antonio, TX; 4) Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 5) University of Texas Southwestern Medical Center, Dallas, TX; 6) Lehigh Valley Health Network, Bethlehem, PA.

Acute lymphoblastic leukemia (ALL), the most common childhood malignancy, remains a major cause of cancer-related morbidity and mortality in children. Substantial variability across ethnic groups in prevalence and prognosis of ALL exists; Hispanic children have a higher incidence of ALL compared to Caucasian children, and also have a less favorable outcome. We genotyped 29 highly potential candidate genes with 672 tagged single nucleotide polymorphisms (SNPs) in a case-control sample of Caucasian and Hispanic children to identify biomarkers that play a role in the risk for childhood ALL and to determine whether differences in allele frequency of SNPs in the candidate genes are associated with the observed differences in ALL rates between Caucasians and Hispanics. We found 39 SNPs within 13 genes that showed a significant risk effect for ALL in Caucasians under the additive model after correction for multiple testing. The major finding was obtained for LMO1 for which not only highest significance (OR=1.90, P=0.00003) but also multiple (N=13) SNPs were significantly associated with ALL. This gene was not previously reported in genome wide association studies (GWAS) of ALL susceptibility. Of note is that SNP rs6959427 within IKZF1, a gene for which a potential role in ALL has been previously indicated from a GWAS study, was highly significant in Caucasians but not in Hispanics. In Hispanics 24 SNPs within 9 genes showed significant association under the additive model after correction for multiple testing with the most significant finding for SNPs within FBXW7 and MLL (OR=0.55, P=0.002 and OR=1.87, P=0.002, respectively). SNP rs941997 in BLNK was a common SNP significantly associated with ALL in both ethnicities (OR=1.40, P= 0.035 and OR=1.76, P=0.005 in Caucasians and Hispanics, respectively). In addition SNPs within ETV6, RUNX1 and CHEK2 were significantly associated in both ethnic groups. A substantial difference (>20%) in minor allele frequency between the controls of both ethnicities was observed for 37 (6%) SNPs analyzed. However, no significant correlation was found between the ethnic specific allele frequency and association with ALL. Our findings support the hypothesis of a polygenic model in which ALL develops through a variety of interrelated genes. We also show that the genetic associations with ALL susceptibility are population specific.

452/T

Genetic variants in *ITPKC* gene and susceptibility to cervical carcinoma. *T. Chang[1], Y. Yang[2,4], Y. Lee[1,3,5], T. Chen[2], S. Chang[1], W. Lin[1].* 1) Med Res Dept, Mackay Memorial Hosp, Taipei, Taiwan; 2) Gynecology and Obstetrics, Mackay Memorial Hosp, Taipei, Taiwan; 3) Pediatrics, Mackay Memorial Hosp, Taipei, Taiwan; 4) Gynecology and Obstetrics, Taipei Medical University, Taipei, Taiwan; 5) Pediatrics, Taipei Medical University, Taipei, Taiwan.

Cervical cancer is strongly associated with infection by oncogenic forms of human papillomavirus (HPV). However, HPV infection alone is not sufficient for progression to cervical cancer. It is now recognized that host immunogenetic background play an important role in the control of HPV infection and the development of cervical cancer. Inositol 1,4,5-trisphosphate 3-kinase C (ITPKC) is a kinase of inositol 1,4,5-trisphosphate (IP3), which is a second messenger molecule in various types of immune cells including T cells, macrophages, and neutrophils. It negatively regulates T-cell receptor signal transduction by decreasing the amount of IP3 in the cytoplasm, which consequently downregulate the Ca^{2+}/ nuclear factor of activated T-cells signaling pathway. The aim of this study is to investigate the association between *ITPKC* gene polymorphisms and the risk of cervical cancer in the Taiwanese population. We selected 7 tag SNPs (rs2561531, rs2561528, rs890934, rs2303723, rs10420685, rs2561536, and rs2290693) and 1 putative functional SNP (rs28493229) to be genotyped in 128 cervical squamous cell carcinoma (CSCC) patients and 211 age/sex matched healthy controls by using the Pre-Developed TaqMan Allelic Discrimination Assay. The presence and genotypes of HPV in CSCC patients were determined by PCR. We found no significant association between any polymorphisms or haplotypes examined and overall CSCC risk. In addition, no significant association was observed between HPV-16 positive CSCC patients and controls. Our results suggest that specific variations in the *ITPKC* gene did not confer susceptibility to CSCC in the Taiwanese population.

Pleiotropic effects of diabetes risk loci on colorectal cancer risk: The Multiethnic Cohort (MEC) and Population Architecture using Genomics and Epidemiology Studies (PAGE). *I. Cheng[1], C. Caberto[1], M. Tiirikainen[1], L. Wilkens[1], F. Schumacher[2], B. Henderson[2], L. Kolonel[1], C. Haiman[2], L. Le Marchand[1].* 1) University of Hawaii, Honolulu, HI; 2) University of Southern California, Los Angeles, CA.

Colorectal cancer and diabetes are common chronic diseases that share several risk factors. Previous epidemiologic studies have demonstrated a 30% increased risk of colorectal cancer associated with Type-II diabetes, which is likely attributed to the interplay between obesity, hyperinsulinemia, and hyperglycemia. We investigated whether genetic risk loci for diabetes have pleiotropic effects on the risk of colorectal cancer. Nineteen risk SNPs for Type-II diabetes were selected from genome-wide association studies of this disease (up to September 2009) and genotyped in a case-control study of 1,599 colorectal cancer cases and 6,045 controls nested in the MEC under the auspices of the PAGE project. Odds ratios (OR) and 95% Confidence Intervals (CI) were estimated by unconditional logistic regression to evaluate the association between SNPs and colorectal cancer risk. We identified four diabetes SNPs associated with the risk of colorectal cancer: rs7961581 (TSPAN8, LGR5), rs4402960 (IGF2BP2), rs5219 (KCNJ11), rs7578597 (THADA). The strongest association was for rs7578597 (THADA) such that individuals carrying the CC genotype had a 2.1-fold increased risk of colorectal cancer in comparison to those with the TT genotype (95% CI: 1.54-2.99; P<0.0001). Consistent patterns of association were seen across the African American, Japanese American, and Latino populations. This SNP in the THADA gene results in a missense mutation, Thr1187Ala, and aberrant gene expression in THADA has been observed in pancreatic islets of individuals with and without Type-II diabetes. On-going analyses are evaluating the associations between these SNPs and circulating levels of insulin, insulin-like growth factor-I, insulin-like growth factor binding proteins, and C-reactive protein in the MEC. In summary, our findings suggest that diabetes risk loci have significant pleiotropic effects on the risk of colorectal cancer.

454/T

Obesity-related genetic variants are associated with endometrial cancer risk. *R.J. Delahanty[1], J.R. Long[1], Y.B. Xiang[2], Q. Cai[1], Y.T. Gao[2], A. Beeghly-Fadiel[1], W.H. Xu[2], W. Zheng[1], X.O. Shu[1].* 1) Vanderbilt Epidemiology Center, Institute of Medicine & Public Health, Eighth Floor, Suite 800, 2525 West End Ave, Nashville, TN 37212; 2) Shanghai Cancer Institute, Shanghai, China.

Endometrial cancer is the most common gynecologic malignancy. Obesity is a well established risk factor for endometrial cancer. Recent genome-wide association studies (GWAS) have identified multiple genetic markers for obesity. Using data from a recently completed GWAS scan data from a population-based case-control study of endometrial cancer in Shanghai, we investigated the association of obesity-related genetic markers with endometrial cancer. Our sample consisted of 832 cases and 1834 controls. We identified a total of 92 loci previously associated with obesity or BMI by using the GWAS catalog at http://genome.gov/gwastudies. We applied two approaches in the study: 1) to evaluate “exact” obesity-related SNPs via directly genotyped or imputed variants that are common in our study population (≥5%) and 2) to integrate “regional” obesity-related genetic information by examining all common SNPs that are in linkage disequilibrium (LD) with originally reported obesity-related variants. Using logistic regression with adjustment for age and education, we evaluated associations between 86 of the 92 SNPs in the catalog either by direct genotyping or imputation. Of those, 12 of 86 (14%) variants showed an association with endometrial cancer. For 11 of these 12 associations, the “regional” method identified a variant in LD with the originally reported variant that had a more significant P-value in our study than the variant identified in the original report. The “regional” method identified an additional 24 of the 86 (28%) loci for which SNPs in LD with the originally reported variant also reached statistical significance. Thus, through use of the two methods, 36 of 86 (42%) loci associated with obesity and BMI also showed an association with endometrial cancer. We conclude that many of the same alleles associated with obesity and BMI also increase the risk of endometrial cancer and that a “regional” analysis of originally reported GWAS findings may help refine risk alleles between populations and thus improve the transferability of findings between studies.

455/T

Identification of Genetic Risk Factors for Cutaneous Squamous Cell Carcinoma Susceptibility on Chromosome 7. *J. Fleming[1], A. Dworkin[2], A. Balmain[3], A. Toland[1].* 1) Molecular, Virology, Immunology, and Medical Genetics Dept., The Ohio State University, Columbus, OH; 2) National Institute of Health, Bethesda, MD; 3) Cancer Research Dept., University of California San Francisco, San Francisco, CA.

Non-melanoma skin cancer (NMSC) is the most common cancer in the world. A recent report indicates that more than 3.5 million NMSCs were treated in 2006; of those, 700,000 were cutaneous squamous cell carcinomas (SCC). Factors such as ultraviolet light exposure, industrial carcinogens, and tobacco are all predisposing factors to SCC; however little is known about the genetic risk factors driving this disease. If we are able to identify genetic risk factors, we can target people at risk of developing SCC through more extensive screening measures and develop better treatment options, which will prevent cancer and reduce health care costs. Previously, a SCC susceptibility locus, *Skts5*, had been identified on mouse chromosome 12 by linkage analysis on F1 backcrosses between resistant *Mus Spretus (Spret/GS)* and susceptible *Mus Musculus (NIH/Ola)* mice. *Skts5* is a 14-Mb region with 65 coding elements. Other susceptibility loci identified in these crosses show preferential allelic imbalance in skin tumors, indicating that allele-specific somatic genetic alterations in these regions may be driving cancer development and progression. The orthologous locus to *Skts5* in humans maps to 7p21 and 7q31. The question of this study is whether genetic variations at *SKTS5* are playing a role in human SCC susceptibility. We hypothesize that human SCC tumors will show allele-specific somatic genetic changes at *SKTS5* and that these alterations contribute to SCC risk. Low-resolution genotyping was performed in tumor vs matched normal DNA from 50 patients with multiple independent tumors using ABI genotyping of microsatellite markers. Markers mapping to 7p21 and 7q31 showed preferential allelic imbalance with p-values of 0.047 and 0.016 respectively. In order to identify candidate genes at *SKTS5*, we performed high-resolution genotyping using Sequenom MassARRAY. Normal and tumor DNA from 443 patients were analyzed across 70 single-nucleotide polymorphisms (SNPs) mapping to top candidate genes at *SKTS5*. Our results indicate that 6 SNPs at *SKTS5* show statistically significant evidence of preferential allelic imbalance in SCC tumors. We conclude that one or more of these SNPs is driving SCC susceptibility. The identification of functional germline variants that contribute to SCC susceptibility provides an initial step in developing genetic screening for this disease.

Eighteen Insulin-like Growth Factor (IGF) pathway genes, circulating levels of IGF-1 and its binding protein (IGFBP-3), and risk of prostate and breast cancer. *F. Gu[1,2], F. Schumacher[3], F. Canzian[4], N. Allen[5], R. Kaaks[6], E. Riboli[7], R. Ziegler[8], P. Kraft[1,2] on behalf of Breast and Prostate Cancer Cohort Consortium.* 1) Program in Molecular and Genetic Epidemiology; 2) Department of Epidemiology, Harvard School of Public Health, Boston, MA, USA; 3) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA; 4) Genomic Epidemiology Group, German Cancer Research Center (DKFZ), Heidelberg, Germany; 5) Cancer Epidemiology Unit, University of Oxford, Oxford, OX3 7LF, UK; 6) Division of Cancer Epidemiology, German Cancer Research Center (DKFZ), Heidelberg, Germany; 7) School of Public Health, Imperial College London, London, UK; 8) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD, USA.

Circulating levels of insulin-like growth factor I (IGF-1) and its main binding protein, IGF binding protein 3 (IGFBP-3), have been associated with risk of several types of cancer. Heritable factors explain up to 60% of the variation in IGF-1 and IGFBP-3 in studies of adult twins. We systematically examined common genetic variation in 18 genes in the IGF signaling pathway for associations with circulating levels of IGF-1 and IGFBP-3. A total of 286 single nucleotide polymorphisms (SNPs) were genotyped in over 5500 Caucasian men and 5500 Caucasian women from the Breast and Prostate Cancer Cohort Consortium (BPC3). After adjusting for multiple testing, SNPs in the IGF1 and SSTR5 genes were significantly associated with circulating IGF-1($p<2.1x10-4$); SNPs in the IGFBP3 and IGFALS genes were significantly associated with circulating IGFBP-3. Multi-SNP models constructed using SNPs that were significant in univariate analyses explained $R2=0.62\%$ of the variation in circulating IGF-1 and 3.9% of the variation in circulating IGFBP-3. We saw no significant association between these multi-SNP predictors of circulating IGF-1 or IGFBP-3 and risk of prostate or breast cancers. In conclusion, common genetic variation in the IGF1 and SSTR5 genes appears to influence circulating IGF-1 levels, and variation in IGFBP3 and IGFALS appears to influence circulating IGFBP-3. However, these variants explain only a small percentage of the variation in circulating IGF-1 and IGFBP-3 in Caucasian men and women. Further studies are needed to explore contributions from other genetic factors such as rare variants in these genes and variation outside of these genes.

457/T

Replication of breast cancer risk loci in a Cypriot case-control association study. *A. Hadjisavvas[1], M.A. Loizidou[1], J.P. Ioannidis[2,3,4], K. Kyriacou[1].* 1) Department of EM/Molecular Pathology, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus; 2) Department of Hygiene and Epidemiology, University of Ioannina School of Medicine, Ioannina, Greece; 3) Biomedical Research Institute, Foundation for Research and Technology-Hellas, Ioannina, Greece; 4) Tufts Clinical and Translational Science Institute and Center for Genetic Epidemiology and Modeling, Tufts Medical Center and Tufts University School of Medicine, Boston, MA, USA.

Over the last three years, seven genome-wide association (GWA) studies, which have identified 11 associations with robust statistical support for influencing breast cancer susceptibility, have been published pertaining to susceptibility loci in FGFR2, MAP3K1, LSP1, TOX3 (formerly known as TNRC9), COX11 and at 1p11.2, 2q35, 3p24, 6q25.1, 6q22.23 and 8q24.21. Most GWA studies and replications have been conducted in Northern European populations and to a lesser extent in Asians, and Ashkenazi Jews. It is important to assess whether these variants confer risk across different populations and also to assess the magnitude of risk conferred. To evaluate whether the GWAS derived risk variants contribute to breast cancer in the Cypriot population, we genotyped these 11 variants in 1,109 Cypriot female breast cancer patients and 1,177 healthy female controls. A total of four of the eleven single nucleotide polymorphisms (SNPs) were found to be nominally significantly associated with breast cancer risk in the Cypriot population. Based on estimated power, 5 associations would be expected to be nominally significant. The correlation coefficients of effect sizes (per-allele OR) between the Cypriot population and the GWAS populations was 0.58 (p=0.064), while allele frequencies were very similar (r=0.88, p<0.001). Overall, we show modest concordance for breast cancer GWAS-discovered alleles and their effect sizes in the Cypriot population.

458/T

Promoter variants in genes involved in the cell cycle and DNA repair pathways and the susceptibility to childhood acute lymphoblastic leukemia. *J. Healy[1], C. Richer[1], J. Dionne[1], H. Bélanger[1], M. Larivière[1], M. Ouimet[1], V. Gagné[1], V. Weth[1], K. Benhamza[1], P. Beaulieu[1], H. Massé[1], M. Bourgey[1], M.-H. Roy-Gagnon[1,2], D. Sinnett[1,3].* 1) Division of Hematology-Oncology, Research Center of the Sainte-Justine University Health Center, University of Montreal, QC, Canada; 2) Department of Social and Preventive Medicine, Faculty of Medicine, University of Montreal, QC, Canada; 3) Department of Pediatrics, Faculty of Medicine, University of Montreal, QC, Canada.

Acute lymphoblastic leukemia (ALL) is the most common neoplasm among children and is likely caused by multiple genetic and environmental factors. However the identification of established genetic risk factors for ALL has been impeded by the complex and heterogenic nature of the disease which likely reflects complex etiologic mechanisms. In this study, we postulated that a combination of cis-acting sequence variants in multiple genes sharing functions in the G1/S cell cycle checkpoint and DNA double-strand break repair pathways could influence interindividual variability in the susceptibility to ALL by modulating gene expression and affecting the overall outcome of these core regulatory processes. In a comprehensive pathway-driven case-control approach, we used hierarchical modeling to investigate gene- and pathway-based associations with childhood ALL and to explore putative gene-gene interactions, while integrating prior biological and functional information into the analysis. We identified variants in genes involved in both cell cycle control (*CDKN2A* rs36228834, *CDKN2B* rs2069416, *HDAC1* rs1741981) and DNA repair (*BRCA1* rs3092986, *XRCC4* rs3763063, *XRCC5* rs11685387) that are significantly associated with increased childhood ALL risk, and pathway analysis supported a role for both processes in leukemogenesis (cell cycle OR(95%CI)= 1.21(1.07-1.38); DNA repair OR(95%CI)= 1.28(1.10-1.47)). This study provides a strong rationale for further elucidation of the mechanisms through which aberrant cell cycle control and double-strand break repair are involved in childhood ALL susceptibility.

Genetic association with Leukocyte Telomere Length and Cancer Risk: the NHLBI's Framingham Heart Study. *S.J. Hwang[1,2], J.M. Murabito[1,3], C.L. Rosenberg[4], B.E. Kreger[1], G.L. Splansky[1], S.L. Neuhausen[6], S.C. Hunt[7], A. Aviv[8], D. Levy[1,2,5].* 1) Framingham Heart Study, Framingham, MA; 2) Center for Population Studies, National Heart, Lung, and Blood Institute, Bethesda, MD; 3) Department of Medicine, Boston University School of Medicine, Boston, MA; 4) Section of General Internal Medicine and the Sections of Hematology/Oncology, Boston University School of Medicine, Boston, MA; 5) Divisions of Cardiology and Epidemiology, Boston University School of Medicine, Boston, MA 02118; 6) Department Population Sciences, The Beckman Research Institute of the City of Hope, Duarte, CA 91010; 7) Cardiovascular Genetics Division, University of Utah School of Medicine, Salt Lake City, UT 84112; 8) Center of Human Development and Aging, New Jersey Medical School, Newark, NJ 07101.

GWAS recently identified significant associations of SNPs near *OBFC1* and *CXCR4* with leukocyte telomere length (LTL), with individuals carrying the minor alleles having longer LTL. Telomere dynamics have been linked to cancer, but it is unknown whether genetic variants regulating LTL are associated with cancer risk. We characterized the association between SNPs near *OBFC1* and *CXCR4* and LTL and tested whether genetic variants determining LTL are associated with cancer risk. The study sample was composed of 1138 Framingham Heart Study offspring participants with data on LTL, cancer incidence, family history of cancer, and genotype data for rs10786774 near *OBFC1* and rs13024450 near *CXCR4*. Cancer incidence through December 2008 was verified with pathology reports for all participants. We characterized the association between the number of minor alleles for both SNPs and LTL using linear regression adjusted for age and sex. We tested for significant association between time to cancer diagnosis and genetic variation using Cox's proportional hazard models. Results: individuals carrying 0 minor alleles had the shortest LTL , the trend of increasing telomere length by number of minor allele was significant with p-value of 2.7×10^{-10}. We tested for cancer risk for 157 incident cases relative to 926 cancer-free controls and observed an association with cancer risk among carriers of 1 or more minor alleles relative to those with 0 minor alleles (Hazard Ratio=1.61, 95%CI,1.05-2.47, p=0.029). The association persisted after adjusting for age, sex, body-mass-index, cigarette smoking, and family history of cancer. Our results warrant further study in independent samples and suggest genetic variants regulating LTL also confer increased risk for incident cancer.

460/T

CDH10 mutation profiles in pancreatic ductal adenocarcinomas (PDAC). *N. Jinawath[1,5], K. Murphy[2], A. Norris[2], A. Klein[3], R. Yonescu[2], C. Iacobuzio-Donahue[2], J. Brody[4], A. Meeker[2], A. Jinawath[6], S. Harada[2], C. Griffin[1,2,3].* 1) Inst Gen Med, Johns Hopkins Hosp, Baltimore, MD; 2) Department of Pathology, Johns Hopkins Hosp, Baltimore, MD; 3) Department of Oncology, Johns Hopkins Hosp, Baltimore, MD; 4) Department of Surgery, Jefferson Center for Pancreatic, Biliary and Related Cancers, Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA; 5) Research Center, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 6) Department of Pathology, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand.

Pancreatic cancer has a dismal prognosis. 5-10% of pancreatic cancer patients report a family history of pancreatic cancer. Genes associated with some familial cancer syndromes such as *BRCA2*, *STK11*, and *PALB2* only explain a small portion of the patients with familial pancreatic cancer. Therefore further studies to identify additional susceptibility genes are needed. One of the driver mutator genes proposed in a recent global mutation analysis of sporadic pancreatic cancers by Jones et al (Science 2008 Sep 26;321(5897):1801-6) is *CDH10*, a little known cadherin gene that is expressed in normal prostate and brain tissue. We analyzed 42 familial pancreatic cancer patients (that had at least 2 relatives with PDAC) for germline alterations of the *CDH10* gene. We identified one patient with a balanced chromosomal translocation and a second patient with a non-synonymous alteration. We narrowed the breakpoints of the constitutional t(5;20)(p14.2p11.1) using BAC FISH, somatic cell hybrids and SNP array. The breakpoint on chromosome 5p14.2 was in frontal proximity of *CDH10*, while that on chromosome 20p was in the pericentromeric region. Thus, we hypothesize that this translocation may result in altered *CDH10* expression in the patient, acting like a germline mutation that inactivates one copy of the gene. Subsequent sequencing analysis did not identify a germline mutation in *CDH10*. Analysis of the patient's tumor using 6 STR markers on 5p14.2 demonstrated a region of LOH covering *CDH10*. The second patient had a germline missense mutation in a highly conserved cadherin cytoplasmic domain on exon 12 (p.Arg688Gln). Tumor tissue was not available from this individual. We found no nonsynonymous changes in exon 12 among the 106 control samples nor in public databases (1000 Genomes project March 2010 release and dbSNP build131). We further investigated whether *CDH10* region is prone to LOH in sporadic PDACs by analyzing STR profiles of 29 microdissected PDACs and identified 38% of tumors with LOH. IHC using a CDH10 antibody is in progress and preliminarily shows a difference in staining pattern between normal pancreatic ducts and tumor tissue. Taken together, our data suggest that CDH10 alterations are important in the development of pancreatic cancer. Further functional studies are needed to elucidate the tumor suppressive role of CDH10 in pancreatic carcinogenesis.

Copy number alterations of BCAS1 in squamous cell carcinomas. *S.Y. Kim[1], Y.I. Kim[1], A. Lee[2], J. Kim[1], B.H. L[1], S.H. Lee[1], S.W. Nam[1], S.H. Lee[1], W.S. Park[1], N.J. Yoo[1], J.Y. Lee[1], S.H. Kim[1].* 1) Dept Pathology, CUMC, Seoul, Seoul, Korea; 2) Dept. Hospital Pathology, CUMC, Seoul, Korea.

Background: BCAS1, located in 20q13, is amplified and overexpressed in breast cancers. Even though BCAS1 is expected to be an oncogene candidate, its contribution to tumorigenesis and copy number status of other malignancies are not reported. To elucidate BCAS1's role in squamous cell carcinomas, we investigated copy number status and expression level of BCAS1 in several squamous cell carcinoma cell lines, normal keratinocytes and primary tumors. Methods: We quantitated BCAS1 gene by real-time PCR. Expression level of BCAS1 was measured by real-time RT-PCR and immunoblot. Resultes: Seven (88%) out of eight squamous cell carcinoma cell lines showed copy number gain of BCAS1 with various degrees. BCAS1 gene in some cervical cancer (60%) also showed copy number gain. However, expression level did not show linear correlation with copy number changes. Conclusions: In this study, we identified common copy number gain of BCAS1 in squamous cell carcinoma cell lines. Due to lack of linear correlation between copy numbers of BCAS1 and its expression level, we could not confirm that overexpression of BCAS1 is common finding in squamous cell carcinoma cell lines.

462/T

Fine mapping of 5p12 locus in Ashkenazi Jewish breast cancer cases and controls. *T. Kirchhoff[1], P. Pal[2], A. Dutra-Clarke[1], V. Joseph[1], M.M. Gaudet[3], V. Devlin[1], Q. Waisfiz[4], C.A. Hudis[1], K. Offit[1].* 1) Dept Medicine, Mem Sloan Kettering Cancer Ctr, New York, NY; 2) John Hopkins Hospital, Baltimore, MD; 3) Albert Einstein School of Medicine, Bronx, NY; 4) Netherlands Cancer Institute, Amsterdam, Netherlands.

Over a dozen low-penetrant breast cancer susceptibility loci have recently been identified through genome wide association studies GWAS). Of the four breast cancer GWAS studies initially reported, association of 5p12 with breast cancer risk was noted in three (Iceland, Breast Cancer Association Consortium [BCAC], and Cancer Genetic Markers of Susceptibility [CGEMs]) and, we report here, this association is also observed in retrospective analysis of data from our GWAS in Ashkenazi Jews (PNAS 105:4340, 2008). In the CGEMS data, the 5p12 SNP showed stronger association with breast cancer risk in postmenopausal women, suggesting a link with estrogen receptor-positive tumors. Our GWAS of the Ashkenazi Jewish (AJ) population showed association with this locus for rs6893211, with weaker effect size (OR=1.12, p=0.002), but with a stronger signal when a sliding window haplotype analysis was used. The association signal described in these studies maps to relatively large ~200kb region on 5p12, near 2 candidate genes: MRPS30 and LOC441070. Here we examined the structure of the association signal in the AJ population in order to fine map the involved region at 5p12. We genotyped 47 SNPs across ~1.3 Mbp region of 5p12 utilizing a Sequenom platform. 1000 breast cancer cases and 1000 controls were analyzed. We confirmed a modest association with rs4391175 (p= 0.07) and rs1392970 (p=0.09) in the MRPS30 locus. In contrast to other reports, the strongest association signal was near the 5'UTR of FGF10 for 4 correlated SNPs across a ~200kb region. Sliding window haplotype analysis revealed the presence of susceptible common haplotype significantly associated with breast cancer risk in these subsets, (OR=1.23, p=0.0003). This analysis, performed in the AJ population, provides the first evidence pointing to FGF10 as a potential candidate contributing to the 5p12 association signal and breast cancer risk. Confirmatory studies will be performed in larger European ancestry replication cohorts. The results of these analyses, and the prior association with FGFR2 in each of the GWAS studies to date, support the role of mitogen activated pathways in genetic susceptibility to breast cancer. These findings also suggest the FGF pathway as a potential future target for preventive as well as therapeutic approaches.

Exploring breast cancer epistasis in the PRDX genes. *E. Kistner-Griffin[1], B. Wolf[1], E. Hill[1], E. Slate[1], C. Neumann[2].* 1) Division of Biostatistics and Epidemiology, Dept of Medicine, Medical University of South Carolina, Charleston, SC; 2) Dept of Pharmacology, Medical University of South Carolina, Charleston, SC.

Peroxiredoxins (Prdxs) have recently been shown to be upregulated in breast cancer and other malignancies. Overexpression of both Prdx1 and Prdx3 has been associated with breast tumor genesis. As SNPs in the PRDX genes have not been reported in the genome-wide association studies of breast cancer, a novel method called Logic Forest, which allows the discovery of risk variants as well as epistasis, was implemented to thoroughly investigate possible associations. Using the Cancer Genetic Markers of Suspectibility (CGEMS) Breast Cancer cohort available in dbGaP, SNPs within 50kb of each of the six PRDX genes on the Illumina HumanHap550 platform were identified. The cohort consists of 1145 European ancestry postmenopausal women with breast cancer and 1142 European ancestry controls, all from the Nurses Health Study. A Logic Forest model of breast cancer was explored, which allowed for evaluation of interactions between SNPs predictive of breast cancer in the sample through construction of multiple logic regression trees. Testing 85 SNPs in the PRDX genes, we identified an interaction between SNPs upstream of PRDX3, with empirical significance after permutation (p=0.00035). Using a standard logistic regression approach to test epistasis in the PRDX3 gene region would have also allowed for discovery of the same interaction (p=0.00017). Currently, imputation of other SNPs in the genes is being conducted for better coverage of the genetic variation and the Logic Forest model is being refined for improved detection of gene-gene interactions only implicated in a patient subpopulation. In addition, expression quantitative trait loci (eQTLs) of the PRDX genes have been discovered using the publically available SNP and CNV Annotations Network (SCAN) and the Logic Forest approach is being conducted to test for epistasis with both cis- and trans-acting regulators.

464/T

Screening for *BRCA1*, *BRCA2*, *PALB2*, *EMSY*, *CDH1*, *ATM*, *RAD50*, *CHEK2*, and *BRIP1* mutations in high-risk Finnish *BRCA1/2*-founder mutation-negative breast and/or ovarian cancer individuals. *K.M. Kuusisto[1], A. Bebel[1], J. Schleutker[1], S.-L. Sallinen[2].* 1) Institute of Medical Technology, Tampere, Finland; 2) Department of Pediatrics, Genetics Outpatient Clinic, Tampere University Hospital, Tampere, Finland.

Introduction: Two major high-penetrance breast cancer genes, *BRCA1* and *BRCA2*, are responsible for approximately 20% of hereditary breast cancer (HBC) cases in Finland. Additionally, many other genes that interact with *BRCA1/2* in DNA repair pathway increase the risk of HBC. Still, a majority of HBC cases remain unexplained which is challenging for genetic counseling. We aimed to analyze additional mutations in HBC-associated genes and to define the sensitivity of our current *BRCA1/2* mutation analysis protocol used in genetic counseling. **Methods:** Eighty-two well-characterized, high-risk hereditary breast and/or ovarian cancer (HBOC) *BRCA1/2*-founder mutation-negative Finnish individuals, were screened for germline genetic alterations in nine breast cancer susceptibility genes, *BRCA1*, *BRCA2*, *PALB2*, *EMSY*, *CDH1*, *ATM*, *RAD50*, *CHEK2*, and *BRIP1* by using direct sequencing, the high resolution melt (HRM) method and multiplex ligation-dependent probe amplification (MLPA). Carrier frequencies between studied individuals and controls were compared by using Fisher's exact test. **Results:** Four previously reported breast cancer-associated variants, *BRCA1* c.5095C>T, *ATM* c.7570G>C, *CHEK2* c.470T>C, and *CHEK2* c.1100delC, were observed in twelve (14.6%) individuals. Ten of these individuals had *CHEK2* variants, c.470T>C and/or c.1100delC. Seventeen novel sequence alterations and nine amino acid-changing double-variant individuals were identified. No large genomic rearrangements were detected either in *BRCA1* or *BRCA2*. **Conclusions:** In this study, previously known breast cancer susceptibility genes explained 14.6% of the analyzed high-risk *BRCA1/2*-negative HBOC individuals. The role of the *CHEK2* variants in particular should be evaluated in more detail for genetic counseling purposes. Additionally, we identified novel variants that warrant additional studies. Our current genetic testing protocol for 28 Finnish *BRCA1/2*-founder mutations and PTT of the largest exons is sensitive enough for clinical use as a primary screening tool. However, in cases of extremely remarkable cancer history, analysis of the whole coding regions of *BRCA1/2* would be recommended.

465/T

Copy number variation analysis of a pancreatic neuroendocrine tumor in a patient with von Hippel-Lindau disease. *A. Laus, R. Pellegrino, E. Barreto, J. Vidal, J. Casali da Rocha.* National Tumor Bank, National Cancer Inst. Andre Cavalcanti St, 37. Rio de Janeiro, Brazil.

Von Hippel-Lindau disease (VHL) is an autosomal dominant syndrome that results from germiline mutations in gene VHL, a tumor suppressor gene located in 3p25-p26. This syndrome predisposes individuals to develop multiples benign and malign tumors in many organs, including the kidney, the central nervous system, and pancreas. The most pancreas lesions associated with VHL are benign, but same patients can develop pancreatic neuroendocrine tumors (PNETs), that can behave in a malignant fashion developing metastatic disease. Little is known about the molecular anomalies that occurs both in sporadic or hereditary PNETs, and so, the identification of commonly deleted and amplified chromosomal regions may contribute for understanding of molecular pathways involved in tumorigenesis of this type of tumors. The aim of this study was to perform Copy Number Variation (CNV) analysis using microarray approach in a PNET of a patient with VHL disease. The patient is a male, and his clinical manifestations include a haemangioblastoma at age 25, a renal cell carcinoma and a PNET at age 33, and another haemangioblastoma at age 35. The VHL disease was confirmed by sequencing of VHL gene in blood DNA and revealed a frameshift germiline mutation in exon 3 (778delG). The DNA from PNET was extracted using standard methods and CNV analysis was performed using GeneChip Human Mapping 50K Set (Affymetrix, USA). The CNV analysis was performed using Genotyping Console Software (Affymetrix, USA), applying Markov model algorithm. The CNV analysis detected two homozygosis deletions in chromosome 3, one deletion in chromosome 8, and one duplication in chromosome 7. All regions altered were annotated and the genes located there were analyzed according to their biological processes using DAVID Functional Annotat ion Tool. This analysis revealed a deletion of one allele of VHL gene, this being the somatic event that probably initiate the tumorigenic process. Also, was detected a duplication of MET gene, a known oncogene involved in two important pathways of cell proliferation, invasion, resistance to apoptosis and angiogenesis, PTEN/PI3K/AKT/mTOR and RAS/RAF/MAPK pathway. The PPARG gene, deleted in this tumor, is also involved in PTEN/PI3K/AKT/mTOR pathway, and BRAF gene, involved in RAS/RAF/MAPK pathway, was found duplicated. So, these findings strongly suggest the involvement of these two important pathways in tumorigenesis and progression of PNETs in patients with VHL disease.

Smoothened expression is regulated by DNA methylation in cancer cells. *H. Lou[1], H. Li[2], B. Gold[3], J. Sawitzke[1], P. Wright[2], S. Anderson[2], M. Dean[3].* 1) Cancer and Inflammation Section, SAIC Frederick, Inc., NCI-Frederick, Frederick, MD 21702; 2) Cancer and Inflammation Program, Laboratory of Experimental Immunology, SAIC Frederick, Inc., NCI Frederick, Frederick, MD 21702; 3) Cancer and Inflammation Section, National Cancer Institute, Frederick, MD 21702.

The hedgehog (HH) signaling pathway is one of the key regulators of embryonic patterning, tissue regeneration, stem cell renewal, and cancer growth. Smoothened (SMO) protein is the key positive regulator of the HH signaling pathway. To clarify the role of the HH signaling pathway in tumorigenesis, we investigated the expression of SMO, PTCH1, GLI1, GLI2 and GLI3 in thirty-three cancer cell lines. Different expression patterns of HH pathway genes were identified in these cancer cells. Although SMO showed the highest level of expression among these genes, absence of SMO expression was identified in seven cancer cell lines. Furthermore, we performed computational analysis of the SMO 5'-flanking region and Exon 1 to determine the functional elements of the SMO promoter region. Three potential CpG islands and five putative SMO promoter elements were identified. In addition, we have determined the methylation status of three SMO CpG islands using bisulfite sequencing PCR (BSP) and methylation specific PCR (MSP) methods. Hypermethylation of SMO was only found in the cell lines lacking SMO expression. Furthermore, the expression level of SMO mRNA was negatively correlated with the methylation status of the SMO promoter. The expression of SMO in a cell line with a fully methylated SMO promoter (MCF7) was restored by treatment with the demethylating agent 5-aza-2'-deoxycytidine (5'-AZA-dCyd). Our study reveals that the SMO promoter is hypermethylated in certain cancer cell lines and suggests an essential role for epigenetic silencing in regulating SMO expression in various cancer cells.

FOXP3 Polymorphism Association with Prostate Cancer in African-American men. *A. McLauchlin, G. Dunston, T. Mason, L. Ricks-Santi.* National Human Genome Center, Howard University, Washington, DC.

Background: Prostate cancer is the most common cancer of men in Europe, North America and parts of Africa, and a leading cause of death among men in the United States and Western Europe. Some studies report a more aggressive cancer in African American men than in white men. The reason for the disparity is not completely known, however there may be several biological factors involved including variation in immune system activity. FOXP3 expression has been shown to be increased in several cancers, mostly as a function of the increased numbers of regulatory T (Treg) cells in peripheral blood and at the site of the tumor. FOXP3 is a member of the forkhead family of transcription factors that are involved in several cellular processes. Within the natural Treg cell, FOXP3 is responsible for up-regulation of several genes involved in suppression of effector T cells. Recently, FOXP3 has been shown to be expressed in cancer cells. The major objective of this study was to investigate the effect of FOXP3 expression changes in prostate tumor cells with a focus on polymorphisms in conserved regulatory regions as the agents of change. Methods: Four single nucleotide polymorphisms (SNPs) located in a conserved region of intron 1 in the FOXP3 gene were found to be variable only in African and African-American populations. Results: The study found that three of the SNPs were significantly associated with Gleason score as an intermediate marker of tumor aggression (p=0.047). The A allele of one of the SNPs (rs6609859) results in retention of an NFAT binding site in intron 1 of FOXP3 which may result in increased expression of FOXP3 expression. No significant association was found between any of the FOXP3 SNPs and development of prostate cancer. Conclusion: This study shows that common variants in candidate genes underlying host adaptive immune mechanisms may be useful in interrogating the biology of health disparities.

Colon cancer, adenomas and hyperplastic polyps are linked to chromosome 6q27 in a large family with excess colon cancer. *D.W. Neklason[1,2], T.M. Tuohy[1], J. Stevens[3], R.A. Kerber[1,2], W.S. Samowitz[4], B. Otterud[3], L. Baird[3], S.K. Kuwada[5], M.F. Leppert[3], R.W. Burt[5].* 1) Huntsman Cancer Inst, Univ Utah, Salt Lake City, UT; 2) Department of Oncological Sciences, Univ Utah, Salt Lake City, UT; 3) Department of Human Genetics, Univ Utah, Salt Lake City, UT; 4) Department of Pathology, Univ Utah, Salt Lake City, UT; 5) Department of Medicine, Univ Utah, Salt Lake City, UT.

Colon cancer is one of the more familial of cancers with an estimated 20-30% of cases having a hereditary basis. A fraction of this is accounted for by the highly penetrant colon cancer syndromes (5%) and low penetrance genes identified through association studies (6%). Large family studies offer an opportunity to identify moderately penetrant but sufficiently rare genes that would be missed through association studies. The aim of this study was to identify genetic factors responsible for colon cancer using large multigenerational pedigrees with excess colorectal cancer. A 5-generation family with a statistical excess of colon cancer (p=0.0001) was identified through the Utah Population Database, a genealogic resource linked with cancer records. A total of 72 family members were recruited for phenotypic (endoscopic) and genetic study. Adenomas were twice as common in the proximal vs. distal colon. Known colon cancer syndromes were excluded through clinical and molecular evaluation. Family members were genotyped with 554 polymorphic short tandem repeat (STR) markers across the entire genome. Parametric and nonparametric linkage analyses were applied using adenomatous polyps and colon cancer for affection status. The genome-wide scan revealed a maximum LOD score of 3.33 at D6S386 and adjacent markers in agreement. There are 24 RefSeq genes within this region, but none previously implicated in colon cancer risk. One phenotypic feature of the kindred presented an unexpected issue. Many young individuals developed hyperplastic polyps in the colon, however only 23% were located in the proximal colon. These are not typically regarded as precancerous and we do not use them to establish affection status. To test if this observation associated with the genetic predisposition to colon cancer in the kindred, we reran linkage analysis and changed the phenotype of individuals age 45 and younger with hyperplastic polyps or any age with 3 or more hyperplastic polyps from unaffected to unknown. This increased the resulting two-point LOD score from 3.33 to 4.16. (The multipoint analysis using FASTLINK increased from a LOD score of 3.99 to 5.01). This suggests that this particular genetic locus may influence the proliferation of both hyperplastic and adenomatous colonic tissue and may provide clues as to the etiology of the mixed polyposis phenotype which is commonly observed in the clinical setting but poorly understood.

***EMSY* and prostate cancer.** *R. Nurminen[1], T. Wahlfors[1], T. Tammela[2], J. Schleutker[1].* 1) Laboratory of Cancer Genetics, Institute of Medical Technology, University of Tampere and Tampere University Hospital, Tampere, Finland; 2) Division of Urology, Tampere University Hospital and Medical School, Tampere, Finland.

Prostate cancer is the most frequently diagnosed cancer in men in developed countries but the genetic changes underlying the development and progression of prostate cancer, particularly aggressive in nature, are still poorly known. One of the recently identified chromosomal regions in genome-wide association studies (GWAS) and linkage analyses is 11q13 but no causal factor(s) predisposing to prostate cancer has yet been identified. The *EMSY* gene maps to 11q13.5 and is associated with breast and ovarian cancers. Based on this we screened *EMSY* for sequence variants and evaluated their association with prostate cancer risk. The study material consisted of 1175 Finnish unselected and 184 familial prostate cancer cases and 854 unaffected male controls. Exons and exon-intron boundaries were screened for variation using sequencing methods, and potential variants were validated using Taqman assay and High Resolution Melting analysis. We identified 27 sequence variants of which 10 had been previously reported. One of the novel variants, IVS6-43A>G, associated with both unselected (odds ratio (OR) 5.49; confidence interval (CI) 95 % 1.25-24.1; p = 0.022) and familial prostate cancer (OR 7.04; CI 95 % 1.17-42.4; p = 0.042). Furthermore, clinicopathologic case-control and case-case analyses revealed that IVS6-43A>G particularly increases the risk of aggressive unselected prostate cancer (OR 9.83; 95 % CI 2.17-44.6; p = $5x10^{-4}$ and OR 5.85; 95 % CI 1.29-26.5; p = 0.010, respectively). IVS6-43A>G is situated 43 bases upstream of an exon but no functional elements are predicted to map to this site. We found no strong linkage disequilibrium between IVS6-43A>G and other observed *EMSY* variants, however, the linkage disequilibrium with more distant functional variant is still to be evaluated. Our findings suggest that the *EMSY* variant IVS6-43A>G could be used as a biomarker for aggressive prostate cancer, but these results need to be confirmed and the exact role in aggressive development of cancer has to be further evaluated.

470/T

Caspase-8 gene SNPs in prostate cancer susceptibility: a replication study. *M. Parry[1], G. Elliott[1], R. Abo[2], N.J. Camp[2], D.E Neal[3], J.L. Donovan[4], F.C. Hamdy[5], A. Cox[1].* 1) Institute for Cancer Studies, University of Sheffield, Sheffield, South Yorkshire, United Kingdom; 2) University of Utah, Salt Lake City, Utah, USA; 3) University of Cambridge, Cambridge, United Kingdom; 4) University of Bristol, Bristol, United Kingdom; 5) University of Oxford, Oxford, United Kingdom.

Introduction A single nucleotide polymorphism (SNP) in the caspase-8 gene, (CASP8 D302H), has been reported to be involved in susceptibility to breast and pancreatic cancer, melanoma, and glioma, but not colorectal or ovarian cancer. We previously have used a tagging-SNP approach to test the hypothesis that this SNP, or other variants in CASP8, were associated with prostate cancer, in 1009 cases, 987 men with normal serum prostate specific antigen (PSA) levels and 961 men with low serum PSA (<0.5ng/ml). These subjects were drawn from those participating in the UK ProtecT (Prostate Testing for Cancer and Treatment) trial. Of the 15 tagging SNPs in caspase-8 that were genotyped, 7 showed some evidence of association with prostate cancer (P<0.05). The aim of the present study was to attempt to replicate these results in an independent set of case and control subjects. Methods A further independent sample of men from the ProtecT trial formed the replication cohort for this study. Blood DNA samples were available for 1262 men with prostate cancer, 1258 men with normal serum PSA, and 609 men with low serum PSA. SNP genotyping was carried out by 5-prime nuclease PCR (TaqmanTM, Applied Biosystems). The association with prostate cancer was tested using logistic regression, controlling for sample set. Results Genotype call rates for the 7 SNPs were all greater than 95%, and genotype frequencies in control subjects were consistent with those expected under Hardy-Weinberg equilibrium. None of the 7 SNPs yielded significant evidence of association in the replication cohort, although some odds ratios were consistent between the two data sets. We combined the data from the test and replication cohorts to evaluate the overall evidence for association. The rare alleles of rs3769826, rs6435074 and rs6723097 conferred a reduced risk of prostate cancer with per-allele odds ratios (95% confidence interval) [OR(95%CI)] of 0.90 (0.82-0.98), 0.84 (0.77-0.94) and 0.88 (0.80-0.96), and P=0.013, P=0.001 and P=0.004 respectively. The deletion allele of the promoter indel rs3834129 conferred an increased risk of prostate cancer, with OR (95%CI) of 1.15 (1.05-1.27), P=0.003. While these results await further replication, it is interesting to note that the rare alleles of rs3769826, rs6435074 and rs6723097, associated with reduced risk, are associated with increased risk of breast cancer, suggesting the possibility of a different mode of action of caspase-8 in the two tumour types.

An Integrated Approach to Uncover Drivers of Cancer. *D. Pe'er[1,2], O. Litvin[1,2], J. Kim[3,4], F. Sanchez-Garcia[1], H.C. Causton[1], P. Pochanard[3,4], E. Mozes[1], D. Kotliar[1], Y. Tzur[1], L.A. Garraway[3,4], U.D. Akavia[1,2].* 1) Biological Sci, Columbia Univ, New York, NY; 2) C2B2, Columbia Univ, New York, NY; 3) Medical Oncology, DFCI, Harvard Medical School, Boston, MA; 4) Broad Institute, Boston, MA.

Systematic characterization of cancer genomes has revealed a staggering complexity of aberrations among individuals, such that the functional importance and physiological impact of most tumor genetic alterations remains poorly defined. A major challenge involves the development of analysis methods to uncover biological insights from the data, including the identification of the key mutations that drive cancer and how these events alter cellular regulation. We have developed Conexic, a novel Bayesian Network-based framework to integrate chromosomal copy number and gene expression data to detect to detect driver genes located in regions that are aberrant in tumors. The underlying assumption is that a driving mutation might be associated with a characteristic gene expression signature representing genes whose expression is modulated by the driver. Thus our score guided approach searches for genes that are both recurrently aberrant and associated with variance of expression patterns across tumor samples. This method not only pinpoints specific regulators within a large aberrant region, but also by associating drivers with gene modules whose expression vary with the driver, provides insight into the physiological roles of drivers and associated genes. We demonstrated the utility of the CONEXIC framework using a melanoma dataset (Lin et al., Cancer Research, 2008) that includes paired measurements of gene expression and copy number from 62 samples. Our analysis correctly identified known drivers in melanoma (such as MITF) and connected these to many of their known targets, as well as the biological processes they regulate. In addition, it predicted multiple tumor dependencies not previously implicated in melanoma. We tested the effect of knockdown for two predicted drivers, TBC1D16 and RAB27A, and showed that tumors highly expressing these genes are dependent on the same gene for growth. Additionally, gene expression in the associated modules is altered following knockdown as predicted by our model. The identity of these drivers suggests that abnormal regulation of protein trafficking is important for cell survival in melanoma and highlights the importance of protein trafficking in this malignancy. Together, these results implicate a new tumorigenic process in cancer and demonstrate the ability of integrative Bayesian approaches to identify novel drivers with biological, and possibly therapeutic, importance in cancer.

472/T

NPAS3 is a late stage acting progression factor in astrocytomas. *M. Rana[1], TR. Kiehl[2], K. So[3], P. Gould[4], D. Kamnasaran[1,5]*. 1) Pediatrics Research Unit - Centre de recherche du CHUL-CHUQ; 2) Department of Pathology, University Health Network, Toronto, ON, Canada; 3) PRP laboratory, Laboratory Medicine Program, University Health Network, Toronto, ON, Canada; 4) Division of Anatomic Pathology, Department of Medical Biology, CHAUQ Hôpital de l'Enfant-Jésus, Québec, PQ, Canada; 5) Department of Pediatrics, Laval University, Québec, PQ, Canada.

Astrocytomas are the most common primary brain brains and are among the top five causes of cancer related deaths. Despite current treatments, the overall survival of patients still remains poor. In our effort to better comprehend the genetics of gliomas, we explored new therapeutic targets. We previously cloned the human NPAS3 gene and initially identified it as an astrocytoma candidate based on the Cancer Genome Project reporting chromosome 14 deletions (with NPAS3) among ~20-80% of astrocytomas, and with >70% of our panel of 433 human surgically resected astrocytoma specimens having aberrant NPAS3 protein expression. Subsequent functional studies concluded that NPAS3 is a late-stage acting progression factor with tumor suppressive roles. This was based on the discovery of preferential loss of NPAS3 expression in surgically resected human high grade astrocytomas, in comparison to low grade astrocytomas. Furthermore, malignant astrocytoma specimens with loss of NPAS3 expression had loss of function mutations which were associated with loss of heterozygosity. A dominant-negative heterozygous loss-of-function mutation was also identified in a lesion with elevated NPAS3 expression. While an over-expressed or re-expressed NPAS3 in malignant glioma cell lines significantly suppressed transformation, the converse reduced expression significantly and induced more aggressive in-vivo intracranial tumor growth. Most remarkable, knock-down of NPAS3 expression in human astrocytes promoted in-vivo intracranial growth of tumors reminiscent of malignant astrocytomas, in concert with other gliomagenesis pre-disposition genes. In conclusion, our data identified crucial evidence of NPAS3 as a novel tumor suppressor gene with a role in the late-stage progression of malignant human astrocytomas.

Exome sequencing in the identification of breast cancer predisposition genes. *K. Snape[1], P. Tarpey[2], S. Seal[1], A. Renwick[1], G. Bowden[1], D. Hughes[1], M. Ricketts[1], C. Turnbull[1], M.R. Stratton[1,2], N. Rahman[1]*. 1) Section of Cancer Genetics, Institute of Cancer Research, Sutton, United Kingdom; 2) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

Breast cancer is a common condition affecting approximately 1 in 10 women in the UK. The recognised familial clustering of breast cancer, in combination with the known increased incidence in first degree relatives of women with the disease and evidence from twin studies points to a strong genetic susceptibility underlying this disorder. High, intermediate and low penetrance genetic variants that predispose to breast cancer have been identified but only account for <30% of the genetic risk of the disease. By resequencing candidate genes involved in the DNA repair pathway we previously identified intermediate penetrance breast cancer predisposition genes *CHEK2, ATM, BRIP1* and *PALB2*. These genes are characterized by rare, inactivating, primarily truncating mutations that confer a relative risk of breast cancer of 2-4. It is highly plausible that there exist additional genes acting in a similar fashion. Systematic large-scale resequencing offers the opportunity to search for disease genes with an agnostic rather than a candidate-gene approach, and has already proved successful in simple Mendelian disorders. We are utilising whole-exome capture in combination with next-generation sequencing technology in familial breast cancer cases to identify further intermediate penetrance genes that function in pathways not predictable from current paradigms. We have undertaken next-generation sequencing using Agilent SureSelect Target Enrichment technology to sequence the exomes of 22 individuals with familial breast cancer. We are validating and following up all truncating variants that are not known polymorphisms in larger series of breast cancer cases. The analytical processes and up-to-date data will be presented.

474/T

Association of Chromosome 6p Multiple Regions with Nasopharyngeal Carcinoma and Gene Expression Changes in Cancer Tissue. *Y. Song[1], L. Fu[2], Y.H. Fan[1], A.M.G. Wong[2], M.X. Li[1], X.Y. Guan[2]*. 1) Dept Biochemistry, Univ Hong Kong, Hong Kong, hk, China; 2) Department of Clinical Oncology, Univ Hong Kong, Hong Kong, hk, China.

Nasopharyngeal carcinoma (NPC) is a malignancy that has nearly 100-fold higher in southern Chinese than in most European population. NPC clusters in families, which suggests that both geography and genetics may influence disease risk. The age group is younger than most adult cancer patients. A population study has reported that the risk of suffering from NPC is 9.31 times higher in the first-degree relatives of patient with NPC than in the first-degree relatives of spouse. The heritability is 68.08%. We employed case-control analysis to study the association of Chromosome 6p regions with nasopharyngeal carcinoma. Total 360 subjects and 360 healthy controls were included. Significant associations were found for multiple markers (most significant p= 3.36E-05, rs2076483) and genes (*GABBR1, HLA-A* and *HCG9*). Further investigation of the allele frequencies between cases and controls suggested regions of micro-deletion within *GABBR1* and *NEDD9*. Real-time PCR using 11 pairs of NPC biopsy samples confirmed significant decrease in the cancer tissues (p=0.059 and 0.015 respectively). Our study from both genetics and functional points of view demonstrated Chromosome 6p multiple regions contribute to risk of nasopharyngeal carcinoma.

475/T

mRNA expression profiling and siRNA studies identify the short stature homeobox 2 gene (SHOX2) as a downstream target of JAZF1. *W. Tang[1], Y. Fu[1], M. Tarway[1], L. Liu[1], J. Hall[2], L. Prokunina-Olsson[1]*. 1) LTG, DCEG, NCI, NIH, Bethesda, MD; 2) Developmental Biology Center, University of Minnesota, Minneapolis, MN.

Genome-wide association studies (GWAS) have identified genetic variants within *JAZF1* gene to be associated with height, body stature, risk of type 2 diabetes, systemic lupus erythematous and prostate cancer. However, the molecular phenotypes that link *JAZF1* to these diverse traits are currently unclear. We used Ingenuity Pathway Analysis (IPA) to analyze genome-wide mRNA expression in the NCI-60 cell line set and observed that one of the genes with the strongest correlation with *JAZF1* expression (r=0.64, FDR-adjusted $p=4.3x10^{-4}$) was the short stature homeobox 2 gene (*SHOX2*), associated with delayed chondrocyte differentiation and shortened long bones of the limbs in the *Shox2* deficient mouse model. Expression of *JAZF1* and *SHOX2* was also correlated in a panel of non-cancerous human tissues (n=15, r=0.59, p=0.021) and in normal human pancreas (n=36, r=0.68, $p=2.8x10^{-5}$). siRNA knock-down of *JAZF1* expression in the pancreatic cancer cell line PANC1 resulted in a significant decrease of *SHOX2* expression, suggesting that *SHOX2* is a downstream target of *JAZF1*. Our analysis provides the first insights into possible molecular phenotypes relevant for genetic associations reported for *JAZF1* and identified *SHOX2* as a downstream target of *JAZF1*.

476/T

Down-regulated PLZF is associated with anti-apoptosis in Lung Cancer. *X. Wang[1], J. Wang[1], J. Xu[2], L. Wang[2], Y. Bao[3], Z. Zhao[1], Y. Ma[1], Z. Xu[2], L. Jin[1].* 1) State Key Laboratory of Genetic engineering, MOE Key Laboratory of Comtemporary Anthropology, Fudan University, Shanghai, China; 2) Department of Cardiac and Thoracic Surgery, Changhai Hospital, Shanghai, China; 3) Yangzhou No.1 People's Hospital.

The promyelocytic leukemia zinc finger (PLZF) protein, a transcriptional repressor and tumor suppressor, regulates the expression of genes involved in physiological development, proliferation, differentiation, and apoptosis. Apoptosis-inducer TP53INP1, ID1, ID2 and ID3 were considered as functional mediator of apoptosis induced by PLZF expression. So far there has been no research on PLZF in lung cancer. By comparing gene expression profiles in 6 pairs of lung cancer tissues using microarray analysis of gene expression, it has been found that PLZF was down-regulated in lung cancer tissues and the expression levels of PLZF-related genes were also changed accordingly. We further detected PLZF expression in 111 pairs of lung cancer tissues and corresponding normal lung tissues by Real-Time PCR and found that PLZF was down-regulated in 89% of cancer tissues. Moreover, the expression of PLZF mRNA was decreased by 20-fold in 50% of cancer tissues. It suggested that abnormal PLZF expression contributed to lung tumorigenesis. Further analysis found that PLZF expression was associated with patient gender (P = 0.017). Apoptosis TUNEL Assay of 63 pairs of paraffin-embedded lung cancer tissues and their corresponding normal tissues indicated that abnormal PLZF expression may also contribute to anti-apoptosis in lung cancer. The expressions of TP53INP1, ID1, ID2 , ID3, CASP9 and BIRC5 (survivin) were measured in 40 pairs of lung cancer tissues in which PLZF expression was significantly reduced. As expected, the functional mediators of PLZF, TP53INP1, ID1, ID2 and ID3 were down-regulated in more than 75% of lung cancer tissues. Meanwhile, the inhibitor of apoptosis, BIRC5, was up-regulated in 65% of cancer tissues, whereas the mediator of apoptosis, CASP9, was down-regulated in 65% of cancer tissues. This is the first report that deregulation of PLZF plays an important role in the carcinogenesis of lung cancer, and reduced expression of PLZF may contribute to anti-apoptosis in lung cancer. P53INP1, ID1, ID2 and ID3 could be mediators of growth-inhibition and apoptosis induced by PLZF.

477/T

Systematic Detection of Putative Tumor Suppressor Genes Through the Combined Use of Exome and Transcriptome Sequencing. *Q. Zhao[1], E.F. Kirkness[1], O.L. Caballero[2], P.A. Galante[3], R.B. Parmigiani[3], Z. Ye[5], S. Kuan[5], L. Edshall[5], S. Levy[1], A.R. Vasconcelos[4], B. Ren[5], S.J. de Souza[3], A.A. Camargo[3], A.J.G. Simpson[2], R.L. Strausberg[1,2].* 1) Human Genomics, J Craig Venter Inst, Rockville, US; 2) Ludwig Institute, New York Branch, New York, NY 10021, USA; 3) Ludwig Institute, São Paulo Branch at Hospital Alemão Oswaldo Cruz, São Paulo, SP 01323-903, Brazil; 4) Laboratório Nacional de Computação Científica, Laboratório de Bioinformática, Petrópolis, RJ 25651-070, Brazil; 5) Ludwig Institute, San Diego Branch, San Diego, CA 92093-0660, USA.

Cancer arises from gain of function in oncogenes and loss of function in tumor suppressor genes. To characterize two types of frequent genomic events resulting in loss of function in cancer, we took a genome-wide search from exome and transcriptome sequencing data to look for genes with loss of heterozygosity (LOH) and allele specific expression (ASE). The analysis was conducted on a breast cancer cell line and its corresponding control cell line from lymphoblast from the same individual. By comparing variant allele frequencies using exome sequences between the two cell lines, we identified a significant number of LOH events in the breast cancer cell line, which are either clustered in large chromosomal regions or as isolated somatic event. The combination of exome and transcriptome sequence data within the same cell line also revealed genes with ASE events, which comprise 2% to 5% of genes surveyed. Molecular function and cellular network analysis revealed that many of these genes identified by LOH and ASE are known or putative tumor suppressor genes such as BRCA1, MSH3 and SMARCA4, which participate in DNA replication-coupled DNA repair pathways. Our results demonstrate that the combined application of high throughput sequencing to exome and allele-specific transcriptome analysis can reveal genes with known tumor suppressor characteristics, and a short-list of novel candidates for the study of tumor suppressor activities.

478/T

Genetic modifiers of age of onset in Lynch syndrome (hereditary non-polyposis colorectal cancer) in South Africa. *S. Owens[1, 2], D. Velez Edwards[3], A. Vorster[1], U. Algar[4], R. Ramesar[1].* 1) MRC Human Genetics Research Unit, Division of Human Genetics, Institute for Infectious Diseases and Molecular Medicine, University of Cape Town, Cape Town, South Africa; 2) Fogarty International Clinical Research Fellow, Institute for Global Health, Vanderbilt University Medical Center, Nashville, TN USA; 3) Vanderbilt Epidemiology Center, Institute of Medicine and Public Health, Department of Obstetrics and Gynecology, Vanderbilt University Medical Center, Nashville, TN USA; 4) Familial Colorectal Cancer Coordinator, Groote Schuur Hospital, Cape Town, South Africa.

Colorectal cancer (CRC) is the second leading cause of cancer-related deaths in the U.S. and the third leading cause in South Africa, with both genetic and environmental factors playing a role. Hereditary nonpolyposis colorectal cancer (HNPCC), more recently referred to as Lynch syndrome, is an inherited disorder caused by mutations in DNA mismatch repair (MMR) genes. Individuals with HNPCC have an 80% lifetime risk of CRC but the age of onset is highly variable due to additional genetic and environmental factors. We hypothesized that in individuals predisposed to HNPCC with a primary mutation in a MMR gene, one or more secondary mutations act to influence the age of CRC onset. This study aimed to identify such genetic modifiers.

A South African cohort of 232 HNPCC individuals harboring primary mutations in MMR genes *MLH1* and *MSH2* were genotyped for selected polymorphisms in six candidate loci (*GCLC*, *CYP1A1*, *EPHX1*, *IGF1*, *OGG1* and 8q24). Modifier effects for each SNP were tested individually for association to age of onset. Epistatic interactions between potential modifiers were also assessed, including gender-specific effects.

Preliminary Kaplan-Meier analysis for a variant in *CYP1A1* demonstrated a significant difference in age of onset (p=0.04). Analysis for the remaining variants revealed no statistically significant difference in gender, MMR gene mutation or ethnicity.

These results, very likely in addition to other environmental and genetic modifiers currently being investigated, will directly translate into improved clinical management of CRC. This is particularly important in South Africa and other resource-poor countries, where risk stratification based on genetic testing for modifier polymorphisms has the potential to improve surveillance schedules for individuals identified to be at high risk due to a predisposing primary mutation in a MMR gene.

479/T

A large genomic rearrangement in the 17q21 chromosomal region disrupts the *BRCA1* gene. *K. Pylkäs[1], M. Haanpää[1], J. Nikkilä[1], J. Ignatius[1,2], R. Winqvist[1].* 1) Laboratory of Cancer Genetics, Department of Clinical Genetics, University of Oulu, Oulu, Finland; 2) Department of Genetic Counseling, Turku University Hospital, Turku, Finland.

BRCA1 is one of the two major genes associated with familial breast and ovarian cancer susceptibility. Most of the alterations identified in *BRCA1* are point mutations and small insertions/deletions, but an increasing number of large genomic rearrangements have also been identified in different populations. Here we have analyzed 61 index patients of Northern Finnish breast and/or ovarian cancer families for large genomic rearrangements in *BRCA1*. One large rearrangement, deleting most of the gene including the promoter region, was observed in one family with multiple cases of ovarian cancer. The breakpoints of the observed deletion have now been characterized further by MLPA and high-resolution array comparative genomic hybridization (aCGH) analyses for the involved 17q21 chromosomal region. Our results demonstrate that the deletion extends over 260 Kbs in size and leads to the loss of several neighboring genes.

480/T

Carney complex phenotype in patients carrying *PRKAR1A* mutations and *PDE11A* variations. *R. Libe[1], A. Horvath[2], A. Fratticci[1], D. Vezzosi[1], J. Coste[1], K. Perlemoine[1], B. Ragazzon[1], M. Guillaud-Bataille[1], L. Groussin[1], E. Clauser[2], M. Raffin-Sanson[1], X. Bertagna[1], C. Stratakis[2], J. Bertherat[1].* 1) Institut Cochin, INSERM U56, Paris, France; 2) NICHD, NIH, Bethesda, MD, USA.

CNC is an autosomal dominant disorder featuring skin lesions, cardiac and other myxomas and different types of endocrine tumors, among the most common of which primary pigmented nodular adrenocortical disease (PPNAD), and testicular lesions (Large Cell Calcifying Sertoli Cell Tumor, LCCSCT). Mutations in regulatory subunit type 1 alpha (*PRKAR1A*) of Protein Kinase A (PKA) are responsible for the disease in at least 65% of the CNC patients. *PDE11A* inactivating mutations have been described in patients with isolated PPNAD, as well as in patients with bilateral or familial testicular germ cell tumors. We evaluated the impact of *PDE11A* variations on the phenotype in CNC patients who were carriers of a pathogenic *PRKAR1A* mutation. We analyzed the coding sequence of *PDE11A* in 150 patients with CNC and mutations in *PRKAR1A* and in 279 controls free of endocrine tumors and family history. A significantly higher prevalence of *PDE11A* mutations was found among CNC patients compared to controls (25.3% vs 6.8% in the controls, $\chi 2=29$, $p<0.00001$). Within the CNC patient group, the PDE11A mutations were significantly more frequent in the patients with PPNAD versus the ones without PPNAD (30% vs 13%, p=0.025). Similarly, CNC patients with LCCSCT had higher prevalence of PDE11A variations compared to those without LCCSCT (50% vs 10%, p=0.025). In addition, simultaneous inactivation of *PRKAR1A* and *PDE11A* by small inactivating RNAs (siRNA) in HEK293 cells led to increased luciferase activity in a cAMP response elements (CRE)-based reporter assay. Our data suggest an effect of *PDE11A* variations on the risk for developing PPNAD and LCCSCT in the context of CNC. This is consistent with the role of PDE11A, as a susceptibility gene for adrenocortical and testicular tumors, at large. A synergistic effect of inactivating *PDE11A* and *PRKAR1A* mutations may be at play; both defects would lead to increased cAMP signaling, as suggested by the functional siRNA-based assay.

481/T

SDHAF2 and TMEM127 genes in pheochromocytoma and paraganglioma predisposition. *Y. Ni[1,2], J. Moline[1], M. Orloff[1,3], J. Chen[1], C. Eng[1,2,3,4,5].* 1) Genomic Medicine Institute, CLeveland Clinic, Cleveland, OH; 2) Department of Molecular Medicine, Cleveland Clinic Lerner College of Medicine, Cleveland, OH; 3) Taussig Cancer Institute, Cleveland Clinic, Cleveland, OH; 4) CASE Comprehensive Cancer Center, Case Western Reserve University, Cleveland, OH; 5) Department of Genetics, School of Medicine, Case Western Reserve University, Cleveland, OH.

Pheochromocytoma (PC) and paraganglioma (PGL) are tumors of the autonomic nervous system, which can be hereditary or sporadic. Germline mutations in genes that encode succinate dehydrogenase subunits B, C, and D (SDHB, SDHC, SDHD) are well known to associate with PC and PGL. More recently, the Gly78Arg mutation in SDHAF2 encoding succinate dehydrogenase complex assembly factor 2, was identified in 2 familial PGL kindreds. In addition, germline mutations in TMEM127, a transmembrane protein-encoding gene, were shown to confer susceptibility to adrenal PC. We sought to determine the relative contribution of SDHAF2 and TMEM127 genes in predisposition to isolated and familial PC and PGL that were unrelated to RET, VHL or SDHB-D. Of 102 eligible probands, we previously identified 41 (40%) with germline SDHB-D deleterious mutations. Therefore, SDHAF2 and TMEM127 mutation and deletion analyses were performed in the remaining 61 PC-PGL patients (32 PGL, 29 PC; 5 multifocal and/or familial, 56 isolated, unifocal cases; 10-83y, mean 45y). No deletion was detected in any of the cases tested for these 2 genes. There were 2/61 (3%) with germline mutations/variants in SDHAF2: a potential splice variant (c. 371-3C>T) in an isolated case with metastatic thoracic PC diagnosed at the age of 26, and a deleterious Gly78Arg mutation in a 25yo with multifocal neck PGL and positive paternal family history. TMEM127 analysis revealed 4/61 (6.5%) cases with missense variants, 3 carrying the same start codon alteration, Met1Ile. Of these 3 cases, 2 had additional variants, Gly6Asp and Ser33Leu, respectively. The fourth case had a Gly6Asp variant. All 4 cases are isolated adrenal PC patients with relative early age at onset (10-58y, mean 34.75y). We compared the TMEM127 transcript level in these 4 cases to 6 healthy controls by quantitative RT-PCR. Mean mRNA level in all TMEM127 variant carriers was half that of the controls. This result is consistent with the loss-of-function of TMEM127 mutations. In summary, SDHAF2 and TMEM127 germline mutations were identified in addition to our original analysis of SDHB-D and increased the frequency of germline mutations in all incident PGL and PC patients from 40% to 46%. More specifically, TMEM127 variants were predominant in isolated adrenal PC cases. SDHAF2 mutations were associated with earlier onset familial PGL cases based on our and other groups' studies, while we reported the first isolated metastatic PC case with SDHAF2 variant here.

482/T

No recurrent genomic aberrations in Ollier disease related enchondromas as assessed by high-resolution SNP array and expression array: a Genome-wide approach. *T.C. Pansuriya[1], J. Oosting[1], A.M. Cleton-Jansen[1], A.H.M. Taminiau[1], L. Sangiorgi[2], R. Sciot[3], P.C.W. Hogendoorn[1], K. Szuhai[1], J.V.M.G. Bovée[1].* 1) Pathology, Leiden University Medical Center, Leiden, Zuid Holland, Netherlands; 2) Rizzoli Orthopaedic Institute, Bologna, Italy; 3) University of Leuven, Leuven, Belgium.

Ollier disease is a rare, non-hereditary disease which is characterized by the presence of multiple enchondromas (EC), benign cartilaginous neoplasms arising within the medulla of the bone with an asymmetric distribution, and a risk of malignant transformation towards central chondrosarcoma (CS) up to 35%. The etiology of Ollier disease is unknown. Point mutations in *PTH1R* (G121E, A122T, R150C and R255H) have been reported in about 10% of Ollier patients. However, in our series all four reported point mutations in *PTH1R* were absent. We hypothesized that Ollier disease is a mosaic condition. An early post zygotic mutation in a tumor suppressor gene may explain the asymmetric involvement of the skeletal structures. Later on a second hit in some of these affected cells will subsequently lead to EC formation. We therefore undertook genome-wide copy number and loss of heterozygosity (LOH) analysis in 14 EC and 18 CS from 24 Ollier patients using Affymetrix SNP 6.0 array platform. We have included 16 healthy and 10 patient controls. The data were analyzed by R and Nexus software packages. In EC, a large number of small copy number changes were found. Because the number and size of these changes was not different from the controls, these are indicative of known CNVs. Paired analysis indicated absence of LOH in EC whereas most of the CS shared LOH at 6, 9p and 13q. No common genomic alterations were found for all ECs therefore we investigated the candidate genomic regions in each case separately. By using a SNP array approach we identified 5 regions, of which 3 remained valid after confirmatory tests. The 2 excluded regions were known CNV regions. Illumina expression array was performed on 5 EC, 14 CS and 6 controls. Thousands of genes were differentially expressed in EC compared to controls and between EC and CS. With pathway analysis, the p53 pathway (adj. p-value = 0.03) and biosynthesis of steroid pathway (adj. p-value = 0.07) differs between controls and Ollier tumours. Integration of SNP and expression data has allowed us to identify candidate regions which were validated. In conclusion, no genetic alterations are shared by all EC. Our data show conclusively that LOH and common copy number alterations are rare in EC which reflects genetic heterogeneity of the tumor. One could predict that instead small deletions, point mutations or epigenetic mechanisms seem to play a role in the origin of Ollier disease.

483/T

Three novel mutations in *PDE8B*, a cAMP phosphodiesterase highly expressed in the adrenal cortex, in a cohort of patients with adrenal tumors. *A. Rothenbuhler[1], A. Horvath[2], F. Faucz[2], M. Almeida[2], M. Lodish[2], R. Libé[1], M. Nesterova[2], J. Bertherat[1], C. Stratakis[2].* 1) Institut Cochin INSERM U567; 2) NICHD, NIH, Bethesda, MD, USA.

Genetic aberrations in the cAMP signaling pathway have been found to play a role in many types of adrenal tumors (ADTs). Our group identified mutations of a phosphodiesterase (PDE) gene, *PDE11A*, in patients with micronodular adrenocortical hyperplasia (MAH). A genome-wide SNP genotyping study in individuals with adrenocortical hyperplasia leading to Cushing syndrome (CS) that was not caused by known defects indicated that, in addition to the 2q31-33 locus (*PDE11A*), a locus on 5q14, harboring another PDE, *PDE8B*, was likely to contain a disease-related gene. A single base substitution in PDE8B that resulted in a proline-to-histidine change in an evolutionarily-conserved residue of the protein (c.914A>T/p.H305P) was then identified in a female pediatric patient with CS due to MAH. We now studied 40 patients with secreting and non-secreting adrenal tumors for sequence alterations of the *PDE8B* gene and investigated PDE8B's expression in the adrenal cortex and its lesions. Three, previously non-reported PDE8B sequence variants were identified in three patients with secreting adrenal tumors; the first, a splice site mutation which leads to an estimated 20% decreased acceptor site activity of exon 14 (c1365-5 g/a), the second, a single base substitution, that led to a valine-to-isoleucine change in exon 18 (c.2089 G>A/p.V697I) and the third, also a single base substitution, that led to a arginine-to-histidine change in exon 2 (c.362G>A/p.R121H). In vitro transfection experiments showed that each of the missense mutations resulted in lower levels of PDE activity and higher levels of cAMP. Immunohistohemistry (IHC) studies showed an increase of PDE8B expression in the adrenal cortex of patients with adrenal lesions due to other defects of the cAMP-signaling pathway. In conclusion, we found three novel *PDE8B* sequence variations with potential impact on the ability of PDE8B to bind and/or degrade cAMP, and evidence of a counter-regulatory role of this PDE in cAMP signaling in adrenalocortical lesions. These data support a significant role of *PDE8B* in adrenal pathophysiology and/or tumorigenesis.

Shared Genomic Segment analysis identifies a susceptibility locus for breast cancer at 14q23.3. *Z. CAI[1], L.A. Cannon-Albright[2], N.J. Camp[2], A. Thomas[2].* 1) Department of Biomedical Informatics, University of Utah, Salt Lake city, UT; 2) Division of Genetic Epidemiology, Department of Internal Medicine, University of Utah, Salt Lake city, UT.

Breast cancer is the second most prevalent cancer in developed countries. Family history is a major factor in terms of breast cancer risk. High-risk mutations have been found in BRCA genes, e.g. BRCA1 and BRCA2, but these only account for a small proportion of hereditary breast cancer cases. Other rare and common variants have also been suggested. However, even after accounting for all known and putative risk variants there remains substantial “missing heritability.” It is possible that further rare genetic variants exist. The shared genomic segment (SGS) method was developed to identify genomic regions shared by distantly related individuals in extended pedigrees using high-density genomewide SNP arrays. Genomic regions that are shared in excess by diseased individuals in extended high-risk pedigrees are good candidates to harbor disease loci. The SGS method measures allele sharing at consecutive genetic markers across the genome to identify those segments that are shared in excess of that expected by chance. Significance is assessed empirically to account for linkage disequilibrium between SNPs and pedigree structure. It has been shown to have good power to identify disease risk loci caused by rare genetic variations. We applied SGS method to a high-risk Utah breast cancer pedigree containing 10 cases separated by 33 meioses. This pedigree was assessed to contain a significant excess of breast cancer using a cluster analysis in the Utah Population Database. Additionally, risk of breast cancer in this pedigree was assessed not to be due to mutations in BRCA1 and BRCA2. A genomic region measuring 0.33 cM in length at 14q23.3 (65,713kb - 67,004kb NCBI Genome Build 36.3) was detected with high statistical significance (p<1e-6). This region has previously been shown to be differentially expressed across morphological breast cancer subtypes. Also, gene translocations have been identified in this region associated with breast cancer. In conclusion, this region identified by SGS is a strong candidate to contain a rare breast cancer risk variant.

Lifetime environmental exposure to tobacco smoke, genetic susceptibility, and risk of lung cancer in non-smoking Taiwanese. *C. Hsiao[1], C. Chang[1], G. Chang[2], Y. Tsai[3], Y. Chen[4], M. Huang[5], W. Su[6], W. Hsieh[1], P. Yang[7], C. Chen[8], C. Hsiung[1].* 1) Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan; 2) Division of Chest Medicine, Department of Internal Medicine, Taichung Veterans General Hospital, Taichung, Taiwan; 3) Department of Pulmonary and Critical Care, Chang Gung Memorial Hospital, Taipei, Taiwan; 4) Chest Department, Taipei Veterans General Hospital, Taipei, Taiwan; 5) Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 6) Department of Internal Medicine, National Cheng Kung University Hospital, Tainan, Taiwan; 7) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 8) Genomics Research Center, Academia Sinica and Graduate Institute of Epidemiology, National Taiwan University, Taipei, Taiwan.

Environmental tobacco smoke (ETS) has been suggested as a risk factor of lung cancer in nonsmokers. The ETS exposure mainly comes from three sources: childhood and adulthood household passive smoking, and adult work-place passive smoking. Although ETS and genetic factors may play important roles on lung cancer risk, the interactive effect between ETS and genetic factors on lung cancer risk needs to be explored. A total of 1,785 non-smoking lung cancer cases and 1,942 non-smoking healthy controls were enrolled from six medical centers in Taiwan between 2002 and 2009. Genetic polymorphisms of hOGG1 Ser326Cys were determined by the MassARRAY system. ETS history was obtained through personal interview based on a structured questionnaire. Multivariate logistic regression analyses were performed to estimate odds ratios (OR) and 95% confidence intervals (CI) for the risk of lung cancer in exposed vs. non-exposed ETS groups. Childhood ETS had non-significant effects on the risk of lung cancer (OR=1.2, 95% CI= 0.5-2.9) after controlling for adulthood ETS exposure (including adulthood household and work-place). Adulthood household and work-place had independent risk effects on lung cancer (adulthood household: OR=1.3, 95% CI= 1.1-1.6; work-place: OR=1.9, 95% CI= 1.6-2.4). On the other hand, considering the interaction between hOGG1 gene and ETS for the risk of developing lung cancer, comparing with the Ser/Ser genotype, the Cys/Cys genotype had higher risk in ETS exposure group (OR=2.0, 95% CI= 1.1-3.7), but not in the non-ETS group (OR=1.2, 95% CI= 0.6-2.8). It was concluded that the adulthood ETS has prominent effects on the risk of lung cancer, especially work-place passive smoking. In addition, hOGG1 Cys/Cys genotype has modifying effect on lung cancer risk by ETS exposure status among non-smokers.

486/T

The Genetic Epidemiology of Melanoma Prognosis. *G. Cadby[1], S.V. Ward[1], J.M. Cole[2], M. Millward[3], L.J Palmer[1].* 1) Centre for Genetic Epidemiology and Biostatistics, UWA, Nedlands, Western Australia; 2) Western Australian Melanoma Advisory Service, Perth, Western Australia; 3) School of Medicine and Pharmacology, UWA, Nedlands, Western Australia.

Melanoma is the most aggressive form of skin cancer. Australia has the highest incidence of malignant melanoma in the world, and this appears to be rising. Epidemiological research has led to some understanding of the major environmental and genetic risk factors for melanoma, however the role of these factors in melanoma prognosis have not been fully investigated.

The Western Australian Melanoma Health Study (WAMHS) is a population-based case collection and linked biospecimen resource enabling investigation into the genetic epidemiology of melanoma. The WAMHS aimed to recruit all incident cases of invasive cutaneous melanoma in Western Australian adults from January 2006 to September 2009. The final WAMHS sample consisted of 1157 individuals who completed both the questionnaire and gave a blood sample for DNA.

In this analysis, we investigated environmental, host and genetic factors associated with Breslow thickness, which is a prognostic feature of melanoma. Thicker Breslow thickness is associated with poorer prognosis. Our main hypothesis was that the SNPs which increase melanoma-risk are also those which increase Breslow thickness.

A subset of 800 Caucasian WAMHS subjects were genotyped at 42 melanoma-risk SNPs. We investigated several environmental, host and genetic factors associated with Breslow thickness and found Breslow thickness was associated with increasing age (P<0.001), and the presence of naevi on the back (P<0.05). Four SNPs were also found to be associated with Breslow thickness. These were rs12203592 in IRF4, rs1800401 in OCA2, rs1042522 in TP53 and rs1733826 in BRAF. However, none of these associations remained significant after adjustment for multiple testing. Age at diagnosis, the presence of naevi and the four SNPs accounted for 6.8% of variation in Breslow thickness, indicating that there is a large amount of variation unexplained.

This study is the first of its kind to investigate the role of melanoma-risk SNPs in melanoma prognosis. As melanoma mortality and incidence are increasing in Australian adults, identification of the effect of environmental, host and genetic risk factors on prognosis will become increasingly important. Replication of these results, particularly in larger samples, is therefore required.

***CASP8* promoter polymorphism is associated with high-risk HPV types and abnormal cytology but not with cervical cancer.** *K. Chatterjee[1], A-L. Williamson[1,2], M. Hoffman[3], C. Dandara[4].* 1) Division of Medical Virology and Institute of Infectious Disease and Molecular Medicine (IIDMM), University of Cape Town, Cape Town, Republic of South Africa; 2) National Health Laboratory Service, Groote Schuur Hospital, Observatory, Cape Town, Republic of South Africa; 3) School of Public Health and Family Medicine, University of Cape Town, Cape Town, Republic of South Africa; 4) Division of Human Genetics, Faculty of Health Sciences, University of Cape Town, Cape Town, Republic of South Africa.

Background: Only a small fraction of human papillomavirus (HPV) infected women progress to cervical cancer pointing to additional risk factors including host genetics that might play a role in development of cervical cancer. Caspase-8 (encoded by CASP8 gene) plays an important role in generating cell death signals leading to elimination of potentially malignant cells. Genetic variation in CASP8 might influence the susceptibility to cancer. CASP8 -652 6N ins/del polymorphism has been previously reported to influence the progression to several cancers including cervical cancer. The aim of this study was to investigate the role of CASP8 -652 6N ins/del polymorphism in susceptibility to HPV infection leading to pre-cancerous lesions and cervical cancer in South Africans. **Materials and Methods:** The CASP8 -652 6N ins/del polymorphism was investigated in 445 women of black African and mixed-ancestry origin with invasive cervical cancer and 1221 controls matched by age, ethnicity and domicile status. Genotyping for CASP8 -652 6N ins/del was done by PCR-RFLP. Papanicolaou test (Pap smear) was conducted on endocervical scrapings for the control women to test for their cytology status. **Results:** The CASP8 -652 6N del/del genotype did not show any significant association (P = 0.948) with cervical cancer cases. Further analysis within the controls showed a border-line association (P = 0.048) of this polymorphism with abnormal cytology in both ethnicities and significantly high-risk HPV infection (P = 0.030) among the black Africans. **Conclusion:** This is the first study of the role of CASP8 -652 6N ins/del polymorphism in cervical cancer in an African population. This result points towards the importance of variation in CASP8 and its associated genes in the susceptibility to HPV infection and development of pre-cancers.

488/T

Ets1 as a potential target of microRNA-1 in cutaneous squamous cell carcinoma. *D. Gable, J. Fleming, A. Toland.* The Ohio State University Columbus, OH.

Cutaneous squamous cell carcinoma (SCC) is the second most common form of skin cancer, affecting 700,000 people in the United States annually. MicroRNAs are a type of RNA that regulate the expression of other genes. Using miRNA expression arrays, we identified lower levels of microRNA-1 (miR-1) expression in skin from FVB/N mice that are susceptible to chemically-induced skin cancer, compared to skin from Spret/EiJ mice that are resistant. Additionally, murine SCC cell lines showed greatly reduced levels of miR-1 compared to normal skin. We hypothesize that decreased expression of miR-1 in susceptible mice and SCC cell lines suggests a role of miR-1 as a tumor suppressor in skin. To test this hypothesis, we transfected a precursor for miR-1 into a murine SCC cell line, A5, and measured proliferation and apoptosis via an MTT assay and caspase 3/7 assay respectively at 24, 48, and 72 hours post-transfection. The growth rate for cells transfected with miR-1 significantly decreased at 48 to 72 hours post-transfection relative to those negative-control transfected cells at which time apoptosis significantly increased. These data are consistent with our hypothesis that miR-1 may act as a tumor suppressor in the skin. Using in silico prediction programs, we identified a number of genes whose expression may be regulated by miR-1. The transcription factor oncogene, Ets1, emerged as an interesting potential direct target of miR-1. Quantitative PCR and Western analyses revealed decreased Ets1 mRNA and protein expression in A5 cells transfected with miR-1 compared to negative control-transfected cells. Ets1 mRNA expression is also decreased in a normal keratinocyte cell line compared to A5 cells. The inverse correlation in expression suggests Ets1 is regulated by miR-1. Upon performing an MTT assay after co-transfecting A5 cells with a precursor to miR-1 and Ets1, Ets1 appears to increase proliferation independent of miR-1 regulation. Ongoing studies will determine whether Ets1 is a direct target of miR-1. We will also clarify the role of Ets1 in SCC cell apoptosis and migration, and identify other targets and tumor-related phenotypes associated with miR-1.

A chemical genetics screen identifies novel drugs that target steroid biogenesis and receptor signaling which can inhibit the growth of glioma stem cells. *N. Ajewung[1], D. Poirier[2], D. Kamnasaran[1,3].* 1) Pediatrics Research Unit - Centre de recherche du CHUL-CHUQ; 2) Laboratory of Medicinal Chemistry, Oncology and Molecular Endocrinology - Centre de recherche du CHUL-CHUQ; 3) Department of Pediatrics, Laval University, Quebec, Quebec.

Giomas are among the top five causes of cancer related deaths, representing about ~60% of the cases in adults and ~30% in children with primary brain tumors. Furthermore, about five cancer syndromes are associated with patients having a higher risk for developing gliomas during their lifetime. Glioma stem cells represent a fraction of cells within a tumor mass which are postulated to be responsible for tumor re-growth. Most importantly, recent studies have associated glioma stem cells with impeccable treatment resistance mechanisms, leading to an overall poor survival among patients. Since a wide range of genes involved in steroid biogenesis and signaling are expressed in glioma stem cells, our objective was to investigate whether novel classes of drugs that target these gene products can be effective in inhibiting the growth of glioma stem cells. To accomplish this, we screened using a candidate chemical structure approach, a library of 400 drugs which can potentially inhibit steroid biogenesis and cell signaling. By using a panel of human glioma stem cells established from surgical specimens and from glioma cell lines, we discovered a potent drug that inhibits androsterone (male sex pheromone) biogenesis and with the ability to significantly reduce the viability of human glioma stem cells in a dose dependent manner over a one week period. Cells treated with this drug responded by undergoing apoptosis and cell cycle regulatory changes. Furthermore, significant inhibition of transformation was noted. Most remarkable, the toxicity on human astrocytes and neural stem/progenitor cells was minimal, in comparison to the effect on human glioma stem cells. In summary, we have discovered a novel drug from a chemical genetic screen which can significantly inhibit the growth of glioma stem cells, with minimal toxicity on non-transformed human astrocytes and neural stem/progenitor cells.

490/T

Hereditary nonpolyposis colorectal cancer (HNPCC) mutations in patients diagnosed with ovarian cancer in a community setting: is it time to add ovarian cancer in clinical criteria for diagnosis of HNPCC? *S. Cohen, I. Shapira, R. Gralla, K. Sultan, V. John, H. Raftopoulos, J. Lovecchio, A. Menzin, J. Whyte, A. Sakaris, D. Contreras, V. Vinciguerra.* Cancer Genetics, Monter Cancer Center, North Shore-LIJ, Hofstra Medical School, Lake Success, NY.

Background: Up to 10% of ovarian cancers are due to inherited mutations. Of those 85% are due to BRCA 1 & 2 and 13% due to HNPCC mutations. Mutations in HNPCC carry 12% life-time risk for ovarian cancer, 10 fold higher than in the general population. In families with ovarian cancer diagnosis, finding mutations in either BRCA genes or HNPCC genes may provide an opportunity for risk reduction strategies. Objectives: To determine the incidence of HNPCC-related gene mutations in patients with personal or familial ovarian cancer and their likelihood to fulfill Amsterdam I/ II or Bethesda criteria. Methods: Over a 5-year period (2004 -2009), we analyzed the cause of referral for genetic testing and the mutations detected in 1193 consecutively tested individuals (excluding those from families who had been previously tested at our institution to limit the bias for mutation positivity). Forty-one subjects (3.4%) were referred for personal ovarian cancer cancer. The chart review included patient age, self-reported ethnicity, family history, genetic test results and method and which mutation if any was detected. Patients were initially tested for BRCA 1 & 2 mutations if negative they were tested for HNPCC. The ethnic distribution of the 41 ovarian cancer patients was: 16 Ashkenazi, 22 Non-Ashkenazi Europeans, 1 Latino and 2 Asians. Median age at diagnosis was 50 (range 45-60). Results: Twelve patients had deleterious mutations in the BRCA genes (29%; CI 15%-43%) and 5 had deleterious mutations in mistmatch repair genes (12%; CI 4%-26%). The mismatch repair gene mutations detected were two in MLH1 (MLH1 deletion exons 14-19, MLH1 2070insTT), two in MSH2 (MSH2A636P, MSH2 deletion exons 2-7 and 9-10) and one in MSH6 (3108delGT). None of the 41 subjects diagnosed with ovarian cancer at our institution fulfilled clinical criteria for diagnosis of HNPCC. Conclusions: By design Bethesda criteria are broader than Amsterdam I/II criteria and far more likely to lead to testing for HNPCC. Our results show that reliance upon clinical criteria would miss an opportunity to diagnose a large percentage of HNPCC patients. If Amsterdam clinical criteria were expanded to include ovarian cancer in patients with negative mutation testing for BRCA 1 & 2 genes, an additional 12% (5 out of 41) of patients would to have deleterious mutations in HNPCC genes. Genetic testing allows informed decisions on surveillance and preventive strategies for families at risk.

491/T

Spectrum of germline TP53 mutations in breast cancer predisposition. *H. Hanson[1], S. Seal[1], A. Renwick[1], M. Ricketts[1], D. Hughes[1], G. Evans[2], D. Eccles[3], C. Turnbull[1], N. Rahman[1], FBCS(UK) collaboration.* 1) Section of Cancer Genetics, Institute of Cancer Research, Sutton, United Kingdom; 2) University Department of Medical Genetics, St Mary's Hospital, Manchester, United Kingdom; 3) Department of Clinical Genetics, University of Southampton School of Medicine, Princess Anne Hospital, Southampton, United Kingdom.

Germline *TP53* mutations cause Li-Fraumeni syndrome (LFS), a cancer predisposition syndrome associated with sarcomas, breast, brain and adrenocortical tumours. Mutations in LFS families are typically missense mutations that occur at hotspot codons located in the DNA-binding domain. The risk of breast cancer in classic LFS families is high. However, the contribution and mutational profile of *TP53* mutations in breast cancer cases that do not fulfill LFS criteria are unclear. To address this we sequenced *TP53* in 1525 breast cancer cases and in 1334 controls. The breast cancer cases consisted of 1317 familial and 208 non-familial cases and included 385 individuals affected below 31 years. None of the cases had a family history of classic Li-Fraumeni syndrome. We identified ten pathogenic mutations in breast cancer cases and none in controls (p=0.002). The mutations included nine truncating mutations and one pathogenic missense mutation, R337C, which is not in the DNA-binding domain. No hotspot mutations were identified. The family history of breast cancer was modest in the mutation-positive families. The prevalence of mutations was low in the familial breast cancer cases (7/1317) the young onset breast cancer cases (8/385) and the bilateral cases overall (5/330). However, it was appreciable in the small number of individuals with bilateral breast cancer with both breasts affected below the age of 31 years (4/6). We identified non-hotspot missense mutations, including variants in the DNA binding domain, with equal prevalence in both cases and controls. These data demonstrate that the phenotypic effects and penetrance of *TP53* mutations are highly variable and indicate that truncating mutations confer modestly increased risks of breast cancer but typically do not cause Li-Fraumeni syndrome. Furthermore, the identification of missense variants in controls indicates that more caution in attributing pathogenicity to non-hotspot mutations is required. These data have substantial implications for the clinical management of *TP53* mutations.

492/T

Utilization of and referral for genetic services (GS) by 455 unaffected individuals at risk for inherited predisposition to cancer: Pathways to improve identification of individuals at risk for hereditary cancer syndromes. *I. Shapira, R. Gralla, K. Sultan, L. Weiselberg, V. Vinciguerra, H. Raftopoulos, V. John, A. Menzin, J. D'Olimpio, C. Devoe, L. Donahue, D. Budman, S. Cohen.* Oncology, Department of Cancer Genetics, Monter Cancer Center, North Shore-LIJ, Hofstra Medical School, Lake Success, NY.

Background Family history (FH) directs referral of unaffected individuals to GS and is the main strategy to identify hereditary cancer syndromes. Objectives: 1) To determine the rate of deleterious mutations in high risk individuals, based on pedigree, and 2) to identify the origin of their referral. Methods Over a 5-year period (2004 -2009) we analyzed the source of referral for genetic testing and the mutations detected in 1193 consecutively tested individuals. Of 1193 patients tested, 455 (38%) were unaffected by cancer. Of 455 unaffected individuals 80% (364) had pedigrees consistent with hereditary cancer syndromes and 20% (91) had relatives with known deleterious mutations in cancer syndrome genes. Of unaffected carriers 70% (67) had single site testing for known familial mutations. Referring source was: self 113 (25%), GYN 172 (38%), surgeon 111 (25%), PCP 39 (9%) cases, GI 20 (3%). Results Of the 455 individuals at high risk 79 (17%) were carriers of deleterious mutations: 33 BRCA1, 37 BRCA 2, 1 had 2-copies MYH, 1 APC, 3 MLH-1, 3 MSH-2 and 1 MSH-6 mutations. Of the 79 patients with deleterious mutations 26 (33%) were identified by single site testing, 22 (28%) by the Ashkenazi M3-panel, 26 (33%) were identified by sequencing and 2 (6%) by gene rearrangement tests. TEST # of PTS (%) BRCA1 SS 29 (6) BRCA2 SS 29 (6) M3 ONLY 151 (33) M3+REFLEX 64 (14) M3+REFLEX+BART 9 (2) COMP BRCA1/2 143 (31) COMP BRCA1/2+BART 8 (2) SEQ (MLH1/MSH2/MSH6) 9 (2) MLH1/MSH2/MSH6 SS 7 (1.7) APC SEQ 6 (1.7) APC SS 2 (1) MYH SEQ 1 (0.6) TOTAL 455 Table 1: Single site (SS), Ashkenazi panel (M3), Reflex Comprehensive Testing if M3 negative (REFLEX), BRCA rearrangement test (BART), Sequencing (SEQ). Conclusions: Single site testing of a known mutation costs ~ 400$ and in 67 patients (15%) gave rapid information about cancer risk. Of these 39% (26) unaffected individuals were identified as carrying deleterious mutations and 61% (41) individuals found out their cancer risk was average. Primary care physicians identified only 9% of patients with high risk for hereditary cancer syndromes. Discussion: Although FH is the cornerstone of high-risk patient referral to GS, primary care physicians referred only 9% of all patients at risk. FH, public awareness of cancer risk and education will identify at risk populations for referral for GS.

Using Breast Cancer Pathology to Improve Identification of BRCA1 Mutation Carriers. *H. Talbot[1], J. Dunlop[2], A. Ashfield[3], P. Quinlan[3], L. Jordan[4], C. Purdie[4], J. Berg[1,2].* 1) Human Genetics, Centre for Oncology and Molecular Medicine, University of Dundee, Dundee, United Kingdom; 2) East of Scotland Clinical Genetics Service, Ninewells Hospital, Dundee; 3) Surgery and Oncology, Centre for Oncology and Molecular Medicine, Division of Medical Sciences University of Dundee Ninewells Hospital DUNDEE; 4) Department of Pathology, Ninewells Hospital, Dundee.

Introduction. Mutations in the BRCA1 and BRCA2 genes cause a high lifetime risk of breast cancer. Identifying mutation carriers is important for effective treatment, allowing identification of individuals at very high breast cancer risk who qualify for increased screening or prophylactic surgery. Currently, selection for testing is based on family history, with testing available in the UK if the patient has a 20% likelihood of having a BRCA1 or BRCA2 mutation. However, some evidence suggests that using information about breast tumour pathology can improve the identification of patients likely to carry a BRCA1 mutation. This study aimed to confirm the relationship between breast tumour pathology and BRCA1 mutations, and to examine the effect of including pathological data within two BRCA risk prediction models. **Methods**. We reviewed breast tumour pathology in 53 patients: 19 with BRCA1 mutations, 19 with BRCA2 mutations and 15 with a strong family history, but where no BRCA mutation was identified (BRCA0). Evans scores and BOADICEA mutation likelihood scores were calculated for all patients, prior to, and following, the addition of tumour pathology. To incorporate tumour pathology into BOADICEA scores, we used a simple Bayes approach. **Results**. We confirmed that women with BRCA1 mutations were more likely to have oestrogen receptor negative ($p = 0.0096$), progesterone receptor negative ($p = 0.0234$) and triple negative ($p = 0.0023$) breast cancer than those with BRCA2 mutations. The addition of tumour pathology did not significantly affect the identification of patients for BRCA1 testing when using Evans scoring. Using BOADICEA without pathology data, 4 patients with BRCA1 mutations did not meet the 20% threshold for testing. When adding in tumour pathology data to BOADICEA, 3 of these patients reached the testing threshold for BRCA1 testing, but one further patient fell below the testing threshold. We conclude that tumour pathology is an important factor that should be considered when deciding whether to offer testing for a BRCA1 mutation.

494/T

BRCA mutation prevalence and performance of clinical risk assessment tools among Puerto Rican breast cancer patients. *J. Dutil[1], J. Gonzalez-Bosquet[2], M. Echenique[3], J. Matta[4], R. Sutphen[5].* 1) Department of Biochemistry Ponce School of Medicine Ponce, PR; 2) Gynecologic Oncology, Department of Women's Oncology Moffitt Cancer & Research Center Tampa, FL; 3) Cancer Center, Auxilo Mutuo Hospital San Juan, PR; 4) Department of Pharmacology and Physiology Ponce School of Medicine Ponce, PR; 5) University of South Florida College of Medicine Tampa, FL.

Approximately 5-10% of all breast cancers occur due to the inheritance of deleterious mutations in highly penetrant predisposition genes, primarily *BRCA1* and *BRCA2*. Little clinical or research testing of the BRCA genes has been reported in Puerto Rico. Thus, there is a need to further characterize the prevalence and spectrum of BRCA mutations. In order to achieve meaningful clinical testing of *BRCA1* and *BRCA2* in Puerto Rico, it is also necessary to assess the applicability of clinically available risk assessment tools in this population. Using direct sequencing, we screened an unselected sample of 200 newly diagnosed breast cancer cases for the presence of mutations in the *BRCA1* and *BRCA2* genes. Personal and family history of cancer (including cancer types and ages of diagnosis) were collected and used to estimate pre-test likelihood of mutation using the BRCAPRO and Myriad II models. The results are expected to be useful toward 1) understanding the prevalence and spectrum of *BRCA1* and *BRCA2* mutations in Puerto Rico and 2) developing accurate risk assessment tools for the clinical management of hereditary breast cancer syndrome in this population.

A novel XPD mutation in a compound heterozygote with mild sun sensitivity. *T. Falik-Zaccai[1,2], R. Erel-Segal[2], L. Horev[3], O. Bitterman Deutsch[4], K. Zohar[1], L. Kalfon[1], H. Slor[5], G. Spivak[6], P.C. Hanawalt[6].* 1) Div Med Gen, Western Galilee Hosp, Nahariya, Israel; 2) Rappaport Faculty of Medicine, Technion, Israeli Institute of Technology, Haifa, Israel; 3) Department of Dermatology, Hadassah Medical Center, Jerusalem Israel; 4) Department of Dermatology, Western Galilee Hospital, Naharia, Israel; 5) Department Molecular Human Genetics, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 6) Biology Department, Stanford University, Stanford, CA, USA.

The XPD protein plays a pivotal role in basal transcription and in nucleotide excision repair (NER) as one of the ten known components of TFIIH. XPD is involved in maintaining the integrity of the TFIIH complex, and its ATP-dependent 5'-3' helicase activity is essential for NER. Mutations in XPD can result in the DNA repair-deficient diseases xeroderma pigmentosum (XP), Cockayne syndrome (CS), trichothiodystrophy (TTD), cerebro-oculo-facial-skeletal syndrome (COFS), and in combined phenotypes such as XP/CS and XP/TTD. We describe here a 19-year-old individual with very mild sun sensitivity, no neurological abnormalities and no tumors, who carries R683Q and R616Q mutations in the two XPD alleles respectively. Codon 683 variations have been documented for a majority of XPD patients; R683W is the most commonly found mutation. R683Q has been described in four patients with variable symptoms, from mild to severe. Codon 616 mutations are rare. R616P or R616W substitutions cause loss of function; heterozygous patients with these mutations exhibit symptoms of XP, COFS or TTD, determined by mutations in the other allele. The novel mutation R616Q might also result in a null protein, thus our patient's presentation is likely a consequence of the R683Q mutation in a hemizygous state. We have determined that cells from this individual are just as UVC-sensitive as those from an XPD R683Q homozygous patient. Recovery of RNA synthesis after UV treatment and removal of UV-induced cyclobutane pyrimidine dimers from the overall genomes are impaired, implying deficiencies in both transcription-coupled and in global genomic NER.

A Common French Canadian FH Mutation: Implications for Mutation Screening in HLRCC and Fumarate Hydratase Deficiency. *G. Graham[1], N. Kanigsberg[2].* 1) Department of Genetics, Children's Hosp Eastern Ont, Ottawa, ON, Canada; 2) Division of Dermatology, Ottawa Hospital, Ottawa, ON, Canada.

Fumarase is a TCA cycle enzyme and recently recognized tumour suppressor encoded by the fumarate hydratase (*FH*) gene. The co-inheritance of two *FH* mutations produces autosomal recessive fumarate hydratase deficiency, a rare inborn error of metabolism associated with infantile encephalopathy and early lethality. In contrast, heterozygosity for *FH* mutations predisposes to cutaneous leiomyomas, uterine leiomyomas and renal cell carcinoma, the autosomal dominant condition known as Hereditary Leiomyomatosis and Renal Cell Cancer (HLRCC). Identical fumarate hydratase mutations can contribute to both phenotypes. There are 180 *FH* mutation entries in the Leiden Open Variation Database (LOVD). While the majority are missense, frameshift or nonsense mutations, splicesite mutations, deletions and duplications have also been documented. We report our experience with 9 individuals ascertained primarily because of cutaneous leiomyomata, all of whom were found to have *FH* mutations. Seven were of French Canadian origin and 6 of the 7 were heterozygous for c.1293delA. The mutation converts a glutamine to a lysine at residue 432, causes a frameshift and results in the insertion of a stop codon 17 amino acids downstream. This mutation has been reported once previously, also in a French Canadian individual, and we therefore conclude that it represents a common mutation, likely reflective of a founder effect in this population. We discuss the clinical features and family histories of our patients as well as the implications of this finding for mutation screening in individuals of French Canadian ancestry presenting with a personal or family history indicative of either condition. Our preliminary experience would suggest that the penetrance for renal cell cancer associated with this mutation is low, as appears to be typical for other *FH* mutations causing HLRCC. To date there are no prospective studies demonstrating the sensitivity, efficacy, risks or cost-effectiveness of screening for renal malignancy in HLRCC. Until we have an improved understanding of the additional factors predisposing to carcinogenesis in this condition and an ability to predict which mutation carriers will develop renal cancers, we have chosen to screen all carriers of this and other mutations by CT/MRI. Given that our experience with this condition includes aggressive malignancy in a 15-year-old, we are offering predictive testing to at-risk family members as young as 10 years of age.

497/T

Selenium and the Risk of Cancer in BRCA1 Carriers. *J. Lubinski[1], K. Jaworska[1], K. Durda[1], A. Jakubowska[1], T. Huzarski[1], T. Byrski[1], M. Stawicka[2], J. Gronwald[1], B. Gorski[1], W. Wasowicz[3], E. Kilar[4], M. Szwiec[5], D. Surdyka[6], E. Marczyk[7], P. Sun[8], S.A. Narod[8].* 1) Intl Hereditary Cancer Ctr, Pomeranian Med Univ, Szczecin, Poland; 2) Prophylactic and Epidemiology Center, Poznan, Poland; 3) Institute of Occupational Medicine, Lodz, Poland; 4) Regional Oncology Hospital, Swidnica, Poland; 5) Regional Oncology Hospital, Opole, Poznan; 6) Center of Oncology of Lublin Region, Lublin, Poland; 7) Regional Oncology Center, Krakow, Poland; 8) Womens College Research Institute and Dalla Lana School of Public Healt, University of Toronto, Canada.

It has not been established if dietary factors or nutritional supplements impact on the incidence of cancer in high-risk women. We randomised 1135 women with a BRCA1 mutation to 250 micrograms daily of elemental selenium as sodium selenite, or to placebo, in a double-blind trial. After a median follow-up period of 35 months (range 6 to 62 months), there were 60 incident cases of cancer diagnosed in the selenium-supplemented group, versus 45 cases in the placebo group (hazard ratio 1.4; 95% CI: 0.9 to 2.0). Selenium supplementation was not associated with a reduction in the risk of primary breast cancer (hazard ratio 1.3; 95% CI: 0.7 to 2.5), of contralateral breast cancer (hazard ratio 1.5; 95% CI: 0.7 to 3.2). or of ovarian cancer (hazard ratio 1.3; 95% CI: 0.6 to 2.7). The results of this study do not support the recommendation that selenium supplementation should be offered to BRCA1 carriers for chemoprevention. Part II Adnexectomy, genotypes and selenium level as markers of the risk of cancer In these part we conducted a nested case-control study of 68 women with breast cancer and 17 women with ovarian cancer and 170 controls matched 1 to 2. Cases and controls were matched for age at enrolment, past history of breast cancer, oophorectomy and whether they received selenium supplement or placebo during cancer chemoprevention trial. Combinations of clinical status, genotypes and selenium levels strongly associated with extremely low risk of cancer have been identified. The strongest associations have been found for GPX4 variants: a. all nTT and Se level 60-80μg/l - OR 0.32, p: 0.0009; b. all TT and Se level >80μg/l - OR 0.10, p: 0.047; c. for carriers without adnexectomy and with TT variant, Se level >80μg/l - OR 0.038, p: 0.014.

498/T

A novel missense mutation in the PTEN gene in a patient with multiple melanoma and features of Cowden Syndrome. *L.M. PRADELLA[1], E. MARIANI[1], G. GASPARRE[1], L. AMATO[1], S. MICCOLI[1], A. LANZONI[2], C. ISHIOKA[3], K. SAIJO[3], G. ROSSI[4], G. ROMEO[1], D. TURCHETTI[1].* 1) Laboratory of Medical Genetics, Bologna, BO, Italy; 2) UO Dermatologia, Ospedale Bellaria, BO, ITALY; 3) Department of Clinical Oncology Institute of Development, Aging and Cancer Tohoku University 4-1 Seiryo-machi, Aoba-ku Sendai 980-8575, JAPAN; 4) UO Anatomia Patologica, Policlinico di Modena, ITALY.

A 38-years-old male patient was referred to the Cancer Genetics Clinic because of a personal history of multiple melanomas and moles. Indeed, since he was 26 he had more than 60 pigmented skin lesions removed, most of which were melanomas and melanocytic nevi at pathology examination. His history was also remarkable for subtotal thyroidectomy for follicular adenoma and hyperplasia at age 19, followed, 18 years later, by the removal of the remaining thyroid tissue, containing a follicular carcinoma. During the first thyroid surgery a large supraclavicular lipoma was also removed. Clinical examination revealed macrocephaly (>97th percentile), and palmoplantar keratoses. Molecular analysis of the CDKN2A gene failed to find mutations, but the analysis of the PTEN gene revealed the heterozygous substitution G1027A (V343M). The healthy parents and the sister of the patient do not carry the mutation. To our knowledge, this variant has not been reported before, but different substitutions of the same aminoacid (V343E; V343I) are known to be pathogenic. In silico prediction was performed using Polyphen and SIFT softwares: Polyphen predicted this variant to be probably benign while SIFT suggested it could affect protein function. To allow functional studies, PTEN complete cDNA was cloned on an expression vector under the control of a CMV promoter and the V343M substitution was obtained by site-directed mutagenesis. This construct will be used to evaluate the ability of the mutant protein to rescue a sick phenotype on a yeast model. Although melanoma has been occasionally reported in Cowden Syndrome patients, the phenotype of this patient, consistent with atypical mole malignant melanoma syndrome, is unexpected in a PTEN mutation carrier. If the functional assay showed an effect on PTEN function, further studies would be warranted to clarify the genotype-phenotype correlation.

499/T

Double Heterozygosity for BRCA2 and PTEN Germline Mutations in Two Unrelated Probands. *C.G. Somerman, B.M. Boman, B.L. Grey, M.A. Parker, Z.J. Ali-Khan Catts.* Helen F. Graham Cancer Center, Christiana Care Health System, Newark, DE.

BRCA1 and BRCA2 are the most common genes associated with Hereditary Breast and Ovarian Cancer (HBOC). Germline mutations in BRCA1/2 are associated with an increased risk for the breast (female and male), ovarian, prostate and pancreatic cancer. Cowden syndrome (CS) is less common but also associated with hereditary breast cancer and is caused by mutations in the PTEN gene. CS is a hamartomatous tumor syndrome characterized by benign and malignant tumors of the breast, thyroid and uterus and non-cancerous lesions such as mucocutaneous trichilemmomas, acral and palmoplantar keratosis and papillomatous papules. Double heterozygosity is when an individual has two different gene mutations at two separate genetic loci. An extensive literature search using PubMed, Ovid and Google has revealed double heterozygosity for BRCA1 and BRCA2 mutations as well as with Lynch syndrome and HBOC but typically genetic testing for cancer syndromes stops when one mutation is identified. Here we report two unrelated probands that are double heterozygotes for BRCA2 and PTEN germline mutations which has not been previously reported. Proband A was diagnosed with a triple negative invasive ductal carcinoma at age 47, and contralateral fibrocystic changes and ductal hyperplasia. Her family history is significant for ovarian, colon and lung cancer, fibrocystic breast, endometrial fibroids and mental retardation. Proband B was diagnosed with an Estrogen and Progesterone receptor negative invasive ductal carcinoma at age 38, fibrocystic breast, multinodular goiter, 5 adenomatous colon polyps and macrocephaly. Her family history is significant for prostate, breast, brain, colon and lung cancer. Both probands met the diagnostic criteria for HBOC and underwent BRCA1/2 sequencing at a CLIA approved lab and BRCA2 deleterious mutations were identified. In addition, proband A and B met research eligibility criteria for PTEN testing and were found to have deleterious PTEN alterations. By taking a detailed history and elucidating HBOC and CS characteristics these two probands were offered both tests. The alterations in BRCA2 accounted for the history of breast, ovarian and prostate cancer however it did not account for the additional histories. CS does account for some of the additional benign findings. This illustrates the importance of obtaining a detailed personal and family history and exploring all possible genetic syndromes even in the presence of a known deleterious mutation.

The IMPACT study: Identification of Men with a genetic predisposition to Prostate Cancer: Targeted screening in BRCA1/2 mutations carriers and controls. Preliminary Results. *E.K. Bancroft[1,2], E. Castro[1], E.C. Page[1], R.A. Eeles[1,2], IMPACT Steering Committee and Collaborators.* 1) Institute of Cancer Research, Sutton, United Kingdom; 2) Cancer Gen Unit, Royal Marsden Hosp, Sutton, United Kingdom.

Background Men with a mutation in BRCA1 or BRCA2 genes have an increased risk of prostate cancer (PCa) by age 70 (3-5% and 20-23%, respectively). But the real incidence and prevalence of PCa in this population remains unknown and the accuracy and effects of targeted screening are still unclear. Objectives To establish an international PCa targeted screening study in BRCA1/2 mutation carriers in order to determine the sensitivity and specificity of PSA screening in this population. Methods Eligible men are 40 to 69 years old tested for known BRCA1/2 family mutation. Those who do not carry the mutation are eligible as controls. The estimated target population are 500 BRCA1, 350 and 850 controls. PSA is determined annually and the cut-off for biopsy is 3ng/dl. Results To date, 914 men have been recruited in 35 centres (282 controls, 330 BRCA1 and 292 BRCA2). Median age is 53 (40-69). Median PSA value is 0.9, with no differences among the three groups (Controls: 0.81 (0.07-7.4), BRCA1 0.9 (0.1-27); BRCA2 0.9 (0.2-14.7)) 75 men (8.2%) presented with a PSA >3ng/dl (21control, 20 BRCA1, 34 BRCA2). 56 biopsies have been performed diagnosing 23 tumors (5 controls, 5 BRCA1, 13 BRCA2). 85% of tumors diagnosed in BRCA2 were Gleason ≥7 and /or T2 and required radical treatment while in controls 50% were indolent. The estimated Positive Predictive Value (PPV) for PSA screening in BRCA2 is 43.3% vs 32% in controls. Conclusions IMPACT is the largest prospective study to evaluat PCa screening in BRCA carriers. Our data confirms that BRCA2 carries usually present with aggressive PCa and annual PSA determination with a cut-off to biopsy of 3 ng/ml is an accurate method for PCa screening in this population.

Association of Paternal Genotype with Risk of New Mutation in RB1 gene in an Offspring. *A. Ganguly[1], E. Chao[1], S. Francisci[2,3], G. Bunin[4], C. Shields[5], M. Devoto[2].* 1) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Division of Human Genetics, CHOP, Depts. of Pediatrics and of Biostatistics and Epidemiology, University of Pennsylvania; 3) National Center for Epidemiology, Surveillance and Health Promotion, Istituto Superiore di Sanità, Rome, Italy; 4) Division of Oncology, Children's Hospital of Philadelphia, Philadelphia; 5) Wills Eye Institute, Thomas Jefferson University, Philadelphia.

Retinoblastoma (RB) is a malignant neoplasm of the retina, which occurs in infants and young children. This tumor is universally associated with mutation of the RB1 gene. In sporadic, bilateral RB, 94% of a new germline RB1 mutation occurs prior to conception on the paternal gamete. We hypothesize that paternal genotype contributes to risk of fathering a child with a de novo RB1 germline mutation.

To study association of common sequence variants, SNPs, with RB risk, we analyzed genomic DNA from fathers of children with de novo, bilateral RB. These individuals were recruited in Wills Eye Hospital, Philadelphia. We used an array-based approach (Affymetrix, SNP 6.0) to genotype more than 1 million loci in the cases and approximately 1100 ethnically and gender-matched controls.

Following genotyping, careful data cleaning was carried out checking for gender discrepancies, identity by descent (IBDs) to identify related individuals or duplicate samples, and sample heterozygosity to identify possible sample contamination. To ensure genotyping quality we excluded from the analysis individuals that had more than 10% of missing calls. SNPs that were not in Hardy-Weinberg equilibrium in the controls ($p £ 10^{-5}$), that failed genotyping for more than 10% of individuals, or with minor allele frequency (MAF) lower than 1%, were excluded from analysis. Association analyses were carried out with the 1 degree-of-freedom trend test on allele counts, using principal component analysis (PCA) to correct for potential sample stratification including individuals that disagreed with self-reported ethnicity. The final analysis included 95 cases. Genome-wide thresholds were used to identify 3 SNPs as significantly associated with the risk of a new mutation in RB1 gene in an offspring.

A single coding sequence SNP in a drug-metabolizing enzyme achieved genome wide significance with p-value of $8x10^{-13}$. The expression of this gene can vary twenty fold between individuals and is likely to have significant effects on the rate at which xenobiotics are metabolized. Further analysis of this gene and other results will be presented.

Population Admixture Analysis of Hispanic Women at risk for *BRCA1* or *BRCA2* Mutations in High Risk Clinic Populations. *G. Larson[1], G. Rivas[1], J. Herzog[2], R. Ogaz[2], M.B. Terry[3], E. Ziv[4], S. Narod[5], J. Weitzel[2].* 1) Dept. of Molecular Medicine, Beckman Research Institute, City Hope, Duarte, CA; 2) Dept. of Clinical Cancer Genetics Beckman Research Institute City Hope, Duarte, CA; 3) Department of Epidemiology, Columbia University; 4) Department of Medicine, Institute for Human Genetics, University of California; 5) Women's College Research Institute, University of Toronto.

We have sought to characterize the ancestral origins of a variety of *BRCA1* and *BRCA2* mutations from high risk Hispanic women. Our prior work (Weitzel, et al CEBP 14:1666, 2005) has demonstrated conserved haplotypes through the *BRCA1* interval for several recurrent mutations from high-risk Hispanic patients, some exclusive to families with Mexican American or Spanish ancestry. To better define the ancestral origins of our patients in conjunction with the spectrum of *BRCA* mutations observed in our high-risk clinics, we have employed a set of Ancestry Informative Markers (AIMs) in conjunction with reference individuals from the Human Gene Diversity Panel (HGDP) to stratify breast cancer patients with Caribbean/African versus AmerIndian admixture. These data can be cross-validated with self-reported ancestry (country of birth, and city-when available). A set of ~ 100-125 AIMs can be used to differentiate these diverse populations with a high degree of confidence. This information will be used to identify germline *BRCA* mutations common to specific ancestral backgrounds, and to distinguish distinct subset populations that are included in the Hispanic category.

503/T

Linkage study of prostate cancer in high-risk African American families from Louisiana. *E.M. Ledet[1], J.E. Bailey-Wilson[2], D.M. Mandal[1].* 1) Dept Genetics, Louisiana State Univ HSC, New Orleans, LA; 2) NHGRI, NIH, Baltimore, MD.

Prostate cancer is a complex multi-allelic disease and the most common malignancy in men throughout the world. In the United States, a lifetime risk of mortality from prostate cancer is 3% for white men and 4% for African-American men. Thus far, disease susceptibility loci have been identified for this cancer but definite locus-specific information is not established due to the tremendous amount of genetic heterogeneity. Previously, we performed a genome-wide linkage scan on three families using microsatellite markers and identified a region on chromosome 22q13. Given the small sample size of three families, this lod-score value does not reach the genome wide significance level. However, we have since continued recruitment and accrued 20 large high-risk African-American families with at least 3 affected individuals; additionally, 28 large high-risk Caucasian families have been recruited. Demographic information and relevant clinical information has been documented from the hospital pathological report on the affected. Recently an Infinium II HumanLinkage-12 panel (Illumina, Inc.) with 6,090 SNP markers was performed on 180 DNA samples, including 15 African American families and 4 Caucasian families. This panel is optimized for linkage detection for both monogenic and polygenic disorders; SNPs are distributed on every chromosome with an average gap of 441 Kb and 0.58 cM. Three samples were discarded from analysis due to poor array performance, for a total of 177 samples imported into BeadStudio version 3.3.7; a proprietary calling algorithm was used and SNPs which failed quality control or calling were removed from the data set. Quality control and pruning of released SNPs was performed using PLINK. Linkage analysis is ongoing on the African-American cohort with Merlin and Genehunter-Plus. In this study we intend to identify any markers associated with prostate cancer in high-risk African American families and document any correlation between clinical features, such as prostate specific antigen (PSA), 'age of onset' and/or Gleason score.

504/T

Implications of germline HVR-II mitochondrial polymorphisms on Tunisian women affected with breast cancer. *B. Yacoubi Loueslati[1], W. Troudi[2], L. Cherni[2], K. Ben Rhomdhane[3], L. Mota-Vieira[4,5].* 1) Department of Biology, Faculty of Sciences of Tunis, ElManar University, Tunisia; 2) Laboratory of Genetics, Immunology and Human Pathology. Faculty of Sciences of Tunis, ElManar University, Tunisia; 3) Salah Azeiz Oncology Institute, Bab Saadoun, Tunisia; 4) Molecular Genetics and Pathology Unit, Hospital of Divino Espírito Santo of Ponta Delgada, EPE, Azores, Portugal; 5) Instituto Gulbenkian de Ciência, Oeiras, Portugal.

A high incidence of somatic mitochondrial DNA (mtDNA) polymorphisms has been recently reported in a wide variety of human cancers, with some of them proposed as potential markers for the early detection of breast cancer (BC). Nevertheless, little attention has been paid to the potential use of germline mitochondrial sequence variations as genetic risk factors for cancer. To evaluate the germline polymorphism of mitochondrial HVR-II region as genetic risk factor for BC, we performed a case-control study of 70 unrelated Tunisian BC women and 80 healthy age and sex matched blood donors, taking into account their menopausal status. Direct sequencing allowed us to detect a total of 351 polymorphisms for controls, and 248 variants for patients with 47 and 39 segregating sites, respectively. In both groups, more than 50% of the polymorphisms are due to four variants: 315 ins C, 309 ins C, 263 A>G, and 73 A>G. The HVR-II sequences are also classified into haplotypes on the basis of all polymorphisms. A total of 59 different haplotypes were found, twenty of them shared between patients and controls. Both groups had specific haplotypes - 18 in cases, and 21 in controls. Statistical analysis revealed a weak protective effect on BC risk for two mitochondrial polymorphisms - 152 T>C (OR = 0.33, 95% CI 0.12 0.91) and 263 A>G (OR = 0.17, 95% CI 0.06 0.47). In contrast, an increased risk of the occurrence of BC was detected, with the 315+C haplotype (OR = 11.66, 95% CI 1.44 252.23). Although more extensive studies, including different types of cancer and patients with different genetic makeup, are required, in order to improve the understanding of germline mtDNA polymorphisms in carcinogenesis, here we provide evidences that mitochondrial variants may interact to modify the risk for BC.

505/T

Joint effects of germ-line TP53 mutation, MDM2 SNP309, and gender on cancer risk in family studies of Li-Fraumeni Syndrome. *C.C. Wu[1], R. Krahe[2], G. Lozano[2], B. Zhang[2], C.D. Wilson[2], E.J. Jo[3], S. Shete[1], C.I. Amos[1], L.C. Strong[2].* 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Dept Genetics, Univ Texas MD Anderson CA Ctr, Houston, TX; 3) Duncan Cancer Center, Baylor College of Medicine, Houston, TX.

Li-Fraumeni syndrome (LFS) is a rare familial cancer syndrome characterized by early cancer onset, diverse tumor types, and multiple primary tumors. Germ-line TP53 mutations have been identified in most LFS families. A high-frequency single-nucleotide polymorphism, SNP309 (rs2279744), in MDM2 was recently confirmed to be a modifier of cancer risk in several case studies: substantially earlier cancer onset was observed in SNP309 G-allele carriers than in wild-type individuals by 7-16 years. However, cancer risk analyses that jointly account for measured hereditary TP53 mutations and MDM2 SNP309 have not been evaluated in familial cases. Here, we designed a study to assess the associations of cancer incidence with germline TP53 mutation, MDM2 SNP309, gender, and their interactions in family studies and to estimate the cancer risk attributable to these factors simultaneously. A study population that comprised 19 extended LFS pedigrees ascertained with multiple germ-line TP53 mutations provides a unique opportunity to perform this cancer risk analysis in a quantitative way. We extended the novel statistical method in family studies that we recently developed that is structured for age-specific risk models based on Cox proportional hazards regression for censored age-of-onset traits. The dataset consisted of 463 individuals with 129 TP53 mutation carriers. Our analyses showed that the TP53 germ-line mutation and its interaction with gender were strongly associated with familial cancer incidence and that the association between MDM2 SNP309 and increased cancer risk was modest. In contrast with several case studies, the interaction between MDM2 SNP309 and TP53 mutation was not statistically significant. Our results showed that heightened MDM2 levels due to the SNP309 G-allele were associated with accelerated tumor formation in both carriers and non-carriers of germ-line p53 mutations.

506/T

Fine-mapping epithelial ovarian cancer susceptibility loci at 8q24, 17q21 and 19q13. *H. Song[1], J. Tyrer[1], S. Ramus[2], G. Chenevix-Trench[3], M. Rossing[4], R. Ness[5], S. Kjaer[6], M. Garcia-Closas[7], J. Gronwald[8], P. Fasching[9], A. Whittemore[10], C. Pearce[11], S. Gayther[2], P. Pharoah[1], Ovarian Cancer Association Consortium (OCAC).* 1) Dept Oncology, Univ Cambridge, Cambridge, United Kingdom; 2) Department of Gynaecological Oncology, UCL EGA Institute for Women's Health, University College London, UK; 3) The Queensland Institute of Medical Research, Post Office Royal Brisbane Hospital, Australia; 4) Program in Epidemiology, Fred Hutchinson Cancer Research Center, Seattle, WA, USA; 5) The University of Texas, School of Public Health, Houston, TX, USA; 6) Department of Viruses, Hormones and Cancer, Institute of Cancer Epidemiology, Danish Cancer Society, Copenhagen, Denmark and Gynecologic Clinic, Rigshospitalet, University of Copenhagen, Denmark; 7) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, Maryland, USA; 8) International Hereditary Cancer Center, Department Of Genetics and Pathology, Pomeranian Medical University, Szczecin, Poland; 9) University Hospital Erlangen, Department of Gynecology and Obstetrics, Germany; 10) Department of Health Research and Policy, Stanford University School of Medicine, Stanford, USA; 11) University of Southern California, Keck School of Medicine, Los Angeles, California, USA.

Background: A recent genome-wide association study (GWAS) has identified six epithelial ovarian cancer (EOC) susceptibility loci. The aim of this study was to use data from the 1000 genome project to fine map three of the EOC susceptibility loci at 8q24, 17q21 and 19q13 and to identify the potential causal variants for functional study. **Methods:** We narrowed the susceptibility locus to a region bounded by SNPs with r^2 of 0.1 with the top hit at each locus. We imputed genotypes for 5930 cases and 7164 controls for all the common SNPs within the region using data from our GWAS and 1000 genome project. Genotype frequencies in cases and controls were compared using a likelihood ratio test in a logistic regression model. The SNPs were ranked by test statistic. SNP with log likelihood within 6.9 of the top hit (odds 1000:1) were considered as potential functional variants. A set of tagSNPs were selected to tag the candidate causal variants. These were genotyped in 4681 invasive ovarian cancer cases and 5061 controls from 8 studies (from Australia, Europe and USA). **Results:** A total of 32, 19 and 26 tagSNPs were selected for genotyping for 8q24, 17q21 and 19q13 locus respectively. Among these 2 failed for 8q24 locus and 6 each failed for 17q21 and 19q13 locus respectively. The most strongly associated SNP at 8q24 was rs7814937 ($P = 1.66 \times 10^{-8}$), but 17 other SNPs has a log likelihood within 4.6 of rs7814937 (odds 100:1) including the top hits from the initial GWAS (rs1008821 and rs1516982). Similarly 4 SNPs at 17q21 and 15 SNPs at 19q13 remained plausible functional candidates. **Conclusions:** We have identified potential causal variants for ovarian cancer susceptibility at 8q24, 17q21 and 19q13. Studies of EOC in other ethnic groups may refine these further. Functional studies will be needed to determine causal mechanisms.

507/T

Genetic Variants in Inflammation Pathway Genes Modulate Prostate Cancer Risk. *E.M. Kwon[1,2], C.A. Salinas[3,4], Z. Feng[3], S. Kolb[3], J.L. Stanford[3,4], E.A. Ostrander[1].* 1) Cancer Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 2) Program in Human Genetics, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Dept. of Epidemiology, School of Public Health, University of Washington, Seattle, WA.

Chronic inflammation is an important mechanism for the development and progression of several types of cancer including that of the prostate. Genetic variants within the inflammation pathway have been previously associated with prostate cancer (PC) risk, but results have not been consistent. To further elucidate this mechanism in relation to PC, we selected 17 genes in the inflammation pathway and evaluated variants within each gene in relation to PC risk. A total of 144 tagging and amino acid altering single nucleotide polymorphisms (SNPs) were genotyped in Caucasian and African American men participating in one of two population-based, case-control studies (n = 1,458 cases; 1,350 controls). Eleven SNPs in seven genes (*CXCL12, IL4, IL6, IL6ST, PTGS2, STAT3*, and *TNF*) demonstrated a statistically significant association with overall PC risk in Caucasians. Four SNPs in genes *IL4, IL6ST, PTGS2,* and *STAT3* were independently associated after adjusting for covariates. The most significant result was with rs11574783 in the *IL6ST* gene where we observed a nearly 11-fold decrease in risk (OR=0.09, 95% CI 0.01-0.70). Cumulatively, these four SNPs conferred a three-fold elevation in PC risk among men carrying the maximum number of high-risk genotypes (OR=2.97, 95% CI 1.41-6.25). Risk estimates for seven SNPs (one each in *CXCL12, STAT3, VEGF*, and *IL6*, and three in *PIK3R1*), varied significantly according to disease aggressiveness ($p_{homogeneity}<0.05$). SNPs in *AKT1, PIK3R1* and *STAT3* were independently associated with more aggressive PC, demonstrating a 5-fold (95% CI 2.29-11.40) greater risk among carriers of all high-risk genotypes. In summary, our results suggest that SNPs in four inflammation-pathway related genes (*IL4, IL6ST, PTGS2,* and *STAT3*) are independently associated with PC susceptibility with three additional SNPs (in *AKT1, PIK3R1*, and *STAT3*) being independently associated with more aggressive PC. Furthermore, novel associations between PC risk and genetic variants were presented for *IL6ST, STAT4, AKT1*, and *PIK3R1* genes known to play a key role in inflammation. Thus, our results provide evidence to support the hypothesis that chronic inflammation contributes to the development and modulation of PC risk.

Shared Functional Modules Detection in Ovarian Cancer. *S. Hong[1], H. Dong[1], L. Jin[1], M. Xiong[1,2].* 1) Fudan University, Shanghai, Shanghai, China; 2) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030.

Gene co-expression network and functional modules can reveal the potential gene-gene interaction relationships and thus provide a systematic view of gene regulation through a biological process such as tumor genesis, tumor metastasis. To study the gene-regulation pattern of ovarian cancer and understand the mechanism of it, we used two independent ovarian cancer datasets to construct the gene co-expression network and find the common patterns of them. One dataset was obtained from The Cancer Genome Atlas(TCGA) and the other was from Array Express. To estimate the partial correlation matrix of the network, a joint sparse regression model was used. For the reason that genes are usually organized into smaller groups to execute their specific functions as known pathways, we further detected modules from the constructed co-expression network using the dynamic tree cut procedure. We collected several hundreds of biologically meaningful pathways from KEGG and Biocarta and then used Fishers' exact test to look for modules which were significantly enriched with known pathways and also enriched with differential expressed genes. On the other side, we calculated the damage value and vertex degree to find the important genes. The miRNA target analysis was also implemented to search for the important genes using the miRNA data of the TCGA datasets. Our results showed that the two datasets had several common functional modules which were enriched with differential expressed genes as well as biological known pathways. These modules were mainly enriched with Cell Apoptosis, inflammation factor-related pathway, Immune Disorders. These shared pathways and modules may play an important role in ovarian cancer.

A bladder and gastric cancer risk variant of *PSCA* is associated with increased mRNA expression and allelic expression imbalance in bladder tissue. *I. Kohaar, A. Mumy, P. Porter-Gill, L. Prokunina-Olsson.* Laboratory of Translational Genomics, NCI, NIH, Gaithersberg, MD.

A single nucleotide polymorphism (SNP) rs2294008 within the prostate stem cell antigen gene (PSCA) has been identified as a major susceptibility factor for urinary bladder cancer and poorly differentiated diffuse-type gastric cancer. The risk allele T of rs2294008 creates an alternative start codon that extends the signal peptide by nine amino acids. Strong overexpression of PSCA in bladder and prostate tumors compared to normal samples has been previously reported, however, it's unclear how this overexpression is related to the genetic risk variant. Here, we performed quantitative mRNA expression analysis in 39 normal and 42 tumor bladder samples, including 24 matched normal-tumor pairs. We show that mRNA expression of PSCA was significantly increased in tumors compared to matched normal bladder tissue by 5.7-fold (p=0.0060). We observed a 13.8-fold increase in expression in carriers of risk TT genotype (p=0.0080, n=8), compared to a 1.8-fold increase in carriers of non-risk CC genotype (p=0.66, n=7). Since rs2294008 is located within the transcribed sequence (5'UTR or exon 1 of PSCA), we performed an allelic expression imbalance (AEI) analysis in DNA and cDNA of 20 normal and 13 tumor samples heterozygous for rs2294008. The allelic ratio was similar in DNA of normal and tumor samples (60% and 59% of risk allele T, p=0.47) while it was different in cDNA of the same samples (55 % and 72% of risk allele T in normal and tumor samples, p= 0.0020). No AEI was observed in cDNA of normal samples compared to DNA (60 and 55% of risk allele T, p=0.19), while in cDNA from tumors there was a 2-fold increase in expression of risk allele T (p=0.039) while a 5-fold decrease in expression of non-risk allele C (p=0.0062), resulting in 72% of allele T in cDNA compared to 59% in DNA. In conclusion, we show that the risk allele T of rs2294008 is associated with increased mRNA expression of PSCA. The exact mechanism underlying this imbalance and its functional effect for cancer remains to be elucidated.

Somatic mutations in GRM1 promote tumorigenesis. *M.D. Willard, M.L. Lajiness, I.H. Wulur, T.D. Barber.* Translational Science, Eli Lilly and Company, Indianapolis, IN.

Emerging data indicates that G protein-coupled receptors (GPCRs) have a critical but often under-appreciated role in cancer. Specifically, accumulating evidence suggests that modulation of GPCR function may promote cancer progression and metastasis. Metabotropic glutamate receptor type 1 (GRM1) and its role in physiological processes in the nervous system has been well-documented. Recently, the role of GRM1 in cancer progression has emerged. Somatic mutations altering the coding region of GRM1 have been detected in colorectal cancer and glioblastomas, but the functional significance of these mutations is unknown. Here we demonstrate that cancer-associated mutations of GRM1 lead to abnormal receptor localization, interactions, and activity, and consequently, abnormal cellular behavior. These findings suggest that somatic mutations in GRM1 promote tumorigenesis through deregulated receptor activity, and highlight the importance of evaluating GRM1 antagonists to block both the normal and mutant forms of the receptor.

The GWAS-identified prostate cancer associated SNP, rs10993994, regulates microseminoprotein-beta (MSMB). *X. Xu[1], H. Lilja[2,3], R.J. Klein[1].* 1) Program in Cancer Biology and Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY 10065, USA; 2) Department of Clinical Laboratories, Surgery (Urology) and Medicine (GU-Oncology), Memorial Sloan-Kettering Cancer Center, New York, NY 10065, USA; 3) Department of Laboratory Medicine, Lund University, Skåne University Hospital, 205 02 Malmö, Sweden.

Background: Recent genome wide association screens have identified a single nucleotide polymorphism (SNP), rs10993994, as a locus that confers genetic predisposition to prostate cancer. This SNP is located in the proximal promoter of micro-seminoprotein beta (*MSMB*). *MSMB* codes for one of major secretory products of the prostate, β-MSP/PSP94. Though the function of β-MSP is unknown, the protein and a peptide derivative have properties suggestive of tumor suppressors. We have previously shown that rs10993994 genotype is strongly correlated with physiological β-MSP levels in the serum and semen of young healthy men.

Objectives: We hypothesize that rs10993994 is the functional variant responsible for the prostate cancer association signal, and acts through reducing *MSMB* levels, a putative tumor suppressor. Consequently, our objective is to elucidate the regulatory mechanisms underlying rs10993994's influence on *MSMB*/β-MSP levels.

Results: Through promoter reporter activity analysis, we have determined that single nucleotide difference at rs10993994 causes a reduction in *in vitro* transcriptional activity. rs10993994 is located in a predicted CREB binding site; to determine if differential transcription factor binding is responsible for reduced transcription, we performed chromatin immunoprecipitation in the presence and absence of forskolin and found that the risk allele for prostate cancer appears to indeed abrogate a CREB binding site.

Conclusions: Our results indicate that rs10993994, a prostate cancer associated SNP identified from recent GWAS studies, is the functional variant responsible for the association signal and acts through reducing levels of β-MSP, a putative tumor suppressor.

One criticism of genome wide association studies has been the lack of functional follow-up to association signals. Our preliminary findings suggest a compelling possible causal pathway, in rs10993994's association with β-MSP levels and subsequent prostate cancer development. Our current studies include investigating the role of β-MSP in prostate cancer etiology.

Functional glutathione peroxidase 3 polymorphisms associated with increased risk of taiwanese patients with gastric cancer. *I. Yang[1], J.Y. Wang[1,2,3,4], D.C. Wu[5,6], S.W. Huang[1,2], J.Y. Wu[5,6], S.H. Juo[1,7].* 1) Department of Medical Genetics, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Graduate Institute of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Department of Surgery, Faculty of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Cancer Center, and Division of Gastroenterology and General Surgery, Department of Surgery, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung, Taiwan; 5) Division of Gastroenterology, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung, Taiwan; 6) Department of Internal Medicine, Faculty of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 7) Cancer Center and Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Background: Glutathione peroxidase 3 (GPX3) can enhance an antioxidant's capacity and reduce genomic damage caused by oxidants and thus influence tumorigenesis. Hence, we investigated the role of GPX3 as a risk of gastric cancer. Methods: We first conducted a case-control study to test for the association between five tagging single nucleotide polymorphisms (SNPs) of GPX3 and the risk of gastric cancer in Chinese. Multivariate logistic regression analysis was performed to estimate the genetic effect with adjustments for age and sex. Functional studies were performed by using the luciferase reporter assay to assess functional consequences of the significant SNPs. Results: Among five SNPs (rs3763013, rs8177412, rs3805435, rs3828599, and rs2070593) genotyped in 227 cases and 844 controls, three SNPs were significant: intronic SNP rs3805435 (OR = 0.70, P = 0.037), intronic SNP 3828599 (OR = 0.68, P = 0.025), and 3' UTR SNP rs2070593 (OR = 0.48, P = 0.001). The two intronic SNPs rs3805435 and SNP rs3828599 were in linkage disequilibrium (D'= 0.91). Conclusions: The reporter assays showed significant difference in the luciferase expression between protective and risk alleles of two intronic SNPs (P = 0.004), whereas the 3'UTR SNP did not influence the luciferase expression. The present study suggests that the intronic SNPs at GPX3 can influence gene expression leading to an alteration of gastric cancer risk.

513/T

Functional analyses of the effect on RNA splicing of unclassified sequence variants found in cancer susceptibility genes. *P. Gaildrat[1], A. Martins[1], S. Krieger[2], J.C. Théry[1], F. Révillon[3], A. Killian[1], E. Bohers[1], S. Baert-Desurmont[1], J. Tinat[1], A. Rousselin[2], P. Berthet[4], A. Chevrier[5], M.P. Buisine[6], T. Frébourg[1,5], A. Hardouin[2], M. Tosi[1].* 1) Inserm U614, Faculty of Medicine, Rouen, France; 2) Laboratoire de Biologie Clinique et Oncologique, Centre François Baclesse, Caen, France; 3) Laboratoire d'Oncologie moléculaire humaine, Centre Oscar Lambret, Lille, France; 4) Consultation d'Oncogénétique, Centre François Baclesse, Caen, France; 5) Unité de Génétique Clinique, CHU de Rouen, France; 6) Laboratoire d'oncogénétique et génétique moléculaire, CHRU de Lille, France.

The interpretation of the large numbers of variants of unknown biological and clinical significance found in genetic screenings represents a major challenge in medical genetics, and especially in oncogenetics. A large fraction of such unclassified variants (UVs) could influence mRNA splicing. Current efforts aimed at predicting the pathogenicity of germline sequence variants must include analyses of their effect on RNA processing and stability, not only for intronic variants, but also for those found in exons. Considering that patient RNA is not always available, we have used functional splicing assays based on hybrid minigenes transfected into cells in culture, to screen UVs of the mismatch repair genes involved in the Lynch syndrome. In a total of 153 UVs of MLH1 and MSH2 we found that 30 UVs (19.6%) induced a major splicing defect that was subsequently confirmed at the patient RNA level. Notably, among 62 variants encoding missense substitutions of MLH1 nine (14.4%) induced a major splicing defect, indicating that this type of functional screening should take place prior to testing for changes of protein function. We have previously studied 20 UVs of the breast and ovarian cancer susceptibility genes BRCA1 or BRCA2 (Bonnet et al., Journal of Medical Genetics 2008). In order to better define the roles of bioinformatics predictions, of minigene-based splicing assays and of functional assays on patient RNA, we have now studied an additional group of 53 UVs of BRCA1 or BRCA2. The hybrid minigene assay identified splicing alterations in 12 of the 53 UVs (5 with strong effects and 7 with weak effects). Comparisons with bioinformatics predictions confirmed that UVs at deep intronic positions or located at internal exonic positions cannot be predicted reliably, unless they create novel splice sites. We will describe several exonic variants of BRCA2 that affect novel splicing regulatory elements, in addition to the c.5434C to G variant in exon 23 of BRCA1 that we have recently characterized (Gaildrat et al., Journal of Medical Genetics, in press). Our results show that mapping exonic splicing regulatory elements in these major cancer susceptibility genes, by combined in vivo and ex vivo functional analyses of the effects of natural variants on splicing provides important clues for the prediction of the pathogenicity of exonic variants.

NNK metabolism by short chain dehydrogenases/reductases and aldo-keto reductases. *A. Hull[1], J. Engle[2], A. Knipe[2], C. Gallagher[2,3], G. Chen[2], P. Lazarus[3], J. Muscat[2,3].* 1) Biology Dept, Lincoln University, Lincoln University, PA; 2) Dept of Public Health Sciences, Pennsylvania State University College of Medicine, Hershey, PA; 3) Dept of Pharmacology, Pennsylvania State University College of Medicine, Hershey, PA.

Lung cancer is the most common cause of cancer related deaths in the U.S. Smoking is estimated to account for 87% of all lung cancer cases. However, only some smokers develop cancer, indicating that they may be more susceptible to the effects of tobacco smoke carcinogens. One of the major carcinogens in tobacco smoke is the nicotine-derived nitrosamine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK). NNK is reduced to another potent lung carcinogen 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL), which can be glucuronidated by the uridine glucuronosyltransferase (UGT) enzyme family for excretion. Metabolism of NNK to NNAL is carried out by aldoketo reductase 1C1 and 1C2 (AKR1C1 and AKR1C2), and by the short-chain dehydrogenases/reductases carbonyl reductase 1 (CBR1) and hydroxysteroid dehydrogenase 11B1 (HSD11B1). The current study focused on examining the role of individual differences in DNA sequence, mRNA expression, and enzyme activity in CBR1, AKR1C1, 1C2, and HSD11B1 on NNK metabolism. Only very low-frequency coding SNPs exist in CBR1 and HSD11B1. Levels of CBR1 and HSD11B1 mRNA were found to vary significantly in 110 adjacent normal tissue liver samples from different individuals. Reductase activity assays performed with either cytosolic (to measure CBR1 and AKR activity) or microsomal (to measure HSD11B1 activity) fractions of human liver specimens demonstrated no correlation between expression levels of CBR1 mRNA levels and enzymatic activity in cytosol or between HSD11B1 and enzymatic activity in microsomes. The current data shows that variation in activity levels cannot be explained by either DNA sequence variation or mRNA expression. The lack of correlation between mRNA expression and enzymatic activity suggests a complex picture in which the contribution to total activity of the different enzymes varies significantly among individuals. By analyzing tagSNPs of AKR1C1, a haplotype was determined to be associated with lower lung cancer risk in men. TagSNP analysis of CBR1, HSD11B1 and AKR1C2 are underway to identify potential associations of haplotypes important in lung cancer risk.

Evaluation of EGFR,PTENand P53 experssion and association with clinicopathological features in Iranian Colorectal Cancer Patients. *M. Abachi[1], M. Ghaffarpour[2,3,5], M. Salati[1], Z. Nour Mohammadi[4], F. Fereidooni[4], F. Mahboudi[1,6], A. Adeli[6], M. Houshmand[2,5].* 1) Nanocina LTD,Tehran Iran; 2) Medical Genetics Department, National Institute of Genetics Engineering and Biotechnology, Tehran, Iran; 3) Iranian Research Organization for Science and Technology (IROST), Tehran, Iran; 4) The cancer institute of Iran, Imam Khomeini Hospital Complex, Tehran University of Medical Sciences, Tehran, Iran; 5) Special medical center; 6) Pasteur Institute,Tehran Iran.

Background and Aim: Colorectal cancer (CRC) is one of the most important malignancies worldwide.The epidermal growth factor receptor (EGFR) signaling pathway is usually activated in colorectal cancer. EGFR is expressed in 30% to 85% of colorectal cancer patients. Dysregulation of EGFR signaling has been shown to stimulate cell proliferation, angiogenesis, and metastatic spread and to inhibition apoptosis. Tumour suppressor phosphatase and tensin homologue (PTEN) is an important negative regulator for the PIP3/Akt signalling pathway that promotes cell proliferation and inhibits apoptosis. Inactivation of PTEN has been demonstrated in a variety of cancers.It is frequently mutated more often in colon cancer (9%). The p53 protein regulates cell-cycle inhibition and apoptosis in response to DNA damage; thus, mutation or deletion of TP53 resulting in loss-of function often leads to uncontrolled cell growth The objective of this study was to investigate whether the loss of nuclear EGFR ,PTEN and P53 expression correlates with usual clinicopathological parameters. Materials and Methods: Patients and tissue specimens: Tissue samples were obtained from 27 consecutive patients with CRC who were diagnosed at Imam khomaini hospital,Tehran University,Tehran,Iran from February 2007 to January 2010 (10 men and 17 women; age range,38-88 years; with median age of 61.3 years). All tissues were frozen in liquid nitrogen immediately after surgery and stored at -80°C until the extraction of RNA. Histopathological examinations were performed and all tumours were confirmed as adenocarcinoma. Tumor histologic type and grade of differentiation were defined according to the World Health Organization criteria. Experssion analysis of EGFR,PTEN and P53 in tumor samples:Fresh tumors, containing at least 70% of neoplastic cells and their adjacents were extracted for genomic RNA using the QIAamp Mini kit (Qiagen in accordance with the manufacturer's instructions, and then was used as a template for first-strand cDNA synthesis by random priming. followed, EGFR,PTEN and P53 expression status was determined by Real time PCR . Results: In this study we demonstreated 67% overexpression of EGFR, 23% and 13% Down regulation of PTEN and P53 respectivly in colorectal cancer patients .It seems that the high level expression of EGFR play more important in Iranian colorectal cancer patients.

516/T

Detection of BRCA1 and BRCA2 mutations by High-Resolution Melting curve analysis in breast cancer patients from Thailand and Pakistan. *J. Ahmad[1, 2], S. Sangrajrang[3], F. Le Calvez-Kelm[1], N. Kakar[2], C. Voegele[1], S. Daud[4], O. Sinilnikova[5], S.V. Tavtigian[6], F. Lesueur[1].* 1) Genetic Cancer Susceptibility, International Agency for Research on Cancer, Lyon, France; 2) Dept of Biotechnology and Informatics, BUITEMS, Quetta, Pakistan; 3) National Cancer Institute, Bangkok, Thailand; 4) National Center of Excellence in Molecular Biology, University of Penjab, Lahore, Pakistan; 5) Hospices Civils de Lyon, Centre Léon Bérard, Lyon, France; 6) Dept of Oncological Sciences, Huntsman Cancer Institute School of Medicine, University of Utah, Salt Lake City, UT, USA.

The spectrum of BRCA1 and BRCA2 mutations has been characterized in different populations worldwide with significant variation of the relative contribution of these genes to breast cancer between the populations. However, the contribution of mutations in these two genes to breast cancer patients in Pakistani and Thai populations remains relatively unexplored apart from a few genetics studies. Hence, we aimed to perform comprehensive BRCA mutation screening to characterize the frequency and spectrum of mutations within these two genes in a group of high-risk familial or early onset cases, which forms the largest group of breast cancer patients in these two Asian populations. 143 Thai cases and 85 Pakistani cases were enrolled in the study. The entire coding sequence of both genes was scanned for mutation using High Resolution Melting curve analysis followed by DNA sequencing. Two known BRCA1 mutations (p.E1250X and p.G1770fs) and two BRCA1 mutations that are not reported in the BIC database (p.S423fs and p.S1057fs) were observed. The nonsense mutation p.E1250X was identified in two unrelated Thai cases. The frameshift mutation p.S423fs was identified in a Thai case whereas the two other frameshift mutations were identified in two Pakistani cases. In the case of BRCA2, three 3 frameshift mutations (p.E1577fr, p.R1704fr and p.S2559fr) and one nonsense mutation (p.Q1107X) were identified. The nonsense mutation was identified in a Pakistani case and was already reported in BIC database, whereas the three frameshift mutations are novel. p.E1577fr was identified in a Pakistani case, p.R1704fr in two Thai cases, and p.S2559fr in one Thai case. In addition to the pathogenic mutations described above, we identified also some variants of uncertain clinical significance: one known inframe deletion in BRCA1 (p.K1110del), two evolutionarily unlikely missense substitutions (p.G1788C in BRCT domain of BRCA1 and p.G2901D in DNA binding domain of BRCA2) that are predicted to affect protein function, as well as a number of likely to be neutral missense variants, silent variants and intronic variants in both genes. In summary, our findings show that BRCA1 and BRCA2 account for a substantial proportion of hereditary breast cancer and early-onset breast cancer cases in Thailand and in Pakistan. Cost-benefit calculations would be required to determine the circumstances under which BRCA gene testing would be beneficial in these middle-income countries.

Breast Ductal Lavage Revisited: The Case for Using Molecular Markers. *W.A. Alkhayal[1], S.C. Willey[1,4], C.X. Cocilovo[1,4], E.D. Feldman[1,4], M.K. Sidawy[2,4], A-M. Noone[3,4], M. Sharifi[4], J.D. Rone[4], L.R. Cavalli[4], B.R. Haddad[4].* 1) Surgery, Georgetown University Hospital, Washington, DC; 2) Pathology, Georgetown University Hospital, Washington, DC; 3) Biostatistics, Bioinformatics, and Biomathematics, Georgetown University, Washington, DC; 4) Lombardi Comprehensive Cancer Center, Georgetown University, Washington, DC.

Introduction: The diagnostic power of ductal lavage (DL) cytology for early detection of breast cancer is controversial. Our aim is to develop additional screening methodologies to complement cytology and improve early detection of breast cancer. To achieve our goal, we have established a unique biorepository of DL specimens linked to medical history, and tumor and blood samples from the same patient. These specimens are being used to optimize methods for simultaneous evaluation of multiple molecular markers in the same sample. The first phase of the study (establishment of the biorepository and cytology evaluation of DL) will be reported. Methods: One hundred twenty four patients with unilateral breast cancer were prospectively enrolled in an IRB-approved protocol at Georgetown University Hospital between April 2008 and April 2010. DL fluid was obtained from each patient in the operating room under anesthesia immediately before surgery. In each case two DL fluid samples were obtained: one from the breast with cancer and the other from the contralateral normal breast (control). Multiple aliquots from each DL sample were saved for future studies. One aliquot was used for cytology evaluation which was reported under the following categories: insufficient cells, benign cells, mild atypia, severe atypia, and malignant cells. Full clinical and demographic information was entered into a database. Results: Of the 124 women who were enrolled, 114 qualified for the study. Sufficient cells for cytology were present only in 47 (41%) of the affected breast specimens and in 43 (38%) of the non-affected control breasts. In the cases where cytology was possible, we found that in the affected breasts, 51% showed benign cytology, 30% mild atypia, 13% severe atypia, and only 6% malignant cells, compared to 65%, 28%, 7%, and 0%, respectively, in the control, non-affected breasts. Further statistical analysis is being conducted to assess the correlation of these findings with patients' clinical data and demographics. Conclusion: Our preliminary analysis confirms that cytologic evaluation of the DL fluid alone is not sufficient for early breast cancer detection. These findings support our ongoing studies to develop molecular biomarkers that will improve the diagnostic power of DL fluid. Furthermore, these molecular methods can be used to evaluate ductal fluid obtained through other approaches such as nipple aspirate fluid (NAF), and to study spontaneous nipple discharge.

A Novel resequencing Diagnostic Microarray: RDMGGA1.0 chip, customized to diagnose mutations in patients with Breast, Ovarian, Colon, Skin and Multiple Cancers. *D. Bercovich[1], y. Plotsky[2], T. Guy[2], S. Allon-Shalev[3], AM. Lichanska[4], LA. Borsuk[4], C. Tibbetts[4].* 1) Human Genetic Lab, Tel Hai Academic College, Israel; 2) Galil Genetic Analysais (GGA), Kazarin 12900, Israel; 3) The Institute for Genetics, Ha'Emek Medical Center, Afula 18101, Israel; 4) TessArae, Potomac Falls, VA 20165 USA.

Despite the remarkable progress in identifying the genes causing the most common inherited cancers, current diagnostic algorithms do not incorporate all genes and known mutation analysis in the clinical evaluation of affected patients and relatives. In addition, the large genes size and the lack of highly predominant mutational hotspots for most populations frequently make mutation detection in these cancer genes outstandingly challenging, which is costly and time consuming. The interpretation is even more complex as a result of poor studies of gene-gene interactions and genotype-phenotype relationships. To fulfill this technological gap, we developed a new customized resequencing gene chip (RDMGGA1.0) that is focused on 11 genes: BRCA1, BRCA2, APC, MUTYH, MLH1, MSH2, MSH6, TP53, PTEN, P16 and KRAS simultaneously, in a single assay, with high call rate and accuracy. probes were designed to identify each base for all exons, 20 bases of intronic sequence bordering exons in the main tiles, and 3320 most frequent mutations were subtiled. The array uses the Affymetrix resequencing platform. Novel software was developed by TessArae for the data analysis. Amplicons were hybridized to the chip, and nucleotide detection was validated by standard capillary sequencing methods. Hybridization of amplicons with the chip produced high nucleotide sequence readout for all 11 genes in a single assay, with an automated call rate of over 98%. The accuracy of nucleotide calls was 99.99% when compared with capillary sequencing. The new resequencing chip enables efficient analysis of 11 genes with a high call rate and accuracy in one assay, and identifies disease-causing mutations.

519/T

Breast cancer genetics: Lobular histology may be a negative predictor of BRCA mutations. *C. Delozier[1,2,3], A. Rahman[3], E. Ubias[1].* 1) Genetic Medicine, Central CA Faculty Med Group, Fresno, CA; 2) Saint Agnes Medical Center, Fresno, CA; 3) University of California San Francisco-Fresno Medical Education Program, Fresno, CA.

Lobular breast cancer represents 10-20% of all breast malignancies. Constitutional mutations in cadherin, a cell-adhesion molecule, result in a high risk of lobular breast and diffuse gastric cancers. However, BRCA-1 and BRCA-2 are the genes most frequently implicated, and tested for, in "monogenic" predisposition to breast cancer. Soon after clinical testing for BRCA mutations became available, a flurry of publications appeared comparing the histological characteristics of breast cancers in patients with BRCA-1 vs. BRCA-2 vs. BRCA-X (negative for BRCA mutations)patients. The next wave of publications was epidemiological, whereas the current focus is molecular profiling of breast cancers, primarily for somatic mutations. In the interim, histology has been displaced as a major consideration in genetic risk assessment. We believe that lobular histology may be as important a *negative* predictor of BRCA status as pre-menopausal age at diagnosis is a positive predictor. Although infrequently considered, there is some data from the literature to support this idea. Our personal experience is as follows: We have counseled and tested 174 breast cancer patients at significant risk of carying a BRCA mutation, for whom histology was available/adequate and BRCA results were unequivocal. Lobular breast cancer was underrepresented (10/174, 5.7%). Of these 174 breast cancer patients, 22 (12.7%) had a BRCA 1-2 mutation; four of these women had bilateral disease. All 26 tumors were of ductal histology. 152 patients (87.3%) were negative for BRCA 1-2 mutations. All ten lobular breast cancer patients were in this group. Histological analysis is an integral part of every cancer patient's evaluation. Why not take it into consideration in genetic risk assessment?

520/T

Uveal Melanoma Exome Sequencing. *T. Ganguly[1], S. Sherrill Mix[1], E. Toorens[1], E. Chao[2], C. Shields[3], A. Ganguly[2].* 1) DNA Sequencing Facility, School of Medicine, University of Pennsylvania; 2) Department of Genetics, School of Medicine, University of Pennsylvania; 3) Wills Eye Hospital, Thomas Jefferson University, Philadelphia.

Uveal melanoma (UM) is a rare,adult onset primary malignant ocular disease with a significantly high degree of mortality. Monosomy 3 in the tumor is associated with poor prognosis.

We initially performed cancer exome sequence capture using Nimblegen method on two DNA samples,each pooled from four UM lesions with chromosome 3 disomy and four with monosomy respectively. We then followed by sequence capture of matched blood and tumor DNA on the Agilent Whole Exome capture platform. The captured DNA samples were sequenced on 454 and Illumina platforms. The results were analyzed using Gigabayes and Mosaik softwares. The software NextGene (Softgenetics, PA) was then used to eliminate duplicate reads representing bias in the capture step to eliminate false positives.

Cancer exome sequencing identified 211,701 and 158,653 changes within 12 basepairs of any coding exon on the Illumina platform for disomy 3 and monosomy 3 samples respectively. The numbers of changes were 151,037 and 151,706 respectively on the 454 platform. After filtering for optimal coverage (> 16 reads for Illumina; >8 reads for 454 platform), presence of reads in both directions and eliminating sequence changes in homopolymer regions, we found 18 mutations shared between the two sequencing platforms for the disomy 3 UM samples and 12 for the monosomy 3 UM samples. These results were all validated by Sanger sequencing. A frameshift mutation in BAP1 gene was observed in 25% of reads for both UM samples. The BAP1 gene is a tumor suppressor gene that functions in the BRCA1 growth control pathway. Its role in UM tumorigenesis is not known.

The genes with detected mutations were not same for all samples. These changes may represent somatic passenger mutations. The driver mutations, if present, are probably outside the cancer exome. We expect to identify the latter from the results of whole exome sequencing. The results translate basic cytogenetic observations into identification of clinically relevant biomarkers of metastasis and potential therapeutic targets in UM.

This work was partly supported by AACR-Amgen, Inc Fellowship in Clinical/Translational Cancer Research - 07-40-11-CHAO.

Analysis of mutations of the Epidermal Growth Factor Receptor Tyrosine Kinase domain in Non-Small Cell Lung Cancer Brazilian patients. *J. Garcia Carneiro[1], L. Batos-Rodrigues[1], F.A. Bianchi-Leidenz[1], R. Melilo-Carolino[1], M.A. Bicalho[1,2], A. Vilhena[2], N. Amaral[2], L. De Marco[1].* 1) Molecular Medicine Dpt, UFMG, Belo Horizonte, Minas Gerais, Brazil; 2) Thoracic Section, Júlia Kubitscheck Hospital, Belo Horizonte, Minas Gerais, Brazil.

Lung cancer is a major cause of cancer-related deaths worldwide due to its high incidence, malignant behavior and lack of major advancements in treatment strategy. Accumulated evidences show that epidermal growth factor receptor (EGFR) is strongly implicated in the development and progression of numerous human tumors, including lung cancer. Somatic mutations in the tyrosine kinase (TK) domain of EGFR gene are associated to patient's response to TK inhibitors, such as gefitinib and erlotinib. Among all EGFR mutations already reported, small in-frame deletions in exon 19 and a point mutation in exon 21 at nucleotide 2573, leading to a substitution of leucine by arginine at codon 858 (L858R) account for ~90% of EGFR mutations associated with lung adenocarcinomas. Although EGFR mutations are well-studied worldwide, there are no sufficient data about their prevalence in the Brazilian population. Therefore, our study aimed to determine the prevalence of EGFR mutations in 42 Brazilian patients. Since ethnicity appears to play a significant role in determining the percentage of patients with mutations, we correlated our molecular findings with ancestry analyses. Our results showed the presence of exon 19 deletions in only 7.1% of cases. L858R mutation was not found in any of our cases. Ancestry analysis showed a strong African component in cases when compared to control group. For the case group, the proportions of Europeans, Africans and Amerindians were 0.8419 ± 0.0257 (mean ± SE), 0.1153 ± 0.0211 and 0.0427 ± 0.0105, respectively, while for the control group, the results were 0.9162 ± 0.0181, 0.0450 ± 0.0099 and 0.0386 ± 0.0101, respectively. Differences in proportions of African genomic ancestry between the two groups were significant (p value = 0.0004, p<0.05). Our data suggest that Brazilian patients with lung cancer have a low percentage of EGFR mutations that may be explained by the strong African component found in our samples.

522/T

Frequency evaluation of PIK3CA mutations in exons 9 and 20 in Iranian colorectal cancer patients. *M. Ghaffarpour[1,2,6], E. Mohammadi Pargoo[3], M. Abachi[4], S. Sobhani[3], Z. Nour Mohammadi[5], F. Fereidooni[5], M. Houshmand[1,6].* 1) Medical Genetics Department, National Institute of Genetic Engineering and Biotechnology, Tehran, Tehran, Iran; 2) Iranian Research Organization for Science and Technology (IROST), Tehran, Iran; 3) Islamic Azad University Science and Research Campus, Tehran, Iran; 4) Nanocinna Ltd, Tehran ,Iran; 5) The cancer institute of Iran, Imam Khomeini Hospital Complex, Tehran University of Medical Sciences, Tehran, Iran; 6) special medical center,Tehran,Iran.

Background and Aim: Colorectal cancer (CRC) is one of the most important malignancies worldwide and it is the third most common cancer amongst Males and the fourth amongst females in Iranian cancer patients. PI3Ks are heterodimeric kinases involved in the control of cel=AClular growth, transformation, adhesion, and apoptosis. Somatic mutations of PIK3CA were described in CRCs with a frequency ranging from 13.6% to 32%.In CRCs, 3 mutational hot spots were described (E542K, E545K, and H1047R), covering about 80% of all PIK3CA mutations.The aim of this study was to identify PIK3CA gene mutations in exons 9 and 20 among Iranian CRC patients, and to consider whether they are linked with the clinicopathological parameters. Materials and Methods: Patients and tissue specimens: Tissue samples were obtained from 27 consecutive patients with CRC (10 men and 17 women; age range, 32-88 years; with median age of 61.3 years). Histopathological examinations were performed, and all tumors were confirmed as adenocarcinoma. Mutational analysis of PIK3CA in tumor samples: Fresh tumors, containing at least 70% of neoplastic cells and their adjacents were extracted for genomic DNA using the QIAamp Mini kit (Qiagen in accordance with the manufacturer's instructions. We searched for PIK3CA mutations in exons 9 and 20.PIK3CA exon 9 includes codons 542 and 545, PIK3CA exon 20 where the large majority of mutations occur in this genes.The PI3KCA mutational analyses were made by means of PCR sequencing. Results and conclusion: 21 (77.77%) patients had adenocarcinomas and 6 (22.23%) had mucinous adenocarcinomas. patients had stage I, II and III or IV disease with14.76%, 44.44%and 40.8% respectively and histological grade I, II and III with 66.6%,25.92% and 7.4%. respectively. Among the 27 samples analyzed (21were primary tumors and 6were metastases). The frequency of mutations in PIK3CA were present in 11.1% (3 of27) of the samples (11.1% mutation in exon 9(c.1633G>A E545K and no mutation in exon 20).The presence of PIK3CA mutation was not a significance associated with gender, histological grade, age, or cancer stage in patients with adenocarcinoma of the CRC(P>0.05).Although many study have been shown in CRCs, 3 mutational hot spots (E542K, E545K, and H1047R) ,our study indicated mutations were just in exon 9(E542K) and more samples should be investigate in exon 9,20 and other exons of PIK3CA gene.

Genetic heterogeneity in *Tg-Interacting Factor (TGIF)* expression is a modifier of acute myeloid leukemia. *R. Hamid[1], J. Means[2], S. Brandt[2].* 1) Dept Pediatrics, Div Med Gen, Vanderbilt Univ Sch Med, Nashville, TN; 2) Dept Medicine, Vanderbilt Univ Sch Med, Nashville, TN.

TGIF is a homeobox repressor, which has been associated with holoprosencephaly however its role in any other human disease is not known. Interestingly *TGIF* is expressed in hematopoietic stem cells (HSC) and interacts with RA and TGF-β pathways both involved in HSC function. We have previously shown that there is considerable variation in *TGIF* expression in acute myeloid leukemia (AML) derived cell lines. In trying to further understand the basis of this observed variability in TGIF expression, we used real-time PCR to analyze 70 primary AML blast samples for TGIF mRNA abundance. We found that *TGIF* expression was a continuous variable with an eight-fold difference in *TGIF* mRNA levels between the lowest and the highest expressers. Sequence and southern blot analysis of TGIF genomic region in these 70 patients ruled out mutations or gene rearrangements as a cause of this variability in expression. We did notice several previously reported coding and promoter SNPS but none showed significant association with *TGIF* expression. We then hypothesized that the heterogeneity in *TGIF* expression is genetic/inherited in nature and as such present in normal individuals. To explore this hypothesis we determined *TGIF* mRNA abundance in peripheral blood mononuclear cells from 20 CEPH families (200 total individuals). Our data showed that in CEPH samples, *TGIF* expression was a continuous variable with a ~20 fold difference in expression between the lowest and the highest expresser. We then investigated whether the variability in *TGIF* expression in primary AML samples had a clinical consequence for these patients. Log-rank analysis showed that *TGIF* expression in AML patients, correlated significantly with overall survival ($P < 0.0001$). Analyzed as a continuous variable, lower *TGIF* expression was associated with a significantly shorter overall survival (5.5 months vs. 54.0 months) than those with higher expression ($P < 0.0001$). Finally, when patients were grouped by *TGIF* expression and level of expression related to survival, a dose-dependent relationship between TGIF expression and outcome was suggested. These data were confirmed in an independent cohort of 285 Dutch AML patients. In conclusion our data suggest that a) *TGIF* expression is likely a quantitative expression trait and b) as such it may act as a true modifier of AML. These finding have biologic implications for both AML and possibly holoprosencephaly.

524/T

FREQUENCY OF THE TSER 2R/3R POLYMORPHISM IN THE TYMS GENE AND ITS ASSOCIATION TO BREAST CANCER IN A MEXICAN POPULATION. *B. Lazalde[1,2], G. Zambrano-Galvan[2], N. Jimenez-Soto[2], M. Reyes[2].* 1) Biomedical Res Unit, Mexican Inst Social Security, Durango, Mexico; 2) Faculty of Medicine, Universidad Juarez del Estado de Durango, Durango, Dgo. Mexico.

Background: It has been suggested that the TSER 2R/3R polymorphism (a 28-bp tandem repeat) in the TYMS 5'-untranslated region, is linked to modification in risk for some cancers. It also appears to affect the therapeutic and toxic effects of 5-fluorouracyle because thymidylate synthase, the product of TYMS, is its target. Aim: To study the frequency and association of TSER 2R/3R polymorphism of TYMS with breast cancer in a Mexican population. Metods: A hospital-based case-control study was conducted in 98 incident ductal breast cancers in women attended in the Cancer State Center of Durango, Mexico, group matched by age with 91 controls. TSER 2R/3R typification was done from genomic DNA by PCR. Hardy-Weinberg equilibrium and tests for association were done with a software of the Institute of Human Genetics of the Technological University of Munich. Results: Case and control groups were in Hardy-Weinberg equilibrium. Allelic frequencies were: 2R, 0.44 vs 0.39; 3R, 0.56 vs 0.61, and genotypic frequencies 2R/2R, 0.17 vs 0.11; 2R/3R, 0.53 vs 0.56; 3R/3R, 0.30 vs 0.33, for cases and controls respectively. Armitage's trend test: common OR=0.78, p=0.30. Significant allelic or genotypic differences between groups were not found. Conclusions: There was a high frequency of the TYMS TSER 2R/3R polymorphism in the studied groups, but association to breast cancer was not found. On the other hand, due to the high frequency found, the TSER 2R/3R genotyping could be worth with pharmacogenetic aim regarding treatment with 5-fluorouracyle and analogs.

525/T

MiRNA-150 AND miRNA-155 expression patterns are distinct in acute myeloid leukemia versus blast phase of chronic myelogenous leukemia associated with inv(3)(q21q26). *P. Lennon[1], J. Han[1], S. Mulligan[1], P. Hu[1], C. Yin[2], P. Lin[2].* 1) Molecular Genetic Technology Program, School of Health Professions, UT-MD Anderson Cancer Center, Houston, TX; 2) Department of Hematopathology, UT-MD Anderson Cancer Center, Houston, TX.

Inv(3)(q21q26) is a rare recurrent cytogenetic aberration observed typically in acute myeloid leukemia (AML) or blast phase of chronic myelogeneous leukemia (CML- BP). The mechanism of how inv(3) causes leukemia is unknown. A unique feature of AML with inv(3) is that affected patients often have an increased platelet count but profound anemia due to dysregulation of megakaryopoiesis. MiRNA-150 has been shown previously to enhance megakaryopoiesis at the expense of erythropoiesis. MiRNA-155 has been shown to modulate megakaryopoiesis at the hematopoietic progenitor/precursor level by targeting some transcription factors, and that decline of miRNA-155 is required for proliferation and differentiation of megakaryocytes. We hypothesized that in AML or CML-BP associated with inv(3), miRNA-150 and miRNA-155 may contribute to or determine the clinical characteristics of these diseases. To test this, we analyzed miR-150 and miR-155 expression levels in 13 leukemic samples with inv(3) including AML (n=5), CML-BP (n=6) and CML-chronic phase (n=2) by using real-time reverse-transcriptase quantitative polymerase chain reaction. A case of chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) was included as a control. Total RNA extraction was obtained from formalin-fixed paraffin embedded tissue sections. MiRNA-150 and 155 of the total extract were targeted for cDNA conversion (Applied Biosystems' Reverse Transcription Kit). Real-time polymerase chain reaction was used to examine their expression levels. Relative quantitations were analyzed by delta-delta CT method. We found significantly increased miR-150 expression in all 13 cases, particularly in AML and CML-BP. By contrast, expression of miR-155 was increased in CML-BP but decreased in AML and CML-CP. We conclude that miRNA-150 and miRNA-155 expression patterns are distinct among AML, CML-BP and CML-CP. The significantly increased level of miR-150 expression in AML and CML-BP in comparison to CML-CP suggests that miR-150 is implicated in the acute onset or blast transformation, and hence facilitates a more aggressive disease. Also, the differential expression of miR-155 in CML-BP versus AML and CML-CP suggests that it is more implicated in blast transformation than de novo disease. Further studies to compare miR-150 expression in AML and CML-BP cases with or without inv(3) are warranted to explore its potential as a marker for prognosis and targeted therapy.

526/T

Oncogenesis of retinoblastoma associated to the SNPs of low frequency from RB1 gene in Mexican pediatric patients affected with hereditary and non hereditary disease. *M. Macias-Vega[1], J.C. Juarez[1], J.C. Ordaz[1], V. Bosch[1], M. Chávez[1], N. Carranza[1], C. Leal[1], P. Gariglio[2], R. Ocadiz[2], O.A. Pérez[1].* 1) Laboratorio de Oncologia Experimental, Instituto Nacional de Pediatria, Mexico D.F., Mexico; 2) Departamento de Patología Molecular, CINVESTAV IPN, Mexico D.F., Mexico.

BACKGROUND: The single nucleotide polymorphisms (SNPs) from RB1 gene have been classified in two groups: of high frequency (³ 5%) (normal alleles) and of low frequency (£ 5%) (risk alleles), some of them have been found like haplotypes, formed by risk alleles in heterozigosity and homozigosity associated with a high predisposition to develop the disease, with a differential response to the Chemotherapy and have been considered like prognostic markers in patients affected with breast cancer, hereditary retinoblastoma and ovarian cancer. OBJECTIVE To determine the frequency of the risk alleles from RB1 gene in pediatric patients. MATERIAL AND METHODS DNA samples from peripheral blood of 73 patients were analyzed, all samples were genotyped for 15 SNPs from RB1 gene by mean of allelic discrimination with Taq-Man probes. RESULTS The results show that in the control group the normal alleles occurred in homozigosity at 100% in five allelic markers C-779216, C-3042266, C-779170, C-33789354 and C-31604223 whereas in patients group it occurred only in one marker C-33789354, and only two markers more show a frequency nearest to 100% (C-779170 85%, C-31604223 95%), in relation to the risk allele, it was found in heterozigosity in 14 markers in the patients group while it occurred in 7 markers in the control group and it was found in homozigosity in 12 markers in the patients group and only in 6 markers in the control group. CONCLUSIONS Clearly the risk allele is find in high frequency both homozygosity and hetrozygosity in the patients group so the oncogenesis of retinoblastoma is associated with the risk alleles (SNPs) of the RB1 gene, however the extensive analysis of haplotypes will allow in a second phase to determine if any association exist among risk markers and clinical aspects of the disease like a different response of each patient to the pharmacology treatment, its utility like prognostic factor of the malignancy and for the opportune detection of haplotype carriers with high risk to inheriting the disease with at least one affected member as well as it application in diagnostic processes in human preimplantation treatments for assisted reproduction purposes. CONACYT-71020, INP-07/040.

527/T

Genomic Signature of Metastasis in Prostate Cancer Health Disparity. *A. Pearlman[1], C. Campbell[1], E. Brooks[1], A. Genshaft[1], S. Shajahan[1], M. Ittmann[2], G. Bova[3], J. Melamed[4], R. Schneider[5], Y. Shao[6], H. Ostrer[1].* 1) Pediatrics Dept, NYU Langone Medical Center, New York, NY; 2) Pathology Dept, Baylor College of Medicine, Houston, TX; 3) Pathology Dept, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Pathology Dept, NYU Langone Medical Center, New York, NY; 5) Microbiology Dept, NYU Langone Medical Center, New York, NY; 6) Biostatistics Division, NYU Langone Medical Center, New York, NY.

Prostate cancer is the most commonly diagnosed cancer in men. When detected early, prostate cancer can be cured, although most therapies, such as radical prostatectomy and radiation therapy, often result in significant side effects, including erectile dysfunction and urinary incontinence. Current biomarkers of metastatic potential have limited predictive value, resulting in life-preserving, albeit debilitating, radical treatments. In Caucasian American (CA) men, the disease is indolent in ~75% of diagnosed cases when left untreated. The disease is more prevalent and aggressive among African American (AA) men, resulting in a well-known racial health disparity. To investigate the genomic basis of metastatic disease and this disparity, we studied the somatic copy number alterations of primary tumors from 29 AA and 20 CA men and 52 hormone refractory metastasis samples from 12 CA patients with multiple metastases collected at autopsy. All 49 primary tumors had clinical attributes associated with invasive local disease, including stage II-IV and Gleason score 5-9 that were similar between the AA and CA groups. Unsupervised hierarchical clustering of a summarized metastasis profile along with the 49 primary tumors resulted in the compelling observation that 8 out of 29 AA primary tumors (28%) segregated with the metastasis cluster, whereas only 2 out of 20 CA primary tumors (10%) segregated with the metastasis cluster. This 2.8-fold ratio (bootstrap 95% confidence interval = 1.7-3.78, 800 iterations) of AA primary tumors over CA primary tumors was consistent with the previously reported rate of racial health disparity of mortality. A novel genome scanning method developed in-house identified genes undergoing natural selection in the metastases. The top candidate genes, KCNQ3, KCNB2, ASAH1, CDH13 and WWOX, that are potential drivers of the metastatic process and correlates of the racial health disparity may do so by facilitating the escape from anoikis through the control of potassium ion and ceramide concentrations. A risk model based on the top candidate metastasis signature genes predicted a metastasis cohort (n=14) with sensitivity-AUC = 0.95. These observations can be harnessed to gain a deeper understanding of the basic cellular biology of metastasis and can be used clinically to predict whether a primary tumor is likely to metastasize.

528/T

Prevalence of common mutation frequency in codons 12, 13 of K-ras gene among Iranian colon cancer patients. *S. Sobhani[1], M. Ghaffarpour[2], Z. Nour Mohammadi[3], M. Houshmand[2].* 1) Islamic Azad University Science & Research Campus, Tehran , Tehran, Iran; 2) Medical Genetics Department, National Institute of Genetics Engineering and Biotechnology, Tehran, Iran; 3) The cancer institute of Iran, Imam Khomeini Hospital Complex, Tehran University of Medical Sciences, Tehran, Iran.

Back ground and Aims: Colorectal cancer (CRC) is the most gastrointestinal cancer in United States and Europe, and the third most common cause of cancer-related death. The development of colorectal cancer is a multiple process that can take place, because of the various mutations in proto-oncogenes, tumor suppressor genes, and epigenetic changes in DNA too. K-ras gene encodes a signal transducer protein which is a GDP/GTP binding protein. Mutation analysis in K-ras is known as a predictive biomarker in colorectal cancer. According to recent researches, somatic mutations in codons 12, 13 of K-ras gene are discovered in 40% - 50% human CRCs. The aim of this study was to estimate the contribution of K-ras gene mutations in codons 12, 13 in the incidence, and its association with clinicopathologic, sex, stage and familial history in Iranian colon cancer patients. Materials and Methods: Genomic DNA was extracted from tissue samples using QIAamp mini kit. Exon 1 which includes codons 12, 13 as two hot spots in this gene, was amplified with specific primers. After running the PCR products on 1.5% agarose gel, they were analyzed with automated sequencing method. Finally, we have blasted the sequences in ncbi, and statistical analysis of the data performed with SPSS software. Results: In this study, we have analyzed 18 (12F, 6M) tissue specimens of colon cancer patients using PCR/Sequencing method for codons 12, 13 of K-ras gene. 3 of 18 patients (16.6%) have shown a point mutation in codon 12 (2 G>A, 1 G>T) and none of them (0%) have shown mutation in codon 13. The presence of K-ras mutation does not have a significant association with gender, histological grade, age or cancer stage in patients with adenocarcinoma of the CRC (P>o.o5). Discussion: mutation in exon 12, 13 are not common in Iranian patients. We suggest whole genome sequence for our patients.

529/T

Biomarkers of response to IGF1R inhibition in osteosarcoma. *K. Sol-Church[1], E.A. Kolb[2], D. Kamara[2], D.L. Stabkey[1].* 1) Dept Biomedical Res, Alfred I duPont Hosp Children, Wilmington, DE; 2) Cancer Therapeutics Laboratory, Alfred.I. duPont Hospital for Children, Wilmington, DE.

Objective: To evaluate signaling pathways influencing response in osteosarcoma (OS) tumors to the inhibition of the IGF-1 receptor (IGF1R). Methods: Recent preclinical studies have demonstrated that a subset of osteosarcoma xenografts is consistently sensitive to IGF1R inhibitors (OS1, OS2, OS9 and OS17) and a subset consistently resistant to IGF1R inhibitors (OS31 and OS33). This study investigates molecular pathways that differentiate the tumor lines. Results: Following inhibition of IGF1R with the inhibitor R1507, a fully humanized monoclonal antibody, xenograft tumor lines sensitive to IGF1R inhibition demonstrate a decrease in IGF1R, EGFR, AKT and MAPK phosphorylation within 48 hours of treatment. In contrast in the 2 resistant tumors OS31 and OS33, there is an increase in AKT and MAPK phosphorylation as well as EGFR mRNA and protein expression. Loss of TP53, a negative regulator of EGFR was also observed in both resistant tumors. In addition, a known Sp1 polymorphic binding site at -216 on the EGFR promoter is able to predict tumor response: IGF1R inhibitor sensitive tumors either carry the -216 T/T, and G/T genotype corresponding to higher constitutive EGFR protein expression. The 2 tumor lines resistant to IGF1R inhibition are homozygous G at this site. The G/G polymorphism predicts lower constitutive expression of EGFR but a rapid induction of EGFR expression and signaling in response to IGF1R inhibition. Transfection assays with the T and G genotypes using a luciferase reporter confirm these results. Pathway focused gene expression analysis and miRNA profiling are ongoing that will give clues as to the mechanism of response to chemotherapy in these tumor types. Conclusion: OS cells and tumors resistant to R1507 may survive in the presence of IGF-IR signal inhibition through an increase in EGFR expression mediating signaling involving MAPK. Efficiency of this change in EGFR expression can be predicted by a SNP in the EGFR promoter. Inducible mechanisms of resistance should be evaluated in sarcomas in response to potent targeted therapies.

Clinical utility of inherited markers in determining need for repeat biopsy: results from placebo arm of the REDUCE® study. *J. Sun[1], A.K. Kader[1,2], P.J. Newcombe[3], B.H. Reck[4], S.T. Kim[1], T. Jin[1], Z. Zhang[1], S. Tao[1], G.T. Platek[4], C.F. Spraggs[3], J.C. Whittaker[3], V.E. Mooser[5], J.D. McConnell[2], S.L. Zheng[1], L.D. Condreay[4], R.S. Rittmaster[4], J. Xu[1,2].* 1) Center for Cancer Genomics, Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC, USA; 2) Dept of Urology, Wake Forest University School of Medicine, Winston-Salem, NC, USA; 3) GlaxoSmithKline Research and Development, Harlow, UK; 4) GlaxoSmithKline Research and Development, Research Triangle Park, NC, USA; 5) GlaxoSmithKline Research and Development, King of Prussia, PA, USA.

Purpose: Management of men following negative prostate biopsy for prostate cancer is challenging. The predictive performance of currently available clinical parameters such as prostate specific antigen (PSA) for prostate cancer is limited. Recently, 33 PCa risk-associated single nucleotide polymorphisms (SNPs) have been identified from genome-wide association studies. We sought to assess whether supplementing existing predictors with the prediction of prostate cancer on subsequent biopsy. Methods: Study subjects included 1,654 men in the placebo arm of the four-year randomized REduction by DUtasteride of prostate Cancer Events (REDUCE®) trial, where all subjects had PSAs between 2.5-10.0 ng/mL, a negative prostate biopsy at baseline and underwent scheduled prostate biopsies at years 2 and 4. Results: Of 1,654 men who had at least one prostate biopsy over four years, 410 (25%) and 124 (7%) were diagnosed with prostate cancer and high-grade PCa (Gleason grade ≥ 7), respectively. Differences in the genetic score between men with positive and negative biopsies were highly significant even after adjusting for other clinical variables ($P = 3.58 \times 10^{-8}$). The AUC for prostate cancer prediction of the genetic score was 0.59, higher than any other individual clinical parameters including PSA (AUC = 0.54). When the genetic score was added to the best clinical model including five parameters (age, family history, free/total PSA ratio, prostate volume, and number of cores at base biopsy), the AUC increased from 0.60 to 0.64. The differences in detection rates between men with lower or higher genetic risk at each quartile of estimated risk based on the best clinical model ranged from 9.31% to 13.66% for prostate cancer and 2.89 to 6.16% for high-grade prostate cancer, providing strong evidence for the added value of genetic markers in risk prediction. Conclusions: For men with an initial negative biopsy, genetic markers may be used to supplement existing predictors to better predict for prostate cancer and high-grade prostate cancer on subsequent biopsy.

531/T

Altered miRNA expression in lymphoblastoid cell lines of Finnish familial prostate cancer cases. *T. Wahlfors[1], H. Mattila[1], D. Fischer[2], M. Schindler[2], H. Oja[2], J. Schleutker[1].* 1) Lab Cancer Gen, Inst Med Tech, University of Tampere, Tampere, Finland; 2) Tampere School of Public Health, University of Tampere, Finland.

Identifying new risk factors and explaining their functionality in prostate carcinogenesis and prostate cancer prognosis would have instant clinical utility, especially with aggressive disease status. Non-coding RNAs, like miRNAs can be informative for the identification of men who may be at elevated risk for prostate cancer and men at risk for developing a more aggressive disease outcome. Based on the current knowledge predisposition to PrCa is arising from multiple alterations in the genome and most often these variations are low penetrant and challenging to find. Since considerable amount of miRNAs are located within intronic regions and regulated by the host gene promoter, miRNA expression profiles gives us one possibility to study disease related variations in non-protein coding chromosomal areas and could lead to identification of regulatory variants. miRNA expression from 186 lymphoblastoid cell lines from both affected (N=111) and unaffected (N=75) individuals from Finnish multiplex prostate cancer families were included in this study. Isolation of total RNA was done using standard Trizol protocol and Agilent Human miRNA V2 Oligo Microarray kit was used for miRNA detection. After quality checking and data normalization different statistical methods were used for data analyses for example Ward's method for clustering and Random Forest method for ranking. Selected set of miRNAs were used for validation with TaqMan MicroRNA Assays. Based on the initial clustering analysis we were able to separate the healthy controls (N=36) from the cancer patients (N=63). Healthy individuals were members from 17 families and cases from 38 families making a total number of analyzed families 56. Case and control cohorts did not overlap concerning the family history. We identified six miRNAs (miR-770-5p, miR-202, miR138-2, miR431, miR-513c and miR487b) that were mostly affecting to clustering. Those miRNAs and 13 other miRNAs (based on expression differences or ranks from Random Forest) were chosen for further validation. Validation results of miR-151-5p, miR-151-3p, miR-29c, miR-557 and miR-195 were consistent with the array results. Other validation results were either opposite or the expression was too low to draw any conclusions. Confirmed miRNAs warrant further studies to identify the mechanism underlying and validation in larger sample set.

532/T

Gene expression profile for early relapse patients of colorectal cancer. *Y. Wang[1], I.P. Yang[1], J.W. Wang[1,2,3,4], S.H. Juo[1,5].* 1) Department of Medical Genetics, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Graduate Institute of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Department of Surgery, Faculty of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Cancer Center, and Division of Gastroenterology and General Surgery, Department of Surgery, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung, Taiwan; 5) Cancer Center and Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Colorectal cancer (CRC) is one of the most frequent cancers and a common cause of cancer-related deaths in the developed world. The recurrence rate among patients with early-stage CRC is more than 20%. The overall 5-year survival rate of CRC patients ranges from 40% to 60%. Here we developed a multiplex, quantitative gene expression assay to test for a gene expression profile comprising 21 candidate genes for early relapse (defined as a recurrence of 12 months after surgery) of CRC. These 21 genes were previously identified from a microarray study and the majority of them are involved in metastasis. The multiplex assay is performed on the GenomeLab™ GeXP Genetic Analysis System (Beckman Coulter Inc.) where the gene expression level was compared with a reference gene. Using as little as 40ng of total RNA extracted from frozen fresh tissues, the GeXP platform can detect as low as 0.5-fold change in expression level. Thus it can provide a more subtle change that is hard to be achieved by tranditional quantitative real-time polymerase chain reaction. In addition, the GeXP multiplex feature allows genes of interest and an internal control to be analyzed in a single well for improved accuracy. A total of 60 frozen tissue samples of CRC were analyzed and they are consisted of adenocarcinoma (98%) and mucinous carcinoma (2%). The results indicated that fibroblast growth factor 2 (FGF2), matrix metallopeptidase 9 (MMP9) and pitrilysin metallopeptidase 1 (PITRM1) had higher expression levels in the patients with early relapse than those with non-early recurrence (p£0.05). Fibroblast growth factor-2 (FGF2) is a prototypic angiogenesis inducer, matrix metallopeptidase 9 (MMP9) and pitrilysin metallopeptidase 1 (PITRM1) both are proteinase. The present study augments that the previous results from the microarray study where several genes were implied in early relapse of CRC. Using this multiplex gene expression system, we are allowed to quantitatively interrogate several candidate genes simultaneously. We are currently underway to further confirm of the importance of these three genes in an independent samples.

MICA-STR genetic diversity and its association with ovarian cancer in a northern Chinese population. *Y. Fan[1], W. Yu[1], P. Ye[1], Z. Wang[2], Q. Meng[1], Y. Duan[1], X. Liang[1], W. An[1].* 1) Institute of Transfusion Medicine, Blood Center of Dalian, Dalian, Liaoning, China; 2) Department of Gynecologic Ontology, Dalian Obstetric and Gynecological Hospital, Dalian, China.

MHC class-I chain related gene A (MICA) maps 46 kb centromeric to HLA-B and is highly polymorphic. The MICA-NKG2D system plays an important role in the anti-tumor immune responses. Ovarian cancer, a polygenic disease, is the leading cause of death among malignant gynecological tumors, and genetic factors are critical for the induction of this malignancy. We postulated MICA gene as a susceptibility factor for ovarian cancer. In this study, 97 unrelated patients newly diagnosed with ovarian cancer and 102 randomly selected healthy controls were enrolled. All subjects were of Han ethnicity and were local residents in Liaoning province, northern China. Peripheral blood with EDTA anticoagulant was collected after each person's informed consent. Genomic DNA was isolated from blood samples by commercial DNA extraction kit. The short tandem repeat polymorphism of exon 5 of MICA gene (MICA-STR) was determined using fluorescent polymerase chain reaction-capillary electrophoresis. The allele frequencies of the five MICA-STR variants in the control group were 10.8% (A4), 22.1% (A5), 34.8% (A5.1), 17.6% (A6), and 14.7% (A9), respectively. The frequency of the MICA-A5 allele in ovarian cancer patients was significantly higher than that in the controls (33% vs. 22.1%, P=0.015, odds ratio=1.739, 95% confidence interval=1.113-2.718). The results suggest that the MICA-A5 allele appears to increase the susceptibility to ovarian cancer in this population. The potential interaction between MICA and other genetic factors remains to be further studied.

Chromosomal abnormalities in ossifying fibromyxoid tumor of soft parts. *S. Gebre-Medhin[1], F. Vult von Steyern[2], O. Brosjö[3], H. Domanski[4], N. Mandahl[1], F. Mertens[1].* 1) Deparment of Clinical Genetics, University and Regional Laboratories, Skåne University Hospital, Lund University, Lund, Sweden; 2) Deparment of Orthopedics, Skåne University Hospital, Lund University, Lund, Sweden; 3) Department of Orthopedics, Karolinska University Hospital, Stockholm, Sweden; 4) Deparment of Pathology, University and Regional Laboratories, Skåne University Hospital, Lund University, Lund, Sweden.

Ossifying fibromyxoid tumor (OFMT) of soft parts is an uncommon, rarely metastasizing tumor of uncertain cellular origin which predominantly occurs in the extremities of the adult. Clinically, the tumor often presents as a small painless subcutaneous mass displaying a partial peripheral ring of calcification upon radiography. Microscopically, there are often nests and cords of round-shaped cells in a myxoid stroma surrounded by an incomplete layer of ossified tissue. Among the few cases of OFMT that have been cytogenetically examined to date no recurrent clonal chromosomal abnormalities have been identified. Thus, although OFMT, based on histological and ultrastructural grounds, have been suggested to possibly harbor a common cytogenetic rearrangement, this remains to be shown. In the present work we report three new cases of OFMT which were investigated using cytogenetic, fluorescent in situ hybridization (FISH), and short nucleotide polymorphism (SNP) array analyses. Together with previous published karyotypes our findings indicate that rearrangements involving the short arm of chromosome 6 are common in OFMT.

535/T

Gene mutation and protein functional alteration in nevoid basal cell carcinoma syndrome and familiar keratocystic odontogenic tumor. *Y. Lu, XD. Wang, HG. Zhu, WM. Ye, SL. Zhang, D. He, MB. Zhang, TT. Zhang, GF. Shen, WT. Chen.* Oral and Maxillofacial Surgery, Ninth People's Hospital,Shanghai Jiaotong University School of Medicine, Shanghai, China.

Objective: To investigate PTCH gene mutation and alteration of PTCH protein function in nevoid basal cell carcinoma syndrome (NBCCS) families and familiar keratocystic odontogenic tumor families. The activity of Hedgehog pathway in tumor sample of proband from each family was also studied. Methods: NBCCS and familiar keratocystic odontogenic tumor families were collected according to major and minor criteria. Mutation of PTCH and PTCH2 gene were detected by PCR and directly sequence analysis. Alteration of PTCH protein function after gene mutation was forecasted by bioinformatics analysis. Gli protein, one of key molecule in Hedgehog pathway, was detected by immunohistochemistry in tumor sample of proband from each family. Results: Seven families were collected, including five NBCCS families and two familiar keratocystic odontogenic tumor families. In two NBCCS families, a new 3bp deletion mutation of PTCH c.1537_1539delGAT or c.1540_1542delGAT (p.513delD or p.514delD) and a nonsense mutation of PTCH c.2776ACC>ACT (p.W926end) were detected. In two familiar keratocystic odontogenic tumor families, a missense mutation of PTCH c.3277 CGA>GGA (p.G1093R) and a new splice mutation of PTCH c.339+1G>C (NM 000264.3, 'A' in promoter ATG as the first base in the sequence) were detected. Mutation of p.513delD or p.514delD might affect transmembrane domain of PTCH protein. Mutation of p.W926end might affect the second functional domain of PTCH protein. Mutation of p.G1093R might affect active site of PTCH protein. Expression of Gli protein was detected in all cancer samples of probands from all families. Conclusions: Multiple keratocystic odontogenic tumors were main and first reason to hospital in collected NBCCS families. Keratocystic odontogenic tumors were the only symptom in familiar keratocystic odontogenic tumor families. Different mutation might affect PTCH protein function through different way. No PTCH mutation was detected in three NBCCS families, so maybe other gene take responsible for NBCCS in these families. Key molecule of Hedgehog pathway might be therapy target for NBCCS and Keratocystic odontogenic tumor.

536/T

microRNA regulates the responses to ionizing radiation by controlling MAPK signaling in lung cancer cells. *H. ARORA[1], W.Y. PARK[1], H.Y. SUNG[1], A.K. PARK[1], S. JIN[2], S.M. DONG[3], J.H. AHN[4].* 1) BIOMEDICAL SCIENCE, SEOUL NATIONAL UNIVERSITY, SEOUL, Korea; 2) Departments of Radiation Biology, Gilin University College of Medicine, China; 3) Division of Translational & Clinical Research I, Research Institute, National Cancer Center; 4) Department of Biochemistry, Ewha Women University College of Medicine, Seoul 158-907, Korea.

To understand the microRNA-mediated posttranscriptional control of the responses to ionizing radiation (IR), we examined time-series profiles of genome-wide microRNA expression upon 2 Gy γ-irradiation in radioresistant H1299 and radiosensitive H460 human lung cancer cell lines. We selected differentially expressed microRNAs (DEmiRs) according to the statistical analysis (ANOVA, $p<0.05$) in H1299 cells and H460 cells. The enrichment analysis showed that MAPK signaling pathway is targeted by DEmiRs in both cell lines. However, the reported target genes in these two pathways were differentially regulated in a concerted manner. We cross validated our analysis and found that over 60% of the mRNAs that were predicted by our analysis are significantly changed. From these results, we suggest that IR-induced regulation of microRNA might affect the regulation of MAPK signaling pathways in a concerted manner, which may confer the resistance to ionizing radiation.

SUCCINATE DEHYDROGENASE SUBUNIT B (SDHB) IMMUNOSTAINING IN GASTROINTESTINAL STROMAL TUMORS (GIST) ASSOCIATED WITH CARNEY-STRATAKIS SYNDROME, CARNEY TRIAD, AND WILD-TYPE GIST. *M.B. Lodish[1], K. Janeway[2], J. Gaal[3], E.R. Ball[1], M. Raygada[1], S.Y. Kim[4], C.A. Stratakis[1].* 1) Developmental Endocrinology , NICHD, NIH, Bethesda, MD; 2) Dana Farber Cancer Institute, Boston, MA; 3) Medical Center Rotterdam, The Netherlands; 4) National Cancer Institute, Bethesda, MD.

Gastrointestinal Stromal Tumors (GIST) are rare neoplasms of the GI tract arising from the interstitial cells of Cajal. While most adult GIST patients have activating mutations in *KIT* or *PDGFRA* and respond to therapy using tyrosine kinase inhibitors (TKI), pediatric GIST patients do not have mutations in these genes, are thus termed wild-type (WT), and do not respond as well to TKI therapy. Mutations in genes *SDHB,-C,-D* (SDHx) encoding subunits of succinate dehydrogenase (mitochondrial oxidation complex II) have been implicated in the pathogenesis of WT GIST. We recently reported that up to 29% of patients with WT GIST harbor germline SDHx mutations, in the absence of co-existing paraganglioma (PGL)(1). SDHB immunohistochemistry (IHC) has been shown to have a sensitivity of 84-100% to detect the presence of an SDHx mutation (2). We investigated whether SDHB IHC could effectively discriminate between SDHx-related and non-SDHx-related GIST in a cohort of patients with WT GIST, including GIST from patients with Carney-Stratakis syndrome (CSS) and Carney Triad (CT). CSS is characterized by the presence of PGL and GIST inherited in an autosomal dominant manner. SDHx germline mutations are present in the majority of patients with CSS. Carney triad (CT) is a rare syndrome that is associated with GIST, PGL, and pulmonary chondroma; the causative genetic defect remains unknown. SDHB IHC was perfomed on 20 WT GISTs from 20 unrelated patients. Nine of these patients had wild-type GIST alone, the remainder had CSS or CT. Results of IHC were compared to SDHx mutational status. All GISTs from patients with CSS/CT were SDHB negative by IHC (n=11). Negative SDHB immunostaining was seen in 5 tumors from patients with WT GISTs, only one of whom had a known SDHx mutation. A total of 4 GISTs from 4 patients were SDHB positive by IHC and none of these harbored germline SDHx mutations. Although SDHx mutations are not present in patients with CT, the negative SDHB expression in GIST samples isolated from these patients implicates the SDH pathway in the pathogenesis of this disease. We conclude that SDHx mutations are present frequently in pediatric and young adult patients with wild-type GIST; an absence of SDHB immunoreactivity is observed in 100% of GISTs associated with SDHx mutations and in all CT/CSS related GISTs. Prediction of microsatellite instability in colorectal cancer based on pathologic and genetic data. *N. Roslin[1], M. Mrkonjic[2,3], A. Hyde[4], C. Greenwood[1,2], D. Fontaine[4], S. Raptis[2,3], A. Pollett[3], P. Laird[5], V. Pethe[3], T. Chiang[1], D. Daftary[6], E. Dicks[4], S. Thibodeau[7], S. Gallinger[2,3,6], P. Parfrey[4], H. Younghusband[4], T. Hudson[2,8], J. McLaughlin[2,3,6], R. Green[4], B. Zanke[6,9], J. Beyene[1,2], A. Paterson[1,2], B. Bapat[2,3].* 1) Hospital for Sick Children, Toronto, ON, Canada; 2) University of Toronto, Toronto, ON, Canada; 3) Mount Sinai Hospital, Toronto, ON, Canada; 4) Memorial University of Newfoundland, St. John's, NL, Canada; 5) University of Southern California, Los Angeles, CA, USA; 6) Cancer Care Ontario, Toronto, ON, Canada; 7) Mayo Clinic, Rochester, MN, USA; 8) Ontario Institute for Cancer Research, Toronto, ON, Canada; 9) Ottawa Hospital Research Institute, Ottawa, ON, Canada.

Approximately 15% of colorectal cancer (CRC) tumours show high frequency of microsatellite instability (MSI-H). These cancers show different clinicopathological features from microsatellite stable (MSS) tumours, may respond differently to chemotherapy, and are common in patients with HNPCC. To identify MSI-H tumours, Jenkins et al. (2007, Gastroenterology, 133:48-56) proposed MsPath, a logistic regression model to predict MSI status based on clinical features. The MsPath score, based on model parameter estimates, ranged from 0 (1% probability of MSI-H) to 6.6 (91% probability). The authors recommended a threshold of 1.0 (4% probability) to send samples for MSI testing, in order to have high sensitivity. rs1800734, located in the promoter region of *MLH1*, has been shown to be associated with MSI status (unpublished data; $p=3.38x10^{-6}$, OR=1.74 (95% CI 1.38, 2.20) for the minor allele). We evaluated the predictive abilities of MsPath in a sample of 401 CRC tumours from patients in Newfoundland (NL), re-fit a model which included rs1800734 in the sample from NL, and assessed the predictive abilities of the models in 310 CRC tumours from Ontario (ON). MsPath scores for all samples were calculated using the model published by Jenkins et al. (2007). Logistic regression was used to fit the 6 variables in MsPath and rs1800734, using an additive coding for the SNP. Models were assessed by constructing a receiver operating curve, and calculating the area under the curve (AUC). All analyses were performed using R 2.6.1 (www.r-project.org). In NL, MsPath scores were higher in MSI-H tumours than in MSS/L tumours (mean 3.5 and 1.5, respectively). The AUC was 0.86. Using the cutoff of 1.0, 162 (40%) of the samples would not be sent for MSI testing; 2 of these were MSI-H (sensitivity 94%). The score had a specificity of 44%. When the model was re-estimated in the NL data, including the SNP, rs1800734 was significant at the 5% level, and appeared to be associated with MSI status independently of the variables in MsPath. In the ON data, addition of the SNP did not significantly improve the predictive ability of the model. The model proposed by Jenkins et al. had an AUC of 0.86 in the ON data; the AUC was also 0.86 when rs1800734 was added to the model. Although rs1800734 was significant when added to the model, it did not improve the predictive ability of MsPath. Thus, it is of little benefit to add this SNP to MsPath.

"Micronesian" Autosomal Recessive Aplastic Anemia. *M. Dasouki[1], S. Abhyankar[2], R. Calado[3].* 1) Dept. of Pediatrics & Medicine, Univ Kansas Med Ctr, Kansas City, KS; 2) Dept of Medicine, Univ Kansas Med Ctr, Kansas City, KS; 3) Hematology Branch. National Heart, Lung, and Blood Institute. National Institutes of Health. Bethesda, MD.

Aplastic anemia is a clinically and molecularly heterogeneous disorder which occurs in various bone marrow failure (BMF) syndromes. Known causes of BMF include Fanconi anemia and the recently described telomeres related disorders. Telomeres are made up of a variable number of tandem repeats (TTTAGGG in humans), show inter-individual length variability and are involved in maintaining genetic stability. Patients with idiopathic aplastic anemia have shorter telomeres than normal controls. Genes known to cause aplastic anemia include: the telomerase RNA component gene (TERC), telomerase reverse transcriptase gene (TERT), interferon-gamma gene (IFNG), NBS1, PRF1 and SBDS. Here, we describe a large Micronesian family with 11 siblings, three of whom developed aplastic anemia at an average age of 15 years. Two of these affected siblings (a sister & brother) died at 9 and 21 years of age respectively. The surviving affected sister is 21 years old now, and was diagnosed with aplastic anemia 5 years ago. She showed no physical signs of Fanconi anemia. Peripheral blood lymphocytes spontaneous, as well as MMC & DEB induced chromosome breakage analysis was normal. Telomere length determined by qRT-PCR was normal in the proband, her parents and her two "HLA matched" phenotypically healthy brothers. These results suggest a new form of recessively inherited aplastic anemia in this Micronesian family. SNP array homozygosity mapping followed by candidate gene DNA sequencing or whole exome sequencing may allow the identification of the genetic cause of this novel aplastic anemia. The telomere complex related aplastic anemias will be reviewed.

Germline CDH1 mutation can be co-segregated with inherited invasive lobular breast carcinoma in the absence of diffuse gastric cancer. *Y. Bignon[1], X. Ze Ming[1,2], L. Lai Sheng[1,2], C. Lacquet[1], F. Penault-Llorca[1], N. Uhrhammer[1].* 1) Dept Oncogenetics, LOM UMR 484 INSERM, Clermont-Ferrand, France; 2) Sun Yat-Sen University Cancer Center, 651 Dongfeng Road, East, Guangzhou, P. R. China,510060.

Present data are highly suggestive but do not unequivocally prove the co-segregation of germ-line CDH1 mutations and inherited invasive lobular breast cancer (ILBC). In order to clearly demonstrate the role of constitutional CDH1 mutations in ILBC, we conducted a screening study on a large family with five ILBC cases, including two bilateral ILBC cases. Noteworthy no diffuse gastric cancer (DGC) was observed in this family. Screening of the CDH1, BRCA1 and BRCA2 germ-line mutations was performed on blood samples from a Caucasian family with five pathologically confirmed ILBC cases but without DGC case. When available, loss of heterozygosity (LOH) and immunohistochemistry (IHC) analyses were performed on the corresponding tumor samples. Follow-up data is available for all living familial members. Other families with CDH1 germline mutations were reviewed in the local database of our center. The key words 'CDH1, germ-line mutation, lobular breast cancer, diffuse gastric cancer' were employed for searching Pubmed and google scholar. Results: No BRCA1 or BRCA2 mutation was found. A deleterious CDH1 germ-line mutation,c.283C>T (pQ95X),was found in the three living women with ILBC, and a healthy 71-year-old male. The mutation was also present in two obligate carriers, non of them died of DGC. According to the "two hits" model, loss of the second CDH1 allele in one of the breast tumors was attested by LOH and IHC studies. Four patients with both ILBC and DGC in hereditary DGC families have been reported in the literatures, with ILBC occurring either synchronously or prior to DGC , the lapse from the diagnosis of ILBC to the diagnosis of DGC was 8-9 years in non-synchronous cases, whereas two of the three living ILBC cases in the present family had ILBC diagnosed more than 12 years ago. A second family with a germ-line CDH1 mutation (c.1582del) without any DGC cases was found in our database, the proband was affected by a pathologically confirmed ILBC at age 48, after 15 years of follow-up there was no evidence of DGC in this woman or her relatives. No follow-up data for other ILBC cases with CDH1 mutation was available in the literatures. In conclusion, germline CDH1 mutation can be co-segregated with ILBC in the absence of DGC. The risk of DGC in these families and the underlying molecular mechanism leading to this phenotypic divergence, such as the epistatic effects of other genes, merit further study.

Incidence of germ-line SUFU mutations in sporadic medulloblastoma. *A. Remenieras[1], J. Bombled[1], G. Pierron[2], M. Barrois[1], J. Grill[4], P. Varlet[3], O. Delattre[2], B. Bressac-De Paillerets[1], L. Brugières[4].* 1) Department of Biopathology, Institut Gustave Roussy, 94805 Villejuif, France; 2) Unité INSERM 830. Laboratoire de Génétique et Biologie des Cancers Section de Recherche Institut Curie, 75005 Paris, France; 3) Department of Neuropathology, Sainte-Anne Hospital, UMR Inserm U894; Psychiatry and Neurosciences Center, University Descartes Paris 5, France; 4) Department of Pediatric Oncology, Institut Gustave Roussy, 94805 Villejuif, France.

Medulloblastoma (MB) is the most common pediatric brain tumor. Five histologic subtypes are described: classic MB, desmoplastic/nodular MB, MB with extensive nodularity (MBEN), anaplastic and large cell MB. Involvement of the sonic hedgehog signaling pathway in the genesis of these tumors has been well established with the presence of somatic mutations in Patched 1, suppressor of fused (SUFU) or smoothened mainly in the desmoplastic/nodular subtype. Several cases of patients with desmoplastic/nodular MB or MBEN carrying germ-line mutations of the SUFU gene have been described including two families previously described by our group. To assess the incidence of SUFU germ-line mutations according to the age at diagnosis and histologic subtype in patients with sporadic MB, the 12 exons of SUFU were analyzed by direct sequencing of genomic DNA in all 119 consecutive patients treated for a MB in the pediatric department of the Institut Gustave Roussy and for whom a blood sample was available. In this series, 50 patients were under 4 at diagnosis. Patients with a familial history of MB were excluded from the analysis. Additionally a Q-PCR was performed to identify genomic rearrangements. Putative splice site mutations were subsequently studied by transcript analysis. Six mutations were identified by sequencing: 3 were frameshift mutations, 1 was a nonsense mutation and 2 were intronic (one targeted exon 11 splice site (c.1297-1G>C) and the other was a c.318-10delT). In the last case, transcript analysis indicates that c.318-10delT mutation induces skipping of exon 3. Mutations were inherited from a healthy parent in 3/5 cases in which the parents could be tested and it was a de novo mutation in the 2 other cases. The characteristics of patients with a germ line mutation of the SUFU gene were a young age at diagnosis(6/6 under 4 at diagnosis) and a desmoplastic/nodular or MBEN histology (6/6 patients). Additonally, 11 different unknown variants were identified in 13 patients. Some of them may be ethnogeographic polymorphisms as we identified them more than once in patients with African origin. No rearrangement was identified by Q-PCR. Germ-line mutations of the SUFU gene are not a rare event in patients diagnosed during the first years of age with a desmoplastic/nodular MB or MBEN even in the absence of familial history of cancer.

542/T

Inactivation of SDHD in the pituitary tumor of a patient with acromegaly and familial paragangliomas due to a novel SDHD mutation. *P. Xekouki[1], MQ. Almeida[1], A. Lytras[2], M. Azevedo[1], E. Ball[1], B. Pasini[3], K. Pacak[4], A. Horvath[1], G. Tolis[2], CA. Stratakis[1].* 1) Section on Endocrinology Genetics, Program on Developmental Endocrinology Genetics (PDEGEN), Eunice Kennedy Shriver National Institute of Child Health & Human Development (NICHD), National Institute of Health (NIH), Bethesda, Maryland 20892,USA; 2) Division of Endocrinology & Metabolism, "Hippocrateion" General Hospital, Athens, Greece; 3) Department of Genetics, Biology and Biochemistry, University of Torino, Italy; 4) Reproductive and Adult Endocrinology Program, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland 20892, USA.

Mutations in the subunits B, C and D of succinate dehydrogenase (SDH) mitochondrial complex II have been associated with the development of paragangliomas (PGLs), Carney-Stratakis syndrome (CSS), as well as with renal and papillary thyroid cancer (SDHB). In addition, a case of testicular seminoma has been reported in association with SDHD mutation. Here, we report a unique case of acromegaly and multiple familial extra-adrenal PGLs. The proband, a 37 year-old male, presented with a pituitary macro-adenoma. During pre-surgical imaging for trans-sphenoidal surgery (TSS), bilateral carotid body masses with characteristics typical of PGL were revealed. Biochemical evaluation showed elevated plasma and urinary levels of catecholamines and further imaging showed multiple PGLs; bilateral adrenalectomy revealed extra-adrenal PGLs in close proximity to the adrenal glands, rather than the expected pheochromocytomas. During TSS, a GH-secreting macroadenoma was partially removed. The patient was placed on somatostatin (SMS) analogue therapy with near-complete remission of acromegaly. Genetic analysis revealed a novel SDHD mutation (c.298_301delACTC), leading to a frame-shift and a premature stop codon at position 133 of the protein; the patient's peripheral leukocytes mRNA confirmed SDHD haploinufficiency. MEN1, AIP and CDKN1B mutations were not found; two common polymorphisms were detected in the CDKN1B (c. 326 T>G p.V109G) and AIP (c. 682 C>A, p. Q228K) genes. SDHD Loss-of-heterozygosity (LOH) in the GH-secreting adenoma was investigated by quantitative real-time RT-PCR. SDHD protein expression was assessed by Western blot and immunohistochemistry (IHC). Amplification of the SDHD WT allele was significantly reduced in the pituitary tumor in relation to the patient peripheral blood (SDHD WT allele copy number, 0.3 ± 0.04 vs. 1.0 ± 0.01; $p < 0.0001$). SDHD expression by Western blot and IHC was decreased in the pituitary tumor with SDHD mutation, compared to a GH-secreting adenoma negative for SDHD mutation. In conclusion, we describe the first kindred with a germline SDHD pathogenic mutation, inherited PGLs and acromegaly due to a GH-producing pituitary adenoma. SDHD LOH and down-regulation of protein in the GH-secreting adenoma supports SDHD's involvement in the pituitary tumor formation in this patient.

543/F

Genome Wide Scan of Malignant Melanoma Identifies Additional Pigmentation Gene Influencing Risk. *C.I. Amos[1], J.E. Lee[2], W.V. Chen[1], E. Pugh[3], K.F. Doheny[3], C.C. Laurie[4], L.-E Wang[1], Q. Wei[1].* 1) Dept Epidemiology, MD Anderson Cancer Ctr, Houston, TX; 2) Dept Surgery, MD Anderson Cancer Ctr, Houston, TX; 3) Center for Inherited Disease Research, 333 Cassell Drive, Suite 2000, Baltimore, MD; 4) Department of Biostatistics, Box 359461, University of Washington, Seattle, WA.

Malignant melanoma causes 75% of skin-cancer related death and siblings of cases have an approximately 4-fold higher melanoma risk, suggesting the importance of genetic factors in its etiology. We therefore conducted a genome-wide association analysis of melanoma using samples and data from 1781 melanoma cases from M.D. Anderson Cancer Center and 1050 age and sex-matched healthy controls. Samples were anlyzed using an Omni 1M Quad V1-0_B SNP chip and standard quality control filters were applied with assistance from the GENEVA coordinating center including removing SNPs and samples with low call rates (<95% and < 90% respectively), and removing non-Caucasians and genetic outliers. After filtering, 818237 SNPs had minor allele frequency >0.01, passed the Hardy-Weinberg Disequilibrium test (p> 10-5) and were retained for analyses. Analyses were conducted using logistic regression in PLINK. Results identify known causal regions such as MC1R (rs4785751, p=3.4 x 10-10) and CDK2NA region (rs1889680, p=4.89 x 10-7). However, in addition one SNP in HERC2 reaches genome wide significance (rs12913832, p=7.9 x 10-8) and several additional interesting candidate loci are highly suggestive: DACH1 (rs17613530, 5.7 x 10-6) and CSMD1 (rs2617055, p= 5.9 x 10-6). HERC2 influences hair and eye pigmentation (iris color), and skin sensitivity to sun and freckling. We are further investigating the effects of these SNPs according to skin pigmentation type and history of sunburns. These results further expand knowledge about the role of skin pigmentation in determining risk for sporadic melanoma.

Copy Number Variation Associated with Risk of Aggressive Prostate Cancer. *F. Demichelis[1,2], S.R. Setlur[3], S. Banerjee[4], C.X. Chen[1], D. Oldridge[1], B. Stenzel[5], J.Y.H. Chen[3], N. Kitabayashi[1], M. Poptsova[1], G. Schaefer[5], J. Bektic[5], G. Bartsch[5], C. Lee[3], H. Klocker[5], M.A. Rubin[1].* 1) Department of Pathology and Laboratory Medicine, Weill Cornell Med College, New York, NY; 2) Institute for Computational Biomedicine, Weill Cornell Med College, New York, NY; 3) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 4) Department of Public Health, Weill Cornell Med College, New York, NY; 5) Department of Urology, Innsbruck Medical University, Innsbruck, Austria.

Prostate cancer (PCA) remains a major public health problem with over 219,000 cases diagnosed per year in the U.S. and 27,000 expected deaths. There is widespread consensus that we need biomarkers to identify aggressive PCA at the earliest point. Multiple genome-wide association studies and follow-up validation studies have discovered a few dozen SNPs associated with PCA risk, however their effect is low to moderate with unknown biological implications. Herein, we report for the first time a comprehensive survey to discover germline Copy Number Variants (CNVs) associated with risk of aggressive PCA. **Methods**: Germline DNA from 742 men with PCA (cases) and 811 men with negative prostate biopsies (controls) from the PSA Screening Tyrol Cohort (Austria) was profiled using a genome-wide oligonucleotide platform (Affymetrix 6.0). SNP-based analysis was applied to control for ethnicity and genotype similarity (e.g., first degree relatives). 5,239 CNV loci (30% previously unreported) were evaluated by applying a computational approach for the Identification and genotyping of germline Changes in Copy Number (IgC2N). We explored for age and PSA-adjusted CNVs associated with increased risk of developing PCA and aggressive PCA. **Results**: Twenty-two of 56 previously reported PCA risk SNPs were validated including loci at 6q, 7p, 7q, 8q (region 1 and 3), and 17q. Of the investigated CNVs, 43% had frequencies below 10%. Sixty-seven CNVs showed significant association with one of the two phenotypes (FDR<10%). For the majority of the CNVs that showed an association, the minor allele frequencies were < 20% and the best tagged SNP had an R^2 < 0.5. 47% of the top ranked CNVs overlapped or were in proximity of gene coding regions and 4 of these showed significant allelic RNA expression imbalances in a set of 50 prostatic tissue samples. Gene ontology analysis of the top ranked CNVs for aggressive PCA risk nominated the calcitonin gene-related polypeptide receptor, which is known to function as a proangiogenic growth factor, suggesting a possible underlying mechanism for cancer progression. **Conclusions**: We have identified CNVs in gene coding regions as having significant associations with the risk of PCA and more importantly aggressive PCA. Germline risk factors might help guide clinicians toward active surveillance or definitive treatment (eg, surgery, radiation therapy). Three candidate CNVs have been identified and are being validated on a large US PSA screening cohort.

Genetic analysis of neuroblastoma in African American patients. *M. Devoto[1,4], V. Latorre[1], S. Diskin[2], M. Diamond[2], H. Zhang[3], H. Hakonarson[1,3,4], J. Maris[2,4].* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Oncology, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA.

In the last two years, genome-wide association studies in neuroblastoma patients have revealed several loci associated to increased risk of disease. These include a region of chromosome 6p22 containing the predicted genes FLJ22536 and FLJ44180, the genes BARD1 on chromosome 2q35 and LMO1 on chromosome 11p15, and a copy number variable region on chromosome 1q21. These studies have all been carried out in North American patients of European descent, which constitute the majority of neuroblastoma cases. Extension of these findings to other ethnic cohorts is important to confirm their validity beyond the Caucasian population. The different pattern of linkage disequilibrium present in other ethnic groups may also help to better define the limits of the association signals and identify specific causal variants. We have collected a group of 326 self-reported African-American neuroblastoma patients and genotyped them using the same high-density SNP chips that were used for the study of the patients of European descent, namely the Illumina HumanHap 550K and 610Quad. A group of 2500 African-American unaffected children genotyped on the same platforms was identified to use as controls in the association tests. Standard quality control procedures were applied to remove samples with low call rates and high heterozygosity, and SNPs with low call rates, excess deviation from Hardy-Weinberg equilibrium in controls, and minor allele frequency less than 0.01. Association analysis was performed by stratified Cochran-Mantel-Haenszel chi-square test after multi-dimensional scale clustering of cases and controls in homogeneous groups based on genome-wide data to account for population substructure. Among the known loci, the one that was most consistently replicated was BARD1, with six SNPs showing p<0.05 (smallest p=0.0004 for rs7587476). Two SNPs in the FLJ22536/FLJ44180 region had nominally significant p-value (smallest p=0.02 for rs1928174), and only one in LMO1 (p=0.02 for rs4237769). Overall these results support the hypothesis that the same genetic factors affect risk of neuroblastoma in both populations, but a larger number of cases is necessary to definitely confirm the findings from the Caucasian cohort in the smaller African-American sample.

As with many complex diseases, it is recognized that low-penetrance variants likely play an important role in conferring risk of colorectal cancer. Large-scale genome-wide association studies (GWAS) and replication studies are needed to elucidate inherited risks, and understand how known environmental contributors to disease risk may modify the effects of associated genetic variants. The Genetics and Epidemiology of Colorectal Cancer Consortium (GECCO) is a collaborative effort comprised of a coordinating center and scientific researchers from well-characterized cohort and case-control studies conducted in North America, Australia, and Europe. Currently, the consortium comprises the following studies with inclusion of over 30,000 participants: the Assessment of Risk for Colorectal Tumours in Canada (ARCTIC) study; the Carotene and Retinol Efficacy Trial (CARET); the Colon Cancer Family Registry (C-CFR); Darmkrebs: Chancen der Verhütung durch Screening (DACHS); the Diet, Activity, and Lifestyle Study (DALS); the Health Professionals Follow-up Study (HPFS); the Multiethnic Cohort (MEC); the Molecular Epidemiology of Colorectal Cancer (MECC) study; the Nurses' Health Study (NHS); the Physicians' Health Study (PHS); the Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial; the VITamins And Lifestyle (VITAL) cohort; the Women's Health Initiative (WHI); a case-control study from the University of Nantes in France; and a case-control study from the University of Hawai'i. This international consortium aims to accelerate the discovery of colorectal cancer-related variants by replicating and characterizing GWAS findings, conducting a large-scale meta-analysis of existing and newly generated GWAS data, and performing targeted sequencing and fine mapping. A key strength of GECCO is the ongoing harmonization of detailed clinical, epidemiologic, and outcome data across consortium studies. This will allow evaluation and characterization of GWAS findings with respect to interactions with environmental factors. Future plans include investigation of rare variants, survival studies, and incorporation of gene-expression and tumor characteristics. This international collaboration of studies encompassing over 30,000 research participants with detailed environmental data provides an excellent opportunity to investigate how genetic variants and environmental risk factors contribute to the etiology of colorectal cancer.

Dissecting the genetic susceptibility architecture of breast cancer using GWAS information and gene expression data. *C. Hicks, A. Pannuti, L. Miele.* Cancer Institute, University of Mississippi Medical Center, Jackson, MS.

Genome-wide association studies (GWAS) are a powerful technique for identifying common genetic variants associated with breast cancer. However, to date, data from GWAS have not been maximally leveraged and integrated with gene expression data to infer the causal association between gene expression and the disease. We present a novel integrative genomics approach that leverages information from GWAS with gene expression data to dissect the genetic susceptibility architecture of breast cancer. We hypothesized that genes containing SNPs associated with breast cancer share the genetic susceptibility architecture functionally, interact with each other and their downstream targets in biological pathways; and that combining GWAS information with gene expression data could increase the power to identify novel genes which could not be identified using GWAS alone. We tested these hypothesizes using 130 genes containing 400 SNPs identified from 40 GWAS covering 120, 000 cases and 130,000 controls; and two gene expression data sets on Caucasian (42 cases and 143 controls) and Asian (43 cases and 43 controls) populations. We performed both supervised and unsupervised analysis assuming the gene and pathway as units of association. We identified 70 candidate genes in the Caucasian population and 30 genes in the Asian population with good evidence ($P<0.05$) of distinguishing breast cancer patients from controls. Pattern recognition analysis revealed that candidate genes are functionally related and identified a novel set of genes which have similar expression profiles with candidate genes. Pathway prediction revealed that genes containing SNPs associated with breast cancer interact with each other and their downstream targets in intricate biological pathways. Among the identified pathways included the P53, apoptosis, kinase and AKT pathways. Additionally, genes containing SNPs with large ($P<10-5$) and small effects ($P<10-3$), had shared patterns of expression and were involved in the same biological pathways. We found differences in patterns of gene expression between Caucasians and Asian populations. Results show that integration of gene expression data with GWAS information provides putative functional bridges between GWAS and pathways, thereby serving as a potential powerful approach to identifying biological mechanisms underlying GWAS findings in breast cancer, and to infer the causal association between gene expression and the disease.

Gene-asbestos interaction and lung cancer risk from a genome-wide association study. *C. Liu.* Dept Environmental Hlth, HSPH, Boston, MA.

Epidemiologic studies of occupational and population-based case-control studies have consistently observed increased lung cancer risk with occupational asbestos exposure, while the molecular mechanisms of nonmutagenic carcinogens including asbestos remain largely unknown. To evaluate the association between lung cancer linked to asbestos and genetic variability, we conducted a genome-wide association analysis in 1,000 Caucasian cases and 1,000 Caucasian controls using Illumina Human 610-Quad BeadChips. Cumulative lifetime asbestos exposure score (AES) was calculated from self-reported duration and intensity of occupational and nonoccupational exposures. A total of 12.1% of cases and 8.5% of controls had "high" AES (determined by a priori cut point).

549/F

Association scan of all trait-associated SNPs identifies association between pancreatic cancer and SNP in childhood diabetes gene, HNF1A. *B. Pierce, H. Ahsan.* Health Studies, Univ Chicago, Chicago, IL.

Stringent significance thresholds are required in genome-wide association studies (GWAS) because many statistical tests are conducted. As a result, weakly associated SNPs with p-values above genome-wide significance thresholds are not detected, even in large studies. One way to partially alleviate the multiple testing penalty is to focus association studies on subsets of SNPs with high prior probabilities of association. Using data on 1,763 pancreatic cancer cases and 1,802 controls of European descent from the Cancer Genetic Markers of Susceptibility (CGEMS) GWAS study (PanScan-I), we examined associations with pancreatic cancer risk for 1,663 SNPs that have been shown in GWAS studies to associate with human phenotypes other than pancreatic cancer (according to http://www.genome.gov/GWAStudies/). This method has two key advantages: (1) the SNPs tested are very likely to be (or tag) functional variants and (2) the number of SNPs tested is drastically lower than a typical GWAS, resulting in less stringent p-value thresholds. Association tests were conducted using a log-additive genetic model and logistic regression adjusted for age, sex, and two axes of ancestry derived from principal components analysis. Using this method, we have identified many novel candidate SNPs for pancreatic cancer based on departure from QQ plot expectations. Our strongest association signal comes from HNF1A and is statistically significant after a Bonferroni correction. HNF1A is also known to harbor genetic variants that influence risk for maturity-onset diabetes of the young and circulating CRP concentrations. PanScan-II data will soon be available, and we will attempt to replicate this finding prior to this presentation.

Identification of loci associating with histiocytic-dendritic cell neoplasms using a canine genome wide study. *A.L. Shearin[1], H.G. Parker[1], E. Cadieu[1,2], B. Hedan[2], M. Breen[3], J. Cullen[4], A. Grone[5], G. Rutteman[5], C. Andre[2], E.A. Ostrander[1], E.V. Schmidt[1,6,7].* 1) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Institut de Génétique et Développement de Rennes, Université de Rennes, Rennes, France; 3) Department of Molecular Biomedical Sciences, College of Veterinary Medicine, North Carolina State University, Raleigh, NC; 4) Department of Population Health and Pathobiology, College of Veterinary Medicine, North Carolina State University, Raleigh, NC; 5) Faculty of Veterinary Medicine, Utrecht University, Utrecht, The Netherlands; 6) Cancer Research Center at Massachusetts General Hospital, Boston, MA; 7) Department of Pediatrics, Harvard Medical School, Boston, MA.

While comparatively rare, histiocytic-dendritic cell neoplasms remain devastating. Their status as human orphan diseases urges adaptation of novel genetic strategies to identify their pathogenesis. Breeding bottlenecks and strong selective pressures have caused strong genetic predispositions for many cancers in specific canine breeds. The 25% incidence of histiocytic sarcomas in Bernese Mountain dogs (BMD) offers a unique opportunity to understand the genetic basis of dendritic cell neoplasms. We performed sequential genome wide association studies (GWAS), initially using 240 BMD samples from the U.S. followed by a confirmatory study using 234 European BMDs. Comparing 19,000 informative SNPs, a single-marker chi-squared analysis corrected for population structure and kinship yielded significant associations with the disease phenotype at 2 loci ($p<1.1 \times 10^{-7}$ and $p<2.5 \times 10^{-6}$). Focused genotyping and sequencing of the most highly associated region identify a 300 kb candidate region. This region contains a disease-associated haplotype for which 75.0% of cases are homozygous versus 20.8% of controls. However, this haplotype is also tightly linked ($r2 \geq 0.8$) with additional individual segments spread over the whole region, making causative mutational analysis difficult. Indeed, ten linked SNPs over the whole region predict 75% of the cases with a false positive rate of 5%. Using GM-CSF/IL4-dependent dendritic cell cultures, we are performing functional analyses of candidate genes in the region. Notably, the segments spread across the region that are linked to its core haplotype contain predicted transcriptional regulatory elements. We are therefore testing the effects of these DNA segments using standard transcriptional analyses to evaluate the possibility that multiple associating regulatory SNPs are involved in the pathogenesis of the histiocytic sarcomas. Since the candidate region is syntenic with several genome-wide human disease associations, our results may offer interesting comparative insights into genetic association studies. A second locus identified in the BMD is largely confined to the European population, possibly because this locus has approached fixation in the U.S. BMD population. Future studies of genetic interactions between these two loci offer the potential to understand regulatory pathways that cause poorly understood histiocytic-dendritic cell neoplasms.

551/F

Identification of multiple genetic variants related to nasopharyngeal carcinoma predisposition through genome-wide scan. *W. Su[1], K. Tse[1], M. Yang[1], Y. Chang[1], Y. Shugart[2,3].* 1) Chang Gung Molecular Medicine Research Center, Chang Gung University, Kwei-Shan, Tao-Yuan, Taiwan; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Genomic Research Branch, Division of Neuroscience and Basic Behavioral Science, National Institute of Mental Health, National Institutes of Health, Bethesda, MD.

Nasopharyngeal carcinoma (NPC) is a multi-factorial malignancy closely associated with genetic factors and Epstein-Barr virus infection. Recently, we have conducted a genome-wide association study (GWAS) in 277 NPC patients and 285 healthy controls within the Taiwanese population, analyzing 480,365 single-nucleotide polymorphisms (SNPs) using Illumina HumanHap 550 BeadChip. Twelve statistically significant SNPs were identified and mapped to chromosome 6p21.3 in the major histocompatibility complex region. These association signals were replicated in two independent sets of case-control samples. Two of the most significant SNPs (rs2517713 and rs2975042; $p = 3.9 \times 10^{-20}$ and 1.6×10^{-19}, respectively) were located in the HLA-A gene. Moreover, we detected novel significant associations between NPC and two genes: specifically, gamma aminobutyric acid b receptor 1 (GABBR1) (rs29232; $p = 8.97 \times 10^{-17}$) and HLA-F (rs3129055 and rs9258122; $p = 7.36 \times 10^{-11}$ and 3.33×10^{-10} , respectively). Notably, the association of rs29232 remained significant (residual $p < 5 \times 10^{-4}$) after adjustment for age, gender, and HLA-related SNPs. Furthermore, higher GABAB receptor 1 expression levels can be found in the tumor cells in comparison to the adjacent epithelial cells ($p < 0.001$) in NPC biopsies, implying a biological role of GABBR1 in NPC carcinogenesis. To our knowledge, it is the first GWAS report of NPC showing that multiple loci (HLA-A, HLA-F, and GABBR1) within chromosome 6p21.3 are associated with NPC. Following the GWAS study, we made an effort to search systematically for copy number variations (CNVs) that confer increased risk to NPC using the same dataset. We generated CNV calls using four different softwares and used 15 internal duplicated samples to look for best filtering criteria. CNVs were selected if same CNVs were identified from two independent softwares to increase credibility of prediction. Association testing and follow-up replication analyses confirmed the CNVs were associated with NPC.

552/F

Excess Germline Copy Number Variations Detected in Familial Pancreatic Cancer. *J.A. Willis, S.H. Olson, R.C. Kurtz, R.J. Klein.* Memorial Sloan-Kettering Cancer Center, New York, NY.

Background: Pancreatic adenocarcinoma is a rapidly fatal disease. Identifying the human germline variations involved in pancreatic cancer may help to uncover novel therapeutic targets and to develop clinical screens. Although single-nucleotide polymorphisms (SNPs) have been associated with pancreatic cancer risk, the contribution of germline copy number variations (CNVs) remains unclear. To explore this contribution, we performed genome-wide CNV discovery and analysis using a case-control cohort. Methods: 263 pancreatic cancer cases and 203 healthy, unrelated controls were recruited for this study at the Memorial Sloan-Kettering Cancer Center. DNA was collected from each individual via blood, saliva, or buccal sample and genotyped on the Illumina Human CNV370-duo SNP array. Normalized probe data (log R ratio and “B allele frequency”) from the array were processed separately for each individual by a hidden Markov model (PennCNV) to generate CNV calls. We used logistic regression to test for differences in overall CNV burden, adjusting for sample quality, ancestry, DNA source, age, and experimental batch effects. Results: Our discovery experiment yielded a total of 32,146 CNV calls in the study cohort. Quality-control filtering was applied at the sample-level by excluding those individuals with B allele frequency drift >0.002, log R ratio standard-deviation >0.24, and greater than 200 CNV calls. A total of 40 samples (9,619 CNVs) were removed in this filtering step. Our final dataset was derived from 244 cases and 182 controls, and is comprised of 22,527 CNV calls (14,017 deletions; 8,510 duplications). Our preliminary analysis has identified a significant excess of CNV burden in cases ($n = 32$) having multiple family history of pancreatic cancer versus controls (case-control burden ratio = 1.34; per-CNV odds ratio = 1.013, $p = 0.032$). Conclusions: Excess germline CNV burden was identified in cases with multiple family history of pancreatic cancer. To understand the biological basis of this association, we are exploring whether specific CNV loci (or gene targets) are commonly detected in this group.

553/F

A rare deletion on chr18q22.1 contains a palindromic AT-rich repeat and may increase risk of ileal carcinoids. *K. Walsh[1], A. DeWan[1], M. Choi[1], L. Hsu[1], M. Jurkiewicz[1], J. Yao[2], M. Kulke[3], K. Oberg[4], J. Hoh[1].* 1) Division of Chronic Disease Epidemiology, Yale University School of Public Health, New Haven, CT; 2) Department of Gastrointestinal Medical Oncology, MD Anderson Cancer Center, Houston, TX; 3) Department of Medical Oncology, Dana-Farber Cancer Institute, Boston, MA; 4) Department of Endocrine Oncology, University Hospital, Uppsala, Sweden.

Carcinoid tumors are rare neuroendocrine tumors with high genomic instability, most frequently found in the small intestine. Little is known about the genetic factors involved in the disease, but loss of chromosome 18q22-qter is an early event in ileal carcinoid tumorigenesis. We hypothesized that rare constitutional copy-number variants (CNVs) may predispose some individuals to develop ileal carcinoids. We applied multiple CNV calling algorithms to Illumina 300K array data to identify CNVs involved in carcinoid pathogenesis. Although no CNVs were significantly associated with case-status, a rare 40kb deletion at Chr18q22.1 was identified in five cases but no controls. qPCR analysis on the full case-control set identified this deletion in 14/226 cases (6.6%) and 2/98 controls (2.1%). This intergenic deletion is located in a genomic region which is lost in 60% of all ileal carcinoid tumors. The deletion is not flanked by any regions of high sequence homology, making non-allelic homologous recombination an unlikely mechanism for the genesis of this CNV. At the center of the deleted region is a palindromic AT-rich repeat, which may play a role in formation of this CNV. Palindromic repeats can cause DNA to form cruciforms and are known to induce double-strand breaks, causing non-Robertsonian translocations. However, it is unknown if palindromic repeats can induce other types of chromosomal aberrations, such as CNVs. To explore this, data from the Database of Genomic Variants and the UCSC genome browser were used to determine if palindromic repeats are associated with CNVs in the human genome. Dinucelotide repeats greater than 30 bases were analyzed, of which 6,291/37,429 (16.8%) were palindromic (ATn or TAn). Compared to other dinucleotide repeats, palindromic repeats were more commonly found within CNVs ($p = 0.016$). When stratified by CNV type, palindromic repeats were significantly associated with deletions ($p = 0.014$), but not duplications ($p = 0.333$). After controlling for length and the overlap with genes, LINEs, SINEs, and LTRs, the association between palindromic repeats and CNVs remained significant in a logistic regression model ($p = 0.0176$). Further work is needed to determine if this candidate CNV influences carcinoid risk, and if palindromic repeats promote CNV formation. Because this association is driven by copy-number deletions, potential mechanisms must account for the formation of deletions without reciprocal duplications.

Mining GWAS Data to Find Etiologic Variation Common to NSCL/P and Breast Cancer. *B. Erickson[1], K.K. Ryckman[2], J.C. Murray[1,2].* 1) Department of Molecular & Cellular Biology, University of Iowa, Iowa City, IA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA.

Background: Epidemiologic data has shown an increased incidence of breast cancer in women born with nonsyndromic cleft with or without cleft palate (CL/P). Several studies of both breast cancer and nonsyndromic CL/P have found association within intron 2 the *FGFR2* locus. Several GWAS studies have been published on breast cancer and CL/P and we mined this data for other sites of genetically associated variation shared between these two disease phenotypes. **Objective:** Investigate common regions of GWAS signals between recent breast cancer and CL/P studies. **Methods:** Seven breast cancer GWAS studies and five CL/P GWAS studies were identified for use in this study. We generated a list of SNPs associated at significance ($< 10^{-5}$) ordered by genome position from published data and dbGAP. Regions were noted as having common GWAS signals between breast cancer and CL/P studies if SNPs were located within a common linkage disequilibrium (LD) block, or in cases where LD block structure was less defined, SNPs separated by less than 1.5 Mb. In regions with common GWAS signals, we are using TaqMan genotyping and sequencing to identify rare SNPs associated with CL/P that may have functional importance. **Results:** Only 35kb separate breast cancer GWAS (rs2981582) and CL/P GWAS (rs2912787) SNPs near *FGFR2*. These SNPs are within one LD block in the CEU Hapmap population. Chromosome 2 was the location of the next closest common GWAS signal between CL/P (rs11900952) and breast cancer (rs17030257) 135kb apart SNPs surrounding the thyroid adenoma associated gene (*THADA*). Chromosome 10q21.2 near Zinc Finger Protein 365 (*ZFN365*) was a common GWAS site with a CL/P SNP (rs1475084) separated from a breast cancer SNP (rs10995195) by 317kb. The final common GWAS signal site was at 8q24 between CL/P (rs7015145) and breast cancer (rs13281615) SNPs separated 1.4 MB. **Conclusions:** The proximity of GWAS signals suggests an element in or near intron 2 of *FGFR2* plays a role in both CL/P and breast cancer. The common GWAS signals in close proximity on 10q21 and 2p21 are currently being genotyped and sequenced with breast cancer signals prioritize focusing smaller regions to find a CL/P etiologic variant. While the separation of the SNP sites near 8q24 may suggest different etiologic variants near that locus contributing to each disease, a common etiologic variant risk for CL/P and breast cancer could still be identified with closer genotyping and sequencing.

555/F

Discovering epistatic genetic interactions associated with neuroblastoma. *M. Capasso[1], K. Bosse[2], S.J. Diskin[2], Y.P. Mosse[2], H. Hakonarson[3], A. Iolascon[1], M. Devoto[4], J.M. Maris[2].* 1) CEINGE Biotecnologie Avanzate, Napoli, Italy; 2) Children's Hospital of Philadelphia, Center for Childhood Cancer Research, Philadelphia, PA, USA; 3) The Children's Hospital of Philadelphia, Center for Applied Genomics, Philadelphia, PA, USA; 4) The Children's Hospital of Philadelphia, Division of Genetics, Philadelphia, PA, USA.

Background. We have demonstrated that polymorphisms in the BRCA1 interacting gene BARD1 are associated with high-risk neuroblastoma (NBL) using a genome-wide association approach (Capasso, Nat Genet 2009). The mechanism by which BARD1 impacts susceptibility to NBL remains undefined. Here, using a two-locus analytic method, we sought to identify genes that might increase susceptibility to NBL development by their interaction with BARD1.

Methods. We performed an interaction analysis based on two datasets comprising 1433 cases and 3221 controls, and 1627 cases and 2575 controls, respectively, genotyped with the Illumina HumanHap 550K. Six databases (BIND, BIOGRID, MINT, HPRD, STRING, IntAct) were queried to identify the proteins known or predicted to interact with BARD1. A regression analysis method implemented in PLINK was utilized to test for pairwise interactions between BARD1 SNPs and SNPs of these genes.

Results. A total of 109 proteins were reported in the six databases as known or predicted to interact with BARD1. Twenty-two of these were included in three or more of the databases, and were the focus of subsequent interaction analyses. In the first dataset, the most significant interaction was found between the intronic SNP rs919581 of the PTN gene (pleitropin) and rs17487792 of BARD1 (OR=1.45, $P=9\times10^{-5}$). The PTN SNP showed no effect in the single SNP analysis (OR=0.97, P=0.50) while the BARD1 SNP showed highly significant association with NBL (OR=1.36, $P=2\times10^{-16}$). The statistical interaction between the two SNPs was confirmed in the second dataset (OR=1.45, $P=1\times10^{-4}$). The OR of the highest-risk genotype (homozygote at the minor alleles for rs17487792 and rs919581) relative to the most common genotype at the two loci combined was 9.69. SNP rs17487792 is in high LD (r2=0.96) with rs2070096, which is predicted to regulate BARD1 splicing. Experiments are ongoing to test if BARD1 isoforms related to this SNP affect physical interaction with PTN.

Conclusions: PTN and BARD1 variants may act in an epistatic fashion to promote NBL tumorigenesis. Future work will focus on identifying the mechanism of this interaction, and discovering if somatically acquired alterations in these genes may contribute to a high-risk NBL phenotype.

Variation at 9p24.3 (*DMRT1*) is associated with susceptibility to testicular germ cell tumor. *S.L. Ciosek[1], P.A. Kanetsky[1], N. Mitra[1], S. Vardhanabhuti[1], D.J. Vaughn[1], M. Li[1], R. Letrero[1], K. D'Andrea[1], D.R. Doody[2], J. Weaver[3], A. Albano[4], C. Chen[2,5], J.R. Starr[2,5,6], D.J. Rader[1], A.K. Godwin[3], H. Hakonarson[4], M.P. Reilly[1], S.M Schwartz[2,5], K.L. Nathanson[1].* 1) University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Fox Chase Cancer Center, Philadelphia, PA; 4) The Children's Hospital of Philadelphia, Philadelphia, PA; 5) School of Public Health, University of Washington, Seattle; 6) School of Medicine, University of Washington, Seattle, WA.

Testicular germ cell tumor (TGCT) is the most common malignancy diagnosed in young men. Risk factors include family history and undescended testis. We previously have shown that the rare gr/gr deletion increases risk for TGCT (Nathanson 2005). In genome-wide association studies, we and our UK colleagues independently identified SNP markers in or near *KITLG* and *SPRY4* as risk alleles for TGCT (Kanetsky 2009; Rapley 2009). *BAK1* also was found to increase risk. Here we report the results of our expanded GWAS that included 72 additional (a 26% increase) TGCT cases. In total, we compared 349 TGCT cases to 919 controls and found 6 markers at 5 novel autosomal loci that surpassed our secondary significance threshold (5×10^{-6}). After imputation to determine those hits likely to be falsely positive, we brought 2 markers each from 3 loci (at or near *DMRT1*, *PFTK1*, *SLC25A31*) into replication. The replication set consisted of 439 cases and 960 controls from a population-based case-control study in Washington state and parents of 204 of the cases. We observed an association between TGCT and rs7040024 ($P_{trend}=2.1 \times 10^{-6}$) and rs755383 ($P_{trend}=2.1 \times 10^{-4}$), both of which map to *DMRT1*; markers mapping to *PFTK1* and *SLC25A31* did not replicate. The per-allele odds ratio for the major A-allele in rs7040024 was 1.69 (95% CI 1.36, 2.10), and homozygous carriage of the major A-allele increased risk nearly three-fold (OR 2.96; 95% CI 1.52, 5.73) as compared to homozygous carriage of the minor C-allele. In a case-parent analysis, inheritance of two A-alleles at rs7040024 was associated with over a three-fold risk (OR 3.59; 95% CI 1.58, 8.12). Associations did not differ by tumor subtype, and there were no differences found when the cases were stratified by family history of TGCT or personal history of undescended testis. *DMRT1*, or doublesex and MAB3 related transcription factor 1, codes for a DNA binding protein that is expressed in the nuclei of Sertoli cells, spermatogonia and spermatoctyes of adult males. *DMRT1* is conserved across many species, and is known to play a role in testis determination in mammals, as well as sex determination in vertebrates. Of particular interest, all TGCT susceptibility loci identified to date affect pathways that regulate the survival, proliferation and migration of primordial germ cells. Additional genetic studies as well as studies to elucidate the biological basis of the increased risk of TGCT associated with the identified loci are planned.

Fine-Scale mapping of breast cancer loci: From tag SNP to causal variant. *M. Ghoussaini[1], A. Cox[2], E. Dicks[1,3], P. Pharoah[1,3], D. Easton[1], A. Dunning[1], BCAC (Breast Cancer Association Consortium).* 1) Department of Oncology, University of Cambridge, Strangeways Research Laboratory, Worts Causeway, Cambridge, CB1 8RN; 2) Institute for Cancer Studies, University of Sheffield, Sheffield, UK; 3) Department of Public Health and Primary Care, University of Cambridge, Strangeways Research Laboratory, Worts Causeway, Cambridge, CB1 8RN.

More than 260 new disease loci, including 18 breast cancer loci, have been discovered via Genome Wide Association Studies (GWAS) but, for almost all of these, identifying the causal variant remains a challenge. Identification of the causative variants is central to understanding the genes and mechanisms involved in cancer pathogenesis. We generated a catalogue of all 20,020 common variants in the LD blocks, with a frequency of 2% or greater in Europeans, defined by 18 known breast cancer susceptibility variants, using data from the 1000 Genomes Project (www.1000Genomes.org). These regions range in size from 30 to 1050Kb. Two loci contain no known genes, four contain a single gene and the majority contain several. Total numbers of common variants per locus vary widely (452 to 2,696). The number of SNPs that are candidates for being the primary causative variant (defined as correlated with the best hit with r2 more than 0.1) range from 42 to 675 per locus. An example is the 8q24 breast cancer locus, which spans 150Kb and contains no known genes. It is located ~ 800 kb downstream of the FAM84B gene and ~400 kb upstream the pro-oncogene c-MYC. Using data from the 1000 Genomes Project, we catalogued 603 variants in this locus, of which 227 have a detectable correlation with GWAS tag SNP rs13281615 and were thus considered to be potentially causative. Sixty-eight tag SNPs for these 227 variants have been genotyped in 13,410 cases and controls from the SEARCH study. A new variant (rs1562430) was found to be more significantly associated with breast cancer than the original GWAS tag SNP (p-trend=5.8x10-7, OR=0.85,CI= [0.80-0.91]) versus (p-trend=2.2x10-5, OR=1.14, CI= [1.07-1.21]), correlation between the two variants is 0.40. Further refinement of the set of potential causal variants may be possible through genotyping in case-control studies of different ethnicities.

Genome-wide association analysis of familial lymphoma. *V. Joseph[1], T. Kirchhoff[1], A. Dutra-Clarke[1], V. Devlin[1], N. Hansen[1], J. Przybylo[1], J. Bhatia[1], M. Kedmi[1], J. Maragulia[1], S. Mukherjee[2], DB. Yehuda[3], L. Engel[4], J. Brown[5], O. Paltiel[3], R. Klein[2], A. Zelenetz[1], K. Offit[1,2].* 1) Dept. Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Sloan-Kettering Institute, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Hadasaah University, Jerusalem, Israel; 4) Department of Epidemiology and Biostatistics, Memorial Sloan-Kettering Cancer Center, New York, NY; 5) Dana Farber Cancer Center, Boston, MA.

The incidence of lymphoma has doubled over the past two decades in the U.S; however, the etiology of the most common types of the disease remains unknown. There is increasing evidence that points to genetic predisposition in the development of lymphomas. Genome-wide association analysis (GWAS), have proven to be useful tools for the identification of common inherited susceptibility loci for human cancers. With increased public availability of population control data, GWAS designs now significantly benefit from reduction in genotyping and cost. In this study, we sought to discover novel germ line variants predisposing to lymphoma using GWAS. We carried out a two-stage association analysis to identify common genetic loci conferring risk for development of lymphomas. In the first stage we have performed a GWAS using Affymetrix 6.0 SNP arrays on 292 kindreds of lymphoma showing family history of the disease, affecting at least 2 first degree relatives. The phase 1 is comprised of 46 patients (probands) with Hodgkin's disease (HD) and 246 cases of non-Hodgkin's lymphoma (NHL), of which 26% are follicular subtypes and 35% diffuse large cell subtypes. As controls, we have used publically available data acquired from dbGAP initiative on 1013 individuals genotyped by Affymetrix 6.0 as part of schizophrenia and bipolar disorder GWAS. To reduce population heterogeneity, both cases and controls chosen were of European (EU) ancestry. After rigorous QC and population stratification adjustments, in stage 1, we identified 200 SNPs with p<10E-4; one of which reached the genome-wide level of significance (p<10E-7). The top 150 independent loci were passed to a replication stage on 2500 lymphoma cases and 2500 controls, all of EU ancestry. Approximately 20 SNPs replicated initial associations observed in Phase 1. Using multivariate analysis, we are currently testing these findings for associations with lymphoma subtypes. There is preliminary evidence of germ line variants in humans increasing risk for lymphocytic malignancies. Moreover, for a subset of SNPs, we observe significant association with multiple subtypes indicating a more common genetic origin of lymphoid malignancies. The observed associations point to involvement of novel molecular pathways which may provide new insights into the molecular pathogenesis of lymphoma.

Genome Wide Association Study to Identify Single Nucleotide Polymorphisms (SNPs) Associated with the Development of Erectile Dysfunction in African-American Men Following Radiotherapy for Prostate Cancer. *S. Kerns[1], H. Ostrer[1], R. Stock[2], W. Li[3], J. Moore[2], A. Pearlman[1], C. Campbell[1], Y. Shao[4], N. Stone[2, 5], L. Kusnetz[2], B. Rosenstein[2, 6].* 1) Department of Pediatrics, New York University School of Medicine, New York, NY; 2) Department of Radiation Oncology, Mount Sinai School of Medicine, New York, NY; 3) Queens/Elmhurst Hospital Center, Department of Radiation Oncology, Jamaica, NY; 4) Division of Biostatistics, New York University School of Medicine, New York, NY; 5) Department of Urology, Mount Sinai School of Medicine, New York, NY; 6) Department of Radiation Oncology, New York University School of Medicine, New York, NY.

Purpose: Clinical factors do not fully explain the variability in development of normal tissue toxicities resulting from radiotherapy for prostate cancer. A predictive tool incorporating genetic factors could therefore assist clinicians and patients in weighing the benefits of radiotherapy with the risks of developing chronic side effects. Methods: A genome-wide association study was performed to identify SNPs associated with erectile dysfunction (ED) among a cohort of African-American prostate cancer patients treated with external beam radiation therapy. All men were followed-up for a minimum of one year after treatment with the five-item Sexual Health Inventory for Men (SHIM) questionnaire to assess erectile function. Only men with a pre-treatment SHIM score ≥ 16, indicative of good erectile function, were included in the study. Of the 79 patients included, 27 patients were defined as cases based on a post-treatment SHIM score £ 7, and 52 patients were defined as controls based on a post-treatment SHIM score ≥ 16. Results: We identified the rs2268363 SNP, located in the follicle stimulating hormone receptor gene, as significantly associated with ED using a chi-square association test and correcting for multiple comparisons (unadjusted p-value = 5.46x10-08; Bonferroni p-value = 0.028). We identified four additional SNPs that tended toward significant association with unadjusted p-value < 10-06. A multivariate logistic regression model that incorporated estimated ancestry and four of the top-ranked SNPs was a more accurate classifier of ED than a model that included only clinical variables. Conclusions: To the best of our knowledge, this is the first genome wide association study to identify SNPs associated with adverse effects resulting from radiotherapy for prostate cancer. It is also important to note that the SNP that proved significantly associated with ED is located within a gene whose encoded product plays a role in gonad development and function. Another key finding of this project is that the majority of the top-ranking SNPs were specific to people of African ancestry and would therefore not have been identified among a cohort of patients of European ancestry. This study supports the feasibility of using a genome-wide approach to investigate genetic predisposition to radiation injury and warrants validation with a larger and separate cohort of prostate cancer patients.

Genome-wide association study to detect CNV associations with Cutaneous Melanoma. *Y. Xu[1], E. Pugh[2], B. Peng[1], A. Schnell[2], E.Y. Lu[1], K. Hetrick[2], W. Chen[1], J.E. Lee[3], L. Wang[1], Q. Wei[1], C.I. Amos[1].* 1) Dept Epidemiology, MD Anderson Cancer Ctr, Houston, TX; 2) Center for Inherited Disease Research, Baltimore, MD; 3) Dept Surgery, MD Anderson Cancer Ctr, Houston, TX.

Cutaneous Melanoma (CM) causes 75% of deaths from skin cancer and has a significant genetic component as evidenced by family studies and genome-wide association analyses, which have identified several causal or associated loci. In order to further study the genetics of CM, we conducted a genetic analysis of cases and controls recruited from the University of Texas M.D. Anderson Cancer Center (UTMDACC). 2053 cases of CM were collected at the UTMDACC starting in 1993. 1063 controls were collected from relatives and friends of patients visiting the UTMDACC during the same time period. These controls were not biologically related to patients included in this study. Genotyping was performed on Illumina HumanOmni1-Quad_v1-0_B array at the Center for Inherited Disease Research (CIDR), and quality controls were applied by the Gene Environment Association Studies (GENEVA) and UTMDACC. For the melanoma data, the median call rate was 99.97% and the error rate estimated from 69 pairs of study sample duplicates was 1e-5. We applied copy number variation (CNV) calling algorithm PennCNV on the data, and the concordance of CNVs for the same study sample duplicates was 73.61%. We performed genome-wide association tests based on CNV calls from PennCNV. We found that the most significant signal located in the region of SPIRE2 gene on chromosome 16q slightly centromeric to the MC1R region. Copy number changes have been validated for a sample of subjects in this region using an RT-PCR quantitative DNA analysis technique.

Development of breast cancer risk model using haplotype analysis of the Ashkenazi Jewish population. *E. Rinella[1], S. Pramanik[2], S. Guha[2], C. LeDuc[2], H. Ostrer[1], Y. Shao[3], A. Pearlman[1], C. Campbell[1], M.B. Terry[4], R. Senie[4], I. Andrulis[5], M. Daly[6], E. John[7], W. Chung[2].* 1) Human Genetics Program, NYU School of Medicine, New York, NY; 2) Pediatrics, Columbia University Medical Center, New York, NY; 3) Division of Biostatistics, NYU School of Medicine, New York, NY; 4) Epidemiology, Columbia University, New York, NY; 5) Ontario Cancer Genetics Network, Cancer Care Ontario, Toronto, Ontario, Canada; 6) Clinical Genetics, Fox Chase Cancer Center, Philadelphia, PA; 7) Cancer Prevention Institute of California, Stanford University School of Medicine & Stanford Cancer Center, Stanford, CA.

Breast cancer risk has a high heritability, yet the genetic markers revealed thus far only account for 20-25% of familial breast cancer cases. The ability to establish genetic risk models is critical for optimizing screening and treatment of breast cancer, but many more variants must be identified. This study utilizes data mining techniques to build on GWAS results by examining IBD (Identity By Descent) segments and haplotypes among homogeneous cohorts of Ashkenazi Jewish (AJ) women. Methods: AJ women with invasive breast cancer and a family history of breast cancer were recruited along with age-matched AJ controls at New York City research institutions. Affymetrix 500K SNP arrays were used to genotype a discovery cohort of 238 breast cancer cases and 237 controls. Individual SNP analysis was conducted using standard case/control association analysis and validated in a replication cohort of 239 cases and 294 controls. The cohorts were combined for haplotype analysis (using an Expectation-Maximization algorithm) and IBD analysis (using GERMLINE/DASH). Association analysis was performed on haplotypes and clusters of shared segments. Biological significance of haplotypes, IBD segments, and individual SNPs was determined using GSEA (Gene Set Enrichment Analysis). Results: IBD segments of (≥30 SNPs) and haplotypes (≥2 SNPs) appearing in at least 10% of the 1008 study subjects were included for analysis. 147 haplotypes containing at least 10 SNPs were significantly associated with breast cancer risk (p=0.00998 - $5.31x10^{-6}$; OR=1.26 - 1.96). These results enhanced the individual SNP association analysis that revealed 73 SNPs (with minor allele frequencies of at least 5%) that were significantly associated with breast cancer (p_C= 0.001 - $6.16x10^{-7}$; OR=1.29 - 4.45). The haplotype analysis confirmed individual SNP results, both spanning 18 common genes (many not previously reported in association with breast cancer risk) and common pathways involved in apoptosis and transcription. Haplotype analysis reveals an additional 211 genes not covered with the individual SNP analysis. Conclusions: An advantage to studying a homogeneous population of cases and controls, such as the AJ women presented here, is the ability to perform haplotype and IBD analyses. Building disease risk models based on such analyses reduces complexity thereby revealing regions associated with breast cancer that were not detectable using the individual SNP analysis commonly found in GWAS.

The MutS homolog hMSH4 interacts with eIF3f in mammalian cells. *YL. Chu, X. Wu, C. Her.* School Molecular Biosciences, Washington State University, Pullman, WA.

Accumulating evidence suggests that members of the mismatch repair family participate in diverse cellular functions in addition to their primary action in DNA damage recognition and repair. Being a member of this family of proteins, the molecular mechanisms involved with the human MutS homolog 4, hMSH4, are poorly defined. It is known that hMSH4 is promiscuous and the heterocomplex composed of hMSH4-hMSH5 is capable of binding to synthetic Holliday junctions. In addition, mice lacking the Msh4 gene display defective chromosome synapsis, leading to testicular and ovarian degeneration and, therefore, male and female sterility. Notwithstanding a low but readily detectable level of hMSH4 in mitotic tissues, the biological function of hMSH4 is largely unknown. In order to better understand the molecular mechanisms associated with hMSH4 in human cells, we have set out to identify potential hMSH4 interacting partners. To this end, screening of a human ovary two-hybrid cDNA library has led to the identification of eIF3f (eukaryotic initiation factor 3 subunit f)—known to play a major role in stabilizing the 40S ribosomal subunit. Intriguingly, recent studies have also demonstrated that eIF3f is involved in the regulation of apoptosis, and the reduction of eIF3f has been documented in several types of human cancers, although the biological mechanism behind this is still unclear. Our preliminary studies have suggested that hMSH4 interacts with eIF3f in human cells, presumably mediated through the N-terminal region of hMSH4. In addition, our confocal microscopic study has indicated that hMSH4 and eIF3f co-localize primarily in the cytoplasm under normal cellular conditions. Functional analysis of this newly discovered interaction in DNA damage response and cell cycle regulation is presently ongoing in the laboratory. It is conceivable that the interplay between hMSH4 and eIF3f may play a role in the pathogenesis and/or proliferation of cancer cells. Furthermore, the results of our current study are likely to be an important steppingstone for elucidating additional molecular functions of hMSH4.

Protein kinase A regulates caspase-1 via Ets-1 in bone stem cell-derived lesions: a link between cyclic AMP and pro-inflammatory pathways in osteoblast progenitors. *M.Q. Almeida[1], K.T. Tsang[1], C. Cheadle[2], T. Watkins[2], JC. Grivel[3], M. Nesterova[1], R. Goldbach-Mansky[4], C.A. Stratakis[1].* 1) Section on Endocrinology and Genetics, Program on Developmental Endocrinology & Genetics (PDEGEN), Eunice Kennedy Shriver National Institute of Child Health & Human Development (NICHD), National Institutes of Health (NIH), Bethesda, MD 20892; 2) Genomics Core, Division of Allergy and Clinical Immunology, School of Medicine, Johns Hopkins University, Mason Lord Bldg., Center Tower, Rm. 664, 5200 Eastern Avenue, Baltimore, MD 21224; 3) Program on Physical Biology, NICHD, NIH, Bethesda, MD 20892; 4) Translational Autoinflammatory Disease Section, NIAMS, NIH, Bethesda, Maryland 20892, USA.

Patients with genetic defects of the cyclic (c) AMP-signaling pathway and those with neonatal-onset multisystem inflammatory disease (NOMID) develop “tumor-like” lesions of the long bones. The molecular basis of this similarity is unknown. NOMID is caused by inappropriate activation of a caspase-1 activating inflammasome. The present study demonstrates that NOMID bone lesions are derived from the same osteoblast progenitor cells that form fibroblastoid tumors in mice and humans with defects that lead to increased cAMP-dependent protein kinase (PKA) signaling. NOMID cells showed high PKA activity, and an increase in their cAMP signaling led to PKA-specific activation of caspase-1. Increased PKA led to inflammation-independent activation of caspase-1 via over-expression of the proto-oncogene and early osteoblast factor, Ets-1. In NOMID cells, as in cells with defective PKA regulation, increased prostaglandin E2 (PGE2) led to increased cAMP levels and activation of Wnt-signaling; increased Wnt-signaling underlies tumor formation in a variety of settings associated with inappropriate PKA activation. Caspase-1 and PGE2 inhibition led to a decrease in cell proliferation of both NOMID and cells with abnormal PKA. These data reveal a previously unsuspected link between abnormal cAMP signaling and defective regulation of the inflammasome and suggest that caspase-1 and PGE2 inhibition may be therapeutic targets in bone lesions associated with defects of these two pathways.

Notch Gain of Function Contributes to the Osteosarcoma in a Mouse Model. *J. Tao[1], S. Chen[1], M. Jiang[1], T. Bertin[1], F. Gannon[2], B. Lee[1,3].* 1) Human & Molecular Genetics, Baylor College Medicine, Houston, TX 77030; 2) Pathology, Baylor College Medicine, Houston, TX; 3) Howard Hughes Medical Institute, Houston, TX.

Human osteosarcoma (OS) is the most common primary bone cancer, comprising approximately 20% of all bone tumors and about 5% of pediatric tumors overall. Most OS occurs sporadically and our understanding of its molecular basis is still limited. From a signaling perspective, dysregulation of several evolutionally conserved pathways including Wnt, TGF/ BMPs, SHH and FGFs has been found in human OS tumor samples and cell lines. Recently, our and other studies suggest that activation of Notch signaling contributes to the pathogenesis of human OS. Notch signaling plays an important role in the developmental processes and adult tissue homeostasis by regulating cell fate determination, proliferation, differentiation and apoptosis. Notch, a transmembrane receptor, releases its intracellular domain (NICD) into the nucleus to regulate transcription of target genes such as the Hey and Hes family of transcription factors. Altered Notch signaling has been associated with several cancers in which the data suggest that Notch can act both as an oncogene and tumor suppressor gene depending on its expression levels and timing. Our previously established human tumor xenografts in nude mice showed decreased tumor growth after chemical or genetic inhibition of Notch signaling, suggesting that its inhibition may be a therapeutic approach for the treatment of OS. To generate a mouse osteosarcoma model and examine the role of Notch signaling in bone tumorigenesis, we established a bitransgenic mouse line that constitutively expressed a single copy of Notch NICD in osteoblasts. The resulting bitransgenic Notch gain-of-function (GOF) mice developed osteosclerosis at age of two months. Histomorphometric and molecular analysis of cavarial and long bones indicated that Notch could stimulate proliferation of immature osteoblasts while inhibiting their differentiation into mature osteoblasts. This gain of function phenotype was reminiscent of osteoblastic tumors. Indeed, aging studies of these GOF mice showed that they spontaneously developed osteoma at 100% penetrance. Of 24 aged mice to date, we have detected multifocal malignant tumors in six of them by gross examination. Pathological analysis confirmed that one of them was telangiectatic osteosarcoma, featured by poorly differentiated osteoblast-like cells, tumor osteoid, necrosis and hemorrhage. Together, our preliminary data support our hypothesis that Notch activation may be a dominant mechanism for OS pathogenesis.

565/F

cAMP and KIT-KITLG signaling interact in testicular tissue and possibly cooperate in predisposition to testicular germ cell tumors: a novel function of PDE11A in testis. *M. Azevedo[1], E. Bornstein[1], A. Horvath[1], c. Kratz[2], M. Nesterova[1], M. Greene[2], C. Stratakis[1].* 1) NICHD/NIH, Bethesda, MD; 2) NCI/NIH, Bethesda, MD.

Testicular germ cell tumors (TGCTs) account for 95% of the cases of testicular cancer, the most common solid malignancy affecting young males. Somatic activating mutations in the proto-oncogene KIT are found in patients with TGCTs, whereas common variations in the KITLG gene have been associated with these tumors. Phosphodiasterase (PDE) 11A (PDE11A) is expressed in several tissues, but is most highly expressed in testis (and prostate). PDE11A’s enzymatic activity, thus, appears to be an important regulator of cAMP signaling in testicular tissue. Recently, we reported PDE11A mutations (and functional polymorphisms) as predisposing factors for the development of TGCTs (1). In this study, we investigated whether the two pathways of cAMP and KIT/KITLG signaling interact in testicular tissue. A TGCT cell line (NTERA-2) was transiently transfected with plasmid DNA expressing either the wild type (WT) or the mutated forms of PDE11A described in patients with TGCTs (R52T, F258Y, G291R, Y727C, R804H, V820M, R867G and M878V); we then determined cAMP levels, PDE and PKA activity, and RNA and protein levels for KIT, KIT/KITLG, and related molecules. cAMP levels were significantly higher in the NTERA-2 cells transfected with all the PDE11A mutations and relative PDE activity was lower. KITLG expression was consistently increased in the presence of PDE11A mutations. Preliminary results suggest that PDE11A and KITLG TGCT-linked alleles co-segregate in families with TGCT. We conclude that KITLG expression consistently increases in the presence of PDE11A-inactivating defects, both at the RNA and protein levels, in TGCTs. This is the first demonstration, in any tissue, of a functional link between the cAMP and the KIT signaling pathways in predisposition to cancer.

566/F

Continued Identification of Ethnic Specific Differences in Breast Cancer and Normal Breast Tissue. *L. Baumbach[1], M.E. Ahearn[1], C. Gomez[1], A. Mejias[1], M. Jorda[1], T. Halsey[2], J. Yan[2], K. Ellison[2], K. Mulligan[2], R. Kittles[3], A. Ashworth[4], M. Pegram[1].* 1) Univ Miami School of Medicine, Miami, FL; 2) Almac Diagnostics, Durham, NC; 3) University of Illinois at Chicago, Chicago, IL; 4) Breakthrough Cancer Research Center, London, UK.

Ethnic-specific disparities in stage of presentation/survival rates exist in breast cancer patients; the cause is unknown. We are continuing to investigate possible genetic contributions to these disparities, we are investigating genomic changes in breast cancer (BC) samples from multi-ethnic cohorts of African-American (AA), Hispanic (His), native African (Kenyan) and non-Hispanic white (Caucasian) women with “triple negative” (ER-, PR-, Her2/Neu-) BC. The overall goal is to identify differentially expressed genes between tumor and adjacent normal tissue that are common or unique among the three groups. We are also analyzing normal breast tissue samples (reduction mammoplasty residual tissue) from AA, His and Cauc women to investigate gene expression patterns across ethnicities in normal breast tissue. Pathology samples are cut from FFPE (Formalin Fixed Paraffin-embedded tissue) blocks marked by pathology as self-matched normal vs. tumor tissue. Almac Diagnostics performs RNA isolation, cDNA preparation, and hybridization of tumor/normal cDNAs to a breast cancer focused gene expression array (Breast Cancer DSA Research Tool). From the Breast Cancer DSA arrays data, a two-way ANOVA (disease state and ethnicity) identified 6479 transcripts with a p-value less than 0.01. Data QC indicated that samples clustered well with respect to ethnicity and adjacent normal vs. tumor tissue. We have identified ethnic-specific expression patterns in the matched normal and tumor samples. Ethnic specific differences between the adjacent normal tissues were also seen and ethnic specific expression differences were noted in small collection of normal breast samples. The same BC samples are being analyzed by array CGH to assess copy number variations in relation to the gene expression differences. In addition, DNA from the AA samples is being evaluated with a panel of ancestry-informative DNA markers. These analyses indicate that high quality gene expression data can be obtained from FFPE samples, and ethnic specific gene expression differences have detected in tumor and matched normal breast tissue across ethnic groups. Validation of these results has important implications for addressing BC health disparities, as well as tailored approaches to prediction, prevention and treatment.

A miRNA inhibitor screen for *KRAS*-selectively lethal miRNAs. *R. Borkowski[1], L. Du[3], A.F. Gazdar[3,4], J.D. Minna[3,4], A. Pertsemlidis[2,3].* 1) Program in Genetics and Development, UT Southwestern Medical Center, Dallas, TX; 2) McDermott Center for Human Growth and Development, UT Southwestern Medical Center, Dallas, TX; 3) Simmons Comprehensive Cancer Center, UT Southwestern Medical Center, Dallas, TX; 4) Hamon Center for Therapeutic Oncology Research, UT Southwestern Medical Center, Dallas, TX.

Lung cancer, especially non-small cell lung cancer (NSCLC), is currently the leading cause of cancer fatalities in the United States, accounting for 30% of the fatalities in males, and 26% in females. Additionally, the five year survival rate for individuals affected by lung cancer has only improved by 3% in the past 35 years. As suggested by the survival data, very few effective treatment options are available for NSCLC, and many vary dramatically in efficacy depending on the genetic status of the tumor. In particular, the presence of mutant *KRAS* in NSCLC serves as a negative predictor for drug efficacy. *KRAS* mutations are found in ~22% of NSCLC tumors, and tumors harboring these mutations are categorically refractory to treatment with Epidermal Growth Factor Receptor (EGFR) Tyrosine Kinase Inhibitors (TKI) gefitinib (Iressa) and erlotinib (Tarceva); furthermore, there are no effective therapies targeted for *KRAS* mutant NSCLCs.

In order to identify genetic susceptibilities specific to *KRAS*-dependent NSCLC, we use systematic miRNA depletion to identify miRNAs, and their target genes and pathways, necessary for the survival of this genetic subset of tumors. A miRNA inhibitor screen can serve to identify not only independent miRNAs involved in selective survival, but also genes and pathways involved that would be obscured by genomic redundancy in a conventional RNAi screen. Using a comprehensive library of miRNA inhibitors coupled with an endpoint assay for cell viability, we have identified several miRNAs that selectively decrease the viability of *KRAS*-dependent NSCLC cell line NCI-H1155 with minimal effect in the wild-type *KRAS* cell line NCI-H1437. These candidates are being validated in an expanded panel of ten cell lines including four *KRAS* mutant, four *KRAS* wild-type, and two immortalized human bronchial epithelial cell lines. miRNAs that, when inhibited, selectively decrease the viability of the refractory tumors will elucidate the pathways and processes necessary for mutant *KRAS*-dependent survival, and will expose individual miRNAs and mRNAs as therapeutic targets.

Identification of the rno-miR-30 family members as a potential central player during 4-nitroquinoline 1-oxide-induced tongue carcinogenesis in rat. *W. Chen[1,2], T. Zhang[1], P. Zhang[1,2], J. Zhang[1], D. Ye[1,2], Q. Xu[1,2], W. Qiu[1].* 1) Department of Oral & Maxillofacial Surgery, Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China; 2) Shanghai Key Laboratory of Stomatology, Shanghai, China.

Objective: Constituents of tobacco can cause DNA adduct formation, and are implicated in the development of oral squamous cell carcinoma (OSCC). However, there are few published studies on the mechanism(s) underlying tobacco associated oral carcinogenesis. It has been widely known that MicroRNAs have an important role in regulation of tumor generation and development. The present study was aimed to analyze the expression profiling of microRNAs and their target genes in rat cancer tissues, which was induced by 4-nitroquinoline 1-oxide (4NQO) and a useful model that mimics tobacco-related human OSCC. Methods: Twenty male Sprague-Dawley (SD) rats were administrated with 0.002% 4NQO in drinking water for 36 weeks, whereas ten rats fed with drinking water were utilized as a control. 15 rats from the 4NQO-treated group developed tongue squamous cell carcinoma, which were confirmed by pathological examination. miRNA and mRNA gene expression profiling studies were pursued using RNA pools derived from 7 tumor and 7 normal tissues, respectively. The significantly expressed miRNAs and mRNAs were verified by RT-PCR followed by gene ontology (GO) analysis in an attempt of building the miRNA-gene correlation network, and miRNA-go-network. Results: 57 miRNAs and 243 mRNA transcripts exhibited differential expression profiles between tumors and normal tongue tissues. Among them, the differential expressions of three miRNAs and three mRNA were validated. In tumor tissues, the expression level of the members of the rno-miR-30 family (rno-miR-30a, -30a*, -30b-5p, -30c, -30d, -30e and -30e*) is only 8% to 37% of their counterparts in the control group. High enrichment GOs including differentiation-related targeted genes and miRNA-gene networks revealed genes of Ubadc1, Ank2, Mybpc1, Ldhb, Cpt2, and Cabc1 as the primary six target genes, which were all known regulated by the rno-miR-30 family. Of the rno-miR-30 family, the three members (rno-miR-30a*,-30d, and -30e*) were the first three highest degree of miRNAs based miRNA-gene networks, and the members (rno-miR-30 b-5p, -30c, -30d, and -30e) were the four of the highest degree of miRNAs uncovered by miRNA-go-network. Conclusions: Rat tongue squamous cell carcinoma induced by 4NQO relates to 57 miRNAs and 243 genes. Decreased expression of the rno-miR-30 family may play a fundamental role in carcinogenesis development especially in biochemical process of oxidation reduction and ion transport.

Genome-Wide Linkage Scan of Colorectal Cancer Families with MMR Deficiency. *M.S. Cicek[1], B.L. Fridley[1], D. Serie[1], W. Bamlet[1], J.M. Cunningham[1], N.M. Lindor[1], J.D. Potter[2], S.N. Thibodeau[1], E.L. Goode[1], the Colon Cancer Family Registry.* 1) Mayo Clinic College of Medicine, Mayo Clinic, Rochester, MN; 2) Fred Hutchinson Cancer Research Center, Seattle, WA.

Substantial evidence from segregation and linkage analyses excluding families with known mutations supports the existence of unidentified susceptibility loci for colorectal cancer (CRC). As part of a larger search to identify novel CRC regions, we assessed linkage in 548 families with no identified germline mismatch repair (MMR) mutations including 129 families with phenotypic evidence of defective MMR (dMMR). We studied families from the Colon CFR, a multi-site NCI-supported consortium, and from Newfoundland, defining dMMR families as those with at least one cancer case with tumor microsatellite instability (MSI-H) or loss of immunohistochemical expression for at least one of following MMR genes: *MLH1, PMS2, MSH2, or MSH6*. Family members (N=737) with an average family size of 5.7 and mean per family of 2.6 and 3.1 for 337 affected and 400 unaffected, respectively, were genotyped using the Affymetrix 10k 2.0 Array or the Illumina Linkage Panel 12 (10,091 pooled SNPs with r2<0.1) and analyzed using MERLIN. Assuming a dominant mode of inheritance, an HLOD of 6.49 in the chromosome 2 *MSH2/MSH6* region (114.3 cM) and an HLOD of 10.91 on the chromosome 3 *MLH1* region (93.3 cM) were observed. The data confirm strong linkage to these known genes. Subsequent MMR gene sequencing on these 129 dMMR families detected 42 families with pathogenic mutations and four families with missense mutations of unknown significance (T764N on *MSH6*, T117R and I219V on *MLH1* and G669V on *MSH2*). In addition, of 51 families exhibiting *MLH1/PMS2* loss, 11 families (22%) segregated pathogenic *MLH1/PMS2* mutations; similarly, of 26 families with *MSH2/MSH6* loss, 14 families (54%) segregated pathogenic *MSH2/MSH6* mutations. Not all families with pathogenic mutations yielded elevated LOD scores, suggesting incomplete linkage-informativeness for some families. Among the remaining 83 dMMR families with no detected mutations, evidence of linkage at *MLH1/PMS2* genes was seen for 65% of the families and at *MSH2/MSH6* genes for 59% of the families; however, other novel regions are suggested.

The metastasis gene MMP-9 is a direct target of the chromatin modifier SMYD3. *A. Cock-Rada, S. Medjkane, N. Janski, J.B. Weitzman.* UMR 7216 - Epigenetics and Cell fate, University Paris Diderot, Paris, France.

Epigenetic mechanisms involved in tumor initiation and progression are becoming an increasing focus of study in the search for new cancer therapies, due to their potential reversibility. Matrix Metalloproteinase-9 (MMP-9) is a proteolytic enzyme that degrades the extracellular matrix and plays an important role in tumor progression and metastasis formation by regulating processes like tumor growth, angiogenesis, escape from immune surveillance, cell migration and invasion. MMP-9 is regulated by several transcription factors but its transcriptional regulation by epigenetic-modifying enzymes is relatively unexplored. SMYD3 is a histone H3K4 methyltransferase with DNA binding capacity, which has been shown to contribute to the transcriptional activation of several genes involved in cancer. It has been shown to be important for tumour proliferation in colorectal, hepatocellular and breast carcinomas and in cellular invasion in cervical carcinomas. We are studying the role of SMYD3 in the regulation of MMP-9 and tumor invasion. In order to identify new regulators of MMP-9 expression at the chromatin level, we characterized several activating and repressive histone marks on the MMP-9 promoter by Chromatin Immunoprecipitation (ChIP) in a reversible bovine cancer model. We observed that tri-methylation of histone H3K4 is an important event in the activation of MMP-9. We studied the expression of several H3K4 methyltransferases and demethylases by quantitative PCR and observed a positive correlation between the expression of MMP-9 and the gene coding for SMYD3. Using over-expression and knockdown techniques to modulate SMYD3 levels, we observed an effect on MMP-9 expression and protein activity in bovine transformed leukocytes and in human fibrosarcoma cells (HT1080). We observed by ChIP that SMYD3 binds to the MMP-9 promoter. We generated HT1080 stable cell lines with shRNA against SMYD3 and observed a decreased binding of SMDY3 to the MMP-9 promoter, along with a decrease in H3K4me3 marks. We are now studying the effect of SMYD3 knockdown on the invasive phenotype of these cells, using matrigel invasion and migration assays. These results identify SMYD3 as a new regulator of MMP-9 in cancer progression.

mir-21 Regulate Sprouty1 Expression in Prostate Cancer Cells. *M. Daremipouran[1,2], B. Kwabi-Addo[2].* 1) Genetics and Human Genetics, Howard University, Washington, DC; 2) Howard University Cancer Center Washington, DC.

Background: Sprouty1 is a negative regulator of fibroblast growth factor signaling with a potential tumor suppressor function in prostate cancer (PCa) cell lines. Biochemical analysis shows that Sprouty1 is downregulated in prostate cancer tissues in comparison to normal prostate tissues. We have previously shown that in some cases DNA methylation is a potential mechanism for the downregulation of Sprouty1 expression, suggesting other mechanisms of gene inactivation could also affect Sprouty1 expression. Recent studies have shown that microRNA-21 (mir-21) is overexpressed in various types of cancers including prostate cancer. It is suggested that mir-21 may have a potential role in regulating the malignancy and metastatic abilities of prostate cancer cells by regulating the tumor suppressors such as; Sprouty1. To elucidate additional molecular mechanism involved in regulating Sprouty1 expression in prostate cancer we investigated the rolls of transcription factors and microRNA expression in Sprouty1 regulation. Methods: Gene knockdown studies were carried out in prostate cancer cell lines with shRNA or siRNA directed towards EGR1, EGR2, GATA2 and GATA4 transcription factors and mir-21 and the RNA expression level validated using quantitative RT-PCR. Protein expression was analyzed by western blotting. Results: Our results demonstrates that knockdown of transcription factors Egr1, Egr2, Gata2 or Gata4 by transfecting prostate cancer cell lines with the corresponding shRNAs resulted in downregulation of Sprouty1 protein expression suggesting that these transcription factors stimulate Sprouty1 expression. On the other hand, the knockdown of mir-21 expression in prostate cancer cell lines, PC3 and DU145 led to increase activation of Sprouty1 expression but we did not see such response in LNCaP cells which does not have detectable basal level of mir-21 expression. Conclusion: Our preliminary observation suggests multiple mechanisms of Sprouty1 regulation, including epigenetic DNA methylation changes and small RNA expression that may act differently depending on the cellular context.

Mad2 is a Critical Mediator of the Chromosome Instability Observed upon p53 and Rb Pathway Inhibition. *P.H.G. Duijf, J.M. Schvartzman, R. Sotillo, C. Coker, R. Benezra.* Department of Cancer Biology & Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY.

Rb and p53 pathway inhibition are key events in the development of chromosome instability and cancer, yet the mechanisms by which this instability arises are unclear. Rb pathway inhibition leads to overexpression of the mitotic checkpoint gene Mad2 via E2F activation. While Mad2 overexpression is sufficient to initiate aneuploid tumor formation, whether it is required to mediate the phenotypes of Rb or p53 pathway inhibition is unknown. We show that Mad2 is upregulated in response to p53 loss as a result of reduced p21-mediated inhibition of cyclin-dependent kinase activity and Rb inactivation. In the context of Rb pathway inhibition, Mad2 overexpression is required for the acquisition of chromosome instability and anaplastic mammary tumor formation. In addition, in a p53 mutant knock-in mouse model that develops tumors with stable, diploid genomes, the Mad2 upregulation and chromosome instability that is caused by p21 loss can be rescued by genetic reduction of Mad2 levels. These results demonstrate that Mad2 overexpression is an essential mediator of the chromosome instability and tumor phenotypes observed upon inactivation of two major tumor suppressor pathways.

Estrogen receptor gene silencing in human breast cancer cells using siRNA. *M. El-Zawahri[1], Y. Luqmani[2], A. Al-Azmi[3].* 1) Faculty of Biotechnology, Misr University for Science & Technology (MUST), 6th October City, Egypt; 2) Pharmaceutical Chemistry Dept, Kuwait University, Kuwait; 3) Molecular Biology Dept, Kuwait University, Kuwait.

The role of estrogen receptor alpha (ERα) in breast cancer has been highlighted by numerous of studies. Consequently, inhibition of ERα has become one of the major strategies for the prevention and treatment of breast cancer. However, failure to overcome development of endocrine resistance limits this approach. Our aim was to produce a model system to investigate cellular consequences of loss-of-function of ERα gene by establishing a breast cancer cell line with a permanent source of small interference RNA (siRNA) to specifically inhibit the production of ERα protein. Three plasmid constructs (plasmid I, II and III) intended to produce intracellular double stranded hairpin RNA to be processed into siRNA targeting different regions of the human ERα mRNA, and a scrambled sequence, were cloned into the pRNA-U6.1/Neo GenScript vector for expression of anti-ERα siRNA from the U6 promoter. MCF-7 human breast cancer cells were transformed with 2 or 4 μg of each plasmid (6 and 24h exposure), using two different transfection reagent conjugates: lipofectin-plasmid-complex containing each of the three different intact plasmid constructs, and XtremeGENE complexed to each of the linearized plasmids. Transformants were rescued by growth in G418 selection medium. Stably transformed cells were propagated in long-term culture. Presence of plasmid DNA in transformants was verified with primers targeting various regions of the vector. ERα mRNA levels were determined by Real-Time RT-PCR, and ERα protein by Western blotting; normalization was achieved by simultaneous analysis of β-actin. Our results showed down regulation of expression of the ERα mRNA in MCF-7 cells transfected with the three anti-ERα siRNA intact plasmid construct compared with the wild-type MCF-7 control cells. Plasmid II showed greater down-regulation than plasmids I and III. Linearized anti-ERα-siRNA construct PII most effectively down-regulated ERα mRNA and protein, compared to G418 resistant transformants containing scrambled siRNA. Complete knockdown was not observed, whereas 4 μg of linearized anti-ERα-siRNA construct PII produced more transformants. 24h exposure did not increase transformation efficiency. In conclusion, we have successfully established a long-term culture of MCF-7 breast cancer cells that exhibit decreased expression of ERα. This is hoped to provide a model system in which to study aspects of endocrine resistance.

CHD1L Induces Mitotic Defects and Chromosome Missegregation through Decreasing Cdk1 activity by Upregulating TCTP. *X.Y. Guan, T.H. Chan, L. Chen, M. Liu, L. Hu.* Dept Clinical Oncology, Univ Hong Kong, Hong Kong, Hong Kong.

Our previous research efforts have led to the identification of CHD1L as a target oncogene responsible for the 1q21 amplification event in hepatocellular carcinoma (HCC). Here, by utilizing a 2D-PAGE proteomic approach, the translationally controlled tumor protein (TCTP), a tubulin binding protein, was identified as one of CHD1L target genes. Using chromatin immunoprecipitaion (ChIP)-PCR and luciferase reporter assays, we found that CHD1L protein directly binds to the promoter region (-733/-1027) of TCTP and activates its transcription. Clinically, overexpression of TCTP was detected in 41.9% of human HCCs, which was significantly associated with CHD1L overexpression ($p<0.001$), and significantly associated with heavy liver cirrhosis ($p=0.024$) and advanced tumor stage ($p=0.049$). In vitro and in vivo functional studies showed that TCTP could strongly promote foci formation, accelerate mitotic phase progression and induce tumor formation in nude mice. Further mechanistic study indicated that during mitosis, the elevated expression of TCTP accelerated the ubiquitin-proteasome degradation of Cdc25C, which in turn led to the failure in the dephosphorylation of Cdk1 on Tyr15 and the decreased Cdk1 activity, finally causing a faster M phase exit and chromosome missegregation. In addition, silencing TCTP expression inhibits its tumorigenicity and reverses the faster M phase progression. Overall, our present study on TCTP defines a novel molecular pathway (CHD1L)-(TCTP)-(Cdc25C)-(Cdk1) during hepatocarcinogenesis by which CHD1L activates TCTP transcription via binding to the latter's promoter region and TCTP overexpression leads to the malignant transformation of hepatocytes with the phenotypes of accelerated mitotic progression and the production of aneuploidy.

Variants on the promoter region of PTEN affect breast cancer progression and patient survival. *T. Heikkinen[1], LM. Pelttari[1], D. Greco[1], J. Tommiska[1], P. Vahteristo[1], P. Heikkila[4], K. Aittomaki[3], C. Blomqvist[2], H. Nevanlinna[1].* 1) Department of obstetrics and gynecology, Helsinki university central hospital, Helsinki, Finland; 2) Department of oncology, Helsinki university central hospital, Helsinki, Finland; 3) Department of clinical genetics, Helsinki university central hospital, Helsinki, Finland; 4) Department of pathology, Helsinki university central hospital, Helsinki, Finland.

The *PTEN* gene functions as a negative regulator of phosphatidylinositol 3-kinase (PI3K), and hence has a direct regulatory effect on PI3K oncogenic pathway activation. Inherited inactivating mutations in *PTEN* cause Cowden syndrome, in which the estimated risk for breast cancer is 25-50%. Low penetrance variation in *PTEN* gene or other members of the PI3K pathway has not been reported. We have screened the *PTEN* gene for germline variation from 84 patients with family history of breast or other Cowden-related cancers using CSGE heteroduplex analysis and direct sequencing, and further genotyped three rare promoter polymorphisms -903GA, -975GC, and -1026CA in 2233 breast cancer patients and 1272 healthy controls. None of the variants associated with breast cancer risk, but all variants associated with worse prognosis. The Cox's regression hazard ratio for 10 year breast cancer specific survival was 2.17 (95% CI 1.52-3.10) p=0.00002, and for 5 year breast cancer death or distant metastasis free survival 1.97 (95% CI 1.40-2.79) p=0.00011 for patients carrying any of the variants.

We evaluated the effects of the promoter variants on transcriptional activity with luciferase reporter assay by cloning the promoter elements carrying different variants into an expression vector and comparing the changes in expression in HeLa and MCF7 cell lines. The variants -975GC and -1026CA had slight, but significantly reduced expression in HeLa cells. All variants were predicted to change transcription factor binding sites when the wild type and variant sequences were compared using Genomatix SNPInspector software. We also compared the gene expression in breast cancer tumors of 10 variant carriers and 10 matched non-carriers and identified 160 differentially expressed genes clustering in distinguished signatures. All three germ line variants exhibited similar gene expression patterns in the tumors.

The genetic analyses together with the gene expression results suggest that inherited variation in the *PTEN* promoter region causing even subtle changes in *PTEN* expression levels or function will affect the tumor progression and gene expression profile in breast cancer, with also clinical implications for reduced survival of breast cancer patients.

Detection of significant DNA copy number alterations in breast tumors from Mexican patients with high-resolution SNP arrays and GISTIC analysis. *A. Hidalgo-Miranda[1], S. Rodriguez-Cuevas[2], R. Rebollar-Vega[1], S. Romero-Cordoba[1], V. Quintanar-Jurado[1], V. Bautista-Pina[2], I. Ciceron-Arellano[1], K. Carrillo-Sanchez[1], S. March-Mifsut[1], G. Jimenez-Sanchez[1], L. Uribe-Figueroa[1].* 1) Laboratorio de Oncogenomica, Instituto Nacional de Medicina Genomica, Mexico; 2) Fundacion Mexicana de Cancer de Mama, Mexico.

Breast cancer represents the second cause of cancer related death in Mexican women, and also represents an important health problem worldwide. Specific patterns of DNA copy number changes in breast tumors have been associated with particular tumor types and clinical behaviors. Analysis of these DNA copy number alterations have been carried out using different methods, like comparative genomic hybridization (either on metaphase chromosomes or different microarray platforms), and more recently, with high density oligonucleotide and SNP arrays. Increased array resolution, as well as the introduction of statistical methods to evaluate the significance of the copy number aberrations, has allowed the detection of particular gene targets in several human tumors. In order to define the pattern of statistically significant DNA copy number changes in breast tumors from Mexican patients, we used a high resolution SNP array to analyze the DNA copy number profiles of 89 breast normal/tumor pairs from Mexican patients. Tumor tissue and peripheral blood lymphocyte DNA from each patient was analyzed with the Affymetrix SNP 6.0 array. All tumor samples contained more than 80% tumor cells. Array normalization and paired copy number analysis using the SNP probes in the array was done using DChip, followed by segmentation using the GLAD algorithm and significant regions were identified using the Genomic Identification of Significant Targets in Cancer (GISTIC) method, both implemented in the GenePattern platform. GISTIC analysis identified 49 significant regions with copy number changes in the tumor compared to the paired normal tissue, including 22 amplifications and 27 deletions. In the amplifications events, seven were considered as "broad" (average: 72 Mb), 11 were "focal" (average: 91 kb) and four were considered as "both". In the case of the deletions, 15 were broad, nine were focal and three were both. Some of these regions have not been previously reported as common areas of copy number change in breast cancer making the analysis of the genes inside these significant regions an interesting research task. To our knowledge, this is one of the first reports regarding high-resolution DNA copy number aberrations in breast cancer from a Latin American population, as well as one of the first analysis using the SNP 6.0 array in combination with a statistical method for the detection of significant regions with DNA copy number changes in breast cancer.

577/F

Expression of miR-141 and miR-223 in ovarian carcinoma correlates with grade. *L.A. Keogh, C. Barret, C. d'Adhemar, P. Smyth, R. Flavin, J.J O' Leary, O. Sheils.* Histopathology, University of Dublin, Trinity College, Dublin, Ireland.

Ovarian cancer is the fifth most common cancer in women, and has the highest mortality rate among gynaecological cancers. This is largely due to the fact that it is difficult to detect at early stages. Each histological subtype of Epithelial Ovarian Cancer (EOC) also has a pattern of pathological progression, making it difficult to pinpoint specific diagnostic and prognostic markers. The primary focus of this study was an evaluation of miRNA expression in serous ovarian neoplasia. MicroRNAs are small, non- coding RNA molecules that are associated with many pathological processes and virtually all cancers. They are robust by nature and can be detected in archival material. The microRNA targets chosen in this study were hsa-miR-141 and hsa-miR-223. These targets were selected following a pilot study of global miRNA expression in ovarian neoplasia previously completed by our group. Two endogenous controls; let-7a and miR-16, were used for housekeeping purposes. N= 200 cases including benign, borderline, and carcinomas from both serous and mucinous subtypes were selected. 10μm sections were cut from formalin- fixed paraffin embedded (FFPE) tissue. These sections were then haematoxylin and eosin (H&E) stained and Laser Capture Microdissection (LCM) was used to harvest pure populations of epithelial cells. Total RNA was extracted using RecoverAll Total Nucleic Acid Isolation kit (Ambion). Total RNA reverse transcribed using Applied Biosystems Taqman MicroRNA Reverse Transcription (RT) kit, and qPCR was performed using specific Taqman MicroRNA assays. Results illustrated a clear trend in expression of miR-141 from benign through borderline to malignancy in mucinous neoplasias. The level of expression of miR-141 was relatively constant through grades of serous neoplasms. miR-223 expression also demonstrated a clear progression from benign through borderline to malignant in mucinous samples, and also in serous samples. There was significant ($p<0.05$) variation in expression of both miR-141 and miR-223 between mucinous and normal samples, and also between serous and normal samples indicating potential utility for these markers in the diagnostic setting.

TP53 isoforms are regulated by the TEL/ETV6 transcriptional repressor in childhood pre-B acute lymphoblastic leukemia. *J. Larose[1], C. Malouf[1,2], B. Neveu[1,2], S. Langlois[1], D. Sinnett[1,3].* 1) Hematology-Oncology, Res Ctr CHU Sainte-Justine, Montreal, Canada; 2) Departement of Biochemistry, Faculty of Medicine, University of Montreal, Montreal, Canada; 3) Departement of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, Canada.

Cancer is the second major cause of death in the pediatric population. The most frequent pediatric cancer, accounting for 25% of all cases, is acute lymphoblastic leukemia (ALL). Throughout the years, many genetic alterations were associated with childhood ALL, including the chromosomal translocation t(12;21) observed in 30-40% of childhood pre-ALL. In utero, this translocation creates the chimera ETV6-AML1 which is insufficient to the complete development of pre-B ALL. Interestingly, when children are diagnosed with pre-B ALL, they carried a deletion of the second allele of ETV6. This causes the complete inactivation of ETV6, a transcription repressor of the Ets family. In childhood leukemia, we believe that ETV6 acts as a tumor suppressor gene because its inactivation is required for the complete development of pre-B ALL. The leukemogenesis events would be fulfilled through the action of the transcriptional targets of ETV6. Using a combination of microarray expression analysis and qRT-PCR assays in leukemia patients, we identified TP53 as one putative transcriptional target of ETV6. The expression of TP53, a well-characterized tumor suppressor is driven by a classic and an alternative promoters. The classic promoter is responsible for the expression of the full-lenght as well as the Δ40 isoforms, while the alternative promoter leads to the expression of the Δ133 isoforms. Using gene reporter assays in HeLa and Jurkat cell lines, we demonstrated that ETV6 represses the activity of both TP53 promoters by targeting a region close to the basal promoter. The analysis of ETV6 constructs deleted either for the DNA-binding domain (ETS domain) or the protein-protein interaction domain (POINTED/PNT domain) indicated that ETV6 doesn't need a consensus EBS/Ets-binding site, unlike other transcription factors of the Ets family. To understand the role of TP53 isoforms (full-lenght, Δ40 and Δ133) in leukemogenesis, we are conducting expression studies in cells from pre-B ALL patients as well as phenotypic studies in leukemic cell lines. This study is a new step toward the understanding of the molecular mechanisms used by ETV6 to regulate transcription and the implication of its transcriptional targets in leukemogenesis.

579/F

Characterization of new transcriptional targets of ETV6/TEL, a transcription factor implicated in childhood pre-B acute lymphoblastic leukemia. *C. Malouf[1,2], S. Langlois[1], J. Larose[1], P. Beaulieu[1], D. Sinnett[1,3].* 1) CHU Sainte-Justine, Montreal, Quebec, Canada, H3T 1C5; 2) Department of Biochemistry, Faculty of Medicine, University of Montreal, Montreal, Quebec, Canada, H3T 1J4; 3) Departement of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, Quebec, Canada, H3T 1C5.

Cancer is the second major cause of death in the pediatric population. The most frequent pediatric cancer, accounting for 25% of all cases, is acute lymphoblastic leukemia (ALL). Throughout the years, many genetic alterations were associated with this type of leukemia, including the chromosomal translocation t(12;21) presents in 30-40% of childhood pre-B ALL. *In utero*, this translocation creates the chimera ETV6-AML1 which is insufficient to the complete development of pre-B ALL. Interestingly, when children are diagnosed with pre-B ALL (2-10 years old), they have a deletion of the second allele of ETV6. This causes the complete inactivation of ETV6, a transcription repressor of the Ets family. In childhood leukemia, we believe that ETV6 acts as a tumor suppressor gene because its inactivation is required to the complete development of pre-B ALL. The leukemogenesis events would be fulfilled through the action of the transcriptional targets of ETV6. Since very few of them have been identified, we previously conducted a genomic study combining microarray and qRT-PCR technologies in leukemia patients. This led to the identification of putative transcriptional targets of ETV6, including IL18/interleukin 18, LUM/lumican, SPHK1/sphingosine kinase 1 and PTGER4/prostaglandin E receptor 4 subtype EP4. Using gene reporter assays in HeLa and Jurkat cell lines, we showed that ETV6 represses the activity of the promoters of IL18, LUM, SPHK1 and PTGER4 in a region close to the basal promoter. The analysis of ETV6 constructs deleted either for the DNA-binding domain (ETS domain) or the protein-protein interaction domain (POINTED/PNT domain) indicated that ETV6 doesn't need a consensus EBS/Ets-binding site, unlike other transcription factors of the Ets family. Since chromatin immunoprecipitation experiments in HeLa cells showed the enrichment of ETV6 in the five promoters, we hypothesized that ETV6 binds an uncharacterized DNA sequence. The combination of bio-informatic studies (MEME and TRANSFAC) and functional experiments (gene reporter assays, DNA-protein interactions studies) will most likely answer this question. This study is a new step toward the understanding of the molecular mechanisms used by ETV6 to regulate transcription and the implication of its transcriptional targets in leukemogenesis.

The Role of Hypoxia in the Response of Ovarian Cancer Cells to Chemotherapy. *L.M. McEvoy[1], S.A. O'Toole[1,2], C.D. Spillane[1,3], G. Kijanka[4], C.M. Martin[1,3], O. Sheils[1], J.J. O'Leary[1,3].* 1) Histopathology, Trinity College Dublin, Dublin, Ireland; 2) Obstetrics & Gynaecology, Trinity College Dublin, Dublin, Ireland; 3) Coombe Women and Infants University Hospital, Dublin, Ireland; 4) Biomedical Diagnostics Institute, Dublin City University, Dublin, Ireland.

Ovarian cancer is the fifth most common cancer in women and the leading cause of death from gynaecological malignancy in the Western world. Approximately 70% of patients present with late stage disease, which has already spread to other parts of the body and the long term survival for late stage ovarian cancer is only 30%. Although most patients respond well to chemotherapy initially, the tumour often recurs and is frequently chemoresistant, contributing to the poor long term survival. Tumour hypoxia is associated with resistance to both radiotherapy and chemotherapy. Hypoxia turns on gene pathways which promote aggressiveness, metastasis and chemoresistance and is a common feature of solid tumours such as ovarian cancer. This study aimed to examine the effect of hypoxia on the response to chemotherapy of two ovarian cancer cell lines, A2780 and A2780cis. The cells were grown in normal oxygen conditions (21% O_2, 5%CO_2) or exposed to hypoxia (0.5% O_2,5%CO_2) and treated with cytotoxic drugs cisplatin or paclitaxel in normoxia or hypoxia as part of a hypoxia design matrix. Following drug treatment for 72 hours, the cell viability was assessed using a standard MTT assay. A2780 cells were sensitive to cisplatin and resistant to paclitaxel, whereas A2780cis cells were resistant to cisplatin and sensitive to paclitaxel. Acute hypoxia exposure before treatment increased resistance to cisplatin in both cell lines by increasing the IC_{50}, however it increased sensitivity to paclitaxel in A2780s, which had a reduced IC_{50} value. Treatment of cells in hypoxia without any pre-exposure increased resistance to cisplatin and paclitaxel in A2780cis however A2780 cells did not follow a dose response pattern in these conditions. Several different gene pathways have been implicated in cisplatin and paclitaxel resistance, and understanding the mechanisms underlying these differential response patterns may provide novel therapeutic targets to improve the outcome for ovarian cancer patients with hypoxic tumours.

581/F

***RAD51C* is a novel predisposing gene for hereditary breast and ovarian cancer.** *A. Meindl[1], H. Hellebrand[1], C. Wiek[2], V. Evren[2], B. Wappenschmidt[3], D. Niederacher[4], T. Kasparek[1], A. Becker[3], H. Schaal[5], D. Schindler[6], R. Schmutzler[3], H. Hanenberg[2].* 1) Dept OB/GYN, Klinikum Rechts der Isar, Munich, Germany; 2) Heinrich-Heine University, Department of Pediatric Hematology, Duesseldorf, Germany; 3) University Hospital, Center for Familial Breast and Ovarian Cancer, Cologne, Germany; 4) Heinrich-Heine University, Department of Obstetrics and Gynaecology, Duesseldorf, Germany; 5) Heinrich-Heine University, Institute for Virology, Duesseldorf, Germany; 6) Department of Human Genetics at the University, Wuerzburg, Germany.

Germ-line mutations in a number of genes involved in the recombinational repair of DNA double-strand breaks are associated with a predisposition to breast and ovarian cancer. While mutations in the two high penetrant genes *BRCA1* and *BRCA2* are associated with high disease risks for both entitites, subsequently identified genes involved in DNA repair like *ATM*, *CHEK2* or *PALB2* and mutated familial breast cancer cases, had been linked to more moderate risks. Recently we identified six monoallelic pathogenic mutations in the *RAD51C* gene of 480 breast and ovarian cancer (BC/OC) families that confer highly increased life time risks (Meindl *et al*., Nat Genet 42:410-414, 2010). Analysis of RAD51C pedigrees indicated that the clearly pathogenic mutations completely segregated with the disease (=84high penetrance"), and screening of some RAD51C-deficient tumors revealed loss of the wild type allele with exclusive retaining of the mutated one (=84tumor suppressor"). We also found a more frequent missense variant (16 out of 480) that confers at least moderate risks for BC/OC families. This more frequent mutation is characterized currently regarding its functional implications, clinical consequences and familial segregations. In addition, we have started to screen further BC/OC families in other RAD51 paralogs like XRCC3 and RAD51B, but identified there up to now only few substitutions. In summary, the results demonstrate firstly, that RAD51C is a novel predisposing tumor suppressor gene and support the hypothesis that most of the familial cases showing no mutations in *BRCA1/2*, are linked to yet unknown genes, which are also highly penetrant, but infrequently mutated. However, it seems that other RAD51 paralogs are not essentially involved in familial BC/OC cases. Nevertheless, our results implicate that more familial cases than formerly expected are sensitive to a treatment with PARP-inhibitors, a conclusion which is also supported by the observation that the penetrance of e.g. *CHEK2* or *PALB2* mutations is higher in familial than in sporadic cases.

TRIM8 controls p53 oncosuppressor and ΔNp63α oncogenic activities. *L. Micale[1], M.F. Carattozzolo[2], C. Fusco[1], F. Galli[3], B. Augello[1], A.M. D'Erchia[2], L. Guerini[3], M.G. Turturo[1], E.V. D'Addetta[1], A. Calcagni[1], M.N. Loviglio[1], G. Pesole[2,4], E. Sbisà[5], A. Tullo[5], G. Merla[1].* 1) Laboratory of Medical Genetics, IRCCS "Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy; 2) Dipartimento di Biochimica e Biologia Molecolare "E.Quagliariello", via Orabona 4, 70126 Bari, Università degli Studi di Bari "A. The p53 oncosuppressor protein plays a crucial role in the protection of genome integrity and the inactivation of its pathway appears to be a common, if not universal feature of human cancer. Although the contribution of its relative p63 to onset and tumor progression is less established it is known that TAp63 isoforms shows a p53-like anti-oncogenic activity, while N-terminal truncated ΔNp63α is characterized by pro-oncogenic potential. Here we describe a previously unknown function for the human E3 Ubiquitin ligase TRIM8 as a new key node for enhancing p53 oncosuppressor activity and, at the same time, for dropping oncogenic ΔNp63α activity. We found that TRIM8 overexpression induces MDM2 degradation leading to p53 stabilization and transcriptional activation, which in turn induces cell cycle arrest. Simultaneously, TRIM8 induces the degradation of the oncogenic ΔNp63aα isoform in a proteasome-dependent way. Remarkably, TRIM8 knockdown prevents p53 activation and ΔNp63α degradation after UV exposure and Nutlin-3 treatment. TRIM8 is located at 10q24.3, a region frequently associated to rearrangements and deletions in different human cancer, particularly gliomas. By qPCR we show that TRIM8 expression is strongly downregulated in glioblastomas cell lines. Our results reveal a previously unknown regulatory pathway of p53 and p63 activities, suggesting TRIM8 as a therapeutic target to enhance p53 oncosuppressor activity function and to impair ΔNp63α oncogenic activity.

APC germinal mosaicism in a patient with Familial Adenomatous Polyposis carrying the c.4666del mutation. *C. Mongin[1, 2], C. Colas[1], F. Coulet[1], M. Eyries[1], Y. Lahely[1], JH. Lefevre[2], Y. Parc[2], F. Soubrier[2].* 1) Laboratoire d'Oncogenetique, GH Pitie-Salpetriere-APHP, PARIS, Ile de France, France; 2) Chirurgie digestive, Hopital Saint Antoine-APHP, PARIS, Ile de France, France.

We report a case of germinal APC mosaicism in a 36 years old male patient diagnosed forGardner syndrome with features of adenomatous polyposis and without family history of polyposis. No mutation was found after the initial screening for APC mutation. The APC gene of his daughter was sequenced because of the occurence of osteomas at five and nine years old, and a germline heterozygous mutation c.4666del, p.Thr1556LeufsX9 was detected. A second reading of the father's sequences, revealed that the germline mutation c.4666del was detectable but in a lower proportion than that predicted by a heterozygous mutation, suggesting the presence of somatic mosaicism in the father. The detection of the mutation in other tissues (buccal swab, normal colon tissue) and in the offspring suggests that it may have occurred early during embryogenesis, before the separation of the embryonic layers. As expected, the higher level of mutated allele was detected in adenomas. The c.4666del mutation is located in the region of APC at risk for Gardner syndrome and this patient had extracolonic features (osteomas). The mutation was missed by sequencing because of the low proportion of mutated cells in blood lymphocytes, but the High Fusion Resolution (HRM) method for pre-screening was tested and showed a better level of detection in this patient. Several dilutions of mutated DNA in wild type DNA show that the HRM technique allows a 5% proportion of the mutated allele to be detected. Sanger sequencing alone is not sensitive enough to detect low mosaicism levels and prescreening methods like HRM could be used for APC analysis because of the high rate of de novo mutations. Mosaicism is an important consequence of de novo APC mutations and must be considered in the diagnosis of apparently de novo cases. Mutation screening of offspring with the disease could be preferred when possible because of the risk of mosaicism. When no mutation is detected it can be envisioned to sequence adenomas DNA as a first step toward identifying APC mosaicism.

584/F

I171V NBN germ-line mutation predisposing to cancer in adults cannot be considered as a risk factor for solid tumors in children. *J. Nowak[1], I. Ziolkowska[1], M. Mosor[1], M. Wierzbicka[2], D. Januszkiewicz[1,2].* 1) Institute of Human Genetics, Polish Academy Sciences, Poznan, Poland; 2) University of Medical Sciences, Poznan,Poland.

MRE11, RAD50 and NBN (MRN) complex is involved in DNA repair and cell cycle checking signaling. NBN being a part of MRN complex plays an important role in genome stabilization. Molecular variants of NBN gene may therefore constitue a cancer risk factor. Recent findings show that cells from NBN gene mutation carriers are characterised by spontaneous chromosome instability which may lead to the induction of malignant transformation. Heterozygous 657del5 mutation in the NBN gene have been described in various groups of cancer patients, like acute lymphoblastic leukemia , non-Hodgkin lymphoma, colon and rectum, prostate cancer and cancer cell lines .The aim of the study was to analyze the frequency of a panel mutations of NBN gene by screening all 16 exons of this gene along with polymorphisms examination. DNA was isolated from peripheral blood of 135 children with acute lymphoblastic leukemia, 270 women with breast cancer, 176 patients with larynx cancer, 93 with second primary tumors of head and neck, 131 with colorectal carcinoma and 1274 healthy individuals. I171V mutation of NBN gene was the most frequent and has been found in 23 patients compared to only 8 in healthy individuals. We observed the high incidence of germinal mutation I171V of NBN gene in breast, colorectal, larynx cancer and in multiple primary tumors. It can be concluded that I171V mutation of NBN gene is associated with predisposition to malignances and NBN allele I171V may be a general cancer susceptibility gene of low or middle risk. In the next step we would like to answer the question whether I171V germinal mutation of NBN gene may constitute risk factor for solid tumors in children. The frequencyof this mutation has been analysed in patients with neuroblastoma (n=66), Wilms' tumor (n=54),medulloblastoma (n=57) and rhabdomyosarcoma (n=82) hospitalized in Pediatric Oncology, Hematology and Bone Marrow Transplantation Department in the years 1987-2010. 2947anonymous blood samples collected on Guthrie cards drawn from the newborn screening program have been used as controls. All the patients and population controls came from the same geographical region. I171V mutation of the NBN gene has been observed in 5 control cases. Among children with solid tumors only in one child with medulloblastoma I171V variant has been found. In conclusion I171V NBN germ-line mutation in contrary to adults cannot be considered as a risk factor for solid tumors in children.

miRNA profiling in normal and tumor bladder tissue samples. *P. Porter-Gill, A. Kaushiva, Y. Fu, L. Prokunina'Olsson.* LTG/DCEG, NCI/NIH, Bethesda, MD.

Urinary bladder cancer (UBC) is estimated as the 9th most common cancer and the 13th leading cause of cancer death worldwide. Environmental exposures such as cigarette smoking and specific occupational exposures are the most important risk factors for UBC. Familial aggregation and the significant racial differences in UBC incidence suggest genetic susceptibility to this disease. Understanding the association between specific genetic changes and the development of UBC may improve the screening program for early detection and treatment. Biomarkers measurable in accessible body fluids such as blood and urine and that can differentiate normal and tumor state, are of particular interest for UBC. microRNAs (miRNAs) that represent a new class of short non-coding regulatory RNA molecules stable in different conditions and easy to measure with quantitative PCR (qPCR) methods, are therefore attractive as potential biomarkers. Several possible miRNA with the potential for predicting disease progression have already been suggested for UBC. In this study, we used a genome-wide unbiased approach and quantified expression of 671 miRNAs with TaqMan Low Density miRNA arrays V2.0 (Applied Biosystems) supplemented with 130 additional miRNA expression assays not present on the arrays, in total quantifying expression of 801 miRNAs. We used RNA prepared with mirVana total RNA extraction kit (Ambion) that preserves miRNA fraction. In total, the miRNA profiling will be performed on 42 tissue samples of transitional urothelial carcinoma and 42 adjacent normal bladder samples with detailed clinical information. The analysis will include comparisons in miRNA expression patterns between normal and tumor tissues, and quantitative level of expression in relation to genotypes of single nucleotide polymorphisms (SNPs) found to be associated with UBC in genome-wide association studies (GWAS). The most interesting miRNAs will be individually tested in plasma samples of the same individuals. The combination of information on genetic susceptibility factors identified by GWAS studies and miRNA expression profiling might provide additional tools for early disease diagnostics and help to guide treatment options.

Integration of miRNA and mRNA expression profiles in breast cancer identifies prognostic markers and associated pathways. *I. Ragoussis[1], C. Camps[1], L. Winchester[1], H. Gee[2], H. Sheldon[2], M. Taylor[2], A. Harris[2], F. Buffa[2].* 1) Genomic Research, Wellcome Trust Ctr Human Gen, Oxford, United Kingdom; 2) Molecular Oncology, Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, OX3 9DS, United King-dom.

mRNA and microRNA expression profiling plays a key role in tumor classification and the identifi-cation of prognostic markers and therapeutic targets for cancer. Since microRNAs target mRNAs, it is important to explore potential benefits of their joint analysis for enhanced prognostic marker and therapeutic target discovery. Here we performed an integrated data-mining of microRNA and mRNA expression profiles across 219 breast cancers (BCs), including correction for clinico-pathological variability. The approach enabled us to discover microRNAs independently prognostic for distant-relapse free survival after correction for 8 pathway gene signatures (e.g. proliferation, hypoxia, invasion) and clinical covariates (e.g. age, nodal involvement, grade). Twelve microRNAs whose expression was prognostic in either ER+ (3 novel and 1 known - miR-128a) or ER- (7 novel and 1 known - miR-210) BCs were identified. Of the latter, miR-342, -27b and -150 were strongly prognostic in ER-/Her2-/PR- cases. To examine whether prognostic importance of specific microRNAs might be due to function on predicted targets in BC, associations between microRNAs, pathways and targets were examined by global expression analysis. miR-210 and miR-27b fulfilled the strict criteria of an intact microRNA-target-pathway relationship and were selected for further validation. Indeed, expression of miR-210 and -27b predicted targets, was inversely correlated with hypoxia and invasion respectively, and prognostic both in this and 2 large independent BC datasets. Following from the confirmation of the validated miR-210 target ISCU, we provide a number of additional target genes for miR-210 and -27b that give an insight in the mechanisms of miRNA action relevant to disease progression, have prognostic value and could offer new therapeutic approaches.

A urine based microRNAs signature for prostate cancer and benign prostatic disease. *M. Rodriguez-Dorantes[1], I. Sálido-Guadarrama[1], H. Miranda-Ortiz[1], P. García-Tobilla[1], S. Solórzano-Rosales[1], D. Saavedra-Briones[2], G. Morales-Montor[2], M. Sánchez-Alarcón[1].* 1) Del Alvaro Obregon, Natl Inst Genomic Medicine, Mexico DF, Mexico; 2) General Hospital Dr. Manuel Gea Gonzalez, Mexico DF, Mexico.

Prostate Cancer (PCa) is the second cause of death in men in industrialized countries. Serum prostate specific antigen (PSA) remains the only molecular marker used as indicator in the detection and management of PCa, it suffers from low specificity. The most effective therapy is radical prostatectomy and androgen ablation, unfortunately many of these patients cross to androgen independence, developing very aggressive tumors with poor prognosis. The important role of microRNAs (miRNAs) and the consequences of their deregulation in the progression of human cancer have been well established. More recently, high-throughput studies in patients have revealed that altered miRNAs profiling can classify cancers and predict outcome with high accuracy. The aim of this study was to evaluate the potential use of urine miRNAs as possible indicators of prostate disease outcome. Thirty six urine samples were collected from patients diagnosed as either PCA or BPD (benign prostate disease) obtained after Digital Rectal Exam (DRE).Total miRNA extraction was performed using the RNAeasy kit according to manufacturer. RNA quality was verify and RT and preamplification reactions were performed. We measure expression of 667 miRNAs by qPCR. MiRNAs expression was determined using comparative Ct method and P-values <0.05 were considered statistically significant. Data Analysis using DataAssist™ Software revealed differential expression of 29 miRNAs associated with several cancer processes. To improve our analysis we use Bioconductor package. After filtering our initial data set, we found 21 miRNAs that were significatively altered in CaP. Most of these are upregulated and only 2 were found to be downregulated. Hsa-miR-184 and hsa-miR-100 was also up regulated in circulating blood. Hsa-let-7 family members are related with tumor suppressor functions in normal conditions and are down regulated in CaP, however we found over-expression of some let-7 miRNAs (let-7b-c-d-e). Hsa-miR-17 a known oncogene member of mir-17-92 cluster; other miRNAs related to oncogene activity associated with proliferation and growth were observed. hsa-miR-150 is related to oncogen activity and promotes the proliferation and growth of gastric cancer cells. Our data suggest that miRNAs obtained from urine samples could provide a powerful tool at aiding early identification of patients with suspected prostate cancer with a great impact in reducing the number of unnecessary biopsies.

NATURAL ANTISENSE RNAs (NATs) IN THE EPIGENETIC MODULATION OF THE CHROMATIN STATUS. *S. Rossetti, N. Sacchi.* Cancer Genetics Program, Roswell Park Cancer Inst, Buffalo, NY.

It is emerging that natural antisense RNAs (NATs) can induce concerted epigenetic changes and heritable biological phenotypes typically induced by cancer genetic rearrangements. Here we show that stable expression of two NATs, one for the colony stimulating factor 1 receptor (CSF1R) and one for the retinoic acid receptor beta 2 (RARB2), in mammalian cells can induce transcriptional silencing of the respective sense transcripts. Analysis of the chromatin associated with the regulatory regions of both CSF1R and RARB2 shows the acquisition of heritable chromatin repressive marks. The observed loss of function in cells stably expressing the NATs indicates the occurrence of homozygous epigenetic silencing at CSF1R and RARB2 alleles. Interestingly, the same epigenetic changes and biological phenotypes can be induced by repressive chromosome rearrangements involving either AML1, one the CSF1R direct transcriptional regulators, or RARA, the upper regulator of RARB2. This suggests that gene specific NATs are mechanistically implicated in the genesis of epigenetic repression of transcription induced by cancer genetic rearrangements involving either AML1 or RARA.

S100A4 regulates tumor growth, motility, and invasion in pancreatic cancer. *H. Sekine, T. Tabata, N. Tsukamoto, N. Chen, K. Sato, Y. Umetsu, K. Nakamura, G. Kim, A. Yamamura, Y. Yoshino, S. Fukushige, M. Sunamura, A. Horii.* Department of Pathology, Tohoku University School of Medicine, Sendai, Japan.

S100A4 protein belongs to the S100 subfamily, which has grown to be one of the large subfamilies of the EF-hand Ca^{2+}-binding proteins, and overexpression of *S100A4* is suggested to associate with cell proliferation, invasion, and metastasis. We observed frequent overexpression of *S100A4* in pancreatic cancer cell lines by quantitative real-time RT-PCR and Western blotting. Tissue microarray analysis validated S100A4 overexpression in primary pancreatic cancer tissues (48/83, 58%), and overexpression of S100A4 associated with perineural invasion (P = 0.029) and invasion pattern (P = 0.001). We further analyzed RNAi-mediated knockdown to address the possibility of its use as a therapeutic target for pancreatic cancer. After *S100A4*-knockdown, only *S100A4*-overexpressing cells showed induction of G2 arrest and eventual apoptosis, and suppression of cell motility and invasion. Microarray analyses revealed that knockdown of *S100A4* induced upregulation of the tumor suppressor genes *PRDM2* and *VASH1*. We then introduced the *S100A4* gene in pancreatic cancer cell lines with low level of *S100A4* expression and found remarkably accelerated cell growth and motility; no change was observed in the *S100A4*-overexpressing cells. Results of microarray analyses after *S100A4* expression vector-mediated induction in two low level *S100A4*-expressing cells showed 72 and 18 genes that were two fold or more commonly upregulated or downregulated, respectively. Among these, *IFI27* and *NOV* were selected as commonly upregulated genes for further characterization, and the results will be demonstrated and discussed. Our present results strongly suggested that *S100A4* is playing an important role in cell growth, motility, and invasiveness in pancreatic cancer, and that characterization of downstream target molecules will provide further information of progression of pancreatic carcinogenesis which can lead to better clinical management of pancreatic cancer patients.

590/F

Polycomb repression of microRNAs in murine lymphoma. *C. Sugiana, A. Adisa, L. Happo, M. Wakefield, C.L. Scott.* Molecular Genetics of Cancer, Walter and Eliza Hall Institute of Medical Research, Parkville, Victoria 3052, Australia.

Over-expression of polycomb group (PcG) proteins has been observed in a range of human cancers documented to have poor treatment outcomes. PcG genes are conserved from flies to humans, important for development and for stem cell function. Studies in mammalian systems have identified them in protein complexes that silence genes involved in many regulatory processes, such as apoptosis, cellular proliferation and senescence. More recently, PcG proteins have been shown to co-occupy microRNA (miRNA) promoters which are targets of crucial transcription factors during development.

Members of the Polycomb Repressive Complex 1 (PRC1), *Bmi1* and *Cbx7*, have been documented to have direct roles as oncogenes, capable of initiating and potentiating murine haemopoietic malignancies. Bmi1 and Cbx7 repress transcription from the *Cdkn2a* locus (encoding both $p16^{Ink4a}$ and $p19^{Arf}$) and act epistatically to the Arf-p53 pathway during tumorigenesis.

To mimic over-expression of PcG as a late hit in advance grade tumors, we introduced *Bmi1* into established Eμ-myc lymphoma cell lines. We are studying the effects of Bmi1 on response to DNA damaging drugs. We hypothesized that Bmi1 may target microRNA regulating important downstream targets.

However, little is known about miRNA regulation and targets and there is no gold standard method for miRNA expression assessment. Therefore, we trialed several of the latest methods for small RNA isolation, quality assessment and qPCR-based expression analysis to test our hypothesis. Analysis results and strengths/weaknesses of each method will be presented and essential considerations for robust miRNA expression measurement will be discussed.

591/F

P53, p21, MDM2 and p16 protein expression and their relations with p21 polymorphisms and p16 Hypermethylation among the ESCC patients in northeastern Iran. *N. Taghavi[1,2,3], F. Biramijamal[1], MR. Abbaszadegan[4], M. Sotoudeh[3], H. Khademi[3], O. Moaven[4], R. Malekzadeh[3].* 1) Med Gen, NIGEB, Tehran, Iran; 2) Khatam-Al-Anbia hospital, Social Security Organization, Gonbad Kavous, Golestan, Iran; 3) DDRC, Tehran university of medical sciences, Tehran,Iran; 4) Bu-Ali Research Institute,MUMs, Mashhad, Iran.

Backgrounds and Objectives: High incidence and mortality rate of Esophageal Squamous Cell Carcinoma [ESCC] have been reported in the northeastern Iran; however the complex network of molecular alterations underlying the ESCC progression is not clearly elucidated in this reign. Tumor suppressor genes, P53, P21 (waf1/cip1) and P16 INK4a, and the proto-oncogene, MDM2, are considered as the essential G1 cell cycle regulatory genes that loss of their function is associated with ESCC carcinogenesis. Two polymorphisms of p21 gene, (rs1801270) and (rs1059234),as well as, p16 methylation may affect the protein expression and play a role in esophageal cancer susceptibility. The present study was aimed to investigate the expression of p53, p21, p16 and MDM2 proteins in relation to p21 polymorphisms, aberrant methylation of P16 gene, and some possible risk factors, such as cigarette smoking in ESCC patients of northeastern Iran. Methods: The expression of p53, p21, p16 and MDM2 proteins were investigated Immunohistochemically, on paired tumor tissues and available paraffin-embedded blocks of adjacent normal specimens of 126 ESCC patients, along with normal esophageal tissues of 100 healthy subjects. Genotyping of p21 polymorphisms were determined using PCR-RFLP method, and methylation status of the p16 promoter gene, was also assessed with Methylation-Specific-PCR. Result: The over-expression of p53, p21, but not MDM2, as well as p16 under-expression was associated with esophageal squamous cell carcinogenesis, however their expression was not associated with p21 polymorphisms in ESCC patients.On the other hand, P16 methylation was significantly associated with decreased p16 expression (P = 0.03), as well as, p53 over-expression (P = 0.02)in these patients. Furthermore, there was an synergistic interaction between cigarette smoking and either p53 over-expression or p21 polymorphisms in ESCC carcinogenesis. in addition, it has been shown that p21 polymorphisms was not associated with p16 methylation also. Conclusion: Among the population studied in northeaster Iran, our data showed a possible crosstalk between involved molecular mechanisms including p16 methylation and p53 over-expression, as well as a gene- enviroment interaction between cigarette smoking and p21 polymorphisms or p53 over-expression in susceptibility to esophageal squamous cell carcinoma in northeastern Iran.

592/F

Cisplatin resistance in cancer: role of copper pathway genes. *B.D. Teitge, G. Macintyre, D.W. Cox.* Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

There is evidence that the copper transport system plays a role in tumour resistance to cisplatin, a platinum based chemotherapeutic drug. Several copper transport genes have been associated with cisplatin resistance, but the contribution of each is unknown. Five genes proposed to play a role in cisplatin resistance (*ATP7B*, *ATOX1*, *CTR1*, *CTR2*, *COMMD1*) were each cloned into a Chinese hamster ovary cell line at a single location, under the control of a tetracycline-inducible promoter. Each cell line was verified for sequence and integration. Using this controlled expression system, *ATP7B* expression alone was sufficient to confer resistance to copper, and *CTR1* (copper transporter1) expression enhanced cisplatin sensitivity. Surprisingly, overexpression of *CTR2* did not confer resistance to cisplatin, while *ATP7B* (copper ATPaseB, defective in Wilson disease) or *ATOX1* (anti-oxidant protein1) over-expression conferred a minimal increase in resistance to cisplatin. However, combined expression of *ATOX1* and *ATP7B* enhanced resistance to cisplatin, suggesting that these proteins have an additive, though subtle impact on cisplatin resistance. In support of other studies, we conclude that the cisplatin resistance of some tumours is likely determined by the aberrant, or reduced, expression of a single gene, *CTR1*. However, the detection of over-expression of other copper pathway genes, such as *ATP7B*, in a tumour may not fully explain the cisplatin resistance observed. Given this dissimilarity in the transport of cisplatin and copper, we investigated whether cisplatin affects the localization of the copper-dependent transcription factor, ATOX1. Using confocal microscopy and sub-cellular fractionation, ATOX1 was found to undergo nuclear relocalization when activated by copper. Cisplatin reduced the nuclear relocalization of ATOX1. This is the first demonstration that cisplatin might have an antagonistic effect on a copper chaperone, and demonstrates the dissimilarity in cisplatin and copper transport.

NOVEL MLH1 DUPLICATION IDENTIFIED IN COLOMBIAN FAMILIES WITH LYNCH SYNDROME. *C. Trujillo[1], V. Alonso-Espinaco[2], M.A. Giráldez[2], H. van der Klift[3], L. Carvajal-Carmona[4], J. Muñoz[2], F. Balaguer[2], T. Ocaña[2], I. Madrigal[5], I. Tomlinson[4], M. Milà[5], J. Wijnen[3], A. Castells[2], S. Castellví-Bel[2].* 1) Genetics Section, Dr. Erfan & Bagedo General Hospital, Jeddah, Saudi Arabia; 2) Gastroenterology Department, Institut de Malalties Digestives i Metabòliques, Hospital Clínic, CIBEREHD, IDIBAPS, University of Barcelona, Barcelona, Catalonia, Spain; 3) Center for Human and Clinical Genetics, Leiden University Medical Center, The Netherlands; 4) Wellcome Trust Centre for Human Genetics, Nuffield Department of Medicine, University of Oxford, UK; 5) Biochemistry and Molecular Genetics Department, Hospital Clínic, CIBERER, IDIBAPS, Barcelona, Catalonia, Spain.

Lynch syndrome (LS) accounts for 2-3 % of all colorectal cancer (CRC) and it is the most commonly inherited CRC form. Germline mutations in the DNA mismatch repair (MMR) genes MLH1, MSH2, MSH6, PMS2 and EPCAM underlie the majority of cases of LS. Aim: To identify the genetic mutation responsible for LS in an extensive Colombian family and to study its prevalence in this population. Material and methods: A large LS family from Colombia complying Amsterdam criteria II was studied by immunohistochemistry (IHC), and molecular screening of the MMR genes was performed initially by MLPA (multiplex ligation-dependent probe amplification). Results were confirmed by additional independent MLPA, Southern blot and sequencing. Specific mutation screening was developed by a rapid PCR test. Results: Index case tumor IHC results (MLH1-, MSH2+, MSH6+, PMS1-) pointed to a molecular defect in the MLH1 gene. Indeed, the MLPA analysis detected a duplication of exons 12 and 13 of MLH1. Afterwards, this mutation was confirmed by and independent MLPA test and characterized precisely to span 4,219 base pairs (bp) from the 3' boundary of intron 11 to the 5' boundary of intron 13 by Southern blot and sequencing. Furthermore, specific screening for this MLH1 duplication in this family permitted to identify 6 additional carriers and 13 non-carriers of this MLH1 duplication. Also, when screening independent CRC Colombian cases, another carrier family of this same duplication was identified from the same geographical area. Conclusions: A novel duplication of exons 12 and 13 of the MLH1 gene was detected in 2 independent LS families from Colombia. A putative founder effect for this LS mutation in the Antioquia area could be suggested.

594/F

Complex genetics in the original Gardner syndrome kindred 109. *T.M. Tuohy[1], M.W. Done[1], M.F. Leppert[2], R.W. Burt[3].* 1) High Risk Cancers Clinic, Huntsman Cancer Inst, University of Utah Salt Lake City, UT; 2) Department of Human Genetics, University of Utah,Salt Lake City, UT; 3) Department of Medicine, Huntsman Cancer Inst, University of Utah, Salt Lake City, UT.

Familial Adenomatous Polyposis (FAP) is an autosomal dominant colorectal cancer predisposition syndrome characterized by hundreds to thousands of colonic polyps and, if untreated by a combination of screening and/or surgical intervention, a ~99% lifetime risk of colorectal cancer. Additional cancers are also associated with the condition, albeit at lower frequencies. A variant of the condition, historically referred to as Gardner syndrome, is associated with extra-colonic features, notably desmoid tumors, multiple epidermoid cysts, osteomas of the mandible and skull, and dental abnormalities. Since the condition was mapped in the majority of clinically verified families to the *APC* gene, over 900 clinically pathogenic mutations have been identified, and several studies have addressed trends in the available data towards phenotype-genotype correlations. We report genetic lesions in both *APC* and *MUTYH* that segregate through kindred 109, one of the most severely affected FAP kindreds studied to date, originally reported by E.J. Gardner, whose description gave rise to the historically used term Gardner syndrome. Archived samples from the original linkage studies were studied in parallel with recently obtained samples from research participants recruited from clinical services at the Huntsman Cancer Institute, and analyzed for phenotype-genotype correlation. We have used sequence and STR analysis of the *MUTYH* locus, together with archived pedigree information to track the segregation pattern in affected branches of the kindred. In the oldest living generation, both individuals with the *APC* mutation alone died before the age of 30, while 3 out of 4 individuals, ages (70 - 73), with both the *APC* frameshift mutation and the *MUTYH* variant of uncertain significance are still living. However, among the next generation, 1 out of 8 individuals, ages (33 - 48), with the *APC* mutation alone died ate the age of 46, while all 4 individuals, ages (38 - 51), with both the *APC* mutation and the *MUTYH* variant of uncertain significance are still living. This observation contrasts with the observations of Sieber et al (2004) who found that deficiency of *MUTYH* enhanced the tumorigenesis phenotype in Min mice, which, analogous to K109, also harbor a chain-terminating mutation in exon 15 of *APC*. Although preliminary, our results may offer a useful avenue of exploration of a possible interaction between the *APC* and *MUTYH* pathways that differs from the mouse models.

BRCA1/2 mutations in pancreatic cancer patients and their clinical characteristics. *E. Dagan[1,2], R. Epelbaum[3,4], R. Gershoni-Baruch[1,4].* 1) Inst Human Genetics, Rambam HealthCare Campus, Haifa, Israel; 2) Dept of Nursing, Faculty of Welfare and Health Sciences, University of Haifa, Haifa, Israel; 3) Inst of Oncology, Rambam HealthCare Campus, Haifa, Israel; 4) Ruth and Bruce rapoport, Faculty of Medicine, Technion-Inst of Technology, Haifa, Israel.

Background and aim: In Ashkenazi Jews three predominant mutations in BRCA1/2 genes were found, with a frequency of 2-3% in the healthy population, and 20% to 40% in breast and ovarian cancer patients, respectively. The present study aimed to evaluate the frequency and clinical relevance of BRCA1/2 predominant mutations in Ashkenazi pancreatic cancer (PC) patients. Methods: A cohort of 42 PC patients was recruited from the Institute of Oncology at Rambam HealthCare Campus. Of these, 38 [13 (34.2%) females and 25 (65.8%) males] who were of Ashkenazi origin, were included. Following informed consent form, sociodemographic, clinical and health behavior profile were collected at patient-researcher encounter. Data were complemented via the patients' oncology charts, when needed. A blood sample was drawn for the genetic testing. Results: Nine patients (23.7%) were found to carry one of the three predominant mutations in BRCA1/2 genes. Of these, seven carried the 6174delT mutation in BRCA2 gene and two had the 185delAG mutation in BRCA1 gene. Earlier age at diagnosis was noted among mutation carriers compared to non-carriers (58.7years±7.0 and 65.0years±9.8, respectively, p=0.049). Eight (88.9%) PC patients with BRCA1/2 mutations compared to nine (34.6%) non-carriers reported on positive family history of breast, ovarian or pancreatic cancer (p=0.05). Most of the PC patients disclaimed engagement in physical activity (n=25, 65.8%) and 26 (68.4%) were non-smokers. No differences between carriers and non-carriers were found as regards history of heart diseases and diabetes mellitus. Conclusions: Taken together, more than 20% of PC patients of Ashkenazi descent were found to carry a mutation in BRCA1/2 genes, mainly in BRCA2. Mutations in BRCA1/2 constitute a major cause for PC in Ashkenazi Jews and carriers are diagnosed about five years earlier than non-carriers. These findings should be applied to the clinical setting and genetic diagnosis for PC patients and family members at risk is warranted. Furthermore, BRCA2 mutation carriers should be monitored for early detection for PC.

The development of the cutaneous neurofibroma. *E-M. Jouhilahti[1], S. Peltonen[2], T. Callens[3], E. Jokinen[1], A.M. Heape[4], L. Messiaen[3], J. Peltonen[1].* 1) Department of Cell Biology and Anatomy, Institute of Biomedicine, University of Turku, Finland; 2) Department of Dermatology, University of Turku and Turku University Hospital, Finland; 3) Department of Genetics, Medical Genomics Laboratory, University of Alabama at Birmingham, USA; 4) Department of Anatomy and Cell Biology, Institute of Biomedicine, University of Oulu, Finland.

Cutaneous neurofibromas are the hallmarks of neurofibromatosis type 1 (NF1). They are composed of multiple cell types, and are currently believed to arise from small nerve tributaries of the skin. A key finding in the context of this view has been that only subpopulations of tumor Schwann cells harbor bi-allelic inactivation of the NF1 gene (NF1-/-). Our aim was to further elucidate the pathogenesis of cutaneous neurofibromas. Cells expressing biomarkers associated with multipotency were detected in cutaneous neurofibromas. A method for isolating and expanding multipotent neurofibroma-derived precursor cells (NFPs) from dissociated human cutaneous neurofibromas was developed and employed to analyze their growth and differentiation potential. In analogy to solitary cells resident in neurofibromas, NFPs were found to express nestin, and had the potential to differentiate at least to Schwann cells, neurons, epithelial cells and adipocytes. Mutation analysis of the NFPs revealed that their genotype was NF1+/-. The results lead us to speculate that the development of cutaneous neurofibromas includes the recruitment of multipotent NF1+/- precursor cells. These cells may be derived from the multipotent cells of the hair roots, which are often intimately associated with microscopic neurofibromas.

Transcription Independent Over-expression of Insulin-Like Growth Factor II in Adrenal Hyperplasias. *K.S. Nadella, C. Johnson, M.Q. Almeida, L. Isaac, S. Koliavasilis, K. Pfeifer, C. Stratakis.* NICHD, Bethesda, MD.

Insulin like growth factor-II (IGF2), a key regulator of cell growth is tightly regulated in its expression during embryogenesis and normal growth through imprinting. H19 transcript, an untranslated RNA regulates the expression of IGF2. IGF2 and H19 are reciprocally imprinted genes where IGF2 is expressed from paternal and H19 from maternal alleles. Loss of imprinting of IGF2 leading to biallelic expression was reported in many cancers including the adrenocortical tumors. IGF2 binding to IGF type I (IGF 1R) receptor mediates mitogenic and antiapoptotic effects while its binding to mannose 6-phosphate/IGF type 2 (M6-P/IGF 2R),a receptor with tumor suppressor function modulates the levels of IGF2 by targeting it to lysosomes for degradation. Since alterations of IGF2 axis is associated with the pathogenesis and progression of adrenal tumors, we have investigated the expression of IGF2 in three different subsets of human adrenal leisons, namely Massive Macronodular Adrenocortical Disease (MMAD), Cortisol Producing Adenomas (CPA) and Primary Pigmented Nodular Adrenocortical disease (PPNAD), to see if IGF2 is differentially regulated between adrenal hyperplasias (MMAD and PPNAD) and other lesions. Our aim is to determine the utility of IGF2 as a biomarker and a possible therapeutic target to distinguish and treat these disease subsets. Western Blotting analysis from 23 tumor samples revealed over expression of IGF2 protein in 4/6 MMAD, 4/6 CPA and 4/11 PPNAD tumors. Immunohistochemistry further confirmed the tumor specific accumulation of IGF2 protein in cytoplasmic compartment. To investigate the molecular mechanisms responsible for IGF2 over expression we screened samples for loss of imprinting by measuring biallelic expression of IGF2 and H19 transcript through previously reported single nucleotide polymorphisms in IGF2 and H19 genes. We also quantitated total IGF2 mRNA using qRTPCR. We did see loss of imprinting in some samples. However, no correlation was observed between loss of imprinting and total RNA levels and more importantly between IGF2 RNA and protein. Our data therefore suggest a post transcriptional mechanism for IGF2 protein stabilization either through loss of function mutations in IGF2R or in IGF2R binding sites in IGF2 that might have lead to observed accumulation of IGF2 and therefore its availability for enhanced proliferation of adrenal cells. Experiments are on to further address this possibility.

598/F

Non-coding miRNA-141 distinguishes Hashimoto's Thyroiditis and papillary thyroid carcinoma. *E.R. Cantwell, P. Smyth, J.J. O'Leary, O. Sheils.* Department of Histopathology, Trinity College Dublin, Ireland.

MicroRNAs (miRNAs) are small non-coding RNAs approximately 22 nucleotides in length which function as regulators of gene expression. Disregulation of miRNAs has been associated with initiation and progression of oncogenesis in humans. Recently, our group described a unique miRNA expression signature distinguishing papillary thyroid carcinoma (PTC) cells from normal cell lines. The miR-200 family members' miR-141 and miR200a were found to be significantly up-regulated in PTC cells. An investigation into the expression of miRNA-141 in a series of archival thyroid neoplasms (n = 111; classic PTC, follicular variant PTC, follicular thyroid carcinoma (FTC), Hashimoto's thyroiditis, or normal thyrocytes) was performed. Each cohort had a minimum of 20 validated samples surgically excised within the period 1980 - 2009. All samples were derived from the Irish population thereby minimising potential geographical variation. 7μm formalin-fixed paraffin-embedded sections were cut, mounted on slides, deparaffinised and Haematoxylin and Eosin (HE) stained. Laser capture microdissection was used to specifically dissect neoplastic cells from the surrounding tissue. RNA was extracted from the harvested cells and quantitative RT-real time PCR was performed. Comparative CT analysis was applied using RNU6B as an endogenous control. Statistically significant ($p<0.01$) differential expression profiles of miR-141 were found between tissue types. Hashimoto's thyroiditis samples and follicular variant PTC displayed a statistically significant down-regulation compared to both classic PTC and normal thyrocytes. The rate of Hashimoto's thyroiditis in PTC cases has been reported to be between 0.5% and 38%. It is of interest that Hashimoto's thyroiditis thyrocytes, which are postulated by some to be in a stage between normal epithelium and classic PTC, have a significantly altered miR-141 profile compared to both classic PTC and normal thyrocytes. In conclusion, miRNA expression profiles differentiate Hashimoto's thyroiditis thyrocytes from normal and PTC thyrocytes. MiRNAs may act as potential biomarkers for fvPTC in the differential diagnosis of papillary-type thyroid carcinomas.

Identification of the regulatory networks of miR-199a-2 in testicular germ cell tumors. *S. Gu[1], Y.K. Suen[1], H.H. Cheung[1], W.Y. Chan[1,2].* 1) School of Biomedical Sciences, Chinese University of Hong Kong, Shatin, Hong Kong; 2) Lab of Clinical and Developmental Genomics, NICHD, NIH, Bethesda, MD.

Previous studies showed that DNA hypermethylation silences the expression of miR-199a-2 in testicular germ cell tumors (TGCTs), resulting in the overexpression of its target PODXL (podocalyxin-like protein). miR-199a-2 knockin suppressed cell proliferation and migration in vitro and tumor growth and metastasis in vivo. High levels of PODXL are found in several types of tumors. Since it was reported that mammalian miRNAs have an average of 300 conserved targets per miRNA family, it is likely PODXL is not the only target of miR-199a-2 in TGCT. The role of the other targets of miR-199a-2 is not known. To understand the network of genes regulated by miR-199a-2 in TGCTs, proteomics and function genomics analyses of miR-199a-2 knockin TGCT cells (NT2 cells) were performed. miR-199a-2 knockin and vector control NT2 cells were cloned by limiting dilution. Total cellular proteins of the cloned cells were analyzed by two-dimensional gel electrophoresis. A number of proteins up- or down-regulated by miR-199a-2 were identified. These proteins were isolated and further analyzed by mass spectrometry. Differences in gene expression caused by miR-199a-2 knockin were also investigated using expression chips. Among the differentially expressed genes, those of two oncoproteins were found to be down-regulated and those of four tumor suppressors were up-regulated by miR-199a-2. The proteomic and functional genomic data will be collated and the networks comprised by the differentially expressed genes/proteins will be constructed using bioinformatics programs. Results obtained would lead us to understand the pathways modulated by miR-199a-2 that underscore the behavior of TGCT cells.

Inherited polymorphisms in the RNA-mediated interference machinery and microRNA expression in lung cancer. *M. Rotunno[1], Y. Zhao[2], A.W. Bergen[3], J. Koshiol[1], L. Burdette[1], M. Rubagotti[4], R.I. Linnoila[5], F.M. Marincola[6], P.A. Bertazzi[4], N.E. Caporaso[1], L. McShane[2], E. Wang[6], M.T. Landi[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, MD, USA; 2) Division of Cancer Treatment and Diagnosis, National Cancer Institute, NIH, MD, USA; 3) Stanford Research Institute, Stanford, CA, USA; 4) University of Milan, Italy; 5) Center for Cancer Research, National Cancer Institute, NIH, MD, USA; 6) National Institutes of Health Clinical Center, NIH, MD, USA.

MicroRNAs (miRs) are known to have an important role in lung cancer, the largest cause of cancer mortality worldwide. We investigated whether single nucleotide polymorphisms (SNPs) in the RNA-mediated interference machinery involved in miR maturation are associated with lung cancer risk and survival and with miR expression profiles in lung cancer tissue. We analyzed 12 SNPs in the *PolR2A*, *Drosha* and *Dicer* genes (*POLR2A*, *RNASEN* and *DICER1*, respectively) in DNA extracted from blood of 1,984 cases and 2,073 controls from the Environment And Genetics in Lung cancer Etiology (EAGLE) study. In addition, we investigated miR expression profiles in 165 lung adenocarcinoma (AD) and 125 squamous cell carcinoma (SQ) tissue samples from the same population using a custom oligo array. We assessed the association of individual genotypes and of haplotypes with lung cancer risk in the full cohort using unconditional logistic regression models, and with lung cancer-specific survival in patients using Cox regression models. For the lung cancer cases, the associations of the SNPs with miR expression profiles were assessed using two-sample t-tests and global permutation tests were performed to confirm statistical significance of associations with full miR expression profiles. There was no association between SNPs or haplotypes and lung cancer risk overall. However, we identified a haplotype in *RNASEN* that was significantly associated with shorter lung cancer-specific survival (hazard ratio for mortality = 1.86, 95% CI = 1.19-2.92, p-value = 0.007). In addition, a SNP within the same *RNASEN* haplotype was associated with alterations in miR expression profiles in lung adenocarcinoma (global p-value=0.001). The 56 miRs affected by this *RNASEN* variant included miRs known to have tumor suppressor or oncogenic potential or to be associated with survival, such as the let-7 family, miR-21, miR-25, miR-126, miR15a, and others. This study provides the first evidence that inherited variation in the miR-processing machinery might affect miR expression levels and lung cancer-specific survival.

Elucidation of mRNA targets of miR-222 and miR-25 in thyroid cell lines. *P. Smyth[1], S. Aherne[1], L. Smith[2], J. O'Leary[1], O. Sheils[1].* 1) Histopathology, University of Dublin, Trinity College, Dublin, Ireland; 2) Fluidigm Corp., San Francisco, CA, USA.

Thyroid cancer is the most common endocrine malignancy and accounts for the majority of endocrine cancer deaths each year. The majority of thyroid tumours are papillary thyroid carcinomas (PTC) and are well differentiated, indolent and are associated with good prospects of survival. Anaplastic carcinomas (ATC), however, are very aggressive with survival rates of less than one year in most instances. Studies on miRNA expression in PTC have found an aberrant miRNA expression profile in PTCs compared with normal thyroid tissues and have identified certain miRNAs that have become associated with this disease, such as miR-221, miR-222, and miR-146. This study investigated the functional roles of two miRNAs; miR-222 & miR-25 in the context of ATC. To explore this, miRNA mimics and inhibitors were transfected into thyroid cell lines. An unbiased genome wide approach using Affymetrix™ microarrays was utilised to elucidate the mRNA targets of miR-222 & miR-25 in the thyroid cell lines. Statistical analysis of the data produced from these experiments identified almost 100 mRNAs of diverse functions that are that are either directly or indirectly targeted by miR-222 and miR-25. The down-regulation of 23 and 22 mRNA targets in response to miR-25 and miR-222 expression respectively were successfully validated using Fluidigm® real-time PCR technologies. Gene ontology analysis of the miR-25 target gene list showed it to be significantly enriched for genes involved in cell adhesion. The reduction of TRAIL and MEK4 protein expression in response to miR-25 expression was validated using western blots. The gene targets of these two miRNAs provide an interesting insight into their possible roles in thyroid cancer progression.

Interaction of a BAR Adapter Protein, Bin1, with Ku Affects the Maintenance of Telomere Length and Cancer Development. *A. Ramalingam[1], J.B. DuHadaway[1], P.S. Donover[1], G.C. Prendergast[1,2,3].* 1) Lankenau Institute for Medical Research, Wynnewood, PA; 2) Department of Pathology, Anatomy & Cell Biology; 3) Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA.

Ku70 and Ku80 together form one of the essential complexes that cap telomere ends and are central to the nonhomologous end joining (NHEJ) DNA repair pathway. Recently we showed that a murine BAR adapter protein, Bin1, physically interacts with Ku70/Ku80 in an *in vitro* protein-protein interaction assay. Bin1 ablation in mouse mammary glands delayed tissue modeling and drove cancer progression, and mice mosaic for *Bin1* showed increased susceptibility, particularly to lung cancer. Keratinocyte epithelial cell lines deleted for *Bin1* showed increased tumorigenicity in syngeneic mice. Absence of *Bin1* rendered the cells less susceptible to etoposide, a topoisomerase II inhibitor, but did not affect the sensitivity of the cells to similar double strand break(DSB)-causing other chemical agents or γ-irradiation. This etoposide-resistance of *Bin1* deletion could not be explained by change in Ku localization, change in DSB formation nor by a change in drug uptake by endocytosis. However, presence of *Bin1* resulted in decreased NHEJ repair in a plasmid-based assay. More importantly, deletion of fission yeast homologue of *Bin1* resulted in telomere lengthening. It is well known that alterations in telomere length lead to chromosomal aberrations and eventually to the development of cancer. Using *Bin1* null keratinocytes and siRNA and overexpression experiments, we plan to look at the telomere length maintenance in a mammalian system to help explain the tumorigenic ability of *Bin1* null cells in the absence of altered telomerase activity. Also, there is evidence suggesting a link between telomere length and fecundity. One of the notable phenotypes of *Bin1* mosaic null mice was extended female fecundity. Altered telomere length due to the lack of Bin/Ku interaction might explain the extended period of fecundity in those mice.

603/F

Germline *SDHC* whole-gene deletion in a patient with malignant extra-adrenal pheochromoctyoma: reconsideration of clinical testing strategy. *J. Moline[1,2], J.L. Chen[1,2], C. Eng[1-3].* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH; 2) Lerner Research Institute, Cleveland Clinic, Cleveland, OH; 3) Taussig Cancer Institute, Cleveland Clinic, Cleveland, OH.

Approximately 25% of incident pheochromocytoma (PC) and/or paraganglioma (PGL) patients have been found, in a population-based study, to carry germline mutations in the genes responsible for multiple endocrine neoplasia type 2 (*RET*), von Hippel-Lindau disease (*VHL*) and hereditary PC-PGL syndrome (*SDHB, SDHC, SDHD*). *SDHB* and *SDHD* mutations account for the majority of those with heritable PGL. Those who are found to have an *SDHB* mutation typically have extra-adrenal PC, with the prevalence of malignancy in population-based studies being 14-35%. While *SDHD*-related PGL can be malignant, the rate is much lower than for *SDHB*. Because *SDHC* has never been associated with malignant PC, and typically characterized by benign unilateral head and neck PGL, *SDHC* testing is not clinically considered in the setting of malignant PC. A 49-year-old white female presented to the emergency room with severe abdominal pain, which may have been related to a viral illness. However, on further investigation, masses of the retroperitoneum, iliac wing, and sacrum were detected on CT scan. Pelvic bone biopsy revealed metastatic PGL. Plasma norepinephrine was elevated at 16,260 pg/ml (ref 80-520) and dopamine 52 pg/ml (ref 0-20). Past medical and surgical history was significant for hypertension, palpitations, sweating, and hypertensive crisis during total abdominal hysterectomy for uterine fibroids one year earlier. Family history was negative for PC and PGL. Given the finding of an extra-adrenal malignant pheochromocytoma in the patient, clinical *SDHB* sequencing was pursued, but only a SNP was found (c.765+29G>A). We performed mutation and large rearrangement analyses for *SDHB*, *SDHC*, and *SDHD*, as well as 2 newly identified PC/PGL predisposing genes, *SDHAF2*, and *TMEM127*. No sequence variations or large rearrangements were detected in *SDHD*, *SDHAF2*, or *TMEM127*. While we detected the *SDHB* IVS7 SNP, we also found a heterozygous *SDHC* deletion encompassing exons 1 through 6. While deletions of 1 or 2 *SDHC* exons have been described in patients with PC/PGL, this represents the first report of a patient with a whole gene deletion of *SDHC*. Notably, this patient is also the first known to have a malignant abdominal pheochromocytoma in the setting of a germline *SDHC* mutation. Our observations suggest that *SDHC* analysis, including for large deletions, may be considered following negative *SDHB* and *SDHD* testing for patients with malignant extra-adrenal pheochromocytoma.

604/F

The familial association of multinodular thyroid goiter with ovarian Sertoli-Leydig cell tumors is attributable to germ-line DICER1 mutations. *M. Tischkowitz[1,2,3], A. Bahubeshi[1,2,3], M. Niedziela[4], N. Sabbaghian[1,2,3], T. Rio Frio[2, 5], N. Hamel[2,5], C. Pouchet[1,2,3], L. Gilbert[6], P.K. O'Brien[7], K. Serfas[8], P. Broderick[9], R. Houlston[9], F. Lesueur[10], E. Orsola-Malpighi, via Massarenti 9, 40138 Bologna, Italy; 12) Division of Endocrinology, Metabolism and Genetics, Internal Medicine Department, University of Kansas Medical Center, Kansas City, KS, USA; 13) Department of Pathology, CHU Sainte-Justine, 3175 Chemin de la Côte-Ste-Catherine, Montréal, Québec H3T 1C5, Canada; 14) Department of Pathology, McGill University, Montreal, Quebec, Canada; 15) Children's Hospital and Clinics of Minnesota, St. Paul, Minnesota, USA; 16) The International Pleuropulmonary Blastoma Registry, St. Paul, Minnesota, USA.

BACKGROUND Sertoli-Leydig Cell Tumors of the Ovary (SLCTO) are rare tumors which occur in the second and third decades. Familial cases have been described, usually in the context of multinodular goiter (MNG). Germline mutations in DICER1, a gene that codes for an RNase III endoribonuclease, have recently been identified in children with pleuropulmonary blastoma (PPB), some of whom have a family history of MNG and gonadal tumors including SLCTO. DICER1 is involved in the generation of small double-stranded microRNAs and endogenous small interfering RNAs from long double-stranded substrates. Given the tumor spectrum of PPB families and the heterogeneous functions of DICER1 we hypothesized that DICER1 mutations could be responsible for previously reported SLCTO/MNG families. METHODS We ascertained three cases of familial MNG/SLCTO and screened affected probands for mutations in the DICER1 gene by high-resolution melt analysis. We investigated the ovarian tumors from these probands for loss of heterozygosity and protein expression by immunohistochemistry (IHC). RESULTS We identified truncating DICER1 mutations in all three families. Analysis of the ovarian tumors showed no loss of heterozygosity. In all three SLCTO arising in DICER1 mutation carriers, IHC analysis showed increased expression of DICER1 in Sertoli cells, but not in Leydig cells. CONCLUSION The identification of DICER1 mutations in familial MNG in association with SLCTO explains an observation first made by Fraumeni and colleagues 36 years ago. In addition, this report shows that DICER1 mutations predispose to both MNG and SLCTO independently of PPB. The median age at diagnosis of SLCTO in three cases with mutations was 18 years, which falls between the average age of onset of 25 years in sporadic SCLTO and the median age at diagnosis of eight years in PPB-associated SLCTO. None of the DICER1-related tumors showed evidence of LOH, and even though the numbers are small it seems likely that DICER1 does not function as a classic tumor suppressor gene, but it may instead be that the tumors develop as a result of miRNA dysregulation through a possible haploinsuffiency effect.The IHC results underscore the seemingly complex staining pattern of DICER1 protein expression in DICER1-asssociated tumors seen in PPB tumors arising in DICER1 mutation carriers where DICER1 expression was lost in tumor-associated epithelium but was retained in the mesenchymal tumor cells.

605/F

The incidence of breast cancer in women with Neurofibromatosis type 1: a cohort study in Detroit metropolitan area. *X. Wang[1], A.M. Levin[2], F.D. Vigneau[3], N.K. Levin[4], M.A. Tainsky[4].* 1) Dept Medical Genetics, Henry Ford Health System, Detroit, MI; 2) Department of Epidemiology and Biostatistics, Henry Ford Health System, Detroit, MI; 3) Epidemiology Unit Metropolitan Detroit Cancer Surveillance System, Surveillance, Epidemiology and End Results (SEER) Program, Wayne State University School of Medicine, Detroit, MI; 4) Program in Molecular Biology and Genetics, Karmanos Cancer Institute, Wayne State University School of Medicine, Detroit, MI.

Neurofibromatosis type 1 (NF1) is one of the most common cancer predisposition syndromes with an incidence of 1 in 3,500 worldwide. Its clinical expression and severity is highly variable. Certain neoplasms or malignancies are over-represented in NF1. They include gliomas, neurofibromas, malignant peripheral nerve sheath tumors, gastrointestinal stromal tumors, pheochromocytomas, rhabdomyosarcomas, and chronic juvenile myelocytic leukemia. The disease is caused by mutations in the NF1 gene, which encodes neurofibromin. Neurofibromin is a tumor suppressor which down-regulates the Ras signaling pathway. Previous studies with small sample size or death certificate-derived Multiple-Cause Mortality Files failed to reveal an increased risk of breast cancer. However, in 2007, Sharif investigated 304 women from the NF1 genetic registry in the U.K. and described a 4.9-fold increase in breast cancer among women with NF1 under age 50. Henry Ford Health System (HFHS) has a long history of providing specialty care for NF1 patients in the Detroit Metro area. We have collected information from 81 women with NF1 seen in HFHS from 1985 to 2009. These cases were linked to the Surveillance Epidemiology and End Results (SEER) registry covering the Metropolitan Detroit Area. Fifty six women (69%) were under age 50. Six women (7.4 %) developed invasive breast cancer before age 50. One of them was diagnosed with one local and one regional stage primary invasive breast cancers. Three women developed invasive breast cancer after age 50. One of these patients was diagnosed with one local and one regional stage primary cancers. In addition, one woman was diagnosed with three primary ductal carcinoma in situ (DCIS) cancers in her 40s. Two women over age 50 were also diagnosed with DCIS. The probability for women in the general population to develop breast cancer by age 50 in the U.S is only 1.9. Using standardized incidence ratios (SIRs) calculated based on the SEER age-adjusted invasive breast cancer incidence rates, our findings demonstrated a statistically significant increase of breast cancer incidence occurring in NF1 women under age 50, which is comparable to the Sharif study and supports the hypothesis that women with NF1 have an increased risk of developing breast cancer at a younger age. The higher incidence is most significant in the women between age 30 and 39 in our cohort.

606/F

C-MYC and IGH Amplification In a Patient With Burkitt-Like Lymphoma. *A.L. Zaslav[1], S. Saferali[2], M. Bellone[3], F. Lan[2], B. Kiner-Strachan[2], Y. Hu[3], T. Ahmed[3], T. Mercado[1], R. Ponce[1], E. Knorr[1], H. Lee[1], D. Tully[1], G. Evans[1], M. Schuster[2].* 1) Department of Pathology, Cytogenetics Laboratory, Stony Brook University Medical Center, Stony Brook, NY; 2) Blood and Bone Marrow Stem Cell Transplantation Program, Stony Brook University Medical Center, Stony Brook, NY; 3) Department of Pathology, Stony Brook University Medical Center, Stony Brook, NY.

Gene amplification and the subsequent over expression of the amplified oncogene play an important role in tumor pathogenesis. Here, we present a 68 year old female patient with Burkitt-Like Lymphoma (BLL) with amplification of the C-MYC oncogene without the t(8;14)(q24;q32) or its variants and amplification of IGH. Standard chromosome analysis was performed on bone marrow (BM). FISH using the LSI IGH (14q32)/BCL2 (18q21) Dual Color probe and the LSI IGH/MYC/CEP 8 Tri Color probe was performed on BM and a lymph node biopsy. BM analysis revealed a normal 46,XX female karyotype in 19 metaphases. BM FISH demonstrated a normal signal pattern for both probes in 200 of 200 nuclei each. FISH results on the lymph node biopsy demonstrated a signal pattern consistent with a t(14;18)(q32;q21) in 91.5% of the nuclei, 3~4 copies of C-MYC (8q34) and 3 copies of IGH (14q32) in 24.5% of the nuclei. This patient had BLL with areas of the tumor that were consistent with follicular lymphoma (FL). The presence of the t(14;18)(q32;q21) confirmed the FL population. Our patient also had amplification of both C-MYC and IGH without the t(8;14)(q24;q32) or its variants. The significance of the IGH amplification to our knowledge is not known. Patients with BLL with a t(14;18)(q32;q21) and C-MYC amplification are rare and have been a poor prognosis. It is possible that this group of patients may represent a distinct morphologic subtype of BLL. FISH analysis for C-MYC amplification in these patients would be useful in the treatment and monitoring of their clinical course. Our patient will be carefully monitored and treated aggressively to prevent disease progression. Further studies are necessary to determine the significance of these findings.

Hereditary diffuse gastric cancer (HDGC) associated with a novel truncating *CDH1* mutation: Possible association with non-Hodgkins lymphoma (NHL). *J. Horn[1], S. Modesitt[2].* 1) Cancer Center, University of Virginia Health System, Charlottesville, VA; 2) Division of Gynecologic Oncology, Department of Obstetrics and Gynecology, University of Virginia Health System, Charlottesville, VA.

Background: Hereditary diffuse gastric cancer (HDGC) is associated with mutations in the *CDH1* gene. Outside of lobular breast carcinoma, the occurrence of other extra-gastric tumors associated with *CDH1* mutations is not well-established. We report here a family found to carry a novel truncating *CDH1* mutation in which an atypical constellation of malignancies has arisen. Case: The female proband had previous diagnoses of breast cancer (confirmed pleiomorphic lobular) and non-Hodgkins lymphoma (NHL); notably, her mother was also diagnosed with both breast cancer and NHL. In addition to the mother-daughter pair above, the family reported a nephew to the mother who was also diagnosed with NHL. The known tumor spectrum in the family includes gastric, breast, genitourinary, and skin cancers, as well as NHL. Methods/Results: Due to the strong family history of breast cancer, *BRCA* mutation testing was performed first via Myriad Genetic Laboratories and no mutation was identified; large rearrangement testing, bar the standard 5-site mutation panel in *BRCA1*, was not performed. Subsequently, *CDH1* mutation testing on the proband was carried out through the City of Hope Molecular Diagnostic Laboratory. A frameshift mutation was identified which should give rise to a truncated E-cadherin protein lacking the evolutionarily conserved cytoplasmic domain. Conclusions: In this family, two women (one with a confirmed *CDH1* mutation and one obligate carrier) and a man who is at 50% risk to have inherited the *CDH1* mutation all carried diagnoses of NHL. Other cancers atypical for HDGC occurring in the family in possible or obligate *CDH1* mutation carriers include a bladder cancer, as well as another bladder or kidney cancer. We therefore postulate an association between HDGC and NHL, and perhaps other extra-gastric cancers. NHL has been reported in at least one other HDGC family, though this was a solitary gastric lymphoma that occurred concurrently with diffuse gastric cancer; the authors attributed the NHL to *H. pylori* infection. The single occurrence within that family limits the clinical interpretation of whether the NHL occurred as a manifestation of HDGC. However, the presence of three cases (two in either confirmed or obligate mutation carriers) in our HDGC family supports the possibility of NHL as a component tumor of HDGC and merits further exploration.

History of Cancer in Nineteen Consecutive Pedigrees with Schwannomatosis. *N. Shah[1], R.J. Spinner[2], D. Babovic-Vuksanovic[1].* 1) Medical Genetics, Mayo Clinic, Rochester, MN; 2) Neurosurgery, Mayo Clinic, Rochester, MN.

INTRODUCTION: Schwannomatosis is a rare genetic disorder that must be distinguished from neurofibromatosis type II (NF2), with which it shares its characteristic benign peripheral nerve sheath tumors. It is a tumor predisposition syndrome, in which candidate genes recognized to date implicate tumor suppressor pathways. It may be associated with hitherto unidentified risk of malignancy that may warrant specific surveillance or prophylactic interventions. However, risk for development of tumors other than schwannoma and meningioma in patients and their relatives is not known. METHODS: We reviewed the records of all patients with schwannoma evaluated in our department between May 1998 and April 2010. We excluded all patients with clinical features or family history of NF2. We found 31 unrelated individuals with at least one histologically confirmed schwannoma. NF2 mutation assay was performed on blood and/or tumor in 7 of these 31 with all results negative. None had a relative independently meeting schwannomatosis diagnostic criteria due to unknown vestibular imaging status. Of the 31, 26 had 2 or more non-intradermal schwannomas. 21 of these 26 had magnetic resonance imaging (MRI) confirming no vestibular involvement. 2 of these 21 were under age 30, and 4 of the remaining 5 without MRI were over age 45 but had no signs or symptoms of 8th nerve dysfunction. This left 19 'definite' (12/19 male, 63%) and 6 'possible' cases (2/6 male, 33%). We analyzed their pedigrees for the presence of cancer. RESULTS: Amongst the 19 definite cases, average age of onset of schwannomatosis symptoms was 36 years. 3 individuals had associated malignancy. 1 Ewing's sarcoma diagnosed age 12, 1 breast cancer diagnosed age 64 and 1 patient with several metachronous squamous and basal cell skin cancers at separate sites at unknown ages. Of the 6 possible cases, average age of onset of schwannomatosis symptoms was 31 years and there was no primary malignancy noted to the time of last follow-up. Family history of 1st or 2nd degree relatives of the definite cases revealed 15 primary malignancies in 14 individual relatives that occurred prior to 60 yrs. Similar evaluation of the possible cases revealed 8 primary malignancies in 8 individual relatives. CONCLUSION: Risk of malignancy in schwannomatosis patients and their relatives may be increased but further studies are needed to delineate the magnitude of this risk before recommending preventative management.

609/F

Increased Prevalence of Non-Clear Cell Renal Cell Carcinoma in PTEN Hamartoma Tumor Syndrome. *J. Mester[1, 2], L. Rybicki[2, 3], C. Eng[1, 2].* 1) Genomic Med Inst, Cleveland Clinic, Cleveland, OH; 2) Taussig Cancer Institute, Cleveland Clinic, Cleveland, OH; 3) Quantitative Health Sciences, Cleveland Clinic, Cleveland, OH.

PTEN Hamartoma Tumor Syndrome (PHTS) is a multi-system autosomal dominant disorder causing increased risks for several benign and malignant neoplasias. PHTS includes patients with Cowden syndrome (CS) and Bannayan-Riley-Ruvalcaba syndrome (BRRS) found to have a germline mutation of the PTEN tumor suppressor gene. Diagnostic criteria for CS have been developed which includes renal cell carcinoma (RCC) as a minor feature. Yet, the National Comprehensive Cancer Network (NCCN) recently deleted awareness or screening for RCC in their most recent CS management guidelines. Somatic PTEN loss-of-function is an important step in sporadic renal carcinogenesis, and a few case reports reveal mostly clear cell RCC in PHTS patients. However, the prevalence of RCC and precise pathologic sub-histologies have not been formally studied. In our series of 155 PTEN mutation-positive subjects recruited by relaxed International Cowden Consortium criteria or presence of a known germline PTEN mutation, we identified 6 patients diagnosed with RCC: 2 males (ages 11 and 53) and 4 females (ages 44, 45, 58, and 64). Based on SEER data, 0.0164 RCC cases were expected for the total group, giving a Standardized Incidence Ratio of 365.9 (95% CI 148.3-760.9, $p<0.001$). Mutations included 2 frameshift, 3 nonsense (R130X, 2 R335X), and a missense (D24H). All RCCs were unifocal with no RCC-related metastases or deaths. Histology was variable and complex: 3 patients had papillary lesions, one with focal clear cell features; 2 had clear cell RCC, 1 one of which also had granular histology and the other with tubular, trabecular, and papillary features; and the last had a concurrent mucinous and spindle cell RCC. Family history was negative for other relatives with RCC. Given that papillary RCC makes up only 10-15% of all RCC cases in the general population, the relative prevalence of this histology in this patient group is notable and should prompt clinicians to place PHTS on the differential diagnosis list for patients with a personal or family history of papillary RCC. We recommend that physicians caring for patients with PHTS remain mindful of the >350-fold increased risk for RCC and have a low threshold for investigating possible RCC in PHTS patients with relevant complaints. Renal ultrasound is not sensitive for detecting papillary RCC compared to clear cell RCC and so PHTS patients should have alternate renal imaging (CT or MRI).

610/F

Characterization of *BRCA1*-deficient breast cancer transcriptomes by RNA-Seq reveals novel transcript isoforms. *E. Lalonde[1,2,3], K.C.H. Ha[1,2], L. Li[1,3,4], W.D. Foulkes[1,3,4,5], J. Majewski[1,2].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Genome Quebec Innovation Center, McGill University, Montreal, Quebec, Canada; 3) Program in Cancer Genetics, Departments of Human Genetics and Oncology, McGill University, Montreal, Quebec, Canada; 4) Lady David Institute for Medical Research and Jewish General Hospital, Montreal, Quebec, Canada; 5) Research Institute of the McGill University Health Center, Montreal, Quebec, Canada.

Next-generation RNA sequencing (RNA-Seq) characterizes the transcriptome at an unprecedented single-base resolution. Producing massive amounts of sequencing data, RNA-Seq presents significant computational challenges and requires novel strategies to efficiently extract information from the data. In particular, RNA-Seq can reveal novel transcript isoforms arising from aberrant alternative splicing which is known to contribute to cancer pathogenesis. Here, we use RNA-Seq (Illumina Genome Analyzer II) to characterize the transcriptomes of five *BRCA1*-deficient breast cancer samples. A matched lymphoblastoid cell line and a normal breast epithelial cell line are used as controls. We present examples of novel alternative splicing events (ASEs) distinguishing the *BRCA1* breast cancer transcriptome.

We detected ~1500 ASEs that are not annotated in the RefSeq or UCSC databases and that are expressed 10-fold higher in at least two of our breast cancer samples compared to the control samples. Over half of these ASEs are exon skipping events and over a third provide evidence for new exons. A promising example found in four of the samples involves skipping of exon 12 in *PALB2* leading to a frameshift, a premature termination codon and obliteration of a WD40 domain. Of interest, the WD40 domain is essential for binding BRCA2, cell cycle control and apoptosis. We have also identified an unannotated exon in *POLB*, an important gene in base excision repair. This ASE has previously been described by others as an infrequent event yet it is highly expressed in four of our *BRCA1*-deficient samples and in some cases has higher expression than the wildtype isoform.

We have described the transcriptomic landscape of *BRCA1* breast cancers. In addition to an in-depth analysis of alternative splicing, our group has identified various recurrent, unannotated genomic variations, such as SNVs and indels, as well as several gene fusions, the result of genomic rearrangements. These results provide a comprehensive overview of breast cancer transcriptomes and shed light into characterizing important pathways involved in its tumorigenesis. Furthermore, our findings will help increase our knowledge of *BRCA1* related mechanisms as we shift towards personalized medicine diagnosis and treatment. Finally, we demonstrate that RNA-Seq is effective in revealing various transcript abnormalities in cancer.

Identifying Novel Expressed Gene Fusions in MCF-7 Cell Line Using Next Generation Sequencing. *O. Sakarya[1], H. Breu[1], L. Popescu[1], M.W. Muller[1], P. Vatta[1], B. Krishnaswami[1], G. Ojewole[1], A. Wong[1], N. Garg[1], Y.N. Wang[1], J.P. Bodeu[1], R.C. Nutter[1], M. Mooney[1], J.P. Brockman[2], P.P. Whitley[2], K.S. Bramlett[2], M. Radovich[3], A.S. Siddiqui[1], F.C. Hyland[1].* 1) Biological Information Systems, Life Technologies, Foster City, CA; 2) Ambion R&D, Life Technologies, Austin, TX; 3) Indiana University School of Medicine, Indianapolis, IN.

Chromosome aberrations, especially gene fusions, are implicated in the initiation of tumorigenesis. Various gene fusions are important diagnostic and prognostic indicators in leukemia, sarcomas, and other solid tumors. High throughput RNA sequencing (RNA-Seq) allows characterization of gene expression and of exon splicing patterns of expressed transcripts. We developed a new junction finder algorithm in order to identify and quantify exon splicing events using paired end RNA-Seq. With this algorithm, the single read and paired end splice junction evidence are stored in directed splicing graphs. Using these splicing graphs, we investigate the splicing patterns in two MicroArray Quality Control (MAQC) samples, and in the breast cancer cell line MCF-7. We sequenced 129,950,066 and 113,147,501 uniquely mapped pairs of RNA-seq reads from the MAQC samples Human Brain Reference (HBR) and Universal Human Reference (UHR). Compared to RefSeq annotations, we found 136,671/14,271 and 138,536/14,083 known/putative exon junctions in UHR and HBR, respectively. We further compared the sequencing depth required to distinguish low-expressed variants by progressively mapping barcoded libraries and report that ~70% of alternative splicing events were accessible with ~20,000,000 and ~82% with ~40,000,000 qualified read pairs. The remainder of the junctions were detectable only at higher depth. Of the 36 fusion junctions called for UHR, we verified 16 with TaqMan assays including the known BCR-ABL and GAS6-RASA3 fusions. Next, we sequenced the breast cancer cell line MCF-7, obtaining 192,246,750 uniquely mapped pairs of RNA-Seq reads. We identified 123,386 known and 17,317 putative junctions, and we called 60 fusions, of which 10 were between genes from different strands or chromosomes. These included the recently discovered MCF-7 fusions BCAS4-BCAS3, ARFGEF2-SULF2, AHCYL1-RAD51C, ABCA5-PPP4R1L and TBL1XR1-RGS117. We detected five other novel fusions at lower expression levels which are undergoing validation. These novel fusions suggest enrichment in the number of translocation events between Chromosomes 1, 17 and 20 during the evolution of the MCF-7 genome. We report thousands of previously unknown splicing events including five novel gene fusions in a breast cancer cell line. Easy and low-cost genome-wide detection of novel gene fusions allows interrogation of large numbers of tumor samples and discovery of biologically important gene fusions.

Identifying determinants of tumorigenesis and drug resistance from comprehensive exome DNA and RNA sequence of major breast cancer cell lines. *R.J. Cho[1,2], S. Durinck[2], N.J. Wang[2], J.W. Gray[2], P.T. Spellman[2].* 1) Dermatology, UCSF, San Francisco, CA; 2) Division of Life Sciences, Lawrence Berkeley National Laboratories, Berkeley, CA.

Individual cell lines have long provided stable, ontogenic models of tumorigenesis and drug resistance for diverse cancer types. To date, the lack of comprehensive, detailed sequence information has greatly limited the ability to link specific mutations and pathways to phenotype. We have completed both DNA sequencing of all coding sequence and digital RNA sequencing of transcripts in 40 of the most commonly studied breast cancer cell lines. Our results clarify the relationships between established oncogenes and molecular subclasses of breast cancer. Through structural and gene expression analysis of mutations, we propose a hierarchy of candidate drivers validated in sequencing of primary breast cancers. Finally, we report on silencing of a subset of these candidates, toward functionally validating their roles in tumorigenesis.

BRCA2 mutation analysis in familial and early onset prostate cancer. *C. Maier[1,2], I. Wiest[2], M. Luedeke[1,2], K. Herkommer[3], A. Rinckleb[1,2], H. Surowy[2], M. Schrader[1], W. Vogel[1,2].* 1) Urologische Klinik, Univ Ulm, Ulm, Germany; 2) Istitut fuer Humangenentik, Univ Ulm, Ulm, Germay; 3) Urologische Klinik, Klinikum rechts der Isar, Munich, Germany.

Although prostate cancer (PCa) is known for the highest heritability (42%) among common cancers, its genetic background is the least clarified and thus, the practice in genetic screening is the most backward. To date, the strongest known PCa risk is caused by the BRCA2 gene, as described for male mutation carriers within breast and ovarian cancer families. Studies in prostate cancer cohorts have further demonstrated more aggressive forms of PCa with an earlier onset and shorter survival for BRCA2 mutation carriers. In order to assess the role of BRCA2 in PCa cases from families without the strong hereditary breast and ovarian cancer history, we have started mutation analysis on probands that were recruited solely on the criterium of PCa familial clustering. The full family sample comprises 379 pedigrees with a total number of 1073 affected men (2.8 per family), for which at least one affected individual has donated blood. Presently, 284 probands have been screened, each as the youngest diseased case of 284 pedigrees. As an early onset group, 96 sporadic PCa cases were included with an age of 60 years or younger at the time of diagnosis (mean: 55.7; range: 29 - 60 years). In the total number of 380 cases sequenced for mutations, five (1.32%) were found to carry truncating BRCA2 variants, three frameshift (c.1813insA, c.3847insGT and c.4449delA) and two nonsense (K2013X and Q2499X) mutations. Further six rare alleles, which could influence splicing (IVS2-7T>A), or functionally alter the peptide sequence (P655R, K1025E, S2697N, E2981K and I3412V), remain as variants of unknown significance after literature and database search. The mutation frequency, as compared to the estimates of 0,1 - 0,7% for the general population, seems elevated in our probands with familial PCa (5 out of 284; 1.76%) and in probands with aggressive disease (4 out of 184; 2.17%). The carrier frequency could be enriched to 4.0% (3 out of 75) in a subgroup of probands where at least two relatives exhibited aggressive PCa. Early age of onset seemed not relevant in our cohort. Although BRCA2 turned out to be responsible for PCa clustering in particular families, and probably for a more severe manifestation, predictive testing would require additional inclusion criteria (e.g. family history of breast and ovarian cancer) in order to identify a significant number of BRCA2 mutation carriers at PCa risk.

614/F

Understanding the role of the JAK2 susceptibility haplotype in myeloproliferative neoplasms (MPN) phenotype and predisposition using targeted next generation sequencing. *S. Mukherjee[1,2], O. Kilpivaara[3], H. Hunter-Zinck[6], A. Viale[5], N.D. Socci[4], R.L. Levine[3], R.J. Klein[1].* 1) Cancer Biology and Genetics Program, Memorial Sloan-Kettering Cancer Cancer Center, New York, NY; 2) Gerstner Sloan Kettering Graduate School of Biomedical Sciences, New York, NY; 3) Human Oncology and Pathogenesis Program, Memorial Sloan-Kettering Cancer Center, New York, NY; 4) Computational Biology Center, Memorial Sloan-Kettering Cancer Center, New York, NY; 5) Molecular Biology Program, Memorial Sloan-Kettering Cancer Center, New York, New York; 6) Program in Computational Biology and Medicine, Cornell University, Ithaca, NY.

Myeloproliferative neoplasms (MPN) is a clonal disorder of hematopoietic lineage. There are three types of MPN- polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF). The somatic mutation JAK2 (V617F) is present in hematopoietic cells of many MPN patients. In our previous genome-wide study, we (and others) have identified an allele at the JAK2 locus (rs10974944) that predisposes to the development of JAK2 (V617F)-positive MPN. We also found that JAK2 (V617F) is preferentially acquired in cis with the predisposition allele (G). This led to several possible hypotheses including haplotype-specific variation in a regulatory motif, genotype-specific splicing, or an increased mutation rate at this locus. To dissect the functional variant(s) and to understand the haplotype-specific acquisition of somatic mutation, we carried out targeted sequencing of 300KB haplotype block harboring JAK2 using next generation sequencing technology (RainDance and SOLiD sequencing). We compared MPN cases that are homozygous for risk allele (GG-MPN cases) with the ones that are homozygous for wild type allele (CC- MPN cases). We found that GG-MPN cases have significantly higher number of single nucleotide variants in the JAK2 locus compared to CC-MPN cases. We observed the same pattern in healthy individuals with whole genome sequencing data published by 1000 genomes project and others. We looked into the selection pressure at JAK2 locus to determine if purifying or positive selection is influencing the observed haplotypic differences of single nucleotide variants. To identify the functional variant(s) that results in haplotype-specific mutation acquisition in MPN cases, we are analyzing sequence specific differences (such as motif / regulatory elements) between these two groups of patients. Our study is helpful to understand the etiology of MPN phenotype and predisposition.

615/F

Targeted Resequencing for SNP Discovery using Massive Single-Plex PCR and Next Generation Sequencing. *C.M. Robbins[1], E.M. Lange[2], W. Tembe[3], A.M. Ray[4], K.A. Zuhlke[4], W. Isaacs[5], K.A. Cooney[4], J.D. Carpten[1].* 1) Integrated Cancer Genomics Div, TGen, Phoenix, AZ; 2) Department of Genetics, University of North Carolina, Chapel Hill, NC; 3) High-Performance Bio-Computing Division, TGen, Phoenix, AZ; 4) Department of Internal Medicine, University of Michigan Medical School, Ann Arbor, MI; 5) Johns Hopkins University School of Medicine, Baltimore, MD.

Recent advances in Next Generation Sequencing (NGS) afford new opportunities for large scale SNP discovery across the entire human genome. However, there is also a need to search for variants within specific intervals of the genome. Several methodologies have been developed for reducing genomic complexity to allow for more targeted resequencing. Among these methods is the RainDance picoliter massive single-plex PCR assay, which provides the capability to assess up to 10,000 independent amplicons in a single reaction. To test the feasibility of utilizing this method for variant discovery, we designed a RainDance PCR assay containing 3,148 amplicons, which encompass a total of 2,328 exons from 221 genes predominantly across the 17q21-22 region of the human genome that showed evidence of being associated with hereditary prostate cancer in previous genome-wide linkage scans (GWS). This custom primer library pool was used to generate microdroplets of each unique amplicon with one DNA sample in one single PCR reaction. Individual pools of amplicons from each sample were then used as template for NGS using the Life Technologies SOLiD version 3-Plus system. To increase throughput and provide for more efficient sequencing, we employed a series of sixteen unique molecular barcodes for pooled sequencing on the SOLiD system. To date, a total of 94 individuals have been sequenced using our approach. On average 2230 variants were identified per DNA sample. Here we will provide data on the number of both novel and known Single Nucleotide Polymorphisms (SNPs) as well as quality assessment and overall performance of the RainDance method and performance metrics for SOliD NGS. Our experience has provided the opportunity for building out an efficient process and pipeline for targeted resequencing using NGS.

Discovery of New Genes for Inherited Predisposition to Breast Cancer by Exome Sequencing. *C. Spurrell, T. Walsh, M. Lee, MC. King.* University of Washington, Seattle, WA.

BRCA1, BRCA2, and multiple other genes harbor mutations that significantly increase risk of breast cancer, but the genetic bases of breast cancer in most severely affected breast cancer families remain unresolved. We hypothesize that the remaining familial risk of breast cancer is due to individually rare alleles of moderate to high penetrance, some in known genes and many in as-yet-undiscovered genes. In order to discover these new breast cancer genes we are performing exome sequencing on a large number of families excluded for all known genes. We select two cases per family for exome sequencing. Exome libraries are sequenced to at least 50x coverage and then filtered for rare variants likely to truncate proteins. Approximately 10-15 events per family survive this filter. We validate these variants by Sanger sequencing, then genotype each validated variant in all family members to evaluate co-segregation with breast cancer. In the proband of one high-risk family, the only variant to pass our filtering steps was a nonsense mutation in CDH1, p.W156X. Mutations in CDH1 have been reported to cause inherited predisposition to gastric cancer and lobular breast cancer. In this family, two individuals with lobular breast cancer and one with gastric cancer are heterozygous for CDH1 p.W156X. In the pedigree there remain three unexplained cases of ductal breast cancer. We are currently sequencing a second proband in the family to identify a gene responsible for the ductal breast cancers. Exome sequencing will clarify within family genetic heterogeneity and reveal novel mutations and new gene for breast cancer susceptibility.

617/F

International Cancer Genome Consortium Data Portal. *J. Zhang[1], S. Haider[2], A. Cros[1], S. Gnaneshan[1], J. Guberman[1], J. Hsu[1], Y. Liang[1], J. Wang[1], C. Yung[1], A. Kasprzyk[1].* 1) Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 2) University of Cambridge, Computer Laboratory, Cambridge, UK.

The International Cancer Genome Consortium (ICGC) (http://www.icgc.org) orchestrates a multi-national effort to catalogue genomic abnormalities in 50 different tumour types and subtypes. For each type, 500 pairs of matched tumour and normal tissues will be studied using multiple technological platforms. ICGC's data, which will be generated independently by each of its 50 member institutions, will be linked to cancer etiology, drug response, and patient survival. As they are generated the data sets are integrated and made available to the public via the ICGC data portal (http://dcc.icgc.org). The first version of the portal includes four different data types: simple mutations, copy number mutations, structural rearrangements, and gene expression. In addition to the ICGC data, several external data sets, such as Ensembl Gene, KEGG Pathway, and Pancreatic Expression Database, have also been federated to provide support for more sophisticated queries such as 'find all non-synonymous coding mutations identified in PIK3R1 for all cancers' or 'find all members of the Toll-receptor pathway having deletions in stage III breast cancer'. As the ICGC data increases and the portal's functionality is further improved it is expected that this will become an increasingly important resource for cancer researchers with diverse user requirements.

MSI detection by next-generation sequencing in Lynch syndrome patients. *H. Westers, J. Lops, P. van der Vlies, G.J. te Meerman, R.M.W. Hofstra.* Genetics, Univ Med Ctr Groningen, Groningen, Netherlands.

Lynch syndrome, the most common cause of hereditary colorectal cancer is an autosomal dominantly inherited disorder. It is well-established that germline mutations in the mismatch repair (MMR) genes MLH1, MSH2, MSH6, and PMS2 cause Lynch syndrome. A hallmark of MMR deficiency is microsatellite instability (MSI) and this instability occurs in more than 90% of the tumours of Lynch syndrome patients. Therefore, MSI is a very useful diagnostic marker of MMR deficiency. MSI is determined by analysing, on length, an international consensus panel of five microsatellite markers, using DNA from normal and tumour tissue of the same patient. It has been proposed that carriers of a heterozygous MMR gene mutation show a low degree of MSI in blood lymphocytes before tumour diagnosis (up to a few percent). This instability was detected by a PCR cloning and sequencing approach. However the current diagnostic methods are not sensitive enough to detect these very low frequency mutations in presymptomatic mutation carriers. As this would be a perfect test to identify carriers of MMR gene mutations we have set up an analysis using next-generation sequence technology that is able to detect these low levels of instability in a single run. Two MSI mononucleotide markers, NR21 and BAT26, were PCR-amplified with DNA from MSI-high tumors, MMR mutation carriers and DNA from controls as templates. The MSI profile of the tumour DNAs obtained by sequencing exactly matched the MSI profile obtained by marker length analyses indicating that MSI profiling using next-generation sequencing is well possible. In fact using bar-coding we were able to analyze easily 10 individuals in a single lane. The previously reported low MSI frequency in mutation carriers we could prove. However the instability detected did not differ from the instability found in control samples making this type of MSI analysis not predictive for MMR mutation carriers.

619/F

Are rare copy number variants increased in breast-ovarian cancer predisposition families? *A.C.V. Krepischi[1], E.M.M. Santos[1], M.I.W. Achatz[1], S.S. Costa[2], D. Carraro[1], B. Lisboa[1], L.P. Kowalsky[1], C. Rosenberg[2].* 1) AC Camargo Cancer Hospital, São Paulo, SP, Brazil; 2) Institute of Biosciences, University of São Paulo, Brazil.

The impact of the genome structural variations known as CNV (copy number variation) on human diseases is increasingly evident, mainly due to the wide spread use of array-based comparative genomic hybridization (array-CGH). These large scale copy number variations are related to human variability, and may influence susceptibility to complex diseases, including cancer. Although a few major genes of cancer susceptibility have been identified, pathogenic mutations on these genes do not account for most of the predisposition in high-risk cancer families. We selected 52 unrelated cancer patients, members of breast-ovarian cancer predisposition families for array-CGH investigation. The goal was disclosing rare constitutional genomic imbalances that could harbour yet not described predisposition genes, defining novel risk or susceptibility cancer markers. The experiments were conducted on a 180K whole-genome Agilent oligoarray platform. The detected DNA copy number changes were compared both to our reference dataset (100 healthy Brazilian individuals), and to the Database of Genomic Variants (DGV); we defined as "rare copy number variants" (RCNV) those containing genes and covered by £3 individual CNVs documented in DGV. A total of 416 CNVs were identified in the cancer sample (average of 8.2±4.4 CNV per individual). The initial results point to a slight increase in the average of CNVs per individual in the breast cancer patients (8.2) when compared to the control sample (6.8), although larger numbers are needed to statistically confirm this trend. Regarding the RCNVs, a total of 33 were detected in 22 (~42%) patients, while the remaining 30 did not show any RCNV, although one of them exhibited a whole extra chromosome X. The corresponding frequency among controls were 17 RCNV detected among 14 (35%) of the controls. Several of the identified genomic imbalances either comprise entire genes or are intragenic rearrangements, many of which may play a role in cancer.

620/F

Identification of 13 germline *APC* mutations in Familial Adenomatous Polyposis Saudi families. *H. Abalkhail[1], M. Faiyaz-Ul-Haque[1], N. Al-Sanea[2], A. Abduljabbar[2], L. Ashari[2], S. Al-Homoud[2], F. Al-Dayel[1].* 1) Department of Pathology & Lab Med (MBC 10), King Faisal Special Hosp, Riyadh, Saudi Arabia; 2) Department of Surgery, King Faisal Specialist Hospital, Riyadh, Kingdom of Saudi Arabia.

Familial adenomatous polyposis (FAP) is an autosomal dominant inherited form of colorectal cancer caused by germline mutations in the tumor suppressor APC gene (5q21-q22). The Classical form of FAP is characterized by the development of 100's-1000's adenomatous polyps in the colon and rectum at an early age in life. The APC gene encodes a 2843 amino acids distributed over 15 coding exons. To date, the majority of mutations reported are nonsense, deletion or insertion mutations that result eventually in premature protein truncation. Materials & Method: We analyzed the entire coding region of the APC gene using polymerase chain reaction (PCR) and direct sequencing with primers specifically designed to amplify the coding region of exon 1-15 and exon /Intron boundaries. Results: Mutational screening of the APC gene was carried out in 40 individuals (probands and family members) of Saudi's referred from the Colorectal Surgery Clinic at King Faisal Specialist Hospital and Research Centre with the aim to confirm the diagnosis and to detect the causative pathogenic mutations, to enable the presymptomatic diagnosis in at risk family members. In this study we report 13 germline mutations, the changes detected are predicted to result in protein truncation or splice alterations including: 4 nonsense, 4 small deletion (1-5 base pairs), 1 insertion, 1 splice alterations and 3 missense mutations (I1307K, E1317Q and D1822V) known to either be associated or indirectly cause cancer predisposition. Four of the detected mutations, including nonsense, small deletions and a splice site variant were novel. Furthermore, 12 novel unclassified variants (possibly damaging) of unknown clinical significance were detected. Conclusion: The result of this study represents the first Molecular analysis of APC gene in Saudi Arabia and displays the existence of novel pathogenic mutation in Saudi families. The molecular testing of APC gene is of great importance not only in the diagnosis and the management of FAP but also in the implications of screening regimens in at risk family members, thus modifies management, decrease cost, and reduce the psychological trauma for the tested individual.

621/F

Novel germline *PALB2* truncating mutations in African-American breast cancer patients. *Y. Zheng[1], J. Zhang[1], Q. Niu[1], D. Huo[2], O. Olopade[1].* 1) Center for Clinical Cancer Genetics and Global Health, Department of Medicine, The University of Chicago, Chicago, IL 60637, USA; 2) Department of Health Studies, The University of Chicago, Chicago, IL 60637, USA.

The contributions of germline mutations in *BRCA1* and *BRCA2* to inherited susceptibility to breast and/or ovarian cancers have been well documented over the past two decades. Mutation screening of genes functionally related to *BRCA1* and/or *BRCA2* has revealed mutations in genes such as *CHEK2*, *ATM*, *BRIP1*, and *PALB2*. It has been demonstrated that PALB2 acts as a bridging molecule that connects BRCA1 and BRCA2 and thus facilitates BRCA2-mediated DNA repair. Truncating mutations in *PALB2* were reported to be enriched in Fanconi anemia, breast and pancreatic cancer patients in various populations. To date, there are no studies in African-Americans. We evaluated the contribution of *PALB2* germline mutations in familial and sporadic African-American breast cancer patients. After excluding 19 breast cancer cases that previously tested positive for *BRCA1/2*, our cohort contains 260 breast cancer patients, including 20 patients with strong family history (first- and/or second-degree relatives affected by breast and/or ovarian cancer, FDR + SDR $n \geq 3$; age of onset = 45.2 ± 10.9 yr [mean ± SD]); 25 patients with moderate family history (FDR + SDR n = 2; age of onset = 44.6 ± 7.4 yr); 69 patients with weak family history (FDR + SDR n = 1; age of onset = 44.7 ± 9.6 yr); and 146 non-familial or sporadic breast cancer cases (age of onset = 43.6 ± 10.0 yr). After direct sequencing of all the coding exons, exon/intron boundaries, 5'UTR and 3'UTR of *PALB2*, three (1.15%; 3 in 260) novel monoallelic truncating mutations were identified: c.758dupT (exon4), c.1479delC (exon4) and c.3048delT (exon 10); together with 50 sequence variants, 35 of them are novel. None of the truncating mutations were found in 262 controls from the same population. Interestingly, these three deleterious mutations were detectable in both familial and non-familial groups: the patient with c.758dupT had a weak family history, the patient with c.1479delC had a strong family history, whereas the patient with c.3048delT reported no family history of breast and/or ovarian cancer. These data suggest that *PALB2* mutations may have variable penetrance and be causative for both familial and non-familial breast cancer among African-Americans. To our knowledge, this is the first report of *PALB2* truncating mutations in African-American breast cancer patients, underscoring the need for further studies to better understand the mutation spectrum of *PALB2* in diverse populations.

Systems biology approach to genome-wide survival analysis of ovarian cancer. *H. Dong[1], S. Hong[1], R. Cheng[3], L. Jin[1], M. Xiong[1,2].* 1) Sch Life Sci, Fudan Univ, Shanghai, China; 2) Human Genetics Center, University of Texas School of Public Health, Houston, Texas, U.S.A; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas USA.

Genetic and epigenetic alternations that are likely to cause tumor formation are often organized into complex biological networks. It is the whole system and the system dynamics that play an essential role in giving rise to cellular function/dysfunction. Here we report to use system biology and network approaches to develop novel analytic strategies for genome-wide survival analysis of ovarian cancer using The Cancer Genome Atlas (TCGA) data. Expressions of 12,042 genes were measured in 408 tumor samples by Affymetrix U133A, expressions of 799 miRNAs were measured in 485 tumor samples by Agilenth 8x15Kv2 and somatic copy number variations (CNVs) were measured in 442 tumor samples by Agilenth 8x15Kv2. The Cox Hazards regression models were used to test for association of CNVs, genes and miRNAs with the survival times of the patients and sparse Gaussian graphical models were used to construct gene or miRNA co-expression networks with response and no response to chemotherapy. We identified 1,083 CNV regions, 259 genes and 28 miRNA including miR934, miR302a, miR551b, miR652 etc, which were significantly associated with the survival time of the patients with the P-values < 0.01. Some of the CNV regions contain known oncogenes in Epithelial cancer (ERBB2, AKT2), tumor suppressor genes in Epithelial cancer (MEN1), and other cancers (SUPT5H), and cancer related genes in Colorectal cancer (SFRS6) and in Breast cancer (ASL, FLNA). We observed that the genes VEGF, ITGB1, MEN1, TRIP13 with CNV gain and genes ERBB2, VASP, FANC1, POLG, ERCC1, TCAP and GRB7 with CNV loss were associated with patients with survival time larger than 5 years. We identified a largest connected subnetwork with response to chemotherapy where a total of 2,911 genes were connected and 56 genes with CNVs significantly associated with survival time, and a largest connected subnetwork with no response where 2,158 genes and 54 genes with CNVs. We also identified a largest connected miRNA co-expression subnetwork with response to chemotherapy where 497 miRNAs were connected and 49 miRNAs were significantly associated with survival times and a largest connected miRNA subnetwork with no response to chemotherapy where 393 miRNAs were connected and 31 miRNAs were significantly associated with survival time. Finally, we identified 19 CNV regions associated with survival times contain the cis-eQTL genes.

Whole-Genome Sequencing of Non-Small-Cell Lung Cancer Samples. *Z. Zhang[1], D. Ballinger[2].* 1) Dept Bioinformatics, Genentech Inc, S San Francisco, CA; 2) Complete Genomics, Mountain View, CA.

Genentech, together with their collaborators at Complete Genomics, sequenced and compared the tumor and normal tissue of a 51-year-old Caucasian male with non-small-cell lung cancer. This was the first time that such a comparison has been made across the whole genome for a lung cancer patient. For the project, Complete Genomics sequenced the patient's primary lung tumor to 60x coverage and adjacent normal tissue to 46x coverage. More than 50,000 single nucleotide variations (SNVs) were discovered in the tumor which yielded about 17.7 somatic mutations per megabase of DNA. In addition, we observed a distinct pattern of selection against mutations within expressed genes compared to non-expressed genes and in promoter regions up to 5 kb upstream of all protein-coding genes, clearly identifying selection pressures within a tumor environment. We will also discuss the identification of somatic structural and copy number variants.

624/F

***KRAS* Variant Limit of Detection on the Applied Biosystems 3500xL Genetic Analyzer.** *C. Davidson[1], K. Champion[3], M-P. Gauthier[1], F. Wang[1], N. Koch[1], J. Boonyaratanakornkit[2], A. Pradhan[1], J. Walker[1], J. Jones[3], A. Felton[1].* 1) Applied Biosystems, Foster City, CA; 2) AcroMetrix, Benicia, CA, United States; 3) Greenwood Genetic Center, Greenwood, SC, United States.

The *KRAS* (v-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog) gene encodes one of the proteins in the RAS-MAPK pathway, one of several signaling cascades downstream of epidermal growth factor receptor (EGFR) activation. EGFR signaling pathways are important in the development and progression of several aggressive cancers, with *KRAS* gene mutations common in pancreatic, lung, and colorectal cancers. Activating *KRAS* mutations have been described most frequently in codons 12 and 13, with a minor proportion of activating mutations described in codons 61 and 146. These mutations result in constitutively active form of KRAS causing EGFR pathway signaling independent of EGFR activation, thus making therapeutic agents that block EGFR, such as cetuximab or panitumumab, ineffective. Here we describe limit of detection experiments for the detection of sequence variants in codons 12 and 13 of the *KRAS* gene. Methodologies investigated include capillary electrophoresis (CE) DNA sequencing, Shifted Termination Assay (STA) detection, single-base extension, pyrosequencing, high resolution melt (HRM), and real-time PCR. Two sample types were used to assess the limit of detection for *KRAS* variants: 1) mixtures at various percentages of gDNA extracted from *KRAS* mutant and wild-type cancer cell-lines; and 2) mixtures at various percentages of *KRAS* mutant and wild-type cells that were formaldehyde fixed and paraffin embedded to create a cell block and sections from which gDNA was extracted. The analytic sensitivity of the above methodologies is described with a detection of *KRAS* variants in codons 12 and 13 possible at a level of 1% or greater. Further, copy number variation (CNV) assessment of *KRAS* mutant cell line gDNA used for both sample types was assessed since it is known that cancer cell lines have CNV of the *KRAS* gene. The 3500xL Genetic Analyzer, the latest capillary electrophoresis platform from Applied Biosystems®, demonstrated an analytic sensitivity of ≥1% for the detection of *KRAS* variants in codons 12 and 13 by means of the single-base extension and shifted termination assay applications. The limit of detection of these applications is equivalent or better than the pyrosequencing, HRM, and real-time PCR approaches. In addition, data is shown that demonstrates it is important to consider the influence of the sample (FFPE versus purified gDNA), copy number, and zygosity when determining the limit of detection for a method or assay.

625/F

The role of genomic heterogeneity in primary tumors from colon cancer patients. *S. Levy[1,2], K. Bethel[3,2], G. Oliveira[1,2], A. Carson[1,2], A. Torkamani[1,2], P. Kuhn[2].* 1) Scripps Genomic Medicine, Scripps Translational Science Institute, La Jolla, CA; 2) The Scripps Research Institute, La Jolla, CA; 3) Scripps Clinic Medical Group, La Jolla, CA.

Accurate genomics-based molecular characterization of genetic lesions occurring in tumor cells will provide better precision in clinical interpretation of cancer tissues. We adopted a genomics based approach to characterize gene based mutational events, in concert with changes in gene expression patterns, in different anatomic areas from the same primary tumor sample. In this manner we hope to understand how tumor heterogeneity impacts the ability to provide a precise molecular characterization of events within tumor tissues. Correspondingly, we have developed a methodology that will permit the association of correlated changes in the genome and transcriptome in relation to tumor locus, i.e. epicenter, invading edge, tumor-normal transition, thus enabling the identification of activating mutational events that are the hallmark of cancer cell progression within the tumor mass. In one particular application of this approach we assayed discrete anatomical loci isolated from a colon tumor and sequenced the exome compartment as enriched by Agilent SureSelect hybridization probes. Somatic mutations were detected by comparison of the DNA variants identified in the exome sequence derived from each tumor locus with orthologous exomic positions from adjacent normal colon tissue and whole blood. Mutational trends derived from such a somatic mutation comparison were correlated with gene expression to identify significantly over- and under-expressed mutational events.

A novel FLT3 in frame Indel mutation (p.Met837delins Ser Arg Ala Pro Pro) in the TK2 domain of an AML patient with t(8;21). *A. Shrimpton, V. Arguello-Guerra, R. Hutchison.* SUNY Upstate Medical University, Clinical Pathology, 750 E Adams St., Syracuse NY13210.

During routine testing for the D835/I836 mutations in the second tyrosine kinase domain of FLT3 in a patient suspected to have AML, a novel additional larger band of equal intensity to the expected 114 bp band was noted. Post Eco R V digestion the additional band was still present and mapped to within the shorter 46 bp fragment. A comparison to wild type sequence revealed that the novel mutation as a deletion of a single T and an insertion of 13 nucleotides (GCCGAGCTCCCCC) which results in an in the frame mutation, pMet837delinsSerArgAlaProPro. The patient also had the t(8;21) translocation consistent with AML-M2. A family history raised the possibility that the novel FLT3 mutation was inherited rather than acquired, however both a cheek scrape sample and post treatment blood sample showed an absence of the novel mutation.

Analysis of oncogenic mutations in the KIT and PDGFRA genes and characterization of gastrointestinal stromal tumors (GISTs) in Arab patients. *M. Ul Haque[1,2], A. Tulba[1,2], F. Al-Dayel[1, 2], H. Abalkhail[1,2], M. Toulimat[1], H. Alhussaini[3], M. Memon[4], S. Bazarbashi[4], A. Al-Abdullatif[1], T. Amin[4], M.B. Satti[5], I. Peltekova[6], S.H.E. Zaidi[7]*. 1) Molec Gen Lab, DPLM, King Faisal Specialist Hosp, Riyadh, Saudi Arabia; 2) Dept. of Genetics & Molecular Pathology, College of Medicine, Alfaisal University, Riyadh, Saudi Arabia; 3) Dept of Pathology, Riyadh Military Hospital, Riyadh, Saudi Arabia; 4) King Faisal Cancer Centre, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 5) Dept of Pathology, King Abdulaziz Medical City, Jeddah, Saudi Arabia; 6) Department of Medicine, Queen's University, Kingston, Canada; 7) Department of Medicine, University Health Network and University of Toronto, Canada.

Gastrointestinal stromal tumors (GISTs) are mesenchymal tumors found in the gastrointestinal tract, which are believed to originate from the interstitial cells of cajal. In GISTs, several mutations have been described in the KIT and PDGFRA genes, both of which encode for type 3 receptor tyrosine kinases. Specific mutations in these genes cause ligand independent activation of these receptors, which result in cell proliferation and progression towards tumor formation. GISTs with certain mutations in the KIT and PDGFRA genes are effectively treated with the specific tyrosine kinase inhibitor, imatinib mesylate (aka Gleevec). Therefore, it is essential to identify the spectrum of oncogenic mutations in GISTs in different ethnic and geographic populations. The present study was conducted to characterize the GISTs in Arab patients. In this cohort of 72 patients, most GISTs occurred in the stomach, followed by the rest of the digestive tract (intestine, colon, rectum, and esophagus). The majority of the tumors expressed CD117 and CD34 antigens, which are diagnostic markers for GISTs. Sequencing of the exons and exon/introns boundaries of the KIT and PDGFRA genes, in which GIST-causing mutations have been described, identified several non-synonymous mutations and unique deletions in the KIT gene. Among single amino acid substitutions, the p.Trp557Arg change was more common than the mutations affecting the p.Val559 and p.Val560 amino acids. All mutations and deletions are located in exon 11 of the KIT gene. This exon encodes for the juxtamembrane domain which inhibits KIT kinase activity in the absence of a KIT ligand. Mutations in this domain are known to cause constitutive kinase activity of the KIT receptor. Histological examination of the GISTs show higher mitotic index in tumors with exon 11 KIT deletions compared to single amino acid substitutions. This is the first report of presentation, characterization and molecular analysis of GISTs in Arab patients. Together, these data are important for the diagnosis of GISTs and the management of patients in this population of distinct ethnicity.

Systematic identification of somatic mutations and virus integrations in liver cancer genomes by target capture sequencing. *K. Tatsuno[1], G. Nagae[1], S. Yamamoto[1], K. Sonoda[1], L. Wang[1], S. Ishikawa[1,2], S. Tsutsumi[1], Y. Midorikawa[1,4], N. Kokudo[3], T. Shibata[5], T. Yoshida[6], H. Aburatani[1]*. 1) Genome Science Div., RCAST, University of Tokyo, Tokyo, Japan; 2) Department of Pathology, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 3) Hepato-Biliary-Pancreatic Surgery Division, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 4) Department of Surgery, Teikyo University School of Medicine University Hospital, Mizonokuchi, Kanagawa, Japan; 5) Cancer Genome Project, National Cancer Center Research Institute, Tokyo, Japan; 6) Genetics Division, National Cancer Center Research Institute, Tokyo, Japan.

Cancer genomes have extensive variations from single nucleotide mutations to large structural variations. And virus integrations into human host chromosomes also associate with genetic alternations in cancer cells. Systematic identification of these mutations and virus integrations would lead to a better understanding of cancer biology. Recently, exon capture methods for massively parallel sequencing have been developed and targeted sequence for thousands of genomic regions becomes possible with shorter time at reasonable cost. With this technology, we sequenced cancer-related exome subsets for 25 pairs of clinical virus positive hepatocellular carcinoma (HCC) and non-tumoral livers of the same patient. Genomic DNAs from clinical samples were sheared using Covaris™ and ligated with illumina GA paired-end adapters to prepare sequencing library. Exons of 1,248 cancer related genes (4.65 Mbase in total length) and HBV genome (3,215 base) were selected for capture targets. DNA fragments with target sequences were captured and enriched using SureSelect™ (Agilent) target enrichment system. Enriched DNA fragments were sequenced using illumina GAIIx sequencer according to manufacturer's protocol. Data analysis was done using illumina's pipeline and sequence data was mapped to hg18 using ELAND. Sequence statistics and mutation analysis were done by in-house programs.

On average we obtained approximately 1.6 giga bases of sequence data using one lane flow cell of illumina GAIIx with 51-cycle paired-end sequencing. About 60% of read sequences were mapped to targeted exons and average read depths for target regions were calculated more than 200X for each sample. About 95% of targeted bases were sequenced at least once and about 80% targeted bases were sequenced at least 20 times. With higher read depth data, we identified more than 300 somatic nonsynonymous single nucleotide substitutions and some of small insertion or deletion mutations. Most of these mutations were novel, while 14 genes were recurrently mutated among 25 samples, e.g. beta-catenin in 6 cases. We also identified many HBV-host human chromosome fusion DNA fragments both in HCCs and non-tumoral livers of HBV positive samples. Details of gene mutation profile of 25 liver cancers and virus integrations of HBV positive samples will be presented.

Mitochondrial DNA haplogroups and susceptibility to prostate cancer in Colombian populations. *C. David[1], C.F Gomez[2,4], N. Ospina[1], J.A Cajigas[5], R.E Andrade[3,4], H. Groot[1], M.M Torres[1].* 1) Facultad de Ciencias , Universidad de los Andes, Bogota, Colombia; 2) Clínica de la Próstata. Fundación Santa Fe de Bogotá, Bogotá, Colombia; 3) Departamento de Patologia y Laboratorios. Fundación Santa Fe de Bogotá, Bogotá, Colombia; 4) Facultad de Medicina,Universidad de los Andes, Bogotá, Colombia; 5) Departamento de Urología.Hospital Militar Central. Bogota,Colombia.

Prostate cancer (PC) is one of the most common cancers and the second leading cause of cancer mortality in Colombian men. Mitochondrial respiratory activity is associated with the generation of reactive oxygen species (ROS), which may contribute to prostate cancer risk. Mitochondrial haplogroups (mtDNA) defined by common polymorphisms has been associated with risk of renal, breast and prostate cancer. Several studies have demonstrated dramatic differences in the risk of prostate cancer among men from different ethnic background. The Colombian population is culturally and genetically very diverse and is part of a complex admixed genetic ancestry. The aim of the present study was to assess the relationship between mtDNA haplogroups and prostate cancer. We sequenced the mitochondrial DNA hipervariable segment I (HSV1) in a population-based study that comprised 168 cases (CA) and 90 unrelated healthy individuals as a control group (CG).The mean age at onset was 68 years for the PC patients and 61 years for the control group. A total of 93 different mtDNA sequences were found in the patients and 58 in the control group. According to the geographical origin attributed to each mtDNA haplogroup, 82% of the mtDNA sequences found in both groups were Native American (A, B, C, and D). The most frequent was A (41.1%CA-43.3%CG), followed by B (22.0%CA-25.6%CG), C (12.0%CA-5.6%CG) and D (6%CA-7.8%CG). European haplogroups (U, H, K, J, M, T and HV) were also found in a lower proportion (12.5%CA-15.6%CG), likewise for African (L0, L1, L2, L3) (6.5%CA-2.2%CG). In this study there was no statistically significant differences between the distribution of mtDNA haplogroups in patients with prostate cancer and the control group, however, haplogroups C and L were more frequent in patients with cancer. In agreement with previous studies, our results showed no comparable association between any of the haplogroups studied and the susceptibility to the disease.

630/F

MTHFR Polymorphisms and Breast Cancer Risk. *M. Hosseini[1], M. Houshmand[2,3], E. Ebrahimi[2].* 1) Dept Sci, Islamshahr Branch, Islamic Azad Univ, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran; 3) Special Medical Center, Tehran, Iran.

Folate plays an important role in DNA methylation, synthesis, and repair; intake has been associated with breast cancer.Two functional single nucleotide polymorphisms (SNPs) in the 5,10-methylenetetrahydrofolate reductase (MTHFR) gene, C677T and A1298C, lead to decreased enzyme activity and affect chemosensitivity of tumor cells.We evaluated these two common polymorphisms and their effects on the folate intake and breast cancer risk association in a Iranian sporadic breast cancer population-based case-control study of 294 breast cancer cases and 120 controls using a PCR-RFLP-based assay. Analyses of affected and controls show that homozygote genotype MTHFR 677CC has the highest frequency in both groups (40.6 in patients and 15.2 in control group). Genotype MTHFR 677 CC most risk factor were in our population: [CC / TT odds ratio, 1.524 (95% confidence interval; CI, 0.854-2.719) p=0.152], CC / CT odds ratio, 1.048 (95% CI, 0.638-1.720) p=0.854], TT / CT odds ratio, 1.455 (95% CI, 0.765-2.767) p= 0.252]. Genotype MTHFR 1298 AA most risk factor were in our population: [AA / CC odds ratio, 2.204 (95% confidence interval; CI, 1.203-4.038) p= 0.01], AA / AC odds ratio, 2.314 (95% CI, 1.434-3.735) p=0.001], CC / AC odds ratio, 0.952 (95% CI, 0.52-1.743) p=0.874]. There was a significant association of breast cancer risk with folate intake was observed in C677T and A1298C polymorphism.

Cancer risk management strategies and perceptions in BRCA1/2 mutation-carrier families five years after test result disclosure. *C. Julian-Reynier[1], J. Mancini[1, 2], E. Mouret-Fourme[3], M. Gauthier-Villars[4], V. Bonadona[5], P. Berthet[6], J-P. Fricker[7], O. Caron[8], E. Luporsi[9], C. Noguès[3].* 1) INSERM UMR 912, Inst Paoli-Calmettes, BP156, Marseille CDX 9, France; 2) Lertim, Aix-Marseille Université, Faculté de Médecine, Marseille; 3) Centre René Huguenin, Saint Cloud; 4) Institut Curie, Paris; 5) Centre Léon Bérard, Lyon; 6) Centre François Baclesse, Caen; 7) Centre Paul Strauss, Strasbourg; 8) Institut Gustave Roussy, Villejuif; 9) Centre Alexis Vautrin, Nancy.

Background: Long term preventive strategies and breast/ovarian cancer risk perceptions of BRCA1/2 mutation carriers/non carriers were studied prospectively. Methods: A French cohort of unaffected female from BRCA1/2 mutated families was followed up for 5 years after test result disclosure, using self-administered questionnaires. Results: Response rate was 74%. Carriers (N=101) were younger (average age ± SD = 37 ± 10) than non carriers (N=145; 42 ± 12). Four strategies accounted for 88% of the carriers' decisions: 50% opted for breast surveillance alone, based on either Magnetic Resonance Imaging (MRI) and other imaging (31%) or mammography alone (19%); 38% opted for either Risk Reducing Salpingo-Oophorectomy (RRSO) and breast surveillance, based on MRI and other imaging (28%) or mammography alone (10%). The other three strategies were: Risk Reducing Mastectomy (RRM) and RRSO (5%), RRM alone (2%), and neither RRM/RRSO nor surveillance (6%). The results obtained on various age-groups are presented here. Over-screening practices were observed among non carriers. Test result disclosure increased short term carriers' high breast/ovarian cancer risk perceptions (p£0.01) and decreased non-carriers' short- and long- term perceptions (p<0.001). During follow-up, high breast cancer risk perceptions increased with time among those who had no RRM and decreased in the opposite case; high ovarian cancer risk perceptions increased further with time among those who had no RRSO and decreased in the opposite case; RRSO did not affect breast cancer risk perceptions. Conclusions: Informed decision-making involves letting women know whether opting for RRSO and breast MRI surveillance is as effective in terms of survival as RRM and RRSO.

The patterns of BRCA1 and BRCA2 mutations in hereditary breast cancer in Iranian population. *F. keshavarzi[1], S. Zeinali[2].* 1) Islamic Azad University-Sanandaj branch, Sanandaj, Kurdistan, Iran; 2) Kawsar Human Genetics Reasearch Center,Tehran,Iran.

Introduction: Mutations in BRCA1 are present in approximately 50% of the early-onset breast cancer families and 80% of the early-onset breast and ovarian cancer families, whereas BRCA2 mutations are believed to account for a comparable percentage of inherited breast cancer cases. Therefore, the demand for BRCA1 and BRCA2 mutation screening is increasing as their identification will affect medical management of people at increased risk for breast and ovarian cancers. In this study we define point mutations, deletions and genomic rearrangements in BRCA genes in many early-onset and familial breast cancer. Material and method: All study subjects) 63 breast cancer patients (at age £ 40 years) or family history of breast or ovarian cancer (were recruited from Feb.2009 to Apr. 2010 at kawsar Human Genetics Research Center, Iran. After collecting blood samples and extracting DNA, their BRCA1 and BRCA2 genes were fully sequenced. Results and Discussion: Many missense substitutions in BRCA1 and BRCA2 genes were identified (Table 1). Here novel mutations are reported (Gly1140Ser, Ileu15Ieu, Ileu26Ieu, Leu3opal (stop codon), INS CD26 Small ins GTCCC^ATCTGcatctgGTAAGTCAGC, IVS7+83(-TT), IVS8 -70(-CATT), IVS2+9(-GC), IVS1-20(-GA), IVS1-8(-AG), IVS2+9(-GC), IVS2+24(-AG) in BRCA1 and Glu1391Gly in BRCA2). The missense substitutions Glu1038Pro, Gly1140Ser were found in large series of breast and ovarian cancer patient and 20% < of matched controls. The missense substitution Gly1738Glu in BRCA1 is pathogenic. Based on our preliminary results some haplotypes may have a pathogenic role in breast cancer development ,the haplotype at the BRCA1 locus defined by alleles Leu871Pro, GLu1038Gly, Ser1613Gly, Gly1140Ser was found in 10 affected families. Further studies are required to confirm the hypothesis that genetic polymorphisms are associated with breast cancer. Key words: BRCA1 gene, BRCA2 gene, genetic polymorphisms, breast cancer, Familial cancer.

633/F

Staining for FGFR2 in breast cancers shows variable nuclear expression that correlates with patient genotype. *A.J. Martin[1], A. Grant[2], A. Thompson[3], C.A. Purdie[2], L. Jordan[2], J.N. Berg[1].* 1) Division of Pathology and Neuroscience, University of Dundee, Dundee; 2) Department of Clinical Pathology, Ninewells Hospital and Medical School, Dundee; 3) Division of Surgery and Molecular Oncology, University of Dundee, Ninewells Hospital and Medical School, Dundee.

Single Nucleotide Polymorphism (SNP) rs2981582 in intron 2 of the tyrosine kinase receptor Fibroblast Growth Factor Receptor type 2 (FGFR2) has been associated with increased risk of breast cancer. The high risk 'A' allele for rs2981582 has been associated with increased mRNA transcription and altered transcription factor binding. However, the effect that this has on FGFR2 protein expression is, as yet, unknown. We used immunohistochemistry to investigate the relationship between rs2981582 genotype and FGFR2 protein expression. 41 samples of invasive ductal carcinoma of no specific type were selected from women of known rs2981582 genotype. Patients were selected as homozygous for the low risk (G) allele (16 patients), heterozygous (A/G) (9 patients), or homozygous for the high risk (A) allele (16 patients). Samples were stained using rabbit polyclonal anti-FGFR2 antibody assessed using the Quickscore method. No significant association between genotype and cytoplasmic staining was identified but a significant association between prominent nuclear staining and the homozygous low risk (G) genotype was demonstrated (X2 for trend=4.1, p= 0.0429). These results are in contrast to those expected, given that increased mRNA transcription and altered transcription binding have been associated with the high risk (A) allele. FGFR2 is a membrane-bound tyrosine kinase receptor, so the nuclear position of protein expression is also surprising. Association between nuclear FGFR2 protein expression and rs2981582 genotype suggests that the mechanism of action of this polymorphism may be more complex than a direct effect on mRNA expression levels, and may relate to FGFR2 function or localisation during breast development or tumourigenesis.

An Online Database of Cancer Genetic Associations from Candidate Gene and Genome Wide Association Studies. *S.D. Schully[1], V. McCallum[2], C.B. Benedicto[1], L.M. Dong[3], W. Yu[4], M.J. Khoury[4,1].* 1) DCCPS, National Cancer Inst, Rockville, MD; 2) OWD, National Cancer Inst, Rockville, MD; 3) DCEG, National Cancer Inst, Rockville, MD; 4) OPHG, CDC, Atlanta, GA.

Since 2001, the Human Genome Epidemiology (HuGE) Literature Finder has been tracking published literature of human genome epidemiologic studies. The HuGE Literature Finder provides access to a continuously updated knowledge base in human genome epidemiology, including information on population prevalence of genetic variants, gene-disease associations, gene-gene and gene- environment interactions, and evaluation of genetic tests. Historically, genetic susceptibility to complex disease has been uncovered through candidate gene studies. However, in recent years, the advent of Genome Wide Association Studies (GWAS) have greatly accelerated the pace of genetic association discovery. Building upon an evaluation of candidate gene studies published by Dong et al in 2008, and in an effort to consolidate the vast amounts of information coming from both candidate gene and GWAS, we have developed an online knowledge base and repository of all cancer genetic associations from GWAS and meta-analyses of candidate gene studies.

635/F

Common leukemia- and lymphoma-associated genetic rearrangements and constitutional t(11;22) in healthy individuals. *J. Song[1], X. Hu[1, 2], H. Liu[3], D. Mercer[1], M. Li[1,2,4].* 1) Hayward Genetics Center, Tulane University Medical Center, New Orleans, LA; 2) Tulane Cancer Center, Tulane University Medical Center, New Orleans, LA; 3) Department of Anesthesiology, Tulane University Medical Center, New Orleans, LA; 4) Department of Pediatrics, Tulane University Medical Center, New Orleans, LA.

Leukemia and lymphoma-associated (LLA-) chromosomal rearrangements play critical roles in the process of tumorigenesis. These genetic aberrations are also important biological markers in the diagnosis, prognosis, and treatment of hematopoietic malignancies. The constitutional t(11;22) is the only recurrent, non-Robertsonian translocation in humans. Balanced carriers usually have no clinical symptoms; whereas affected offspring often demonstrate the supernumerary derivative 22 syndrome (Emanuel syndrome). We hypothesize that both LLA-chromosomal rearrangements and non-LLA-chromosomal rearrangements can occur randomly in normal individuals. To test our hypothesis, we performed sensitive nested RT-PCR on a large number of peripheral blood samples from healthy individuals for selected markers of LLA-chromosomal rearrangements including MLL-PTD, BCR-ABL (p190 and p210), MLL-AF4, AML1-ETO, PML-RARA, and CBFB-MYH11. We found the presence of all of these selected markers in healthy individuals at various rates of incidence. We found no correlation between the incidence and age except for the BCR-ABL p210 fusion, the incidence of which rises with increasing age. To detect the presence of t(11;22) in normal individuals, we performed nested PCR using genomic DNA from peripheral blood samples and found t(11;22) translocation fragments from both der(11) and der(22). Direct sequencing of the PCR products verified the breakpoints. In summary, our data lend strong support to the hypothesis that both LLA-chromosomal rearrangements and non LLA-chromosomal rearrangements occur randomly in healthy individuals, suggesting that these genetic aberrations are random events and are not themselves sufficient for malignant transformation.

An Enhanced International Fanconi Anemia Registry (IFAR). *A.D. Auerbach[1], A. Smogorzewska[2], F.P. Lach[2], M.J. Wrobel[3], M. Sengupta[3], E. Barbour[3].* 1) Human Genetics & Hematology, Rockefeller Univ, New York, NY; 2) Laboratory of Genome Maintenance, Rockefeller Univ, New York, NY; 3) Hospital Informatics, Rockefeller Univ, New York, NY.

Fanconi anemia (FA) is a rare recessively inherited disorder characterized by genome instability, DNA crosslink hypersensitivity, congenital malformations, bone marrow failure, and predisposition to malignancy. The International Fanconi Anemia Registry (IFAR) was established at The Rockefeller Univ. in 1982 in order to collect data regarding patients with FA and their families (1). In addition, the Fanconi Anemia Mutation Database, http://www.rockefeller.edu/fanconi/mutate/, was established in 1998 to accelerate the availability of information on mutations in the 13 FA genes. The new IFAR project is developing a comprehensive, ontology-driven Phenotype Recording Instrument (PRI) and database for FA. The PRI integrates the existing IFAR data held in multiple disparate data sources for a unique look at the FA patient population, which includes the patient data available in the current IFAR database, the polymorphic (SNP) and mutation data available for patients representing the known FA genes. Furthermore, the NIH's Genomics Center (NHGRI) is currently sequencing certain patient tissue samples using Next Generation technology, which will further enhance the current IFAR patient data. The new development effort will also include "deep phenotyping" from new patient history questionnaires. We are hypothesizing the addition of these two data stores, full gene sequencing and deep phenotyping, will add significantly to the understanding of FA while providing a deeper basic scientific understanding of DNA repair mechanisms, and more prognostic ability for the current patient population. The enhanced data model resulting from the aforementioned data sources is being modeled using an OWL ontology defined with Protégé. We are building data mining and visualization tools that will be required to maximize the research view of this integrated patient data. As the name of the existing IFAR system implies, this registry is an International collaboration. The new system will enable worldwide international collaboration between FA researchers. To accomplish this, we are building a web-based system utilizing the Java JSP front-end coupled with an Oracle 10g database backend for performance and data integrity. This is truly a unique medical informatics opportunity made possible because of the 28 year collection of FA data combined with next generation sequencing and deep phenotyping data. 637/F

Integration of modifier genes genotyping into molecular diagnosis of Lynch syndrome is premature. *T. Frebourg[1], S. Houlle[1], F. Charbonnier[1], E. Houivet[2], S. Baert-Desurmont[1], M.-P. Buisine[3], J. Benichou[2].* 1) Dept Genetics, Inserm U614, Rouen Univ Hosp, Rouen, France; 2) Department of Biostatistics, Rouen University Hospital, France; 3) Laboratory of Molecular Biology, Lille University Hospital, France.

One of the first modifier genetic factors identified in Lynch syndrome corresponds to the IGF1 promoter CA repeat, and it had been shown, in 121 *MMR* mutation carriers, that a 17 CA repeat or less was significantly associated to a higher colorectal cancer (CRC) risk and an earlier age of tumour onset (Zecevic et al., J. Natl. Cancer Inst. 2006; 98: 139-43). Wijnen et al. (Gastroenterology 2009;136:131-7) reported, in 675 *MMR* mutations, a significant association between CRC risk and two SNPs, rs16892766 (8q23.3) and rs3802842 (11q23.1), initially detected by GWAS as risk factors for CRC in the general population. We analyzed the effect of these modifier genes in 750 French *MMR* mutation carriers derived from 292 families and including 330 CRC patients (mean age of CRC onset: 43 years). We also analyzed the effect of the Novel 1 SNP (18q21), which has recently been shown to be associated to CRC risk in the general population (Pittman et al., Genome Res. 2009;19:987-93). A significant difference was observed in the CRC-free survival time or the median age of onset of CRC between males and females (log-rank test P < 0.0001), between *MSH2* and *MSH6* mutation carriers (log-rank test P = 0.0315), between *MLH1* and *MSH6* mutation carriers (log-rank test P = 0.0049) but not between *MSH2* and *MSH6* mutation carriers (log-rank test P > 0.05), indicating that our series was representative of Lynch syndrome. In this series, the univariate Kaplan-Meier analysis showed that the CRC penetrance did not differ significantly for the three SNPs and the IGF1 CA repeats, when stratified by genotype and gender. The multivariate Cox analysis (taking into consideration the family effect) stratified for the gender, the mutated MMR gene and date of birth did not reveal that a specific genotype for these 4 genes was associated to a significant hazard ratio increase. We subsequently restricted the analysis to *MSH2* and *MSH2* carriers and did not neither observed any difference. Finally, we performed the statistical analyses only on affected subjects and these analyses did not reveal any significant difference. In conclusion, we did not reproduce the previously published results. We think that this discrepancy might be explain by artefactual associations generated by too small samples. We conclude that genotyping of these polymorphisms should not be integrated into the molecular diagnosis of Lynch syndrome to optimize the follow-up of *MMR* mutation carriers.

638/F

Impact of family history on uptake of risk-reducing surgeries among BRCA mutation carriers. *K.R. Singh[1], J. Gross[2], B. Karlan[2], X. Yan[1], K. Yang[1], X. Guo[1], O. Gordon[1].* 1) Medical Genetics, Cedars-Sinai Medical Genetics Institute-Gilda Radner Program, Los Angeles, CA; 2) Women's Cancer Research Institue at the Samuel Oschin Comprehensive Cancer Center, Cedars-Sinai Medical Center, Los Angeles, CA.

Objective: Lifetime risk of breast and ovarian cancers among BRCA mutation carriers are markedly reduced with prophylactic surgeries, yet only a portion elect to undergo these procedures. This study investigates factors that might influence patients' decisions regarding risk reducing mastectomy (RRM) and risk reducing bilateral salpingo-oopherectomy (RRBSO). **Methods:** Subjects were women with no personal history of cancer and with deleterious mutations in the BRCA1/2 genes who underwent RRM or were participants in the high risk surveillance program at our institution. Medical records were reviewed for age, parity, family history, personal history of breast biopsies, cosmetic surgery, and uptake of prophylactic surgeries. **Results:** Of 134 BRCA carriers, 31(23.1%) elected RRM. 24 of 29(82.8%) with RRM had the procedure within 2 years of genetic testing (surgery dates for 2 were unknown). In the group with RRM, history of mother deceased from breast cancer was 35.5% vs. 8.7% in the no RRM group, p<0.0002. Two women (6.5%) in the RRM group had a sister affected with breast cancer without mother being affected vs. 5(4.9%) in the no RRM group. Uptake of RRBSO was 71.0% in the RRM group vs. 46.6% in the no RRM group, p<0.0025. Forty-six (95.8%) of 48 patients who had RRBSO in the no RRM group had history of mother with pelvic cancer. Parity was higher in the group with RRM than the group without (19% para 0 vs. 46%, p<0.0038). There were no significant differences in mean age at time of genetic testing, history of breast biopsy, or history of cosmetic surgery between the two groups. **Conclusions:** BRCA carriers who had lost their mother to breast cancer were most apt to choose RRM. Numbers of women with only a sister affected with breast cancer were small in both groups and did not suggest significant influence on decision-making. Women with RRM were more likely to have RRBSO than women without RRM. Women without RRM were less parous than those with RRM and may have opted against surgery until completion of childbearing. However, among those without RRM, uptake of RRBSO was highest in women whose mother had pelvic cancer. The impact of losing a mother to cancer may be of under recognized import in patient attitudes regarding prophylactic procedures. Additional studies are needed to assess whether directly addressing this life experience or lack thereof during genetic counseling influences patient behavior regarding surveillance versus prophylactic surgery.

639/F

Mutation analysis of *TSC1* and *TSC2* genes in 2 randomized, double-blind, placebo-controlled studies of everolimus in the treatment of subependymal giant-cell astrocytomas (SEGAs) (EXIST-1) and angiomyolipomas (EXIST-2). *Z. Tsuchihashi[1], W. Liu[1], J. Sampson[2], D.N. Franz[3], J. Bissler[3], C. Kingswood[4], T. Sahmoud[1], D. Kwiatkowski[5].* 1) Novartis Pharmaceuticals Corporation, Florham Park, NJ; 2) Institute of Medical Genetics, Cardiff University, Cardiff, UK; 3) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 4) Royal Sussex County Hospital, Brighton, UK; 5) Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Objectives: Tuberous sclerosis complex (TSC), a genetic disease characterized by multisystemic hamartomas and disabling neurological disorders, is caused by mutations in *TSC1* or *TSC2* that result in constitutive activation of mTOR, a key regulator of cell growth and proliferation, metabolism, and angiogenesis. Lesions occur throughout the body, including the kidney (angiomyolipomas), lungs (lymphangioleiomyomatosis [LAM]), and brain (tubers and SEGAs). Angiomyolipomas can also occur in patients with sporadic LAM independent of TSC. In an open-label phase II trial, everolimus, an oral mTOR inhibitor, significantly reduced TSC-associated SEGA volume. The EXIST (**EX**amining everolimus **I**n a **S**tudy of **T**SC) trials are evaluating the efficacy and safety of everolimus in the treatment of SEGAs (EXIST-1) and angiomyolipomas (EXIST-2). **Methods:** EXIST-1 (NCT00789828) and EXIST-2 (NCT00790400) are randomized, prospective, double-blind, multicenter, phase III trials. In EXIST-1, patients of any age with SEGAs and evidence of serial growth are randomized 2:1 to receive everolimus (initial dose 4.5 mg/m^2/d with titration to trough concentration of 5-15 ng/mL) or placebo. In EXIST-2, patients ≥18 y with a definite diagnosis of TSC or sporadic LAM and ≥1 angiomyolipoma (≥3 cm) are randomized 2:1 to receive everolimus 10 mg/d or placebo. Patients will be treated until progression or unacceptable toxicity. Primary endpoint is SEGA response rate (RR, reduction in volume ≥50%) in EXIST-1 and angiomyolipoma RR in EXIST-2, determined by MRI per independent central radiology review. Secondary endpoints in EXIST-1 include change in frequency of epileptiform events, duration of and time to SEGA response, time to SEGA progression, skin lesion RR, biomarker analyses, and safety. EXIST-2 secondary endpoints include duration of and time to angiomyolipoma response, time to angiomyolipoma progression, skin lesion RR, biomarker analyses, and safety. Target enrollment is 99 patients per study. In both studies, blood DNA samples from all patients are analyzed for the mutation status of *TSC1* and *TSC2* genes. All of the exons and the adjacent intronic regions of these 2 genes are PCR-amplified and analyzed by Sanger dideoxy-sequencing method. Potential association between mutation status and disease phenotype and/or the patients' response to everolimus will be explored. Currently the mutation status of 21 patients has been determined and the updated result from this analysis will be presented.

Gene Set Enrichment Analysis can detect specific biology to interpret and prioritize the results of a Coronary Artery Disease Genome Wide Association Study. *A.J. Stoddard[1], R.B. Lorier[1], A. Matter[1], E.A. Virlee[1], S.K. Pachowitz[1], J.P. Peete[1], D.L. Linzmeier[1], U. Broeckel[1,2,3,4].* 1) Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 2) Department of Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 3) Department of Medicine, Medical College of Wisconsin, Milwaukee, WI; 4) Department of Physiology, Medical College of Wisconsin, Milwaukee, WI.

Background: Prioritizing and interpreting the results of Genome-wide association studies (GWAS) presents numerous challenges, especially for complex disease. Association analysis SNP-by-SNP provides little biological insight, with only rank order to assess priority. Many true associations will rank too low to merit attention. Even when single SNPs are strongly associated they seldom explain a large fraction of heritability for a complex trait. Gene Set Enrichment Analysis (GSEA),which allows associations to be tested as groups bringing biological context to bear, can be used to interpret GWAS results and is here applied to various inflammatory serum markers linked to Coronary Artery Disease (CAD).

Methods: A cohort of 607 Caucasian individuals with CAD was genotyped on Affymetrix 6.0 arrays. Covariate adjusted single SNP logistic regression based association values with plasma biomarker levels were calculated using the PLINK software. SNPs were mapped to genes taking the strongest associated marker per gene. GSEA v2.06 software (Broad) was used with 1229 supplied gene sets augmented with 32 cardiac expression and drug response lists generated from ArrayExpress and CMAP datasets to focus on cardiac context.

Results: For all 7 serum biomarkers considered SELE, ICAM1, IFNG, VCAM1, MPO, MPI and CRP, 3 or more gene sets from the cardiac expression library were in the top 50 most highly enriched gene sets by GSEA (for each biomarker the top 50 sets had an FDR of 0.2-0.3) showing a significant specific detection of cardiac biology (hypergeometric $p < 0.001$ or better in each case). Relevant biology was also revealed in non-targeted gene sets, e.g. the ETS pathway was the highest enriched pathway set for SELE associated genes ($p < 0.001$) with lower (between rank 2000-4000) ranking genes, RBL1, ETS1, CSF1 still contributing to the enrichment.

Conclusion: GSEA is shown to detect specific cardiac biology, combining gene expression with CAD association results, where individual genes would not be considered by association alone. Thus functional biological hypotheses are generated and can be prioritized for follow-up experiments.

641/W

The rs10934857T>C of the GATA2 gene is a susceptibility variant for myocardial infarction. *M.M. Al-Rasheed[1,2,3], M. Al-Najai[1], M.M. Vigilla[1], S. Wakil[1], N. Dzimiri[1].* 1) Genetics Dept, King Faisal Specialist Hospital & Res. Ctr., Riyadh, KSA; 2) Clinical Pharmacy Dept., King Saud University, Riyadh, KSA; 3) School of Pharmacy & Biomolecular Sciences, University of Brighton, UK.

The predisposing effect of GATA2 to acquiring cardiovascular disease still remains to be elucidated. In this study, we first sequenced the GATA2 gene in 200 individuals to identify informative variants of interest. We then selected 3 familiar variants, rs2335052 (A>G), rs3803 (C>T), rs10934857 (T>C), and two novel SNPs herein denoted as ns2713579 (A>G) and ns1573949 (A>G) to test for possible association with myocardial infarction (MI) by the real-time PCR-based techniques. A total of 2633 MI cases versus 1230 controls, all of Saudi origin, were employed for the study. The results pointed to a significant causative association for the rs10934857 with MI [Odds ratio (95% Confidence Interval) = [1.12(1.01-1.24); p=0.031]. Further analysis pointed to the autosomal recessive mode of inherence [1.34(1.13-1.58); p= 0.002] as being responsible for this association. Interestingly, there was no definable link for this variant with coronary artery disease (CAD). Besides, no confounding effect of type 2 diabetes mellitus, hypertension, hyperlipidaemia, or any other variable was observed for this association. These results demonstrate that the GATA2 rs10934857 variant predisposes individual to acquiring MI, but not necessarily manifestation of CAD in our study population.

642/W

Genetic Variation at the DPP4 Locus Influences ApoB Levels among South Asians and Reveals Heterogeneity in Europeans Caused by Adiposity. *S.D Bailey[1], C. Xie[2], A. Montpetit[3], S. Anand[2], J.C Engert[1,4] on behalf of the EpiDREAM investigators.* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Population Health Research Institute, McMaster University, Hamilton, Ontario, Canada; 3) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 4) Department of Medicine, McGill University, Montreal, Quebec, Canada.

The majority of genome-wide association scans (GWAS) performed to date have focused primarily on individuals of European descent. Although some of the identified risk alleles are consistent across ethnicities, performing association scans in other ethnic groups could identify new genes. We used the ITMAT Broad CARe (IBC) array to test 31,739 common SNPs, from 2000 cardiovascular candidate genes, in 2625 South Asian individuals from the EpiDREAM study, individuals screened for the DREAM trial, for an association with levels of apolipoprotein B (apoB). We attempted to replicate seven SNPs, from previously unreported genes, in 1081 South Asian controls from the INTERHEART study. A SNP within the dipeptidyl peptidase IV (DPP4) gene was significantly associated with apoB levels in both the EpiDREAM and INTERHEART studies (β=-0.023, p=1.33x10-4 and β=-0.028, 7.28x10-3, combined n=3706, p=3.09x10-6). Interestingly, the SNP was not associated with apoB in 8973 EpiDREAM individuals of European descent (p=0.94). However, the South Asian samples were significantly leaner than the European samples (average BMI of 26.4±4.3 and 30.4±5.7, respectively). In the lowest European BMI tertile (average BMI=24.6±2.0) we observed a significant association between the SNP and apoB (β=-0.020, p=1.44x10-3). We restricted the analysis to only lean individuals (BMI < 25) and observed an increase in the effect of this SNP on ApoB (EpiDREAM Europeans n=1468, β=-0.029, p=4.38x10-4). This increase was also observed in lean South Asians from both the EpiDREAM (n=1028, β=-0.024, p=9.13x10-3) and INTERHEART (n=577, β=-0.045, p=1.78x10-3) studies. When we analyzed all lean individuals from the entire EpiDREAM study, which includes European, South Asian, Latin American, African American, Native North American and East Asian samples, we observe strong overall evidence of an association between the identified SNP in DPP4 and apoB (n=3207, p=6.98x10-6), which is supported further by the replication in lean South Asians from the INTERHEART sample (p=1.78x10-3). DPP4 is a target of anti-hyperglycemic medication used in the treatment of type-2 diabetes (T2D). DPP4 inactivates two insulinotropic hormones, the gastric inhibitory peptide and glucagon-like peptide 1, and its pharmacological inhibition has been shown to lower both fasting and postprandial glucose levels by prolonging their half-lives. These results increase our understanding of the relationship between glucose and lipid metabolism.

643/W

Evaluation of Variants in the BCAT Gene as Metabolic Quantitative Trait Loci. *L. Elbadawi[1], C. Haynes[2], J. Johnson[2], J. Bain[3], M. Muehlbauer[3], R. Stevens[3], C. Newgard[3], K. Newby[1,4], S. Gregory[2], W. Kraus[1,2], E. Hauser[2], S. Shah[1,2].* 1) Department of Medicine, Duke University, Durham, NC; 2) Duke Center for Human Genetics, Durham, NC; 3) Sarah W. Stedman Nutrition and Metabolism Center, Durham, NC; 4) Duke Clinical Research Institute, Durham, NC.

Background. Metabolic biomarkers for coronary artery disease (CAD) are strongly heritable but the source of the genetic variation for these biomarkers remains to be identified. Derangements in branched-chain amino acid (BCAA) catabolism are heritable in families burdened with early onset CAD. Further, BCAA levels are higher in subjects with cardiovascular disease than in controls without CAD when controlling for confounders. BCAT1 encodes the cytosolic form of the enzyme branched-chain amino acid transaminase that catalyzes the reversible transamination of branched-chain alpha-keto acids to branched-chain L-amino acids essential for cell growth and plays a large role in the BCAA catabolic process. Thus, we tested whether BCAT1 is a metabolic quantitative trait locus (mQTL) modulating BCAA levels and serving as a CAD susceptibility gene. Objectives. Our primary hypothesis was that single nucleotide polymorphisms (SNPs) in BCAT1 would be associated with differential levels of peripheral blood BCAA in patients referred for evaluation of CAD. Secondarily, we hypothesized that these BCAT1 SNPs would be associated with CAD. Methods and Results: Patients undergoing cardiac catheterization for evaluation of CAD at Duke University Medical Center who were enrolled in the CATHGEN biorepository formed the study population. Of these, 2375 subjects had had mass spectrometry based metabolomic profiling of 69 metabolites performed, and were included in this analysis. Genotyping of SNPs RS2242400, RS10505955, RS2353486 in BCAT1 was performed using Taqman assays. Principal component analysis (PCA) was used for multidimensional data reduction, and linear and logistic regression examined the associations of metabolomic factors resulting from PCA with BCAT1 SNPS and BCAT1 SNPs with CAD, respectively. The three SNPs met Hardy-Weinberg equilibrium and had minor allele frequencies of: 0.11, 0.43, 0.36, respectively. PCA identified thirteen factors, including a factor composed of the branched chain amino acids, as previously observed. However, none of the BCAT1 SNPs were associated with levels of this BCAA factor. Further, BCAT1 SNPs themselves were not associated with the presence of CAD. Conclusions. Our data do not support the role of BCAT1 variants as a mQTL for CVD risk. Future studies should evaluate other genes in the BCAA catabolic process to understand the genetic architecture modulating BCAA levels, and predisposing to CAD.

644/W

Identification of a novel candidate gene on chromosome 20p12 influencing variation in lipoprotein-associated phospholipase A2, a risk factor for cardiovascular disease. *P.B. Higgins, V.P. Diego, J.W. Kent Jr., M.A. Carless, T.D. Dyer, D.L. Rainwater, L.A. Almasy, A.G. Comuzzie, J.E. Curran, E.K. Moses, M.C. Mahaney, J. Blangero.* Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

Lipoprotein-associated phospholipase A2 (Lp-PLA2) is a novel biomarker of oxidative stress and inflammation, and is positively associated with risk of cardiovascular disease (CVD). Lp-PLA2 is transported in the bloodstream predominantly by low density lipoprotein (LDL) and partly by high density lipoprotein (HDL). The physiological dynamics of LDL and HDL concentrations in the circulation are intricately related to triglyceride levels. We hypothesized therefore that variation in Lp-PLA2 activity would be significantly influenced by the ambient lipid/lipoprotein milieu. To test this idea, we constructed discrete lipid/lipoprotein environments for LDL cholesterol (LDLC), HDLC, and serum triglycerides by scoring the upper tertile as 1, and 0 otherwise, and performed genotype-by-environment interaction (GEI) analyses of Lp-PLA2 activity in relation to the three lipid/lipoprotein environments. We focus on results from the genotype-by-triglyceride environment interaction (GTI) linkage analysis. From this GTI linkage analysis, we found strong evidence of a quantitative trait locus (QTL) on chromosome 20p12 (genome-wide maximum LOD score = 3.67), as well as evidence of a GTI effect at the QTL (p = 0.003). Within the 1-LOD interval about the chromosome 20p12 QTL, we typed 712 single nucleotide polymorphisms (SNPs). Because we desired to take a Bayesian model selection (BMS) approach toward detecting genetic association with Lp-PLA2 activity, we decided to delimit the model space by screening for SNPs that had a p-value less than 0.005 by a naïve measured genotype association test. This first screen resulted in a reduced set of six SNPs, thus giving a model space of 26 = 64 models of additive SNP effects. BMS identified the most supported model among the reduced set to be the model that contained two specific SNPs, namely rs11905991 and rs605589 (2 degrees of freedom measured genotype association test p = 4.3 × 10-6). The first SNP is in the vicinity of an open reading frame, and thus may be a novel functional gene. The second SNP is at the phospholipase Cβ1 (*PLCB1*) gene, which is known to protect cells against oxidative-stress-induced cell death and to promote mitogenesis. In conclusion, we have identified a novel candidate gene of relevance to the known functionality of Lp-PLA2.

A two-stage matched case-control study on multiple hypertensive candidate genes in Han Chinese population. *T. Kuo[1], M. Kang[1], C. Chung[1], H. Ho[2], C. Ting[2], T. Lin[3], S. Sheu[3], W. Tsai[4], J. Chen[4], H. Leu[5], W. Yin[6], T. Chiu[7], Y. Chen[1], C. Chen[7], C. Fann[1], J. Wu[1], T. Lin[1], S. Lin[5], J. Chen[5], W. Pan[1].* 1) Biomedical Science, Academia Sinica, Taipei, Taiwan; 2) Taichung Veterans General Hospital, Taichung, Taiwan; 3) Kaohsiung Medical University Chung-Ho Memorial Hospital, Kaohsiung, Taiwan; 4) National Cheng Kung University Hospital, Tainan, Taiwan; 5) National Yang-Ming University School of Medicine and Taipei Veterans General Hospital, Taipei, Taiwan; 6) Cheng Hsin Rehabilitation Medical Center, Taipei, Taiwan; 7) Min Sheng General Hospital, Taoyuan, Taiwan.

We performed a two-stage association study of young-onset hypertension on genotype data of single nucleotide polymorphisms (SNPs) from 992 cases and 992 matched controls of Han Chinese in Taiwan. 239 SNPs of 37 hypertension candidate genes with functional importance were investigated. These 37 candidate genes were selected based on the website of genetic association database (GAD) and were classified into five main groups: (1) renin-angiotensin-aldosterone system (RAAS); (2) messenger-related; (3) channels of transporters; (4) energy related; and (5) others with functional importance related to hypertension. 239 SNPs across these genes were selected from those significantly reported in the previous publications and those given by the HaploView software based on their linkage disequilibrium (LD) structure. Single SNP analysis using conditional logistic regression was carried out for individual SNP in this matched case-control study. We identified two SNPs that were strongly associated with hypertension in both two stages. The first SNP (rs2301339) is located at guanine nucleotide binding protein beta 3 subunit (GNB3) and the other one (rs17254521) is located at insulin receptor (INSR). The former is perfectly linked in linkage disequilibrium (LD) with C825T(rs5443) which is associated with the occurrence of splice variant in GNB3 and has been found to be associated with hypertension in Caucasian, but less inconsistent in Asian populations. Despite significant evidence in both linked SNPs, their effect is opposite. This might be due to population heterogeneity and the younger subjects of hypertensive patients used in the present study.

BRAP gene exerts a pro-atherogenic effect via prohibiting NF-κB nuclear translocation. *Y.C. Liao[1, 2, 5], H.F. Lin[3], Y.S. Wang[2], K.C. Chen[2], M.H. Chang[5], S.H.H. Juo[2, 3, 4].* 1) Graduate Institute of Medicine , Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Graduate Institute of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Department of Neurology, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Department of Medical Research, Kaohsiung Medical University, Kaohsiung, Taiwan; 5) Section of Neurology, Taichung Veterans General Hospital, Taichung, Taiwan.

Background The BRCA-1 associated protein (BRAP) gene was recently identified as a susceptible gene to myocardial infarction (MI) in two Asian populations. The rare allele of functional SNP rs11066001 is associated with an enhanced BRAP expression and aggravated NF-κB activity. The present study sought to determine (1) the BRAP effect on stroke and carotid atherosclerosis, and (2) the mechanism beneath its pro-atherogenic effect. **Methods** Three phenotypes including stroke, carotid intimal-medial thickness (IMT), and plaque were used to evaluate the BRAP effect in a Chinese population. The study participants included 769 stroke patients and 1235 stroke- and MI-free volunteers who received carotid ultrasonogrpahy. SNP rs11066001 was genotyped by TagMan method. Human artery smooth muscle cells (HASMCs) were transfected with siRNA targeting at BRAP or scrambled siRNA before treated by lipopolysaccharide (LPS). MTT assay, transwell experiments and ELISA were used to measure the HASMC proliferation, migration and inflammation. **Results** Unlike MI, the SNP was not significant for stroke (p = 0.47). However, the rare homozygotes GG was associated with a 1.82-fold risk to have at least one carotid plaque (p = 0.026) among our healthy subjects. There was a trend of over-represented GG genotype in the subjects with higher plaque index compared to the AA+AG genotypes (GG frequencies in plaque index >= 4, index = 1-3, and index = 0 were 14.7%, 9.6%and 6.6% respectively, trend p = 0.030). There was no association between rs11066001 and IMT values. When cells were treated with LPS, there was an increase of BRAP expression level, HASMC proliferation, migration and secretion of inflammatory markers. Knocking down the BRAP expression led to attenuated proliferation and migration in HASMCs (p < 0.05). In addition, the MCP-1 and IL-8 levels were significantly lower in HASMCs transfected with BRAP siRNA. Knock-down the BRAP gene did not affect the NF-κB mRNA levels, but prohibit the NF-κB activation. In western blot, the nuclear-cytoplasm ratio of NF-κB gene increased when HASMCs were exposed to LPS. Such nuclear translocation was blocked after knocking down the BRAP gene. Immuno-fluorescence stains demonstrated identical findings. **Conclusions** We found BRAP gene confers risks for carotid atherosclerosis,coronary artery disease but not stroke. The pro-atherogenic effect of BRAP is mediated by influencing the NK-kB activity via nuclear translocation.

The rs1333040 Genotypes on 9p21.3 Influence the CDKN2A/B Expression in Coronary Atherosclerotic Plaques. *N. Marziliano[1], F. Orsini[1], M.F. Notarangelo[2], D. Lina[2], S. Veronese[1], C. Berzuini[3], D. Ardissino[2], P. Merlini[1].* 1) Cardiovascular, Azienda Ospedaliera Niguarda Ca' Granda, Milano, MILANO, Italy; 2) Division of Cardiology, Azienda Ospedaliero-Universitaria di Parma, Parma, Italy; 3) Statistical Laboratory, Centre for Mathematical Sciences, Cambridge, United Kingdom.

Coronary artery disease (CAD) is significantly influenced by genetic background. Recent genome-wide association studies have shown that common genetic variants in tight linkage disequilibrium located in human chromosomal region 9p21.3 are associated with ischemic heart disease. However, the mechanisms by which these variants increase the risk of CAD is still unknown. In an elegant study of knock-out mice lacking the CAD locus interval in chromosome 4, Visel et al. (Nature 2010) found that this region is critically required for the normal cardiac expression of two neighbouring cyclin-dependent kinase inhibiting genes, Cdkn2a/b. We investigated the influence of the 9p21.3 variant rs1333040 on CDKN2A/B expression in 30 human coronary atherosclerotic plaques obtained by means of coronary atherectomy from patients with ischemic heart disease. The genotype distribution of rs1333040 was as follows: five atherosclerotic plaques had no risk allele (CC), 10 had one risk allele (CT) and 15 had two (TT). There was a significant (p=0.00013) trend of the expression levels of both genes with the number of copies of the risk allele (C), the expression in the CT plaques being in between that of CC and TT plaques, for both genes. Visel et al. suggested that the non-coding CAD risk interval affects vascular cell proliferation and senescence by modulating the expression of Cdkn2a and Cdkn2b. This view is complemented by our findings showing a link between the genotype of the rs1333040 locus and CDKN2A/B expression in diseased human tissues, which support the hypothesis that sequence variations in the CAD risk interval may act as distant regulatory sequences and be required for the correct vascular expression of CDKN2A/B. Further studies are needed to identify the target human cell in which the 9p21.3 risk allele most influences the reduction in CDKN2A/B gene expression.

GENE-CENTRIC STUDY IDENTIFIES TWO NOVEL GENES, CLCN2 (A VOLTAGE-GATED CHLORIDE CHANNEL) AND KCNAB1 (A VOLTAGE-GATED POTASSIUM CHANNEL) ASSOCIATED WITH BLOOD PRESSURE IN TWO INDEPENDENT IRISH POPULATIONS. *N. McCarthy[1], C. Vangjeli[1], G. Cavalleri[1], K. Shianna[3], N. Delanty[1], E. O'Brien[2], B. Harvey[1], A. Stanton[1].* 1) Royal College of Surgeons in Ireland, Dublin, Ireland; 2) University College Dublin, Dublin, Ireland; 3) Duke Institute for Genome Sciences & Policy, North Carolina, USA.

Objective: Hypertension is highly heritable. Recent genome-wide association studies have identified 13 novel loci associated with BP. However these loci only explain a small proportion of total BP variation. It is recognized that identification of all genetic variants associated with BP will require complementary strategies. Here we report on a targeted candidate gene study with dense SNP coverage of multiple genes involved in electrolyte transport. Design and Method: Using the Illumina GoldenGate platform, we genotyped 1860 SNPs in 81 genes in 358 healthy bank employees who had undergone seated clinic BP measurements (screening population, SP). Only the 35 SNPs, in 21 genes, that were found to be associated with systolic, diastolic or pulse pressure (SBP, DBP or PP) within the SP (p£0.01), were genotyped (Illumina Veracode platform) in a second independent replication population (RP) - these 380 healthy bank employees had undergone repeated 24-hour ambulatory BP monitoring. Association analyses were performed using additive genetic models and adjusted for age and sex. Results: Quantile-quantile plots showed enrichment for significant P-values in both populations. Particularly strongly associated SNPs included a synonymous SNP in a voltage-gated chloride channel gene (*CLCN2*) and an intronic SNP in a voltage-gated potassium channel gene (*KCNAB1*). The *CLCN2* SNP was associated with increased clinic SBP(2.7mmHg, p0.02)in the SP and clinic, daytime and nighttime SBP(2.9mmHg, p0.003; 1.8mmHg, p0.009; 2.1mmHg, p0.001*) in the RP aswell as increased clinic DBP (2.1mmHg, p0.009) in the SP and increased daytime and nighttime DBP(2.0mmHg, p0.00003*; 2.0mmHg, p0.00003*)in the RP . The KCNAB1 SNP was associated with increased clinic SBP(5.5mmHg, p0.04) in the SP and clinic, daytime and nighttime SBP(7.0mmHg p0.0002*; 3.6mmHg, p0.006; 3.5mmHg, p0.005) in the RP aswell as clinic PP(5.9mmHg, p0.001) in the SP and clinic, daytime and nighttime PP(4.0mmHg, p0.003, 2.3mmHg p0.009, 2.5mmHg p0.001*) in the RP . * P-values in RP which exceed the Bonferroni correction for multiple testing. Conclusions: Variants in ion channels CLCN2 and KCNAB have not previously been implicated in the causation of hypertension. These findings indicate strong associations with clinically relevant BP changes; providing new insights into the pathophysiology of BP regulation and potentially pointing to novel drug targets for the treatment of hypertension.

Common single nucleotide polymorphisms associated with QT interval and sudden cardiac death: the FinSCDgen study. *P.A. Noseworthy[1], V. Salomaa[2], A.S. Havulinna[2], A.M. Lahtinen[3], K. Porthan[4], A. Jula[2], P.J. Karhunen[5], M. Perola[6], K. Kontula[3], C. Newton-Cheh[1,7].* 1) Massachusetts General Hospital, Boston, MA 02114, USA; 2) National Institute for Health and Welfare, Helsinki, Finland; 3) Research Program for Molecular Medicine and Department of Medicine, University of Helsinki, Helsinki, Finland; 4) Department of Cardiology, University of Helsinki, Helsinki, Finland; 5) Department of Forensic Medicine, Tampere University Hospital, Tampere, Finland; 6) Institute of Molecular Medicine FIMM, University of Helsinki, and National Institute for Health and Welfare, Helsinki, Finland; 7) Broad Institute, Cambridge, MA 02114, USA.

Introduction: Sudden cardiac death (SCD) comprises 15% of all deaths in western countries and about 2/3 of all cardiac deaths. Although SCD is heritable, its genetic determinants are poorly characterized. We hypothesized that common genetic variants associated with QT interval, arrhythmias and other cardiac phenotypes, would also be associated with SCD.

Methods: We genotyped 36 common (MAF >1%) candidate SNPs in individuals in 4 cohort studies (FINRISK 1992, 1997, 2002 and Health 2000, total n=26,377), and 2 series of forensic autopsies from Helsinki and Tampere (n= 695). We constructed a QT genotype score using the allele copy number and the effect estimates for the SNPs associated with QT interval in prior studies. Adjudication of the cause of death revealed 717 SCDs. Regression models adjusted for age, sex and geographical area. Risk estimates were pooled using fixed effects meta-analysis using inverse variance weights.

Results: Among 5,769 Health2000 subjects in whom ECGs were available, the QT genotype score predicted the observed QT (p<1E-106); the observed QT interval was associated with SCD (p=0.01). The QT score was weakly associated with increased risk of SCD (p=0.04) in Health2000, but not on meta-analysis of all samples (p=0.10). Analyses of individual common variants revealed 5 SNPs associated with SCD at the p<0.05 level. The strongest associations included rs2200733 on chr4q25, previously related to atrial fibrillation risk, with a relative risk of 1.23 (95% CI 1.06 - 1.42, p= 0.006) per minor allele and rs41312391 in an intron of SCN5A, with RR of 1.25 (95% CI 1.10-1.43, p=0.001).

Conclusions: Our study identified five novel genetic variants associated with the risk of SCD. We confirmed the association between QT genotype score and observed QT interval, but failed to show a relationship between QT genotype score and SCD, possibly due to limited power. Larger studies are warranted to fully define the contribution of common genetic factors, alone or in aggregate, to SCD.

Screening for copy number variation and sequencing candidate genes associated with conotruncal heart defects. *K. Osoegawa[1,2], D. Iovannisci[1], M. Ladner[1], K. Schultz[1], B. Lin[1], C. Parodi[1], S. White[1], S. Hawbecker[1], A. Borg[3], G. Shaw[4], E. Trachtenberg[1,2], E. Lammer[1].* 1) Research Inst, Childrens Hosp Oakland, Oakland, CA; 2) Center for Applied Genomics, Childrens Hosp Oakland, Oakland, CA; 3) Department of Oncology, Lund University, Sweden; 4) Pediatrics in the Division of Neonatal & Developmental Medicine, Stanford University School of Medicine.

Congenital heart defects are the most common anatomical grouping of human birth defects, yet little is known about their etiologies. Conotruncal defects are an important pathogenetic subset of congenital heart defects, comprising nearly 20 percent. We previously showed that array comparative genomic hybridization (array-CGH) analysis of DNA samples derived from cleft lip and palate subjects was an efficient and productive method for identifying candidate chromosomal loci, complementing traditional genetic mapping strategies. DNA samples from a population-based sample of ~400 California infants born during 1999-2004 with conotruncal defects were screened for chromosomal microdeletions/duplications as an approach to identify candidate genes for conotruncal defects. Previously identified deletion cases at 22q11.21 were confirmed using array-CGH to evaluate the compatibility of the technology with DNA samples from conotruncal defects. Of 220 cases analyzed, we identified one subject with a novel 3.9 Mb duplication at 8p23.1. Deletions overlapping this 8p23 region have been associated with congenital heart defects. Among males, we also identified four subjects who had 47,XYY or mosaic 47,XYY karyotypes. Each was diagnosed as tetralogy of Fallot. In addition to the genome wide screening, we began developing a strategy for identifying micro-deletions/duplications using multiplex ligation-dependent probe amplification (MLPA) and sequencing of 9 candidate genes that are expressed in secondary heart field cells or for which mutations have been reported in a few infants with conotruncal defects. For sequencing, DNA fragments containing exons from these genes have been amplified via PCR, pooled, and sequenced using the Roche 454 GS FLX system. The current technology allows us to obtain ~1 million sequences per run with an average read length of 450 bases. We will compare DNA sequences obtained from children born with conotruncal defects with reference sequences to identify nucleotide changes associated with conotruncal defects.

Germline GJA1 (Connexin 43), GJA5 (Connexin 40) and GJC1 (Connexin 45) mutations in atrioventricular nodal reentrant tachycardia (AVNRT). *H. Ak Celik[1], C. Hasdemir[2], H.H. Aydin[1]*. 1) Department of Medical Biochemistry, Ege University School of Medicine, Izmir, Turkey; 2) Department of Cardiology, Ege University School of Medicine, Izmir, Turkey.

Connexins are a group of structurally-related transmembrane proteins that assemble to form gap junctions. Multiple connexin types are expressed in heart muscle including Connexin 40 (GJA5), Connexin 43 (GJA1) and Connexin 45 (GJC1). Although, differences in connexin expressions are well documented in acquired adult hearth diseases, their mutations have only rarely been identified. The study population consisted of 4 patients (4 female, age range 37-53 y/o). All patients presented with palpitations. All patients underwent electrophysiologic study and radiofrequency catheter ablation. Transthoracic echocardiography was performed for left/right ventricular function and atrial sizes. All patients had slow/fast type AVNRT. One patient had also nonsustained right atrial tachycardia. All patients had structurally normal heart. We sequenced GJA1, GJA5 and GJC1 genes from genomic DNA isolated from peripheral lymphocytes. Silent and heterozygous missense GJA1 (Connexin 43) mutations were identified in all patients. GJA5 (Connexin 40) mutations were indentified in 3 patients and GJC1 (Connexin 45) mutations were determined only in 2 patients. We hypothesize that atrioventricular nodal reentrant tachycardia has a genetic basis and the genes encoding heart muscle connexins may play role in pathogenesis of AVNRT.

Gene and protein activation of mitogen activated protein kinases in post-infarcted patients. *R. Akbarzadeh Najar[1], S.M.H. Ghaderian[1], A.S. Tabatabaei Panah[2]*. 1) Department of Medical Genetics, Faculty of Medicine, Shahid Beheshti University of Medical Sciences and Health Services, Tehran, Iran; 2) Department of Biology, Basic Sciences Faculty, Islamic Azad University, East Tehran Branch (Ghiamdasht), Tehran, Iran.

Purpose Remodeling in the failing heart involves several cell signal transduction pathways which are regulated in the heart in direct response to changes in mechanical loading conditions. Activation of mitogen-activated protein kinases (MAPKs) signaling cascade are important pathophysiologic regulators during the development of heart failure (HF). In present study, we designed to monitor the activity of these MAPKs in Iranian patients with acute myocardial infarction (AMI) comparing with controls. Methods The degree of activation (Phosphorylation) of p38 kinase, p44/42 extracellular regulated kinase, and c-Jun N-terminal kinase (JNK1/2) and their corresponding activity levels were analyzed in peripheral blood mononuclear cells (PBMCs) of 258 patients with AMI and 250 normal subjects. The expression of p38α mRNA was determined by real time RT-PCR. These analysis were carried out immediately and 12 hours after AMI. The investigation conforms to the principles outlined in the 1964 Declaration of Helsinki. A P value less than 0.05 was considered statistically significant. Results Activity of p38 and JNK1/2 MAPKs were significantly increased in patients with AMI than controls immediately after infarction which was reduced during 12 hours after AMI. There was statistical significant increase in the ratio of phosphorylated p38:total p38 ($P<0.05$) and also a significant increase in the level of phosphorylation of ATF-2 ($P<0.05$) in the patients than healthy individual. However, there were no statistically differences in activation and activity of p44/42 in the patients and controls. A comparison of the patients with control subjects demonstrated that in AMI, p38α mRNA expression was 3.1-fold and 2.2-fold higher than control samples respectively. Conclusion Results of this study indicate that these MAPKs signaling pathway might be activated by AMI which signal transduction involves kinase phosphorylation and play important roles in their activity. Activation of MAPKs mainly p38 and c-Jun N-terminal kinase are associated with different forms of cardiac pathology such as AMI and their signal transduction involves kinase phosphorylation, which play significant roles in gene expression and protein function. Elevated activity of p38 and JNK1/2 MAPKs suggests that they may potentially play significant roles in HF. These observations are particularly intriguing in light of the fact that these regulating factors are important in pathophysiology of AMI and HF.

653/W

Genetic Determinants of Plasma Apolipoprotein A2 Levels are Associated with Atherosclerotic Burden and Progression in Stable Cardiac Patients. *H. Allayee[1], W.H. Tang[2], J. Hartiala[1], Y. Patel[1], S. Hazen[2,3]*. 1) Dept Preventive Med, Univ Southern California, Los Angeles, CA; 2) Department of Cardiovascular Medicine, Cleveland Clinic, Cleveland, OH; 3) Department of Cell Biology, Cleveland Clinic, Cleveland, OH.

Background: Apolipoprotein A2 (ApoA2), the second most abundant protein on high-density lipoprotein (HDL) particles, has been associated with triglyceride metabolism and insulin resistance in animal models, but its role in humans is unclear. We investigated the genetic relationship of HDL cholesterol-adjusted ApoA2 levels with atherosclerotic disease burden and progression in humans. **Methods:** We carried out genome-wide association study (GWAS) for ApoA2 levels adjusted for HDL with 1 million SNPs in 2367 subjects undergoing elective coronary angiography. SNPs that demonstrated genome-wide significant association ($p<10^{-8}$) with ApoA2 levels were also tested for association with future need for revascularization after three years of follow up. **Results:** In our cohort (age 63±11 years, 66% male), a higher ApoA2 levels, expressed as a ratio to HDL, were associated with increased risk of prevalent cardiovascular disease (odds ratio [OR] 1.54; 95%CI 1.42-1.66, $p<0.001$) and need for future revascularization (HR 1.18; 95%CI 1.13-1.24, $p<0.001$). Five loci located on chromosomes 1, 2, 3, 4, and 10 exhibited significant p-values for adjusted ApoA2 levels ranging from 10^{-9} to 10^{-13}. The SNP on chromosome 1 is located upstream of the ApoA2 structural gene and lowers ApoA2 levels by 1 mg/dl per minor allele copy. Of these five loci, subjects carrying the minor allele for SNPs on chromosome 2p12 (6% frequency) and chromosome 4p16.3 (7% frequency) also demonstrated a 2-fold increased risk in need for future revascularization (both HR 2.0, 95%CI 1.6-2.4, $p<0.0001$), consistent with their effects on raising plasma ApoA2 levels. **Conclusions:** In stable cardiac patients, ApoA2, when analyzed in relation to HDL, provides independent association with CVD and risk for future revascularization. The results from our GWAS also support this notion since SNPs that lead to higher ApoA2 levels are also associated with increased risk for future revascularization.

The Effect of Survivorship Bias on Cross-Sectional Case-Control Genetic Studies of Highly Lethal Diseases. *C.D. Anderson[1,2,3], M.A. Nalls[4], A. Biffi[1,2,3], N.S. Rost[1,2,3], S.M. Greenberg[2], A.B. Singleton[4], J.F. Meschia[5], J. Rosand[1,2,3]*. 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Hemorrhagic Stroke Research Group, Department of Neurology, Massachusetts General Hospital, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 4) Laboratory of Neurogenetics, Intramural Research Program, National Institute on Aging, Bethesda, MD; 5) Department of Neurology, Mayo Clinic, Jacksonville, FL.

Background: Survivorship bias is the phenomenon by which individuals are excluded from analysis of a trait because of mortality related to the expression of that trait. In genetic association studies, variants increasing risk for disease onset as well as risk of disease-related mortality (lethality) could be difficult to detect in cross-sectional case-control designs, possibly leading to underestimation of a variant's effect on disease risk.

Methods and Results: We modeled cohorts for three diseases of high lethality (intracerebral hemorrhage, ischemic stroke, and myocardial infarction) using existing longitudinal data. Based on these models, we simulated case-control genetic association studies for genetic risk factors of varying effect sizes, lethality, and minor allele frequencies (MAF). For each disease, erosion of detected effect size was larger for case-control studies of individuals of advanced age (age > 75 years) and/or variants with very high event-associated lethality (Genetic-conferred Relative Risk for event-related death > 2.0). We found that survivorship bias results in no more than 20% effect size erosion for cohorts with mean age < 75 years, even for variants that double lethality risk. Ascertainment of at least 40% of lethal cases in the population further reduces this phenomenon, resulting in < 20% effect size erosion even for cohorts of advanced age with extremely lethal phenotypes. Furthermore, we found that increasing effect size erosion was accompanied by depletion of MAF in the case population, yielding a "signature" of the presence of survivorship bias. Once again, ascertainment of 40% of lethal cases mitigated this MAF depletion.

Conclusion: Our results demonstrate that failure to enroll lethal cases can distort the measured effect sizes for genetic variants affecting both disease incidence and lethality. However, this bias results in less than 20% erosion in observed effect sizes for cohort ages < 75 years, and is further minimized by enrollment of a small portion (40%) of lethal cases in the population. Our simulation provides formulae to allow estimation of effect size erosion given a variant's odds-ratio (OR) of disease, OR of lethality, and MAF. These formulae will add precision to power calculation and replication efforts for case-control genetic studies. Our approach requires validation using prospective data.

Benjamin[17], CHARGE Consortium Inflammation Working Group.* 1) Department of Medicine and Cardiovascular Health Research Unit, University of Washington, Seattle, WA, USA; 2) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX, USA; 3) Department of Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 4) Helmholtz Zentrum München, German Research Center for Environmental Health, Institute of Epidemiology, Neuherberg, Germany; 5) Department of Epidemiology & Prevention, Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC, USA; 6) Institute of Behavioural Sciences, University of Helsinki, Helsinki, Finland; 7) Unit of Genetic Epidemiology & Bioinformatics, Department of Epidemiology, University Medical Center Groningen, University of Groningen, the Netherlands; 8) Institute of Clinical Chemistry and Laboratory Medicine, University of Greifswald, Germany; 9) Division of Clinical Developmental Sciences, St George's University of London, London, UK; 10) Department of Biostatistics, Boston University School of Public Health, Boston, MA, USA; 11) Departments of Pathology and Biochemistry, University of Vermont College of Medicine, Burlington, VT, USA; 12) Department of Medicine, Baylor College of Medicine and Center for Cardiovascular Prevention, Methodist DeBakey Heart and Vascular Center, Houston, TX, USA; 13) Department of Internal Medicine II-Cardiology, University of Ulm Medical Center, Ulm, Germany; 14) National Public Health Institute, Helsinki, Finland and Department of General Practice and Primary Health Care, University of Helsinki, Helsinki, Finland; 15) Interfaculty Institute for Genetics and Functional Genomics, University of Greifswald, Germany; 16) Member of the Netherlands Genomic Initiative (NGI); 17) National Heart, Lung, and Blood Institute's and Boston University's Framingham Heart Study, Framingham, MA, USA.

Background: To identify genetic variants associated with circulating Interleukin-6 (IL-6), a cytokine marker of inflammation and a risk factor for cardiovascular events, we conducted a meta-analysis of genome-wide association data in subjects of European ancestry from ten large studies in the setting of the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium. **Methods:** Participants were from ten community-based studies: the Atherosclerosis Risk in Communities study, the Cardiovascular Health Study, the Framingham Heart Study, Health ABC, the Helsinki Birth Cohort Study, MONICA/KORA, the Netherlands Study of Depression and Anxiety, the Rotterdam Study, the Study of Health in Pomerania, and TwinsUK. Each study used whole genome genotype information to impute to HapMap's CEU panel and employed regression models to relate ~2.5 million single nucleotide polymorphisms (SNPs) to log-transformed IL-6 levels. We then combined study-specific findings in a fixed-effects meta-analysis including up to 20,084 individuals. **Results:** We identified 70 SNPs at two genomic loci whose p-values for association with IL-6 levels surpassed our genome-wide significance threshold corresponding to one expected false positive ($p < 4.0\times10^{-7}$). On chromosome 1, we identified associations with 68 SNPs within and around the gene encoding the IL-6 receptor ($p = 5.3\times10^{-40}$), a part of a protein complex through which IL-6 exerts its actions. Additionally, we identified an association for 2 SNPs on chromosome 6 near the Notch homolog 4 gene ($p = 6.2\times10^{-8}$), whose product is part of an evolutionarily conserved intercellular signaling pathway. **Conclusions:** Our community-based genome-wide association meta-analysis identified two regions that were associated with circulating IL-6 levels. One, in the cytokine's receptor, confirms previous studies. The other, in a region of chromosome 6, may highlight other inflammation-related pathways of importance.

Replication study of plasma lipoprotein levels-associated SNPs identified in recent GWAS. *E.K. Bryant[1], A.S. Dressen[1], J.E. Hokanson[2], R.F. Hamman[2], C.M. Kammerer[1], M.I. Kamboh[1], F.Y. Demirci[1].* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Epidemiology, Colorado School of Public Health, Univ Colorado Denver, Aurora, CO.

Genome-wide association studies (GWAS) have identified a number of genes/SNPs associated with plasma total cholesterol (T-C), low density lipoprotein cholesterol (LDL-C), high density lipoprotein cholesterol (HDL-C), and triglyceride (TG) levels. Most of the previously established lipid genes also confirmed by these GWAS are being comprehensively evaluated by our group using deep sequencing based-SNP discovery strategy. The purpose of this study was to test the replication of GWAS signals from other genes that were not targeted by our sequencing effort in two epidemiological samples, U.S. Non-Hispanic Whites (NHWs, *n*=623) and Hispanics (*n*=410). For each SNP, the association analysis was performed with all lipoproteins regardless of previously reported specific associations. To date nine SNPs have been genotyped and the screening of additional SNPs is underway. Six SNPs showed significant associations with one or more lipoprotein traits among NHWs and the strongest associations ($P<0.01$ after adjusting for gender, age, BMI, smoking) were: *GRIN3A*/rs1323432 with T-C ($P=0.002$) and LDL-C ($P=0.009$), *NUTF2*/rs2271293 with HDL-C ($P=0.009$), and *DOCK7*/rs10889353 ($P=5\text{x}10^{-5}$) & *GALNT2*/rs2144300 ($P=0.006$) with TG. Among Hispanics, the associations were either weaker ($P=0.004$ for rs10889353 with TG) or non-significant but with a similar trend (rs1323432, rs2271293, and rs2144300), probably partly due to the smaller sample size. Ongoing efforts towards defining the spectrum of lipoprotein traits-associated genetic loci/variants and their consistent replication by independent groups across various ethnic populations will help to improve our understanding of genetic regulation of these traits and will likely guide new therapeutic interventions.

657/W

A Genome-wide Copy Number Variation association study of Young-Onset Hypertension in Han Chinese Population of Taiwan. *K.M. Chiang[1,3], H.C. Yang[2], Y.J. Liang[2], W.H. Pan[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Institute of Statistical Sciences, Academia Sinica, Taipei, Taiwan; 3) Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan.

Hypertension is a common and complex disorder. Although many large scale genome-wide association studies of SNPs have been performed, only a few studies have successfully identified the loci that are related to the hypertension, not to mention the scanty Asian studies. Besides single nucleotide polymorphisms (SNPs), copy number variation (CNV) is now being known as an important role in genetic susceptibility to common disease. Young-onset hypertension (YOH) may be a more feasible target disorder to investigate than the late-onset one due to its stronger genetic component. To address this issue, we performed a genome-wide study of association between CNVs and Young onset hypertension. Using the Illumina HumanHap550 BeadChips which contains nearly 4,300 SNPs in approximately 500 reported copy number variant regions of the genome, we typed 400 YOH cases and 400 age and gender matched controls. CNV regions were identified by PennCNV which implements a hidden Markov model (HMM) that integrates multiple sources of information to infer CNV calls for individual genotyped samples. The CNV calls which contain more than 10 SNPs and larger than 50kb were used to analyze. Two different analyses, regional association test and the association tests with sliding-window procedure, were used to identify potential CNVs. We identified some CNVs on the chromosome 1p36.3, 4p16.3, 9q34.3, 11q11, 14q32.33, 16p13.3, 16q24.3, 19p13.3 and 19q13.31, seemed to be associated with YOH. Changes in the copy number level of dosage-sensitive gene may alter the gene dosage. All of the expression levels of the genes which were spanned by these CNVs are currently being tested with the 400 YOH case-control pairs.

Clinical Diagnosis of Marfan Syndrome using an electronic guideline. *J. Dean, A. Ross, C. Brown.* Medical Genetics, University of Aberdeen, Aberdeen, United Kingdom.

The International Nosology for the diagnosis of Marfan Syndrome published in 1996 has become the gold standard for making the diagnosis. The Scottish Marfan Clinical Guideline facilitates use of this nosology in the clinic. In recent years, the discovery of Marfan like disorders such as the Loeys-Dietz syndrome has added weight to the need for a revision of the nosology to take account of these disorders and of increasing knowledge about the clinical spectrum of the fibrillinopathies. The development of targeted treatments such as ARBs currently under trial has also increased the need for accurate diagnosis. A clinical Marfan database has been devised which implements the Scottish Marfan Guideline electronically. Using this database, we have compared the outcome of clinical assessment of the Aberdeen Marfan clinic patients using the International nosology with the results of molecular testing of fibrillin-1, TGFBR1 and TGFBR2. There is a close but not complete correlation between clinical diagnosis and molecular diagnosis. The discrepancy is attributable to several factors including the well known reduced effectiveness of the nosology in children, the difficulty of confirming the clinical features in relatives when family history is needed as a diagnostic criterion, the non-specificity of dural ectasia in connective tissue disorders, and the existence of patients with mild disease and fibrillin mutation. The information presented may help to inform the diagnostic process and the revision of the international nosology.

Identification of novel MYBPC3 gene mutations associated with hypertrophic cardiomyopathy. *J-H. Ding[1], W-J. Yin[2], S. Greene[2], N. Akilla[2], B-Z. Yang[1], P.A. Grayburn[3].* 1) Institute of Metabolic Disease, Baylor Research Institute, Dallas, TX; 2) Institute of Biomedical Studies, Baylor University, Waco, TX; 3) Institute of Cardiovascular Diseases, Baylor University Medical Center, Dallas, TX.

Hypertrophic cardiomyopathy (HCM), an autosomal dominant disorder, represents the most common inherited cardiovascular disorder with a prevalence of 1/500 in the general population. HCM manifests a wide range of clinical features and is the primary cause of sudden cardiac death in young adults. Sarcomeric gene mutations are a well known cause of HCM in both adults and children. More than 450 different pathogenic mutations in at least 17 genes have been identified with large allelic and genetic heterogeneity. The two most frequently mutated genes are the MYBPC3 gene (OMIM #600958) and the MYH7 gene (OMIM #160760). Here we report two novel mutations in two unrelated patients with HCM. Case 1 is a 46-year old Middle Eastern man with severe asymmetric septal hypertrophy (septal thickness 3.3 cm) on echocardiography but no resting outflow tract gradient. He has no family history of sudden death or heart failure. To investigate the molecular defect, genomic DNA was extracted from blood and all exons and flanking intronic regions of MYH7 and MYBPC3 genes were amplified. The PCR products were purified and sequenced. Sequence analysis revealed that the patient is a homozygous for an A-to-G nucleotide change at position 935 in exon 13, which leads to p.K312R mutation in the MYBPC3 gene. This novel mutation was verified by a PCR/restriction test, but was not detected in the normal control subjects. Case 2 is a 53-year old Asian man who underwent implantation of a cardiac defibrillator after being resuscitated from sudden cardiac death. His echocardiogram showed mild asymmetric septal hypertrophy with no resting outflow tract gradient. His DNA sequencing revealed a single base-pair deletion at position 453 in exon 5 (c.453delT), resulting in a frameshift at code 151 (p.Asp151GlufsX8) in MYBPC3. Subsequent subcloning and sequencing also confirmed that the patient was a heterozygous for this novel deletion. Our study suggests that despite the numerous reports of mutations in the MYBPC3 gene, there exist novel mutations in HCM patients of non-European ethnic origins. Further studies will improve our understanding of genetic causes in HCM patients.

Genes for Aging-Dependent Atherosclerosis. *J.R. Dungan[1], A.S. Allen[2], S.H. Shah[3,4], W.E. Kraus[4], E.R. Hauser[3].* 1) Sch Nursing, Duke Univ, Durham, NC; 2) Biostatistics & Bioinformatics, Duke Univ, Durham, NC; 3) Center for Human Genetics, Duke Univ, Durham, NC; 4) Dept of Medicine (Cardiology), Duke University, Durham, NC.

Atherosclerosis is a disease of aging; prevalence and mortality increase with age. The aging process contributes to known cardiovascular effects leading to CAD. Biomarker risk factors for CAD also show age-dependent distributions. We hypothesized that some candidate genes for CAD may also be implicated in aging-dependent atherosclerosis. Our primary aim was to examine statistical interactions between age and CAD candidate genes to generate formal evidence of genetic effects mediated by age. We performed a secondary analysis of 598 SNPs for 498 previously genotyped CAD candidate genes in 1,885 subjects in the Duke Catheterization Genetics (CATHGEN) case-control study. Participants were recruited sequentially through the cardiac catheterization laboratories at Duke University Hospital (Durham, NC, USA). SNPs were genotyped using either TaqMan or Illumina BeadArray. We evaluated age-by-genotype interactions in a gene association model of CAD severity, as quantified by the CAD index, a numerical summery of coronary angiographic data that incorporates extent and anatomical distribution of coronary disease. We fitted a weighted regression model with CAD index as the dependent variable and known CAD risk factors, age at Duke catheterization, genotype (dominant model) and an age*genotype interaction term, with sample weights as implemented in PROC SURVEYREG (SAS 9.2, Cary, NC) to control for the CATHGEN case-control sampling scheme. We defined age as age at cardiac catheterization as this was subject's age at the time the CAD index variable was determined on cath. In addition, we calculated moving average plots of minor allele frequencies (MAF) across age, incorporating both sampling and kernel weights, in order to visualize the unique distributions of MAF across age. We report eight SNPs corresponding to eight different genes that had significant age*genotype interactions. After Bonferroni correction for 598 tests, three SNPs remained highly significant: RS12528807 (PLA2G7 gene); RS12610791 (SPINT2 gene); and, RS1800206 (PPARA gene). Variants in these genes have previously been implicated in cardiovascular, metabolic, and aging phenotypes. Eight SNPs represent candidate genes for aging-specific CAD progression. Finding genes for cardiovascular aging are important to improve care of older people with heart disease. Characterizing the influence of age interactions with gene associations is also critical to refining gene associations with CAD.

661/W

Identifying mitral valve prolapse mutations on chromosomes 11 and 13 using next-generation sequencing. *R. Durst[1,2], M. Leyne[1], RA. Levine[2], SA. Slagenhaupt[1] on behalf of the Leducq Mitral Consortium.* 1) CHGR, MGH, Boston, MA; 2) Cardiology Division, Massachusetts General Hospital, Boston, MA.

Mitral valve prolapse (MVP) is a common cardiac disorder that exhibits a strong hereditary component. Twenty percent of MVP patients will develop severe complications, including congestive heart failure, endocarditis, atrial arrhythmias, embolic events and even sudden death. Surprisingly, very little is known about the developmental etiology of MVP. To date, only mutations in FLNA have been shown to cause non-syndromic MVP. Previously, we identified two MVP loci using genetic linkage analysis in large families: MMVP2 on chromosome 11p15.4 and MMVP3 on chromosome 13q31.3-32.1. We were recently awarded an R102 NHLBI Resequencing and Genotyping Service grant that allowed us to capture and sequence these loci. All sequencing was performed at the Venter Institute. A DNA library of the two loci was prepared using SureSelect technology. After excluding repeat elements we targeted ~50% of each locus. Four individuals from each family, who share only the disease allele, were selected for sequencing. Sequencing was performed on the Solexa sequencer. 97% of the targeted area was sequenced and the average coverage was 310X. Single nucleotide polymorphisms (SNPs) were identified and characterized as potential mutations if they were 1) shared by all four individuals in the family and 2) not present in dbSNP or other public databases. After analyzing familial sharing, there were 155 potential mutations on chromosome 11 and 308 on chromosome 13. These potential mutations were prioritized and evaluated in the following order: 1) coding sequence changes, 2) promotor or splice site changes, and 3) changes in evolutionary conserved regions. Using these criteria, we identified several potential missense mutations in the MMVP2 locus. There are no coding changes in the MMVP3 locus, but there are 25 changes in highly conserved regions adjacent to three genes, GPC6, GPC5 and HS6ST3. We are currently evaluating these mutations for potential function and initiating sequencing in a large cohort of familial and sporadic MVP patients in order to identify additional mutations.

GALNT2, a novel GWAS locus associated with HDL-C, does not alter HDL catabolism. *A.C. Edmondson[1], A. Raghavan[1], J.S. Millar[1], S.A. Khetarpal[1], S. Kathiresan[2], D.J. Rader[1].* 1) Institute of Translational Medicine and Therapeutics, University of Pennsylvania, Philadelphia, PA; 2) Broad Institute and Massachusetts General Hospital, Boston, MA.

Genome wide association studies (GWAS) for quantitative traits, such as blood lipid concentrations, have successfully identified many genes previously implicated in rare Mendelian disorders of lipoprotein metabolism and have also mapped many novel loci. One such novel locus for plasma high density lipoprotein cholesterol (HDL-C) is on chromosome 1 and contains the GALNT2 gene with the most significant SNP located in the first GALNT2 intron. GALNT2 is involved in the first step of O-linked glycosylation of proteins and was never previously linked to HDL metabolism. Hepatic overexpression of GALNT2 decrease HDL-C and knock-down of endogenous mGALNT2 increases HDL-C. However, the mechanism of HDL-C modulation by GALNT2 is unknown. To elucidate this mechanism, mice were injected with human HDL radiolabeled on the protein and cholesteryl ester moieties and kinetic parameters were studied in WT mice and mice overexpressing GALNT2. The mice overexpressing GALNT2 had an approximate 25% decrease in HDL total cholesterol (P = 0.002), reflecting decreased free cholesterol (P=0.004) and decreased cholesterol ester (P=0.002), but an unaltered cholesterol ester/free cholesterol ratio (P=0.603) suggesting normal cholesterol esterification. GALNT2 overexpressing mice did not exhibit significantly altered ApoA-I protein concentration (P=0.10), ApoA-I production rate (P=0.12), and did not have a change in fractional catabolic rate of protein (P=0.68) or cholesteryl ester (P=0.235). GALNT2 overexpressing mice did have a decreased HDL-C/ApoA-I ratio (P=0.0006). There were no major alterations in tissue uptake of HDL cholesterol or protein in GALNT2 overexpressing mice. These results suggest that GALNT2 may affect HDL-C production, rather than catabolism.

Heritability and Linkage of Left Ventricular Diastolic Filling Velocity in the Jackson Heart Study. *L. Ekunwe[1], E. Fox[2], S.G. Buxbaum[1].* 1) Jackson Heart Study, Jackson State University, Jackson, MS; 2) University of Mississippi Medical Center, Jackson, MS.

Background: Left ventricular diastolic filling velocity ratio is frequently used to define diastolic function and is predictive of cardiovascular morbidity and mortality. In other words, it can be thought of as an endophenotype for Coronary Heart Disease (CHD). Other studies have shown a genetic link between diastolic function and its relationship to coronary heart disease. This study's aim is to determine if there is a heritable component to diastolic function with evidence of linkage. The prevalence of diastolic dysfunction is high in this cohort and therefore it is of interest to determine whether there are genetic factors underlying this trait in this African American population sample.

Methods: Three measures of diastolic function were measured: Mitral valve A and E wave velocity, and the ratio of valve A to valve E. These were adjusted for age, sex, body mass Index (BMI) and waist circumference (WC) using SAS PROC GLM. Heritability (h^2) of the residuals was determined using ASSOC in S.A.G.E. Subsequently, multipoint model-free linkage analysis was performed in SIBPAL in S.A.G.E.

Results: Heritability of mitral valve E (E), mitral valve A (A), and ratio of E/A (E/A) were 18, 21%, and 16%, respectively. Suggestive evidence for linkage of both E and A wave velocities were found at the same locus on chromosome 1 at or near microsatellite marker D1S3721 (LOD 1.83 at 72.6 cM and 2.45 at 76 cM, respectively). Strong evidence for linkage was found for E/A (LOD 3.60), however, this was at a different locus on chromosome 1, at 274 cM near D1S1609. Strong evidence of linkage for E/A was also found on chromosome 3p26 (LOD 3.62)and 18p21.2 (LOD 4.08). A LOD of 5.2 was found on 3q26.1 for E wave.

Conclusion: Each of these endophenotypes for CHD were moderately heritable. Evidence for linkage was found on chromosome 18 and at two loci on chromosomes 1 and 3.

A novel missense mutation M185V in the TAZ gene associated with atypical Barth syndrome. *Y. Fan[1], R. Chang[2, 3], M. Fox[4], B.A. Westerfield[1], J. Steller[3], A.S. Batra[3], R.Y. Wang[2,3], K. Dipple[4], N. Gallant[4], L.S. Pena[1], H. Wang[1], E.R. McCabe[4], V.E. Kimonis[3].* 1) John Welsh Cardiovascular Diagnostic Laboratory, Section of Cardiology, Department of Pediatrics, Texas Children's Hospital, Baylor College of Medicine, Houston, TX; 2) Division of Metabolic Disorders, Children's Hospital of Orange County, Orange County, CA; 3) Children's Hospital of Orange County and Department of Pediatrics, University of California Irvine, CA; 4) Department of Pediatrics, University of California Los Angeles, CA.

Barth syndrome is an X-linked recessive disorder characterized by dilated cardiomyopathy, neutropenia, 3-methylglutaconic aciduria, abnormal mitochondria, variably expressed skeletal myopathy, and short stature. The disorder is caused by mutations in the tafazzin (TAZ/G4.5) gene located on Xq28, as first described by Bione et. al. in 1996. Alternative splicing of the gene yields several different proteins, the functions of which remain largely uncharacterized. Sequencing of the TAZ gene is currently the most reliable diagnostic approach for Barth syndrome. We describe an Irish/German family in which the 4-month-old proband presented with respiratory distress, neutropenia and dilated cardiomyopathy with reduced ejection fraction of 10% by echocardiogram. 3-methylglutaconic aciduria was not detected on three urine organic acid analyses in the proband. Family history indicated that his maternal uncle died of endocardial fibroelastosis and dilated cardiomyopathy at the age of 26 months. A novel missense mutation 553A>G (M185V) in exon 7 of the TAZ gene was identified in the proband through bidirectional sequencing. Family studies revealed that the proband's mother, maternal aunt and grandmother carry the same missense mutation. Bioinformatic analysis predicted that this sequence alteration is deleterious by PolyPhen-2 algorithm. This missense mutation was not present in 115 X chromosomes from 81 ethnically-matched control subjects (47 males and 34 females). The identification of TAZ gene mutations is important for the diagnosis and genetic counseling in this family with atypical Barth syndrome that is not associated with 3-methylglutaconic aciduria.

***ATP1B1*, *RGS5* and *SELE* polymorphisms and association with hypertension in African Americans.** *M.U. Faruque[1], G. Chen[2], A. Doumatey[2], H. Huang[2], J. Zhou[2], G.M. Dunston[1], C.N. Rotimi[2], A.A. Adeyemo[2].* 1) National Human Genome Center, Howard University College of Medicine, Washington, DC; 2) Center for Research on Genomics and Global Health, National Institutes of Health, Bethesda, MD.

Background and Purpose: Hypertension is a global public-health burden because of its high incidence and concomitant risks of cardiovascular and kidney diseases, leading to significant mortality and morbidity worldwide. It is known to disproportionately affect populations of African ancestry compared to their European counterparts. In addition to other factors, genetics is thought to play a role in the disease-associated disparity. While increasing number of hypertension associated genetic variants are being reported, few have been replicated in independent studies. Association of chromosome 1q with blood pressure (BP) related phenotypes have been reported in independent linkage studies. Animal studies have showed evidence of linkage of BP-related QTLs in mouse and rat to human 1q syntenic chromosomal loci. Several genes in this hypertension linkage region, including *ATP1B1*, *RGS5* and *SELE*, have been reported to be associated with hypertension. We examined the genetic role of these three genes in hypertension development in African Americans. Materials and Methods: We examined 87 tag single nucleotide polymorphisms (tSNPs) from the *ATP1B1*, *RGS5* and *SELE* genes in a well-characterized cohort of 968 African Americans from Washington D.C. metropolitan area. Single SNP and haplotype association testing was done under an additive genetic model and adjusting for age, gender, body mass index and ancestry-by-genotype (principal components). Results: A total of 12 SNPs were found associated with hypertension and associated traits at a replication p-value < 0.05. The strongest signal for hypertension was for rs2815272 in the *RGS5* gene ($p = 9.3X10^{-3}$). For systolic blood pressure (SBP), rs3917420 in the *SELE* gene ($p = 9.0X10^{-4}$) and rs4657251 in the *RGS5* gene ($p = 9.7X10^{-3}$) were the top hits. Individual variants in these genes had phenotypic effects ranging from -2.2 to 7.2 mm Hg for SBP and -2.0 to 2.8 mm Hg for diastolic blood pressure (DBP). One *SELE* gene haplotype, (CCAGC: rs4656701-rs4363475-rs12038818-rs4786-rs5368) showed statistically significant association with SBP after correction for multiple testing ($p < 0.01$). Conclusions: These findings further confirm the genetic role of *ATP1B1*, *RGS5* and *SELE* in hypertension. Given their physiological role in blood pressure regulation, further studies are warranted to examine the functional significance of this genetic finding.

666/W

Generalization of GWAS-based genetic effects for blood pressure: The Strong Heart Family Study. *N. Franceschini[1], V.S. Voruganti[2], S. Laston[2], K. Haack[2], E.T. Lee[3], L.G. Best[4], J.W. MacCluer[2], J.G. Umans[5], T.D. Dyer[2], S.A. Cole[2], K.E. North[1,6].* 1) Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 3) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 4) Missouri Breaks Industries Research Inc, Timber Lake, SD; 5) Medstar Research Institute, Washington, DC; 6) Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC.

Hypertension is one of the leading causes of morbidity and mortality in the US and disproportionately prevalent among minority populations. Whereas recent genome wide association (GWA) studies have identified several loci associated with blood pressure (BP) traits, the impact of these variants in populations of different ancestral backgrounds is largely unknown. The purpose of the current study was to identify genetic loci influencing BP traits in a biomedically understudied minority population, American Indians. We selected 43 recently identified GWA single nucleotide polymorphisms (SNPs) in 23 loci for genotyping in 3807 American Indian participants of the Strong Heart Family Study (three centers: Arizona, Dakotas and Oklahoma). We applied standard quality control to the genotyped data (call rate>90%). One SNP failed (rs16998073 in the *FGF5* gene) and the remaining 42 were considered further. Center-specific BP residuals were obtained from linear regression models adjusted for age, sex, age^2 and age-by-sex interaction. We then performed an inverse normalization of the center-specific residuals which were used as phenotypes. The residuals were regressed onto SNP dosage using variance component models to account for family relatedness and population history. Summary estimates across centers were combined using a weighted average of point estimates meta-analyses (fixed effects). Interestingly, notable differences in allele frequencies across centers were observed. Six SNPs in five loci were associated with systolic BP (alpha= 0.05): rs9815354 in *ULK4* (p=0.03), rs10491334 in *CAMK4* (p=0.02), rs11191548 near *NT5C2* (p=0.009), rs381815 and rs11024074 in *PLEKHA7* (p=0.02 both) and rs2681492 in *ATP2B1* (p=0.02). In addition, several of the SNPs had effects that were in the correct direction although with p values between 0.05 and 0.20, due to the inherent small effects sizes of these variants and the limited sample size. These findings suggest some genetic susceptibility similarities to BP related traits across European and American Indian populations. Future work in this population should fine map these regions as trans-racial mapping may narrow the implicated regions and help identify the underlying functional alleles.

Replication of genetic association studies in calcific aortic valve stenosis. *N. Gaudreault[1], V. Ducharme[1], M. Lamontagne[1], P. Mathieu[1], P. Pibarot[1], Y. Bossé[1,2].* 1) Centre de recherche Institut universitaire de cardiologie et pneumologie de Québec, Laval University, Quebec, Canada; 2) Laval University Hospital Research Center (CRCHUL), Quebec, Canada.

Calcific aortic valve stenosis (AVS) is a life-threatening disease of the aortic valve with currently no medical treatment available. The incidence of AVS increases with age and is thus a growing public health problem. Previous genetic studies suggest an important genetic component. However, only a handful of studies have attempted to unravel the genetic architecture of AVS. The goal of this study is to validate genes previously associated with AVS. Seven genes were assessed including APOB, APOE, CTGF, IL10, PTH, TGFB1, and VDR. For each gene, we selected SNPs previously associated with AVS and complement with a maximally informative set of common SNPs (tagSNPs) using the European-derived (CEU) HapMap dataset. SNPs were genotyped using the Illumina® BeadXpress platform in 467 patients that underwent surgical aortic valve replacement. These patients were compared to 3294 controls taken from the Illumina® iControlDB genotyped on the HumanHap550 genotyping BeadChip. SNPs not genotyped in controls were imputed using the MACH program and a reference set consisting of the known phased haplotypes of 60 unrelated individuals in the HapMap CEU. Significant p-value thresholds were applied for each gene using the Bonferroni correction. A missense mutation in the APOB gene was significantly associated with AVS (rs1042031, E4181K, p = 1.4E-5). A second SNP located 5.6 kb upstream of the APOB stop codon was also associated with the disease (rs6725189, p = 2.0E-5). Six SNPs surrounding the IL10 locus were strongly associated with AVS (0.006 > p > 8.4E-11). The most compelling association for IL10 was found with a promoter polymorphism (rs1800872) well-known to regulate the production of the encoded anti-inflammatory cytokine. The frequency of the low-producing allele was greater in cases compared to controls (30% vs. 20%, p = 8.4E-11). SNPs in PTH, TGFB1, and VDR had nominal p-values < 0.05, but did not resist Bonferroni correction. This study suggests that individuals carrying specific polymorphisms in the IL10 and APOB genes are at higher risk of developing AVS.

668/W

Tumor necrosis factor-α: investigation of gene polymorphism and regulation of TACE-TNF-α system in patients with acute myocardial infarction. *S.M.H. Ghaderian[1], R. Akbarzadeh Najar[1], A.S. Tabatabaei Panah[2].* 1) Department of Medical Genetics, Faculty of Medicine, Shahid Beheshti University of Medical Sciences and Health Services, Tehran, Iran; 2) Department of Biology, Basic Sciences Faculty, Islamic Azad University, East Tehran Branch (Ghiamdasht), Tehran, Iran.

Purpose Tumor necrosis factor-α (TNF-α) plays an important role in the pathophysiological process of acute myocardial infarction (AMI). A polymorphism within TNF-α gene promoter and contribution of TNF-α converting enzyme (TACE) have been reported to be associated with TNF-α production which may increase susceptibility to heart failure such as AMI. However, the relationship between this polymorphism and susceptibility to AMI and the mechanism of TACE-TNF-α system regulation has poorly been studied. Methods Genomic DNA and peripheral blood mononuclear cells (PBMCs) of 996 patients with AMI and 510 control subjects were extracted within first 24 hours after the onset of AMI. The investigation conforms to the principles outlined in the 1964 Declaration of Helsinki. The -308 G/A TNF-α polymorphism was detected. The mRNA transcription and protein expression levels of TNF-α and TACE were analyzed by real time RT-PCR and flow cytometry respectively as well as plasma TNF-α by ELISA. Intracellular TACE and TNF-α levels were measured using median fluorescence intensity (MFI). A P value less than 0.05 was considered statistically significant. Results The 'A' allele frequency of TNF-α was significantly more frequent in the patients than controls (19.2% vs. 11.5% respectively, P<0.001). Differences in circulating levels of TNF-α were significantly higher in the patients comparing with controls (17.59±0.01 via 11.78±0.02 respectively, P<0.001). The TNF-α and TACE mRNA and protein levels were higher in the patients than controls [(TNF-α/GAPDH, 2.71±0.03 via 1.73±0.02, P<0.001; TACE/GAPDH, 3.21±0.04 via 2.78±0.11, P<0.001) (TNF-α MFI levels: 3.51±0.06 vs. 2.93±0.02, P<0.001; TACE MFI levels: 3.84±0.06 vs. 3.46±0.01, P<0.001) respectively]. There were significant positive correlation between these mRNA and protein expression levels (r=0.66, P<0.001, r=0.78, P<0.001 respectively). Conclusion These data suggest that genetic polymorphism in TNF-α might be helpful for determining susceptibility to AMI in Iranian patients. The TACE-TNF-α system in circulating leucocytes is stimulated which demonstrate that in patients with AMI, TACE expression in PBMC increases with TNF-α expression and processing of TNF-α in PBMC might be regulated by TACE at transcriptional, translational, and post-translational levels in AMI. In this regard, the TACE, an important regulator of TNF-α maturation, could be used as a potential target for inhibition of a cellular source of TNF-α in AMI.

Many common, complex traits are believed to be a result of the combined effect of genes, environmental factors, and their interactions. Echocardiographic measures of left ventricular (LV) structure and function are heritable phenotypes of cardiovascular disease. In a previous genome-wide association (GWA) study of echocardiographic traits, we identified 5 genetic loci harboring common single nucleotide polymorphism (SNP) variants that were associated with variation in LV diastolic dimensions and aortic root size. These variants' main effects explained a small proportion of trait variance. We conducted a genome-wide study of gene-environment interaction in population-based cohort studies participating in the EchoGen and Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortia. Our aim was to identify genetic loci that may interact with environmental factors (EF) to effect echocardiographic traits. Within each of 6 community-based cohorts (N=17,000 individuals of European ancestry), we conducted SNP x EF interaction regressions, using a 1-df test for each of the approximately 2.5 million SNPs across the genome (imputed to the HapMap CEU panel). The echocardiographic outcomes were LV mass, internal dimensions, wall thickness, fractional shortening, aortic root and left atrial size; the environmental factors investigated were age, sex, height and weight. Using a pre-specified P value threshold of 5x10-7, we performed an inverse variance-weighted fixed-effects meta-analysis of GWA data from each cohort. In total, 51 genetic loci met the P-value threshold, 10 of which had a minor allele frequency (MAF) >5%. We observed significant interactions on aortic root size with 1 locus each for age, height and weight, 1 locus with weight on LV mass, 1 locus with height on LV wall thickness, 1 locus with sex on LV internal dimensions, 1 each interacting with sex and weight on fractional shortening, and 1 each interacting with sex and weight on left atrial size. We identified 10 genetic loci harboring common variants that may interact with EFs to influence cardiac structure and function. These findings are novel and are different from loci currently known to have main effects on these traits. Replication studies are needed to confirm; if replicated, these findings warrant further investigation into their functional significance and possible relationship to clinical cardiovascular disease.

Identification of Novel Locus for Familial Thoracic Aortic Aneurysms and Dissections. *D. Guo[1], C. Minn[1], V. Tran-Fadulu[1], E. Regalado[1], J. Coney[1], J. Cao[1], M. Wang[1], R. Yu[2], S. Shete[2.], D. Milewicz[1].* 1) Univ Texas/Houston Med Sch, Houston, TX; 2) Univ Texas/MD Anderson Cancer Center, Houston, TX.

Thoracic aortic aneurysms typically enlarge over time and present as acute aortic dissections (termed TAAD), lead to sudden death. Approximately 20% of patients with TAAD have an affected first-degree relative, suggesting a significant genetic basis to the disease. A large family (TAA254) was identified with an autosomal dominant inheritance pattern of TAAD, with decreased penetrance in women. The aortic disease in TAA254 is relatively stable, with a low risk of dissection compared to previously reported TAAD loci and gene mutations. . Of the nine affected family members diagnosed with ascending aortic aneurysms (ranging from 4.2 to 6.6 cm, with average aortic diameter of 4.8 ± 0.7 cm), only one individual presented with an acute dissection, with an aortic diameter of 6.6 cm. To identify the defected gene for TAAD in this family, SNP-based whole genome linkage analysis was performed, followed with microsatellite fine-mapping. A novel TAAD locus has been identified for the defective gene in this family on chromosome 12, termed TAAD5 locus, with a maximum parametric LOD score of 2.7 and a maximum non-parametric LOD of 3.6 (exact NPL P-value =0.01). Interestingly, four women in the family over 40 years of age (average age of 55.3 ± 20.2 years old) and carrying the affected disease haplotype did not have TAAD, confirming decreased penetrance of this disease in women. Among nine males who were older than 30 years of age (average age of diagnosis is 52.6 ± 13.4 years of age) with the affected haplotype, only one of them had a type A dissection. Our data support the hypothesis that the defective gene causing TAAD in this family is associated with ascending aneurysms having a low risk of dissection. This is in contrast to other TAAD genes, such as TGFBR2, in which there is a high risk of dissection with minimal dilatation. Therefore, this family provides further evidence that understanding the underlying genetic defects causing TAAD can impact the management of families with familial TAAD.

The role of *CAV3*, coding for caveolin-3, in long QT syndrome, Brugada syndrome and sudden adult death syndrome. *P. Hedley[1], J. Kanters[2], E. Behr[3], V. Corfield[4], W. McKenna[5], M. Christiansen[1].* 1) Statens Serum Inst, Copenhagen, Denmark; 2) University of Copenhagen, Copenhagen, Denmark; 3) St George's Hospital, London, United Kingdom; 4) University of Stellenbosch, Cape Town, South Africa; 5) University College London, London, United Kingdom.

Background: Mutations in CAV3, coding for the major constituent of caveolae and a scaffolding protein caveolin-3, have been associated with skeletal muscle disease, cardiomyopathy and most recently, and with a low prevalence, with long QT syndrome and sudden adult death syndrome. The pathogeneic mechanism of these caveolinopathies vary from decreased to increased expression of caveolin-3 to more subtle changes in the interaction between caveolin-3 and signalling molecules and ion channels. We examined the prevalence of CV3 mutations in a large cohort of index patients with long QT syndrome (n = 248), Brugada syndrome (n = 14)and sudden adult death syndrome (n = 34). **Materials and Methods**: *CAV3* was screened for mutations using direct DNA sequencing of exons and exon-close intronic regions of the gene. **Results**: One missense mutation, T78M, was found in one long QT patient. This patient was also carrier of the I400N mutation in KCNH2 and is thus a compound heterozygous carrier of CAV3 and KCNH2 mutations. Family studies revealed that the two mutations were separated in family memebrs and one carrier of the T78M mutation had a normal ECG but a history of syncopes. **Conclusion**: CAV3 mutations are a very rare cause of long QT syndrome and does not seem to play a major role in neither Brugada syndrome nor sudden adult death syndrome.

Genome-wide association study reveals RYR1 as a genetic risk factor for electrocardiogram left ventricular hypertrophy. *K. Hong[1], D. Shin[2,3], S. Lee[2,4], M. Go[5], J. Lim[1], Y. Jang[2,4], B. Oh[1].* 1) Biomedical Engineering, Kyung Hee Univ, Seoul, Korea; 2) Cardiovascular Genome Center, College of Medicine, Yonsei University, Seoul, Korea; 3) 3Yonsei University Research Institute of Science for Aging, College of Medicine, Yonsei University, Seoul, Korea; 4) Severans Medical Research Institute, College of Medicine, Yonsei University, Seoul, Korea; 5) Center for Genome Science, National Institute of Health, Seoul, Korea.

Left ventricular hypertrophy (LVH) is one of the predictors of future cardiovascular events. Recently, genome-wide association studies (GWASs) have led us to new understanding of complex pathologies and LVH is one of the traits. To identify the genetic risk factor for LVH, we performed a GWAS and a replication study for the LVH in this study. The LVH were diagnosed by electrocardiogram and the genome-wide association study was conducted for community-based cohorts [KARE (control, n = 3653 and case, n = 398)] by using Affymetrix SNP array 5.0. The replication subjects came from a hospital of Yonsei University (control, n = 623 and case, n = 402) and their genotypes were determined by TaqMan™ assay. We examined replication analysis in two ways: hospital case-hospital control used in the replication set 1, and in set 2 was hospital case-cohort control. The initial electrocardiogram-LVH GWAS revealed 13 SNPs in four suggestive association loci (p-value < 1×10^{-5}), including *RYR1* locus (rs2960321, P = 1.9×10^{-6}), 8p24.23 (rs7825068, P = 4.7×10^{-6}), *DYNC2H1* locus (rs11225822, P = 2.6×10^{-6}), and *DNAJC7* locus (rs4239268, P = 8.8×10^{-6}). While tendency of association was found in the replication set 1, the replication set 2 revealed significant association to three SNPs of *RYR1* locus (rs2960321, P = 0.002). Meta-analysis indicates the p-value (rs2960321, meta-analysis odds ratio = 1.39, CI 1.24 - 1.57, P = 2.9×10^{-8}) became stronger than the original study. Ryanodine receptors (RyR) are intracellular Ca^{2+}-permeable channels that provide the sarcoplasmic reticulum Ca^{2+} release required for skeletal and cardiac muscle contractions. RyR1 underlies skeletal muscle contraction, and RyR2 fulfills this role in cardiac muscle. Malignant hyperthermia, central core disease, and catecholaminergic polymorphic ventricular tachycardia have been genetically linked to mutations in either RyR1 or RyR2. To confirm whether the *RYR1* and *RYR2* gene have epistatic interaction for the development of LVH, we investigated the epistatic interaction using PLINK program between the *RYR1* and *RYR2* gene, and the results suggested the epistatic interaction between rs2960321 of *RYR1* gene and rs559344 of *RYR2* gene (p = 0.042). We identified a novel candidate gene for left ventricular hypertrophy. The epistatic interaction indicated that biological interaction between two *RYR* genes would be importance for normal cardiac-muscle function.

Comprehensive resequencing of the *CD36* gene in subjects with extremely low or high plasma HDL-C levels. *S.C. Hughes[1], F.Y. Demirci[1], A.S Dressen[1], C.H. Bunker[2], J.E. Hokanson[3], R.F. Hamman[3], C.M. Kammerer[1], M.I. Kamboh[1].* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Epidemiology, GSPH, Univ Pittsburgh, Pittsburgh, PA; 3) Epidemiology, Colorado School of Public Health, Univ Colorado Denver, Aurora, CO.

Coronary heart disease (CHD) is a primary public health concern and among the leading causes of death every year in the United States. Plasma lipid levels are among the major risk factors that influence CHD risk and high levels of plasma high density lipoprotein cholesterol (HDL-C) have been shown to be protective against CHD. *CD36* belongs to the class B scavenger receptor family of cell surface proteins and binds many ligands including thrombospondin and lipoproteins. The aim of this study was to comprehensively evaluate the relation between common and rare variation in *CD36* gene (located at 7q11.2) and plasma HDL-C levels by resequencing ~30 kb-long genomic fragment in individuals with extremely low or high HDL-C levels from two epidemiological samples, U.S. Non-Hispanic Whites (NHWs) and African Blacks. The analysis of sequencing data from individuals with HDL-C levels in the upper 5th percentile (47 NHWs and 48 African Blacks) and the lower 5th percentile (48 NHWs and 47 African Blacks) identified a total of 343 variants, of which 69 were shared by both populations. Of 131 variants observed in NHWs, ~4% were located in exons, ~11% were indels, and ~34% had ≥ 5% minor allele frequency (MAF). Of 281 variants observed in Blacks, ~5% were located in exons, ~15% were indels, and ~37% had ≥ 5% MAF. When considering only exonic variants, 2 out of 5 exonic variants (~40%) in NHWs lead to amino acid changes while 9 out of 13 (69%) in Blacks lead to amino acid changes. No striking differences were observed between the cumulative distribution of rare variants among high and low HDL-C groups in either ethnic group, but some common alleles did exhibit different frequencies between the two HDL-C groups. No striking differences were observed between the allele frequencies of common indels or common variants that result in amino acid changes. Genotyping of all identified rare variants and common tag SNPs in the entire sample sets (623 NHWs and 788 Blacks) is underway and will help to unravel the extent to which the *CD36* genetic variation influences the regulation of plasma HDL-C levels and other lipoproteins.

Using Electronic Medical Records for Genome-wide Association Studies and Admixture Mapping to Identify SNPs Associated with ECG Traits in African Americans. *J. Jeff[1], A. Ramirez[2], J. Denny[2,3], A. Kho[6], M. Ritchie[1], M. Hayes[7], L. Armstrong[7], M. Basford[4], W. Wolf[8], J. Pacheco[8], R. Chisholm[8], D. Roden[2,4,5], D. Crawford[1].* 1) Human Gen, Vanderbilt Univ, Nashville, TN; 2) Department of Medicine, Division of Clinical Pharmacology, Vanderbilt Univ, Nashville, TN; 3) Department of Biomedical Informatics, Vanderbilt Univ, Nashville, TN; 4) Office of Personalized Medicine,Vanderbilt Univ, Nashville, TN; 5) Department of Pharmacology,Vanderbilt Univ, Nashville, TN; 6) Division of General Internal Medicine, Northwestern University, Chicago, IL; 7) Division of Endocrinology, Metabolism, and Molecular Medicine,Northwestern University, Chicago, IL; 8) Center for Genetic Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL.

Several genome wide association studies (GWAS) have identified loci that contribute to electrocardiographic (ECG) parameters, and most have been performed in European-American populations collected from population-based cohorts or surveys. As part of the electronic Medical Records and Genomics (eMERGE) network, we conducted a GWAS in 455 African Americans from the Vanderbilt Genome-Electronic Records Project and Northwestern University NUgene Project. African American individuals that had a normal ECG without evidence of cardiac disease before or within one month following the ECG, without concurrent use of medications that interfere with QRS duration, and who did not have abnormal electrolyte values at the time of the ECG were included. Over 930K SNPs from the Illumina 1M BeadChip were tested for an association with PR interval, QRS duration, QTc interval, and heart rate using linear regression assuming an additive genetic model. Tests of association were performed unadjusted and adjusted for age, sex, PR/QT drug usage and principle components. None of the four traits were associated with a tested SNP at p<5.0x10-8. Chromosome 3 GWAS-identified SNPs that influence ECG traits (SCN5A-SCN10A) in European Americans were not associated in this African American sample (p>0.10); however, the effect sizes trended in the same direction. Interestingly, the minor allele frequencies (MAF) for the GWAS-identified SNPs in European Americans (such as SCN10A nonsynonymous rs6795970; MAF= 43%) are much higher than in African Americans (0.8%). Given these frequency differences, we hypothesized SCN5A-SCNA10A, if associated with ECG traits in African Americans, will have more European ancestry along this genomic region compared to the rest of the genome. We therefore performed an admixture scan for ~800K independent SNPs (r2 <0.80) across the genome using ANCESTRYMAP. For the QRS duration trait, the genome-wide LOD scores ranged from 0.65 to 9.63, and 19 of the 22 autosomes had LOD scores >2.0. Chromosome 3 had the highest genome-wide LOD score (9.63) indicating that chromosome 3 has the most QRS-associated SNPs that differ in allele frequency between the two ancestral populations compared to the entire genome. These results suggest that for ECG traits, European-identified GWAS associations may be generalizeable to other populations such as African Americans.

Functional Analysis of Newly Identified Promoter Polymorphisms of Endothelial Lipase (*LIPG*) in Human Endothelial Cells. *S. Khetarpal[1], A. Edmondson[1], A. Raghavan[1], H. Neeli[2], S. Kathiresan[3], L. Cupples[4], S. Demissie[4], A. Manning[4], S. DerOhannessian[1], M. Wolfe[1], D. Rader[1].* 1) Dept Med, Univ Pennsylvania, Philadelphia, PA; 2) Dept Hospital Med, Temple Univ, Philadelphia, PA; 3) Broad Instit of Harvard and MIT, Cambridge, MA; 4) Boston University and Framingham Heart Study.

Increased plasma levels of HDL cholesterol (HDL-C) are associated with decreased risk of developing cardiovascular disease. Endothelial lipase (*LIPG*) has been associated with HDL-C in GWAS and loss-of-function variants are associated with increased HDL-C in humans. We have also demonstrated association of plasma EL concentrations with metabolic syndrome, coronary atherosclerosis, and inflammation in humans. We further sought to understand how regulatory variation in *LIPG* affects expression of EL and HDL-C levels in humans. We thus performed medical resequencing of the *LIPG* promoter in human subjects from extremes of the HDL-C phenotypic distribution. We identified an excess of rare promoter variants unique to subjects with elevated HDL compared to rare variants in subjects with decreased HDL. We also identified a common promoter haplotype. We hypothesized that promoter variants may alter *LIPG* expression and thus alter HDL-C metabolism. To test this hypothesis, we generated a firefly luciferase reporter construct driven by the *LIPG* promoter. Regulatory variants identified through resequencing were introduced into the luciferase reporter construct via site-directed mutagenesis. We tested these variant constructs in luciferase reporter assays in both HEK293 cells and human umbilical vein endothelial cells (HUVECs), the latter of which endogenously express *LIPG* and thus allow us to assess how promoter variants may affect *LIPG* expression in vivo. Many of the variants identified specifically in high HDL-C subjects were found to significantly decrease gene expression in vitro, consistent with reduced *LIPG* expression leading to elevated HDL-C. Genetic association analysis of the common promoter haplotype in the Framingham Heart Study showed that the common *LIPG* promoter haplotype is significantly associated with decreased HDL-C. The luciferase reporter construct containing the promoter haplotype exhibited increased expression in vitro, as predicted. Subjects with the common *LIPG* promoter haplotype were also found to have significantly increased plasma levels of EL protein, as determined by ELISA. Our results suggest that EL is a physiologically significant modulator of HDL-C metabolism in humans, with regulatory variation of LIPG playing an important role in modulating HDL-C concentration.

Association of the Adiponectin Gene Variations with Risk for Ischemic Stroke in a Korean Population. *Y. Kim[1], O. Bang[2], M. Cha[2], Y. Park[1].* 1) Med Genome Res Ctr, KRIBB, Daejeon, Korea; 2) Dept. of Medical Research, KIOM, Daejeon, Korea.

Stroke is the second-leading cause of death and a major cause of morbidity and mortality worldwide. The evidence of variations in adiponectin (AdipoQ) gene that are associated with ischemic stroke has not been consistent, and it is unclear whether the same loci contribute to associations in the Korean population. Using a Korean population, we tested ischemic stroke- associated AdipoQ markers. In a preliminary genome-wide association study using 320 Affymetrix 250k NSP chips, AdipoQ was found to be associated with ischemic stroke in Koreans. To study AdipoQ, further 673 ischemic stroke patients and 267 unrelated individuals without a history of stroke or transient ischemic attack were examined in a case-control study. Six polymorphisms (rs182052G>A, rs16861205G>A, rs822391T>C, rs822396A>G, rs12495941G>T and rs3774261A>G) that had a minor allele frequency over 1% were strongly associated with stroke ($P < 0.05$). The haplotypes in ht 1 (AGGCGG and AAGTAG) were also significantly associated with susceptibility to stroke ($P < 0.05$). Our findings show that polymorphisms in AdipoQ are associated with a risk for ischemic stroke in the Korean population. This study lends further support to the putative role of AdipoQ in stroke. <<<<.

Transcriptome and exome sequencing for gene discovery in dilated cardiomyopathy. *D. Li, J. Gonzalez-Quintana, N. Norton, J. Siegfried, R.E. Hershberger.* Dept Medicine/Cardiology, University of Miami, Mlami, FL.

Dilated cardiomyopathy (DCM), a primary myocardial disease, is a common cause of heart failure and heart transplantation. Genetic causation of most DCM cases remains unknown even though mutations in numerous genes have been identified. Sanger sequencing of candidate genes, whether for linkage analysis and positional cloning or sequencing of hypothesis-based candidate genes, is challenging, costly and labor intensive. To circumvent these limitations and to accelerate DCM gene discovery, we utilized next generation sequencing (NGS) technology to sequence the transcriptomes of failing left ventricular (LV) myocardium from patients in two multi-generational DCM families. mRNA was isolated from explanted DCM hearts and from nonfailing LV myocardium. The cDNA libraries were sequenced (paired-end 2x76 bp) with Illumina GA II. More than 40 million cDNA sequence reads were produced from each tissue sample, which gave adequate coverage for abundant and rare transcripts (as few as 1 copy/per cell). Genetic variants were identified by comparing the transcriptome sequences with NCBI human reference sequences. Novel variants were identified by filtering out SNPs in publicly accessible databases and those appearing in normal LV myocardium. Conservation analysis (PhastCons and Genomic Evolutionary Rate Profiling methods) and protein functional prediction by PolyPhen were performed for all novel variants. This analysis resulted in a list of 79 genes with novel rare nonsynonymous variants. To narrow the candiate gene list, exome sequencing using NGS with filtering from an additional affected subject was conducted that decreased the shared variant list of candidates to 7 genes. Desmoplakin (DSP), phosphoglycerate mutase 2, and latent transforming growth factor beta binding protein 1 were considered as leading candidate genes due to their relevance to cardiac pathophysiology. A novel nonsense mutation in DSP segregated with multiple affected members in the family and was absent from 370 normal control DNAs. A similar genetic analysis for 6 remaining candidate variants is ongoing. Our study demonstrates that transcriptome and exome sequencing is a promising approach to discover DCM genes.

Phenotypic Spectrum and Genotype-Phenotype Correlations in Loeys-Dietz syndrome. *H. Morisaki[1], H. Ogino[2], Y. Tsutsumi[3], K. Akutsu[1], A. Ono[1], A. Kono[4], M. Higashi[4], T. Kosho[5], S. Mizuno[6], T. Morisaki[1,7].* 1) Dept Bioscience & Genetics, Natl Cerebr & Cardiovasc Ctr Res Inst, Suita, Osaka, Japan; 2) Dept Cardiovascular Surgery, Natl Cerebr & Cardiovasc Ctr, Suita, Osaka, Japan; 3) Dept Cardiovascular Medicine, Natl Cerebr & Cardiovasc Ctr, Suita, Osaka, Japan; 4) Dept Radiology, Natl Cerebr & Cardiovasc Ctr, Suita, Osaka, Japan; 5) Dept Medical Genetics, Shinshu Univ Sch Medicine, Matsumoto, Nagano, Japan; 6) Dept Pediatrics, Aichi Pref Colony Central Hosp, Kasugai, Aichi, Japan; 7) Dept Molecular Pathophysiology, Osaka Univ Grad Sch Pharm Sci, Suita, Osaka, Japan.

Loeys-Dietz syndrome (LDS) is a systemic connective tissue disorder characterized by vascular and skeletal manifestations caused by mutations in *TGFBR1* or *TGFBR2*. Although characteristic craniofacial and arterial manifestations are helpful for diagnosis of the disorder, many features overlap between LDS and Marfan syndrome (MFS), and diagnostic genetic testing is needed for most patients. It is also generally accepted that there is no genotype-phenotype correlation in LDS. In this study, we analyzed the clinical details of 30 Japanese LDS patients with *TGFBR1* (14 patients in 11 families) and *TGFBR2* (16 patients in 14 families) mutations, and compared them with those with MFS to clarify LDS-characteristic features. We also report several phenotypic differences between *TGFBR1* and *TGFBR2* mutation carriers. When compared with patients genetically diagnosed as MFS, LDS patients were physically less dolichostenomelic and more had ocular hypertelorism. Annuloaortic ectasia (AAE) was observed in most of the LDS patients, although it was absent in 11% of those who had already experienced TAAD. Ectopia lentis, a characteristic feature of MFS, was not observed, while congenital retinal abnormalities were observed in 20% of our LDS patients. In radiological findings, the incidence of arterial tortuosity was significantly different in the vertebral arteries as compared with MFS. Dural ectasia was observed in both LDS and MFS, however, the ectatic pattern was different between the groups. Significant differences between patients with *TGFBR1* and those with *TGFBR2* mutations were observed in regard to age at diagnosis, cleft/uvula abnormalities, skeletal involvement, lung involvement, and fulfillment of Ghent diagnostic criteria for MFS. Although hypertelorism and aortic involvement were observed at equally high frequency in both groups, LDS patients with *TGFBR2* mutations tended to have more severe skeletal involvement and be diagnosed at a younger age, often initially as MFS, while those with *TGFBR1* mutations had a greater chance to be diagnosed only when aortic symptoms occurred and diagnosed as familial TAAD. Based on our findings, we conclude that patients suspected of LDS should be carefully examined for LDS-specific features based on both physical characteristics and vascular imaging findings, and should also be tested for *TGFBR1*/*TGFBR2* mutations even if skeletal features are not characteristic.

Identification of a locus for recessive Dilated-Cardiomyopathy on chromosome 2 by linkage analysis in a Bedouin familiy. *E. Muhammad[1], A. Levitas[2], V. Chalifa Caspi[3], E. Manor[4], J. C. Beck[5], V. C. Sheffield[5], R. Parvari[1,3].* 1) Dept Gen & Virology, Ben Gurion Univ, Beer Sheva, Israel; 2) Division of Pediatrics, Soroka Medical Center, Beer Sheva 84105 and Faculty of Health Sciences, Ben Gurion University of the Negev, Beer Sheva 84105, Israel; 3) National Institute of Biotechnology Negev, Ben Gurion University of the Negev, Beer Sheva 84105, Israel; 4) Institute of Genetics, Soroka Medical Center, Beer Sheva 84105 and Faculty of Health Sciences, Ben Gurion University of the Negev, Beer Sheva 84101, Israel; 5) Dept. of Pediatrics - Division of Medical Genetics; Howard Hughes Medical Institute, University of Iowa, Iowa City, IA 52242, USA.

Cardiomyopaties are the most common disorders resulting in heart failure. Dilated cardiomyopathy (DCM), a disorder characterized by cardiac dilatation and reduced systolic function, is the most frequent cause. However, recessive neonatal isolated dilated cardiomyopathy has scarcely been associated with a mutation. We have identified patients with acute DCM in a consanguineous Bedouin family presenting an autosomal recessive pattern of inheritance. Linkage analysis was carried out on five patients, their parents and four healthy sibling using SNPs array and microsatellite markers. One region on chromosome 2[2q35-2q36.3] in an interval of 10cM and 9.5Mb was consistent with linkage. The lod scores for linkage to this region were 3.5 and 4.5 for two point and multiple points, respectively. Two candidate genes encoding structural myocite proteins were sequenced and negated. One of them was the Desmin gene, in which mutations were previously reported to cause a dominant pattern of DCM.

680/W

Effects of Rare, Putatively Damaging Variants in Essential Hypertension in the Population-based CLUE and the Family-based FBPP Samples. *K.H. Nguyen[1], V. Pihur[1], G.B. Ehret[1], S.K. Ganesh[3], A.B. Weder[3], J. Coresh[2], W.H.L. Kao[2], A. Chakravarti[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Dept of Epidemiology, Johns Hopkins Univ, Baltimore, MD; 3) Dept. of Internal Medicine, Univ of Michigan, Ann Arbor, MI.

Essential hypertension (EH), or high blood pressure (BP) with no identifiable secondary cause, is a major risk factor for cardiovascular disease and its complications. While the genetic causes of EH are largely unknown, Guyton's hypothesis contends that genes that regulate salt re-absorption in the kidneys are a primary cause, buttressed by genes identified from Mendelian hypo- and hypertension syndromes. We conducted a pilot medical resequencing project of 11 syndromic hypo-/hypertensive genes in 560 individuals at the extremes of systolic BP. We further selected 11 non-synonymous variants, all predicted to be damaging by both the genetic algorithms in the software SIFT (Sorting Intolerant From Tolerant) and PolyPhen (Polymorphism Phenotyping), as our putative functional candidates and genotyped these in ~7,000 unrelated samples from the population-based CLUE cohort and ~6,500 individuals from the family-based Family Blood Pressure Program (FBPP) using Sequenom technology. The top SNP, rs2681472 in *ATP2B1*, from published genome-wide association studies were also genotyped in the same samples. The genotype data were analyzed for association with four BP traits (SBP, DBP, PP, MAP) using the computer software MERLIN. Due to the rarity of these coding variants (MAF < 5% except one at 8% and one at 12%), only 6 of the 11 variants were present in both cohorts. Two coding variants in the α and γ subunits of the epithelial sodium channel (ENaC) protein complex reached statistical significance in FBPP. rs5742912 (Trp493Arg) in SCNN1G was associated with a decrease of 3 mmHg (residual corrected for age, age2, gender, BMI) in SBP (p= 0.013) and 2 mmHg (residual) in PP (p=0.009), and Thr259Asp in *SCNN1A* was associated with a increase of 2 mmHg (residual) in PP (p=0.002). Both mutations are located in the extracellular loop of the ENaC subunits that is suggested to be the channels' site of action. *SCNN1G* and *SCNN1A* mutations are known in Pseudohypoaldosteronism type 1 and Liddle syndrome, respectively.

681/W

MBL and MIF gene polymorphisms in Turkish children with cardiomyopathy: no association with MBL (codon 54) genotypes, but an association between MIF (-173) polymorphism and CMP. *S. Oguzkan Balci[1], N. Col Araz[2], T. Sever[1], O. Baspinar[3], A. Balat[4], S. Pehlivan[1].* 1) University of Gaziantep, Faculty of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey; 2) University of Gaziantep, Faculty of Medicine, Department of Pediatrics; 3) University of Gaziantep, Faculty of Medicine, Department of Pediatric Cardiology; 4) University of Gaziantep, Faculty of Medicine, Department of Pediatric Nephrology.

Objectives of study: Cardiomyopathy (CMP) is defined as structural and/or functional disorders of the hearth muscle, and it is an important cause of chronic congestive cardiac failure in children. Disturbances of the cellular and humoral immune system are frequently observed in CMPs, and myocardial inflammation is one of the commonest mechanisms in cardiomyopathy. Mannose binding lectin (MBL) is a key molecule in innate immunity with the capacity to bind to microorganisms and kill them by initiating the lectin pathway of complement activation. Macrophage migration inhibitory factor (MIF) is a constitutive element of the host antimicrobial defences and stress response that promotes proinflammatory function of the innate and acquired immune system. It plays an important role in the pathogenesis of acute and chronic infammatory or autoimmune disorders. The aim of present study was to investigate any possible association between polymorphisms of MBL and MIF genes and CMP in a group of Turkish children. **Methods:** The study was approved by the local ethical committee and informed consents were obtained from the patients. Fourteen-children with CMP and 21 age- and sex-matched healthy controls were analyzed for codon 54 A/B polymorphism in MBL gene and -173 G/C polymorphism in MIF gene by using PCR-RFLP methods. **Results:** The distribution of AA, AB, and BB genotypes for MBL codon 54 were 57.1 %, 28.6 % and 14.3 % in CMP compared with 76.2 %, 23.8 % and 0 % in the controls (p=0.261). The allele frequency of A/B in MBL was 71.4 %, 28.6 % in CMP compared with 88 %, 12 % in the controls. (p=0.078). The distribution of GG, GC, and CC genotypes for MIF (-173) were 50 %, 28.6 %, and 21.4 % in CMP compared with 52.4 %, 47.6 % and 0 % in the controls (p=0.157). CC genotype was higher than GG, GC and GG+GC genotypes in patient group (p=0.049, p=0.022, p=0.026, respectively). The allele frequency of G/C in MBL was 72 %, 28 % in CMP compared with 76.2 %, 23.8 % in the controls (p=0.280). The observed genotype counts were not deviated significantly from those expected according to the Hardy-Weinberg Equilibrium for MBL and MIF gene polymorphisms (P>0.05). **Conclusion:** This study is the first to investigate the MBL and MIF gene polymorphisms in Turkish children with CMP. We conclude that CC genotype of MIF (-173) polymorphism may be a risk factor for CMP patients. However, further studies with larger samples are needed to address the exact role of this polymorphism in CMP.

SNPs on Chromosome 5p are Associated with Coronary Artery Disease in the Japanese Population. *K. Ozaki[1], A. Aoki[1], H. Sato[2], A. Takahashi[3], Y. Sakata[2], Y. Onouchi[1], T. Tsunoda[4], M. Kubo[5], S. Ikegawa[6], N. Kamatani[3], M. Hori[2], Y. Nakamura[7], T. Tanaka[1].* 1) Laboratory for Cardiovascular Disease, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 2) Department of Cardiovascular Medicine, Osaka University Graduate School of Medicine, Suita, Japan; 3) Laboratory for Statistical Analysis, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 4) Laboratory for Medical Informatics, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 5) Laboratory for Genotyping Development, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 6) Laboratory for Bone and Joint Disease, Center for Genomic Medicine, RIKEN, Tokyo, Japan; 7) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

Coronary artery disease (CAD) including myocardial infarction (MI), leading cause of death in many countries, results from complex interactions multiple genetic and environmental factors, indicating the importance of clarifying genetic risk factors in their pathogenesis. By means of a genome wide association study in a Japanese population using 250k single nucleotide polymorphism (SNP) markers, we identified a novel susceptible locus for MI on chromosome 5p. A marker SNP showed significant association for MI in several independent Japanese cohorts (combined $P < 10^{-10}$, OR = 1.25; comparison of allele frequency; approximately 5,300 cases and 7,600 controls). Association study using tagging SNPs based on Linkage disequilibrium (LD) revealed that additional two SNPs in modest LD with the marker SNP were also associated with MI. Furthermore, we found that the genotype frequency of these SNPs in individuals with unstable angina pectoris, another severe CAD based coronary atherosclerosis, were nearly identical with those of MI and were significantly associated with the disease. These findings indicate that the SNPs on chromosome 5p are novel genetic risk factor for CAD.

Chromosomal locus 9p21.3: a marker of the angiographic severity of the coronary artery disease. *N. Rivera[1], R. Roncarati[1,2], C. Viviani-Anselmi[1], F. De Micco[3], A. Mezzelani[2], G. Condorelli[4], A. Puca[1,2], F. Airoldi[1], G. Condorelli[1,2], C. Briguori[3].* 1) Multimedica Research Hospital, Milan, Italy; 2) Institute of Biomedical Technologies, CNR, Milan Italy; 3) Clinica Mediterranea, Naples, Italy; 4) University Federico II, Naples, Italy.

Background— Several Genome-wide Association Studies (GWAS) revealed a highly significant link between variations of chromosome 9p21.3 and the risk of coronary artery disease (CAD). Our aims were (1) to assess cardiovascular risk factors along with the function of twelve 9p21.3 genetic variants in Italian Caucasians with CAD and (2) to identify the relationship between genetic susceptibility and coronary vessel anatomic phenotypes and lesion severity. Methods and Findings— We performed a cross-sectional study in an Italian Caucasian group of 1696 subjects with CAD involving one-, two-, or three-vessel CAD. Twelve SNPs from GWAS of CAD were assessed for links between genetic variants at this locus and significant disease in major epicardial coronary vessels. Six single nucleotide polymorphisms (SNPs) (i.e., rs10757274, rs4977574, rs2383207, rs10738610, rs10757278, rs1333049) were strongly associated with both the diameter stenosis and the number of coronary vessels affected. More specifically, in each of the six SNPs, we noticed an increase of the risk-allele frequency as the number of diseased coronary vessels increased. We also observed that (1) the percentage of risk-allele carriers increased dramatically, particularly in subjects diagnosed with significant lesions in the left anterior descending and circumflex arteries, and (2) a strong genetic link between these polymorphisms and the number of diseased coronary vessels Conclusions. The present study showed that six genetic variants at locus 9p21.3 are associated with the angiographic severity and extensions of CAD. Keywords: CAD; severity of coronary vessel; stenosis, cardiovascular genetics; single nucleotide polymorphism; 9p21.

Progressive systemic and stenotic vasculopathy: Candidate genes identified by comparative exome sequencing. *R. Rupps[1,2], C.D. van Karnebeek[3], A.P. Fejes[4], M. Morimoto[1,2], C. Shuen[1,2], T. Markello[5], A. Delaney[4], S. Jones[4], M. Marra[4], C. Boerkoel[1,2].* 1) Dept Medical Genetics, University of British Columbia, Vancouver BC, Canada; 2) Child & Family Research Institute, Children's & Womens th Ctr-BC, Vancouver, BC, Canada; 3) Div Biochemical Diseases, Dept Pediatrics, BC Children's Hospital, Vancouver, BC, Canada; 4) BC Cancer Agency, Genome Sciences Centre, Vancouver BC, Canada; 5) Undiagnosed Diseases Program, National Institutes of Health, Bethesda, MD, USA.

Background: Fibromuscular dysplasia (FMD) is a group of non-atherosclerotic, non-inflammatory diseases of the musculature of arterial walls, leading to stenosis of small and medium-sized arteries. It most commonly affects renal and carotid vessels, but more distal sites may also be involved. A genetic etiology of this systemic disorder is suggested by concordance among monozygotic twins and a 10% familial recurrence rate, but has not yet been identified. **Aim:** To define a cause of FMD, we applied comparative whole exome sequencing in an extreme syndromic form of this vascular disease involving all major arteries. **Case:** This 15 year old boy with an unremarkable family history has a diffuse ischemic vasculopathy involving the non-ostial portion of his medium-sized vessels. Stenosis of the carotid arteries, mesenteric and renal arteries has caused recurrent cerebral infarctions, severe abdominal pain, progressive hypertension and revascularization resembling Moya Moya disease. His other features include an ASD, branch pulmonary artery stenosis, intestinal non-rotation, anal stenosis, and osteopenia with isolated recurrent fractures. Extensive genetic and metabolic investigations yielded normal results. Histopathology of internal carotid artery showed: mild to moderate intimal thickening, calcification and focal fragmentation of the internal elastic lamina. **Methods:** Exonic DNA from the patient and both parents was selected using the Agilent SureSelect kit and sequenced using the Illumina NexGen sequencing platform. Using an autosomal recessive model of disease, rare and novel non-synonymous homozygous and compound heterozygous mutations were identified by comparison of the unique variant positions to dbSNP and 1046 libraries. **Results & Conclusions:** We identified several genes with bi-allelic mutations; one functioning in the RAS pathway is a likely candidate since it modulates formation of functional tight junctions. Biological investigations currently underway will determine if any of these mutations are causative of disease. Understanding the disease in this patient will improve our understanding of arterial biology and provide insight into FMD-like conditions.

685/W

KCNH2 (HERG) gene polymorphisms associated with increased genetic risk condition of non-valvular atrial fibrillation in Koreans. *D. Shin[1,3], A. Park[1], H. Hwang[2], N. Son[1], K. Lee[1], E. Shin[4], J. Lee[4], B. Joung[2], H. Pak[2], M. Lee[2], S. Kim[2], Y. Jang[1,2].* 1) Cardiovascular Genome Ctr, Yonsei Col Med, Seoul, Korea; 2) Division of Cardiology, Yonsei University Health System; 3) Yonsei University Research Institute of Science for Aging; 4) DNA Link Inc, Seoul, Korea.

Atrial fibrillation (AF) is the most frequently and seriously encountered cardiac rhythm disorder in humans and is characterized by chaotic electrical activity of the atrial. Recent evidence indicates the phenotypes of non-valvular AF are more likely to occur in patient with a genetic susceptibility. KCNH2 gene encodes for the HERG protein, a α-subunit of the cardiac IKr channel, which contributes to the repolarization of the cardiac action potential. In this study, we sought to determine the association of genetic polymorphisms of KCNH2 gene with non-familial non-valvular AF. We investigated hospital-based case-control study for a total of 754 Korean subjects, comprising of 354 cases with AF and 400 controls without AF. Genetic screening was carried out by direct DNA sequencing and SNaPShot assay. We examined 9 tagging single nucleotide polymorphisms (tSNPs) in the KCNH2 gene. We did not observe the significant differences in the allele and genotype distributions between patients with AF and control subjects. However, logistic regression analysis represented that tSNP, rs740952 (T25399C; I489I), in exon 6 confers the risk of non-valvular AF in Korean males. The significant association was observed under a dominant model for TT genotype with a decreasing risk of AF (OR, 0.687; 95% CI, 0.481-0.980; P=0.038). In addition, rs740952 was significantly associated with left atrial volume (P=0.013), left atrial dimension (P=0.006) in female group. Haplotype analysis of KCNH2 polymorphisms did not show a significantly different distribution of their haplotype condition between the patients with AF and the controls. However, left atrial dimension increased significantly with the haplotype CGTG in apparent recessive model in males (CGTG/other haplotypes, P= 0.006). We provide evidence that KCNH2 rs740952 SNP may contribute to protect Korean individuals to the risk of non-valvular AF, and may play a role in cardiac remodeling after the development of AF. Further studies together with other IKr channel genes are required to determine the association between AF susceptibility and potassium channel gene functional variants.

Family-based evaluation of polygenic variance explained by genes associated with HDL, LDL, and triglyceride levels. *B.H. Shirts[1], S.J. Hasstedt[2], P.N. Hopkins[3], S.C. Hunt[3].* 1) Pathology, University of Utah, Salt Lake City, UT; 2) Human Genetics, University of Utah, Salt Lake City, UT; 3) Cardiovascular Genetics, Medicine, University of Utah, Salt Lake City, UT.

Over 30 genes have been identified that influence HDL, LDL, and/or triglyceride levels, which are known risk factors for cardiovascular disease. Only a small portion of the total variance in the serum levels of these markers can be explained by these markers. However, case-control studies are unable to estimate the proportion of heritability attributable to associated genetic polymorphisms. We used a sample of over 2200 individuals in 96 pedigrees to evaluate the proportion of heritability explained by 15 SNPs previously associated with HDL, LDL, and/or triglyceride levels while adjusting for age, sex, and BMI using jPAP software for maximum likelihood analysis.

Heritability for HDL, LDL, and triglycerides were 0.54, 0.41, and 0.26 respectively. Of the 15 loci investigated, 6 contributed to the heritable component of HDL level (LIPC, LPL, APOC-APOE, LIPG, APOB, TRIB1), although less than 5% of heritability could be attributed to these loci in a combined model. Eight loci contributed to heritability of LDL level (APOC-APOE, CELSR, APOB, HMGCR, TRIB1, FADS, CETP, LIPC); together these account for less than 10% of the heritability. Five loci contributed to heritability of triglyceride levels (APOA1, TRIB1, GCKR, MLXIPL, APOC-APOE), which together account for approximately 10% of the heritability. Heritability estimates for most loci were larger than estimates of total variance for most loci examined, which is consistent with heritability being only a portion of total variance; however, previously identified associations were not replicated at all loci.

Analysis of family-based samples allows estimation of proportion of polygenic attributable specific genetic loci. Our estimates suggest that known loci do explain a significant amount of variance in HDL, LDL, and triglyceride levels, but that there are additional sources of familial variance yet to be identified.

Titin mutations in arrhythmogenic right ventricular cardiomyopathy. *M. Taylor[1], S. Graw[2], C. Barnes[1], D. Slavov[1], F. Brun[3], B. Pinamonti[3], E. Salcedo[1], W. Sauer[1], S. Pyxaras[3], G. Sinagra[3], H. Granzier[4], L. Mestroni[1].* 1) Adult Med Gen Prog and Division of Cardiology, Univ Colorado Denver, Aurora, CO; 2) Department of Psychiatry, Univ Colorado Denver, Aurora, CO; 3) Department of Cardiology, Hospital and University of Trieste, Trieste, Italy; 4) Department of Physiology, University of Arizona, Tucson, AZ.

Purpose: Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a rare inherited myocardial disease characterized by fibrofatty replacement of the myocardium and a predisposition to cardiac arrhythmias and sudden death. ARVC is familial in up to 50% of cases and the current disease model implicates desmosome dysfunction as the principal pathogenic defect. We evaluated the cardiomyopathy gene titin (TTN) as an ARVC candidate as it is close to the ARVD4 locus and the titin protein connects to the transitional junction at intercalated disks. **Methods:** Patients from 38 ARVC families underwent TTN DNA resequencing provided by the University of Washington, Department of Genome Sciences. Exons and peri-exonic regions of titin isoform N2A (NM_133378) along with additional exons unique to the principal cardiac isoform N2B (NM_003319) were amplified from genomic DNA using PCR. This covered 312 exons (311 expressed as titin protein) and the complete 3' untranslated region. Four of the ARVC families were sufficiently large to test for cosegregation of TTN mutations with the ARVC phenotype and are reported here. **Results:** Four, unique TTN variants were detected in the four families (Thr2896Ile, Ile16949Thr, Pro17706Leu, Ala19309Ser). The Thr2896Ile variant showed compelling genetic evidence that is pathogenic: present in 9 confirmed/obligate ARVC subjects including 2 fifth-degree relatives, absent in over 350 cardiomyopathy and 176 control chromosomes, and was scored 'intolerant' by SIFT and PolyPhen predictive algorithms. Ile16949Thr and Ala19309 were absent in controls and segregated with 'affected' status in smaller ARVC pedigrees. Pro17706Leu, although 'intolerant' and unique, is likely a rare benign polymorphism since it was inherited from the unaffected parent. **Conclusions:** Titin mutations may lead to the ARVC phenotype; disruption of normal spring-recoil properties of the titin protein may account for the phenotype manifestations in the thinner-walled stress-susceptible right ventricle.

CHIP-based sequence analysis of 34 cardiomyopathy genes reveals new genes involved in HCM and DCM and multiple pathogenic mutations in single patients. *A. van den Wijngaard[1], I. Krapels[1], W. Van Dijk[1], A. Stassen[1], P. Lindsey[1,2], Y. Arens[1], P. Helderman[1], C. Marcelis[3], S. Heymans[2,4], P. Volders[2,4], R. Jongbloed[1,2], H. Smeets[1,2].* 1) Clinical Genetics, Maastricht University Medical Centre, Maastricht, Netherlands; 2) Research School CARIM, Univ Maastricht, Maastricht, The Netherlands; 3) Dept Clinic Genet, UMC St. Radboud, Nijmegen, The Netherlands; 4) Dept Cardiol, Maastricht UMC, Maastricht, The Netherlands.

Purpose: Inherited cardiomyopathy is a cardiac disease with an estimated prevalence of 1:500 for hypertrophic cardiomyopathy (HCM) and 1: 2500 for dilated cardiomyopathy (DCM). Both cardiomyopathies show large genetic and clinical heterogeneity and require high-throughput and affordable mutation detection technologies to efficiently integrate molecular screening into clinical practice. Current diagnostic screening of a limited number of genes solves about 60-70% of the familial cases. However, double pathogenic mutations seem to be present in 5-10% of the familial cases. **Methods:** To create a fast genetic screening method for inherited cardiomyopathy, we designed a DNA resequencing array (CardioCHIP 150K34) covering 34 genes in duplicate. We included genes involved in DCM, HCM, non compaction cardiomyopathy, Limb Girdle Muscular Dystrophy and candidate genes based on their presence or protein-protein interaction in the sarcomere. All exons, flanking introns (38bp), the 5'UTR and 3'UTR regions, covering heart- and muscle-specific RNA-isoforms are included. Genomic regions were amplified in 152 LR-PCR's covering 395 exons. **Results:** Recently 250 patients were resequenced for all 34 genes. The mutation detection accuracy is >99%. About 98% of the novel exonic variants were confirmed by conventional sequence analysis. In addition to the mutations detected in the 13 routinely tested genes, we also identified mutations in the additional genes and candidate genes. In several patients up to 4 pathogenic mutations were identified, involved in different pathogenic processes. **Conclusion:** Our data indicate that parallel analysis of multiple genes is a prerequisite for genetic testing in HCM and DCM to rapidly identify the underlying genetic defect(s).

689/W

Gene Expression Analyses in Marathon Runners. *D. Vance[1], M. Stoutenberg[2], G. Chen[1], R. Myerberg[1], D. Tekin[1], L. Nathanson[1], K. Jacobs[2], J. Clark[2], A. Perry[2], P.J. Goldschmidt-Clermont[1], D. Seo[1], E. Rampersand[1].* 1) University of Miami Miller School of Medicine, Miami, FL; 2) University of Miami, Coral Gables, FL.

Individual differences in the prevalence of hypertension and other cardiovascular related traits have been observed in individuals who train for marathons, suggesting underlying genetic variations in fitness levels. Gene expression analyses can be used to identify genes whose expression levels are correlated with quantifiable measures of fitness, such as VO2max, an established metric of cardio-respiratory fitness. To explore the relationship between genetics and fitness, we studied the global gene expression in the leukocytes of sedentary individuals collected before and after a 17-week half marathon training program. Twenty men (29.3 ±1.0yr) were enrolled in the marathon training program. An additional 22 men (27.8 ± 1.4 yr) who performed aerobic activity less that 2 hours per·week-1 served as sedimentary controls. Fasting blood samples, VO2max and measures of body fat composition were collected at baseline and at the completion of the training program for all participants. Leukocyte samples were collected and stored using the Leukolock system (Ambion). To examine the participants' gene expression profiles, the extracted samples were run on the Affymetrix GeneChip Human Gene ST array, which covers 29000 different transcripts. We will use Significance Analysis of Microarrays (SAM) to determine genes that are differentially expressed before and after exercise training. We will also use other methods such as multivariate sparse ANOVA modeling to find genes whose expression corresponds to different levels of VO2max.

690/W

Association of Variants in Candidate Genes Influencing Autonomic Nervous System Functionality with Blood Pressure Level. *C. Vangjeli[1], N. McCarthy[1], G. Cavalleri[1], K. Shianna[2], N. Delanty[1], E. O'Brien[3], A.V. Stanton[1].* 1) Molecular & Cellular Therapeutics, Royal College of Surgeons in Ireland, Dublin 9, Ireland; 2) Duke Institute for Genome Sciences and Policy, 450 Research Drive- B wing, Box 91009 Durham, NC 27708; 3) The Conway Institute of Biomolecular and Biomedical Research, University College Dublin, Belfield, Dublin 4, Ireland.

Genomewide association studies have identified 13 novel loci associated with blood pressure (BP). However only a small proportion of total BP variation is explained by these findings - identification of all BP associated SNPs will require other strategies. Here we report on a candidate gene study with dense SNP coverage of multiple genes involved in the autonomic nervous system (ANS), namely neurotransmitter receptors, metabolisers, and transporters. Using the Illumina GoldenGate platform, we genotyped 2364 SNPs in 168 genes in 358 healthy bank employees who had undergone seated clinic BP measurements (screening population, SP). Only the 58 SNPs in 33 genes, found to be associated with systolic, diastolic or pulse pressure (SBP, DBP or PP) within the SP (p£0.01), were genotyped (Illumina Veracode platform) in a second independent replication population (RP) - these 380 healthy bank employees had undergone repeated 24-hour ambulatory BP monitoring. Association analyses were performed using additive genetic models. Quantile-quantile plots showed enrichment for significant P-values in both populations. Differences in BP (mean,p-value, age and sex adjusted) per copy of minor allele for the top associations signals are tabulated below.

	Clin-icSBP	DaySBP	NightSBP	Clin-icDBP	DayDBP	NightDBP
SLC17A8	4.0*	1.9	-0.3	2.6*	1.9*	0.02
GABRR1	0.9	-0.9	-1.3*	0.7	-0.1	-0.5

Significant results indicated by *. SLC17A8 encodes a sodium-dependent inorganic phosphate cotransporter and GABRR1 encodes the α subunit of the ionotrophic gamma-aminobutyric acid receptors. These genes have not previously been implicated in the causation of hypertension though the influence of the ANS on BP makes the observed associations biologically very plausible.

691/W

A comprehensive genetic study on left atrium size in Caribbean Hispanics identifies candidate genes in 17p10. *L. Wang[1], M.R. Di Tullio[2], A. Beecham[1], S. Slifer[1], T. Rundek[3], S. Homma[2], S.H. Blanton[1], R.L. Sacco[3].* 1) John T. Macdonald Foundation Department of Human Genetics, John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Medicine, Columbia University, New York, NY; 3) Department of Neurology and Epidemiology, University of Miami Miller School of Medicine, Miami, FL.

Background: Left atrial enlargement is associated with cardiovascular disease and stroke. Genetic factors contributing to the left atrium (LA) dimension are poorly understood. We sought to map susceptibility genes for LA size in a large Dominican family dataset and an independent population-based sample from the Northern Manhattan Study (NOMAS). Methods and Results: 100 Dominican families comprising 1350 individuals were studied to estimate heritability and map quantitative trait loci for LA size using variance components analysis. LA dimension was measured by transthoracic echocardiography. A polygenic covariate screening was used to identify significant covariates. LA size had a moderate estimate of heritability (h2=0.42), after adjusting for significant covariates. Linkage analysis revealed suggestive evidence on chromosome 10p19 (D10S1423, MLOD=2.00) and 17p10 (D17S974, MLOD=2.05). Ordered subset analysis found significantly enhanced ($p<0.05$ for increase of LOD score) evidence for linkage at 17p10 (MLOD=2.9) in families with lower LDL level. 2233 single nucleotide polymophisms (SNPs) were used to perform a peak-wide association mapping across 17p10 in 825 NOMAS individuals. Evidence for association were found in NTN1, MYH10, COX10, and MYOCD genes (p=0.00005 to 0.005). Conclusions: Using non-biased genome-wide linkage followed by peak-wide association analysis, we identified several possible susceptibility genes affecting LA size. Among them, MYOCD has been shown to serve as a key transducer of hypertrophic signals in cardiomyocytes. Our data support that polymorphisms in MYOCD modify LA size.

The Combination of Genetics and Corus CAD Gene-Expression Score for the Detection of Obstructive Coronary Artery Disease. *J.A. Wingrove[1], H. Tao[1], M.R. Elashoff[1], J. Blanchard[1], P. Beineke[1], S.E. Daniels[1], S. Rosenberg[1], W.E. Kraus[2], R.S. Schwartz[3], S. Voros[4], E.J. Topol[5], The PREDICT Investigators.* 1) CardioDx, Palo Alto, CA; 2) Duke University, Durham, NC; 3) Minneapolis Heart Institute and Foundation, Minneapolis, MN; 4) Piedmont Heart Institute, Atlanta, GA; 5) Scripps Translational Science Institute, La Jolla, CA.

Background: Coronary artery disease (CAD) etiology and progression is driven by a complex combination of genetic and environmental factors. Peripheral blood gene expression is sensitive to the presence of CAD, but does not directly address the role of other tissues, such as the endothelium and vascular wall, that may be captured by genetic information. We have initiated a study to determine if genetics can complement gene expression and report the impact of 9p21 genotype on the performance of a clinically validated, gene-expression based algorithm designed to detect significant coronary artery disease. **Methods**: DNA and RNA were isolated from 975 Caucasian subjects (369 cases) undergoing coronary angiography and participating in PREDICT, a multi-center trial designed to compare peripheral blood gene expression with the extent of CAD. Cases had > 50% stenosis in >1 major coronary artery; controls had < 25% luminal stenosis in any major coronary artery by quantitative coronary angiography. The gene-expression based test, comprised of expression levels of 23 genes as well as age and gender risk functions, was performed on the 975 subjects. TaqMan was used for genotyping rs10757278, a SNP associated with likelihood of developing CAD that is located at the 9p21 locus. **Results**: Receiver-operator characteristics (ROC) analysis and Net-Reclassification Index (NRI) were used to assess algorithm performance. The baseline AUC of the algorithm was 0.70 ± 0.02; inclusion of 9p21 genotype in the algorithm increased the AUC by 1% to 0.71. Stratification by gender showed a larger increase in AUC in women (0.65 to 0.68) than men (0.66 to 0.67). NRI of the baseline algorithm score compared to the Diamond-Forrester clinical risk score (age, gender, chest pain type) was 20%; addition of 9p21 genotype increased this to 24.6%. **Conclusions**: Combining 9p21 genotype with an existing gene-expression based algorithm for CAD detection resulted in a modest increase in algorithm performance, suggesting that the combination of DNA sequence variants and gene-expression profiling may improve CAD detection. An additional set of previously identified CAD-associated SNPs have also been genotyped and assessed for enhancement of algorithm performance.

Prolonged corrected QT interval in a patient with Paramyotonia Congenital/Hyperkalemic Periodic Paralysis overlap phenotype. *T. Greer[1], B. Powell[1], J. Caton[2], A. Dubin[3].* 1) Med Gen/Metabolism, Children's Hosp Central CA, Madera, CA; 2) Cardiology, Children's Hosp Central CA, Madera, CA; 3) Pediatric Heart Center, Lucile Packard Children's Hosp at Stanford, Palo Alto, CA.

Human skeletal muscle channelopathies are a group of disorders characterized by abnormal ion channel function resulting in muscle fiber overactivity, leading to generalized myotonia, muscle stiffness, cramping, or pain in affected individuals. Mutations occur in genes that encode for potassium (KCNJ2), calcium (CACNA1S), or sodium channels (SCN4A) cause ineffective activation and inactivation. Paramyotonia Congenita (PC) and Hyperkalemic Periodic Paralysis (hyperPP) are just two of six channelopathies that have been well described. Both have autosomal dominant mode of inheritance, with variable expression, even within families. Over 30 disease-causing mutations have been identified in the SCN4A gene that encodes the skeletal muscle voltage-gated sodium channel Nav1.4 in patients with PC and hyperPP. HyperPP is characterized by weakness that occurs with rest after exercise, fasting, cold exposure, and oral potassium loads. Patients with PC generally have attacks of stiffness induced and exacerbated by continued exercise or exposure to cold. There is an overlap phenotype with episodes of paralysis and myotonia that occur independently. Cardiac conduction abnormalities are not generally seen in these phenotypes. Periodic paralysis due to mutations in the KCNJ2 gene (Andersen-Tawil syndrome) can be associated with fatal ventricular dysrhythmias due to prolonged QTc intervals. Also, mutations in the sodium channel gene SCN5A, known to be exclusively expressed in heart tissue, are the cause of a rare cardiac dysrhythmia disorder (Long QT-3 variant syndrome). Péréon, Lande, et al. were the first to demonstrate expression of SCN4A in human heart and reported a family with a SCN4A mutation (R1448C) with the HyperPP/PC overlap phenotype and prolonged QTc intervals. We will describe a second patient with a SCN4A mutation, T704M (n2111C>T), who had the hyperPP/PC overlap muscle phenotype and asymptomatic prolonged QTc. We will describe this unique clinical presentation and the electrophysiological findings. We will also review the evolving understanding of gated sodium channel function in cardiac muscle physiology.

Emerging technologies based on mass spectrometry and nuclear magnetic resonance enable the monitoring of hundreds of small metabolites from tissues or body fluids. Because metabolites change rapidly in response to physiologic perturbations, such metabolite concentrations provide a direct readout of the physiological state in the human body, allowing the discovery of novel proximal biomarkers of disease phenotypes. Furthermore, profiling of metabolites in relevant biological pathways can help elucidate the contribution of genetic variants underlying inherited variation in established risk factors. Among the major risk factors for coronary artery disease and myocardial infarction are serum lipids, including total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), and triglycerides (TG). Using a high-throughput metabolomics platform we quantify metabolites covering a biologically relevant panel of amino acids, sugars, acylcarnitines, and phospholipids. Together with cholesterol, phosphatidylcholines and sphingomyelines species are the major building blocks of the cell membrane. They are biochemically closely linked to TGs by the intermediate of diacyl-glyceride in the Kennedy pathway and by the shared pool of fatty acids that make up their respective side chains. To dissect the effect of published genetic variants influencing serum lipid levels, we tested 151 metabolites in 1,797 participants from the KORA population (Germany) for association and replicated the results in 1,176 participants of the TwinsUK cohort. By analysing lipid concentrations in conjunction with genetic data and metabolite traits (and their ratios), we aim to identify cases where a genetic locus is associated with both a lipid and a metabolite concentration, which would provide new functional information about the underlying biological processes. We report here the initial results of this effort and discuss methodological approaches to metabolite analyses in the context of large population studies. Among others, we identify associations of variants in the *APOA* gene cluster with different ratios of phosphatidylcholines and sphingomyelines ($P = 2.5 \times 10^{-15}$). The here reported co-associations of the *APOA* gene cluster with TG and HDL together with phosphatidylcholines and sphingomyelines now allow us to dissect the effect of this gene cluster on the biochemistry of Apolipoproteins.

FREQUENCY OF VARIANTS OF LONG QT DISEASE GENES IN PATIENTS WITH DRUG-INDUCED LONG QT SYNDROME. *T. Zhang, F. Del-carpio, S. Yao, M. Ahearn, R. Myerburg, N. Bishopic.* University of MIami Miller school of Medicine, Miami, FL.

Background: The long QT syndrome (LQTS) is a hereditary disorder of myocardial repolarization, resulting from mutations in cardiac ion channel genes, and associated with increased risk of arrhythmia and sudden death. Similar arrhythmias and QT prolongation can be induced by certain drugs in a fraction of patients (drug-induced LQTS, diLQTS), and it has been hypothesized that susceptibility to diLQTS may be genetically based. We performed a prospective study of the prevalence of mutations and polymorphisms in genes associated with congenital LQTS among otherwise unselected patients with drug-induced QT lengthening, with or without torsade de pointes (TdP). Method and results: 45 patients with pharmacologically-induced QT prolongation (490-601 msec) and/or TdP were recruited (mean age 55, range 27-95; M:F 1:0.7). Drugs most frequently associated with QT changes were levofloxacin, azithromycin, amiodarone, and haloperidol. Individual exons and intron/exon boundaries of 5 LQTS-associated genes (KCNQ1, KCNH2, SCN5A, KCNE1, KCNE2) were screened for genetic variants. At present complete results of mutational analysis in 28 patients are available. In those, we identified 10 non-synonymous polymorphisms (2 in KCNQ1, 3 in KCNH2, 4 in SCN5A and 1 in KCNE1), 10 synonymous polymorphisms (3 in KCNQ1, 5 in KCNH2 and 2 in SCN5A), and 5 intronic polymorphisms. No variants were detected in KCNE2. Of these 25 variants, 11 have not previously been reported. Conclusion: In this single hospital study of diLQTS, we identified a high frequency of variants in genes associated with congenital LQTs, including 11 novel variants. Locally relevant and ethnically matched control samples have been developed and functional analysis in the novel variants is underway.

696/W

Genetic modifiers predisposing to congenital heart disease in a sensitized population. *H. Li[1], S. Cherry[1], C. Maslen[2], T. Wiltshire[3], R. Reeves[1].* 1) Department of Physiology and Institute for Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, USA; 2) Department of Medicine, Division of Endocrinology, Oregon Health & Science University, Portland, Oregon, USA; 3) Eshelman School of Pharmacy, University of North Carolina, Chapel Hill, NC, USA.

Congenital heart disease (CHD), the most frequent birth defect in human beings, has long been associated with complex genetic syndromes. Trisomy for human chromosome 21 (Hsa21) is the most frequent risk factor for CHD. The frequency of CHD in individuals with Down syndrome (DS) is about 50 times higher than in the general population. However, 50% of people with DS have a normal heart, thus, trisomy 21 is not sufficient to cause CHD. Additional genetic components may contribute to the perturbations resulting from gene dosage effects in trisomy. We have identified polymorphisms in the *CRELD1* gene that are associated with CHD in individuals with DS. To establish a biological basis for this interaction, we have initiated studies of CHD in mouse models of Down syndrome. The *Creld1* null allele was introduced into Ts65Dn mice, which are trisomic for orthologs of about half of the genes on Hsa21. We provide direct evidence that reduced *Creld1* expression exacerbates the occurrence of septal defects in *Ts65Dn, Creld1+/-* trisomic mice. To focus the search for trisomic genes that interact with *Creld1*, we introduced the *Creld1* null allele into Ts1Cje mice. Ts1Cje mice are trisomic for approximately 80% of the trisomic genes in Ts65Dn. Reducing *Creld1* expression in Ts1Cje by crossing in the null allele did not affect the frequency of heart defects in this model, thus it appears that one or more of the 23 conserved genes that is trisomic in Ts65Dn but disomic in Ts1Cje is necessary for the Creld1 interaction affecting heart development. We have undertaken a genome scan in mice to find more disomic CHD modifiers by comparing *Ts65Dn, Creld1+/-* mice with or without septal defects. These results will be compared with an analogous approach in a case/ control study of people who have Down syndrome with or without CHD.

A fine-mapping study for left ventricular mass on chromosome 12p11 identifies potential candidate genes. *A. Beecham[1], D. Della-Morte[2], M.R. Di Tullio[3], L. Wang[1], M.S. McClendon[2], S. Slifer[1], T. Rundek[2], R.L. Sacco[1,2], S.H. Blanton[1].* 1) Department of Human Genetics, Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Department of Neurology and Epidemiology, Miller School of Medicine, University of Miami, Miami, FL, USA; 3) Department of Medicine, Columbia University, New York, NY, USA.

Left ventricular mass (LVM) is an important risk factor for stroke and cardiovascular disease. Previously we found evidence for linkage on chromosome 12p11 (LOD = 3.11) in 1360 individuals from 100 Dominican families, with a significant increase (LOD = 4.45) in a subset of families with high average waist circumference (WC) using ordered subset analysis (OSA). In the present study, we use fine-mapping to confirm and further study the genetic effect on LVM. Association analysis was done in the 1 LOD critical region of the linkage peak in an independent sample of 895 primarily Hispanic individuals (65%). Genotype data were available on 7085 SNPs in the region from 23 to 53 MB. An additive genetic model was used, and adjustment was made for age, sex, BMI, SBP, diabetes, and population substructure (PCA1 and PCA2 from Eigenstrat). In order to follow-up on the OSA, analysis was subset by high and low WC. High WC was defined as ≥ 40 inches in men and 35 inches in women. There were 488 individuals with high and 396 individuals with low WC. Genotype data were available on 4334 SNPs in the 1 LOD critical region of the OSA peak from 23 to 41 MB. To test the difference in genetic effects between the high and low subsets, a Z-score was computed for the difference in β coefficients and significance assessed. The most significant association was in rs10743465, located downstream of the SOX5 gene (p=9.68E-06), which remained significant after multiple testing correction by SimpleM. 17 additional SNPs had p < 0.001, 15 of which were located in or near genes: SOX5(5), SLC38A1(3), BICD1(2), RACGAP1(1), C12orf68(1), PKP2(1), and BHLHE41(2). The most significant difference in genetic effect between those with high and low WC occurred at rs10877703 (p=6.41E-05) in an intron of SLC2A13. 11 additional SNPs had p < 0.001, all located in or near genes: SLC2A13(1), TMTC1(3), ITPR2 (1), CCDC91(2), DDX11(3), and PKP2(1). Evidence for a genetic effect on LVM has been shown on chromosome 12p using both linkage and fine-mapping. SOX5 may play a role in the regulation of LVM and is a good candidate as it has been found associated with other cardiac variables, such as PR interval in a recent genome-wide association study. An interaction of SLC2A13 and other genes with abdominal obesity may contribute to phenotypic variation of LVM. Validation studies are needed to confirm associations, particularly in other populations.

The C4b-binding protein (C4BP) has been hypothesized to be involved in the susceptibility to venous thrombosis (VT) through its binding with protein S (PS), a key element of the coagulation/fibrinolysis cascade. To identify genetic factors that may influence the plasma levels of the three C4BP existing isoforms, Alpha7Beta1, Alpha6Beta1, Alpha7Beta0, we conducted a genome-wide association study by analyzing 283,437 single nucleotide polymorphisms (SNPs) in the GAIT study composed of 387 individuals. Three SNPs at the C4BPB/C4BPA locus were found genome-wide significantly associated with Alpha7Beta0 levels. One of these SNPs was further found to explain ~11% of the variability of mRNA C4BPA expression in the Gutenberg Heart Study composed of 1,490 individuals, with no effect on C4BPB mRNA expression. The allele associated with increased Alpha7-Beta0 plasma levels and increased C4BPA expression was further found associated with increased risk of VT (OR = 1.24 [1.03 - 1.53]) in two independent case-control studies (MARTHA and FARIVE) gathering 1706 cases and 1379 controls. This SNP was not associated to free PS nor total PS. In conclusion, we observed strong evidence that the C4BPB/C4BPA locus is a new susceptibility locus for VT through a PS independent mechanism that remains to be elucidated.

Study of 9p21 genomic region and *USF1* gene associated with predisposition to cardiovascular diseases in Azorean healthy population. *M. Correia[1], N. Bruffaerts[1], A. Balagué[1], T. Pereirinha[1], C. C. Branco[1,2], L. Mota-Vieira[1,2].* 1) Molecular Genetics and Pathology Unit, Hospital of Divino Espírito Santo of Ponta Delgada, EPE, Azores, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal.

Cardiovascular diseases (CVD) are a major source of morbidity and mortality worldwide, including the Azores archipelago where the CVD has a higher mortality rate when compared to mainland Portugal. In order to investigate this question, we characterized 11 SNPs in two regions associated with risk of CVD: 4 on *USF1* gene (rs10908821, rs2516839, rs1556259, rs2774279) and 7 on 9p21 region (rs10116277, rs10757274, rs4977574, rs2833206, rs2383207, rs107557278, rs1333049), covering 9.0 and 44.1 kbp, respectively. Genotyping was performed by real time PCR using TaqMan Assays in a sample of 170 healthy blood donors. The average gene diversity was higher for markers in 9p21 (0.491) than for *USF1* (0.327). Although Azoreans' allele frequencies for 10 SNPs were in agreement with those reported for other European populations, the rs10116277 in 9p21 showed significantly different values (χ^2, p<0,05). All markers were in HWE, excluding two SNPs - rs10116277 and rs2833206 - in 9p21 region, which presented the highest heterogosity (0.776 and 0.759, respectively) and did not show homozygous variant (TT) neither homozygous normal (AA), respectively. Among 18 haplotypes, the most frequent (0.317) was the haplotype risk "**TGGGGGC**" for CAD, MI, stroke and atherosclerosis. Regarding the *USF1* gene 8 haplotypes were estimated, being the "C**T**AA" (0.291) and the "C**T**A**G**" (0.354) the two most frequent. The last one seems to be the haplotype with the highest CVD risk in females, corroborating previous literature data. In order to improve the knowledge of CVD in Azoreans, we are carrying out the joint analysis of all variants of the 9p21 genomic region and the *USF1* gene. We also intend to extend the present study to other candidate gene or regions, which has been recently associated with CVD. Collectively, the results will constitute a valuable resource for future case-control studies on CVD in the Azorean population. (lmotavieira@hdes.pt, Funded by the Azores Government, M 1.2.1./I/002/2008).

Genome-wide (GWAS) and candidate gene association studies have identified ~40 genes/genomic regions assoicated with high density lipoprotein cholesterol (HDL-C), low density lipoprotein cholesterol (LDL-C), and triglycerides (TG). The majority of these studies have been performed in populations of European-descent, and it is unclear if these associations will generalize to other populations. The Population Architecture using Genomics and Epidemiology (PAGE) network was established in 2008 to characterize GWAS-identified variants in diverse population-based studies including Atherosclerosis Risk in Communities, Cardiovascular Health Study, Coronary Artery Risk Development in Young Adults, Multiethnic Cohort, National Health and Nutrition Examination Surveys, Strong Heart Family Study, and Women's Health Inititative. We targeted GWAS-identified SNPs in at least two PAGE studies and performed tests of association assuming an additive genetic model adjusted for age and sex followed by a fixed effects meta-analysis for fasting HDL-C, LDL-C, and ln(TG) levels in ~20,000, ~9,000, and ~2,500 self-identified European American (EA), African American (AA), and Mexican American (MA) adults regardless of lipid lowering medication use. With these sample sizes, we had 80% power at $p<0.05$ to detect effect sizes (β) as low as 0.46, 0.69, and 1.30 for HDL-C; 0.86, 1.28, and 2.43 for LDL-C; and 0.02, 0.03, 0.05 for ln(TG) for EA, AA, and MA, respectively. As expected, most SNPs tested were significant at $p<0.05$ for EA (21/23, 18/19, 10/11) and less so for AA (8/23, 9/19, 5/11) and MA (6/16, 6/12, 7/8) for HDL-C, LDL-C, and ln(TG), respectively. Little overlap was identified across the populations for the three traits: 8/23, 8/19, and 4/11 were significant in both EA and AA while 4/16, 3/12, and 3/8 were significant in all three groups for HDL-C, LDL-C, and ln(TG), respectively. All overlapping associations were significant in the same direction. SNPs that were significant across all three groups included *LPL* rs2197089, *LPL* rs328, *LPL* rs6586891, and *APOA5* rs3135506 for HDL-C; *PCSK9* rs11206510, *PCSK9* rs11591147, and *LDLR* rs6511720 for LDL-C; and *GCKR* rs1260326, *MLXIPL* rs17145738, and *ANGPTL3* rs1748195 for ln(TG). Results from this PAGE study suggest that GWAS-identified variants from studies of European-descent may not necessarily generalize to other populations possibly due to differences in effect sizes, allele frequencies, and linkage disequilibrium.

701/W

Impact of Coagulation Factors on Myocardial Infarction-A hospital based study. *S. Dayakar[1,2], S. Komandur[3,4], P. K. Parvathi Thavanati[5], S. Naik[6], V. Bhupesh Kumar[1], B. Shyamala Sasekeran[2], M. D. Sadhnani[1].* 1) Department of Clinical Biochemistry, Institute of Genetics and Hospital for Genetic Diseases,Osmania University,Begumpet,Hyderabad-500016,India,Email:dayaphdgenetics@gmail.com; 2) Apollo Hospitals Educational & Research Foundation, Apollo Health city, Jubilee hills, Hyderabad-500033, India; 3) Department of Molecular Medicine, Apollo Health city, Jubilee hills, Hyderabad-500033, India; 4) Department of Cytogenetics, Vijaya Diagnostic Centre, Himayatnagar, Hyderabad -500029, India; 5) Instituto de Genetica,Dpto.de Biologia Molecular Y Genomica,Centro Universitario de Ciencias de la Salud,Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 6) Heart Institute, Apollo Health city, Jubilee hills, Hyderabad-500033, India.

Advances in understanding the pathophysiology of Myocardial Infarction (MI) have led to a marked increase in the development of biomarkers for diagnosis, risk stratification, therapeutic decision-making, and assessment of clinical outcomes. It has been shown that,the incidence of MI was related to be high in the presence of various polymorphisms among the genes encoding for various factors, including haemostatic under the influence of environmental predisposition i.e., life styles factors like smoking, alcohol consumption, dietary habits etc. However, their contribution in the development of myocardial infarction (MI) remains controversial.

In the present study, we assessed the sequence variations in three coagulation factors, glycoprotein IIb/IIIa (PI^A), factor V Leiden (FVL) and Prothrombin (FII), in 102 patients with MI and 112 controls(who had not documented history of either stable or unstable angina or myocardial infarction). $PI^{A1/A1}$ genotype was observed in 58.7%, $PI^{A1/A2}$ in 20.61% and $PI^{A2/A2}$ in 20.61% among the patients group. While in control group, 83.92% had $PI^{A1/A1}$ genotype,12.5%$PI^{A1/A2}$ and 3.57% carried $PI^{A2/A2}$, which indicated that PI^{A2} was 2.4 times higher in patient group. Only one patient carried FV Leiden (G1619A) while another patient showed FII mutation (G20210A), both in heterozygous state. Owing to a small number with mutation, statistical analysis was carried out for risk factors (smoking status, hypertension, hypercholesteremia and diabetes mellitus) that differed significantly (P value 0.001, <0.0001, 0.0024 and <0.0001 respectively) between the patient and the control groups.

It can be concluded that, an understanding of gene-environment interactions along with inherited markers can ultimately be used to manage complex diseases through a better utilization of diagnosis,application of pharmacogenetics and genetic counseling.

702/W

Genome-wide linkage and follow-up association analyses of carotid plaque in Caribbean Hispanics. *C. Dong[1], A. Beecham[2], D. Cabral[1], S.H. Blanton[2], R.L. Sacco[1,2,3], T. Rundek[1].* 1) Department of Neurology, University of Miami, Miami, FL; 2) John T. McDonald Department of Human Genetics, John P Hussman Institute for Human Genomics, University of Miami, Miami, FL; 3) Department of Epidemiology, University of Miami, Miami, FL.

Atherosclerosis, a complex subclinical cardiovascular disorder with a substantial genetic component, is the pathology underlying most ischemic strokes and heart attacks. Dissecting the genetic underpinnings of atherosclerosis, therefore, is of great value in assessing an individual's future risk for stroke and cardiovascular disease. This study sought to identify genetic loci influencing carotid plaque in two independent samples. B-mode ultrasound was performed to determine the presence and area of carotid plaque. Power transformation on total plaque area was first conducted to reduce the skewness and kurtosis in both linkage and follow-up association analyses. Variance components analysis was performed to test for linkage using 383 autosomal microsatellite markers in 1,308 subjects from 100 Dominican families. Generalized linear models were used to investigate the association between plaque traits and 18,917 single nucleotide polymorphisms (SNPs) under 1-LOD down regions of linkage peaks in an independent community-based dataset (N=928, 41% Dominicans) from the Northern Manhattan Study (NOMAS). Principal component approach was employed to control for population stratification in the follow-up association analysis. After adjustment for age, hypertension, diabetes mellitus, cigarette pack-years, body mass index, and waist-to-hip ratio, significant heritability was detected for plaque presence ($h^2=0.50\pm0.14$, $p<0.0001$) and plaque area ($h^2=0.17\pm0.04$, $p<0.0001$). Quantitative and dichotomous trait linkage analyses obtained similar results and identified four regions with multipoint LOD scores ≥2.00 on 7q36, 11p15, 14q32 and 15q23. In the follow-up association analysis of four linkage peaks, several SNPs in or near *SOX6, FSD2, AP3S2* and *EFTUD1* were associated with carotid plaque traits with a nominal p £0.0005 in the NOMAS dataset and with a p £0.01 in a Dominican subset. Our findings indicate that carotid plaque has considerable heritability and may be influenced by loci on chromosomes 11p15, 14q32 and 15q23 in Caribbean Hispanics. The *SOX6* gene within the Bone Morphogenic Protein pathway may be of particular interest and could be a candidate for carotid plaque. Further studies in larger populations are needed to validate the observed association, as well as in depth investigation of the genes in these regions to provide fundamental insight to the understanding of atherosclerotic disease.

703/W

***LPA* common variation is associated with Lp(a) levels and myocardial infarction in non-Hispanic blacks in the Third National Health and Nutrition Examination Survey.** *L. Dumitrescu[1,2], K. Glenn[1], K. Brown-Gentry[1], C. Shephard[3], M. Wong[3], M.J. Rieder[3], J.D. Smith[3], D.A. Nickerson[3], D.C. Crawford[1,2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 3) Department of Genome Sciences, University of Washington, Seattle, WA.

Lipoprotein(a) [Lp(a)] levels are an emerging risk factor for cardiovascular disease (CVD) and have been shown to be highly heritable. While much of the genetics impacting Lp(a) levels has been attributed to the kringle IV-2 (KIV-2) copy number variant in *LPA*, the gene that encodes the apo(a) component of Lp(a), the remaining variance has yet to be explained. Currently, the role of other cis-acting factors in *LPA* to the contribution of Lp(a) levels and its relevance to CVD is not completely understood. Furthermore, the extent to which these genetic variants can help to explain the significant differences in levels and risk across diverse populations is sorely understudied. To identify genetic variants associated with Lp(a) levels and possibly myocardial infarction (MI), 20 tagSNPs in *LPA* were genotyped in 7,159 individuals from the Third National Health and Nutrition Examination Survey (NHANES III). NHANES III is a diverse population-based survey with samples linked to hundreds of quantitative traits, including serum Lp(a). Using linear regression, 19 SNPs were tested for an association with transformed Lp(a) levels adjusting for age and sex. Tests of association between *LPA* variants and possible/probable myocardial infarction (MI) were also performed on a subset of participants that underwent electrocardiogram examination. Across the three different NHANES subpopulations (non-Hispanic whites, non-Hispanic blacks, and Mexican Americans), 15 of the 19 SNPs tested were strongly associated with Lp(a) levels in at least one subpopulation at $p<0.0001$. The strongest association (rs1652507, $p=5.4x10^{-34}$, $\beta=-0.54$) was found in Mexican Americans. This association was also observed in non-Hispanic blacks ($p=1.1x10^{-10}$, $\beta=-0.45$) but not in non-Hispanic whites ($p=0.57$, $\beta=0.21$). The additive effects of these associated alleles explained up to 12% of the variance in observed for Lp(a) levels. Additionally, five SNPs were associated with MI risk in non-Hispanic blacks at $p<0.05$. In contrast to previous reports in non-Hispanic whites, alleles associated with increased Lp(a) levels were also associated with decreased risk of MI in non-Hispanic blacks. These results demonstrate that genetic variation within *LPA*, outside and independent of the KIV-2 region, is associated with Lp(a) levels in the general population and may be associated with MI risk in non-Hispanic blacks in a paradoxical manner compared to non-Hispanic whites.

704/W

The transcriptome of human epicardial, mediastinal and subcutaneous adipose tissues in men with coronary artery disease. *S. Guauque-Olarte[1], N. Gaudreault[1], D. Fournier[1], P. Mauriège[1,2], P. Mathieu[1], Y. Bossé[1,3].* 1) Centre de recherche Institut universitaire de cardiologie et de pneumologie de Québec, Laval University, Québec, Canada; 2) Division of kinesiology, Department of social and preventive medicine, Faculty of medicine, Laval University, Québec, Canada; 3) Laval University Hospital Research Center (CRCHUL), Québec, Canada.

The biological functions of epicardial adipose tissue (EAT) remain largely elusive. However, the proximity of EAT to the coronary arteries suggests a role in the pathogenesis of coronary artery disease (CAD). Objectives of this study were to identify genes that are up- or down-regulated among three adipose tissues (AT), namely EAT, mediastinal and subcutaneous and to study their possible relationships with the development of cardiovascular diseases. Samples were collected from patients undergoing coronary artery bypass grafting surgeries. Gene expression was evaluated in all three AT depots of six men using the Illumina® HumanWG-6 v3.0 expression BeadChips. The Significant Analysis of Microarrays (SAM) method was utilized to identify genes differentially expressed among the fat depots. The false discovery rate and the fold change thresholds were set at 10% and 2.0, respectively. The Ingenuity Pathway Analysis system was used to identify the principal biofunctions among differentially expressed genes. The expression of four genes of interest was verified by quantitative PCR (qPCR) in six technical and 25 biological replicates. Twenty-two and 72 genes were up-regulated in EAT compared to mediastinal and subcutaneous AT, respectively. Ninety-four were down-regulated in EAT compared to subcutaneous adipose depot. However, none were significantly down-regulated in EAT compared to mediastinal fat. The expression of the adenosine A1 receptor (ADORA1), involved in myocardial ischemia, was significantly up-regulated in EAT. Levels of the prostaglandin D2 synthase (PTGDS) gene, recently associated with the progression of atherosclerosis, were significantly different in the three pairwise comparisons (epicardial > mediastinal > subcutaneous). The results of ADORA1 and PTGDS were confirmed by qPCR in biological replicates. Overall, the transcriptional profiles of EAT and mediastinal AT were similar compared to the subcutaneous compartment. Despite this similarity, two genes involved in cardiovascular diseases, ADORA1 and PTGDS, were up-regulated in EAT. These results provide great insights about the biology of the EAT and its potential implication in CAD.

Stem Cell Regulatory Gene Polymorphisms Associated with the Promotion of Coronary Artery Disease in Tobacco Smokers. *K.L. Hamilton-Nelson[1], I. Konidari[1], P. Goldschmidt-Clermont[2], M.A. Pericak-Vance[1], D. Seo[2], R. Levitt[3], G.W. Beecham[1].* 1) John P Hussman Institute for Human Genomics, Univ Miami, Miller School of Medicine, Miami, FL; 2) Department of Medicine, Division of Cardiology, Univ Miami, Miller School of Medicine, Miami, FL; 3) Department of Anesthesiology, Univ Miami, Miller School of Medicine, Miami, FL.

BACKGROUND While it is known that CAD is heritable and significantly impacted by tobacco smoke, the mechanisms remain elusive. Recent evidence suggests that biologic variability in stem cell mediated vascular repair may play an important role in coronary artery disease (CAD). We hypothesize that functional polymorphisms in stem cell regulatory genes underlie the promotion of CVD by tobacco smoke in susceptible individuals. To investigate this further, we analyzed a set of 43 candidate genes known to be involved in the regulation of stem senescence and that could affect stem cell mediated vascular repair. METHODS An existing dataset of 1050 cardiac catheterization patients, used in the first genome-wide association study of anatomic coronary artery disease served as the dataset for these analyses. Cardiac angiograms were used to assign a CAD burden index based on size and location of coronary lesions. Smoking status was self-reported. Genotype data were generated using the Affymetrix SNP array 6.0 platform for 900,000 SNPs. Data integrity was ensured with extensive quality controls including sample filters (gender consistencies, efficiency thresholds, etc), SNP filters (Hardy-Weinberg equilibrium, genotyping efficiency, MAF, etc). EIGENSTRAT methods were used to correct for population substructure. Linear regression implemented with PLINK software was used to conduct candidate gene association analyses. Analyses were adjusted for cholesterol, blood pressure, age, sex, and population substructure. Since the stem cell reservoir is known to decrease with age and smoking status, interaction terms between SNP and age, and SNP and smoking status were included in the model. RESULTS Preliminary analyses indicate significant associations between CAD and SNPs in stem cell regulatory genes WNT7A, WNT5A, and MEF2A among smokers ($p<0.006$). More comprehensive analyses are being conducted to further define the association between these candidate genes and smoking status in these subjects. CONCLUSION These data indicate for the first time that WNT7A, WNT5A and MEF2A may be implicated in the promotion of CAD by tobacco smoke. Confirmation in our larger dataset is underway as well as analyses in different populations with differing racial representation. These data provide new insights into how tobacco smoke may promote CAD by altering stem cell mediated vascular repair.

Weight gain is adversely associated with many cardiovascular risk factors such as blood pressure, lipids and glycemia. Few studies have looked at the underlying genetic contribution to change in body weight over the adult life span. We conducted a genome wide association study (GWAS), meta-analysi,s and expression SNP (eSNP) analysis of weight change between 20 and 65 years of age in 17,730 individuals of European descent from 6 cohorts participating in the CHARGE consortium. Longitudinal weight change was modeled using a mixed model with random effects, adjusting for age, age squared and sex among individuals with at least two weight measures at study examinations. GWAS and meta analysis revealed that no loci achieved genome - wide significance. However, several loci showed suggestive evidence of association (p<9x10-5). To further characterize these associations, we utilized eSNPs previously reported in the literature to be associated with altered expression in adipose tissue . After correcting for the number of eSNPs tested (5,182), we observed a suggestive signal at the PAX8 locus (p=7.69x10-5) . PAX genes encode a family of transcription factors that are required for the formation of several tissues in the mammalian embryo. In the thyroid gland, PAX8 is essential in thyroid development and function. PAX8 has been shown to activate expression of several thyroid-specific genes and has been associated with congenital hypothyroidism. Thus, through its action in the thyroid gland PAX8 provides a novel candidate gene and plausible biological pathway for its association with weight change. Further studies are required to replicate and validate these findings.

Rare coding mutations and risk for early-onset myocardial infarction: an exome sequencing study of 1,300 cases and controls. *S. Kathiresan for the NHLBI's Exome Sequencing Program - Early-onset Myocardial Infarction Project.* Program in Med & Pop Genetics, Broad Institute, Cambridge, MA.

Myocardial infarction (MI), the leading cause of death in the United States, is a heritable phenotype and the role for inheritance is greatest when MI occurs early in life. Genome-wide association studies of common variants have identified at least 13 loci associated with early-onset MI; however, the modest proportion of overall heritability explained by common variants suggests that low frequency (0.5% to 5% frequency) or rare (<0.5% frequency) variants may contribute to risk for early-onset MI. To test the hypothesis that rare coding mutations contribute to early MI risk, the U.S. National Heart, Lung, and Blood Institute's Exome Sequencing Program Early-onset MI Project is conducting a large-scale exome sequencing experiment. We are exome sequencing 650 cases with early onset-MI (men £50 and women £60; 450 of whom are of European ancestry and 200 of whom are of African American ancestry) and 650 controls free of MI. To enrich for protective alleles, we have specifically selected controls from population-based cohort studies with a high predicted risk for MI (based on traditional risk factors) but who are free of incident MI on follow-up. We are using solution-based hybrid selection to selectively capture and enrich the exome and next-generation sequencers (Illumina GAII) to sequence the exome. We have targeted 32.7 megabases at 188,260 exons from 18,560 genes. In the first 108 exomes sequenced, for each individual, we have generated ~6 billion bases of sequence, allowing for each targeted base to be read, on average, 177 times. For each individual, approximately 86% of all bases were covered with at least 20x depth. We are comparing several statistical methods recently developed to analyze the contribution of rare variants to complex traits including combined multivariate and collapsing methods (Li and Leal), weighted sum tests (Madsen and Browning), variable threshold tests (Price, Kryukov and Sunyaev), and c-alpha (Neale, Roeder, and Daly)]. The tests incorporate computational predictions of functional effects of rare variants. We have also implemented a network-based test that searches for sub-networks of genes with a significant difference in rare variant burden between cases and controls. We will present initial analyses for 1300 exomes at ASHG 2010.

708/W

Effect of rs662799 (APO A5/A4/C3/A1) on HDL-C concentration is modified by physical activity. *H. Kitajima[1,3], K. Yamamoto[1], K. Ohnaka[2], R. Takayanagi[3], S. Kono[4].* 1) Division of Genome Analysis, Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 2) Department of Advanced Medical Initiatives, Faculty of Medical Science, Kyushu University, Fukuoka, Japan; 3) Department of Medicine and Bioregulatory Science, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; 4) Department of Preventive Medicine, Faculty of Medical Science, Kyushu University, Fukuoka, Japan.

Serum high-density lipoprotein cholesterol (HDL-C) concentration is regulated by both genetic and life-style factors. Recent genome-wide association (GWA) studies have identified genetic variants related to HDL-C concentration. However, interaction between these variants and lifestyles has remained to be elucidated. We report here replication association analysis for the SNPs identified in the previous GWA studies, and SNP-lifestyle interaction analysis in the Japanese general population. We selected 15 SNPs of which MAF were over 0.1 in the HapMap JPT among the SNPs shown to be significantly associated with HDL-C concentration in GWA studies. The selected SNPs were located on the CETP, APO A5/A4/C3/A1, LIPC, LPL, LIPG, ABCA1, LCAT, ANGPTL4, APOB, GALNT2, NR1H3, MADD-FOLH1, FADS, MVK-MMAB, or chromosome 17p13.3 locus. We genotyped these SNPs in the Japanese ongoing cohort study (7,052 subjects) with TaqMan assay. First, we evaluated the association with HDL-C concentration adjusted for sex, age, BMI, alcohol consumption, smoking, and physical activity. The six SNPs, rs3764261 (CETP), rs662799 (APO A5/A4/C3/A1), rs1800588 (LIPC), rs10503669 (LPL), rs2156552 (LIPG), and rs4149268 (ABCA1) showed significant associations. The effect size of additive model was 9.6, 6.7, 5.0, 6.5, 3.7, and 2.6 mg/dl, and the P-value was $6.9x10^{-63}$, $2.1x10^{-45}$, $1.8x10^{-22}$, $7.0x10^{-19}$, $1.4x10^{-7}$, and $2.0x10^{-7}$, respectively. The remaining SNPs did not show significant associations. Second, we conducted the SNP-environment interaction analysis for these six SNPs. We found that rs662799 showed a significant interaction with physical activity in the condition of adjustment for sex, age, BMI, alcohol consumption, and smoking (P-value=0.008). Based on the result, we further analyzed the mean HDL-C concentration in each genotype and physical activity category. The differences of adjusted mean HDL-C concentration between the low and the high physical activity category were 0.6, 1.4, and 3.5 mg/dl in the risk allele homozygosity (G/G), heterozygosity (G/A), and non-risk allele homozygosity (A/A), respectively. In summary, we have confirmed the six loci significantly associated with HDL-C concentration in the Japanese general population cohort. The effect of the rs662799 (APO A5/A4/C3/A1) on HDL-C concentration may be modified by the physical activity. The risk allele G/G subjects may have an impaired adaptation to physical activity that could result in higher risk of atherosclerosis.

The role of calcineurin pathway genes polymorphisms in cardiac parameters variability in normal subjects and patients with cardiovascular diseases. *O.A. Makeeva[1,2], V.M. Shipulin[3], O.G. Polovkova[1], A.A. Lezhnev[3], T.V. Zheykova[1], E.V. Kulish[4], K.V. Puzyrev[1], I.A. Goncharova[1], I.V. Tsimbal'uk[4], V.P. Puzyrev[1].* 1) Research Institute of Medical Genetics SB RAMS, Tomsk, Russia; 2) Research Institute of Complex Problems of Cardiovascular Diseases SB RAMS, Kemerovo, Russia; 3) Research Institute of Cardiology SB RAMS, Tomsk, Russia; 4) Siberian State Medical University, Tomsk, Russia.

Critical role of the calcineurin pathway (CP) in cardiac hypertrophy and heart failure had been demonstrated by experiments *in vitro* and studies of model organisms, though only few studies evaluated the role of CP genes polymorphisms in cardiac parameters variability and relation to different forms of cardiac remodeling. The **aim** of the study was to perform a systematic search for polymorphic variants in CP genes (*PPP3R1, PPP3CA, PPP3CB, GATA4*, and *NFATC4*) and to investigate their possible influence on myocardium characteristics in normal population and patients with cardiovascular diseases. **Methods**: A set of 30 polymorphisms with predicted functional significance, including those leading to amino-acid substitutions; variants in promoters; in predicted transfactor binding sites, and variants in conserved regions had been genotyped. Additionally, tagging SNPs and variants associated with cardiovascular phenotypes in previous researches were studied. A control group consisted of 287 unrelated subjects selected from general population according to normal echocardiographic parameters (1100 medical records were analyzed), patients with arterial hypertension (AH, n=250) and patients with ischemic heart disease (IHD, n=210) were enrolled for the study. Cardiac biopsy samples from 60 patients who undergo cardiac surgery were collected for CP genes expression profile study. **Results**: An association of the *PPP3R1* promoter insertion-deletion polymorphism (*5I/5D*) with left ventricular myocardium mass (LVMM), LVMM index, and LV walls thickness had been revealed in normal population. *5I/5D* variant was also associated with LVMM in patients with essential hypertension; the presence of *5I/5I* genotype was connected with larger echocardiographic indexes both in normal subjects and patients with hypertension. An association of the *GATA4* rs804271 with echocardiography characteristics and systolic blood pressure had been detected in healthy females; rs804271 was related with the presence of left ventricular hypertrophy (LVH) in essential hypertension group. *PPP3CA* tagSNP rs7696663 was associated with LVMMI and other cardiac parameters in patients with AH. *PPP3R1* tagSNP rs11126176 and *GATA4* rs10112596 and rs2898293 were associated the presence of LVH in essential hypertension sample. This preliminary data confirms the possible role of calcineurin pathway genes in cardiac remodeling and other clinically relevant phenotypes.

Bayesian analysis of hepatic lipase (*LIPC*) genetic variation suggests different variants influence HDL-C level and HDL particle size. *P.E. Melton, K. Haack, T.D. Dyer, M.C. Mahaney, J.W. MacCluer, D.L. Rainwater, J. Blangero, L. Almasy, S.A. Cole.* Genetics Dept, Southwest Foundation for Biomedical Research, San Antonio, TX.

The gene for hepatic lipase (*LIPC*) is known to have a major role in lipoprotein metabolism and has been implicated as a regulator of HDL-C concentration and HDL particle size reduction through the reverse cholesterol transport pathway. However, the relationship between *LIPC* and HDL-C levels and HDL particle size phenotypes remains unclear. One *LIPC* promoter variant, -514C>T (rs1800588), has shown association with HDL-C and related phenotypes in a number of studies and is presumed to be functional. This study investigated the biological relationship between *LIPC* genetic variation and HDL-C and five HDL size measures, median diameter of particles containing apoA1 (A1), apoA2 (A2), unesterified cholesterol (UC), esterified cholesterol (EC), and ΔHDL, the difference in fractional absorbance patterns between large and small lipoprotein particles. We deep sequenced 28.7 kb coding and conserved non-coding regions of *LIPC* in 182 founders from 42 extended pedigrees and examined the resulting 625 single nucleotide polymorphism (SNP) genotypes in 1,336 Mexican American participants from the San Antonio Family Heart Study. Genetic association was assessed with measured genotype analysis (MGA) and SNPs with nominal p-values ($p < 0.1$) were used in Bayesian Quantitative Trait Nucleotide (BQTN) analyses. SNPs in high LD ($r2 > 0.9$) were grouped, with the single member with the lowest MGA p-value representing the isocorrelated redundant variant (IRV) set. BQTN identified 18 (five novel) potentially functional SNPs with substantial posterior probabilities (pps > 0.50) associated with one or more of the six investigated phenotypes. Seven SNPs demonstrated pps >0.95: two for HDL-C levels (rs1077834, rs16940299), two for A1 (rs375372, rs12914232), one for A2 and UC (rs11071387), and two for ΔHDL (rs485538, rs8023503). The SNP rs11071387 was associated with four size phenotypes (A1, A2, UC, EC). The promoter SNP, rs1077834, is in an IRV set with three other promoter SNPs, rs1800588, -763A>G (rs10077835) and -250G>A (rs2070895). Promoter variants did not demonstrate substantial pps with any of the five HDL-C size measures. Minor allele frequency ranged from 0.0008 for +106481 G>A (HDL-EC, HDL-UC) to 0.4596 for rs375372 (A1). This comprehensive investigation of *LIPC* genetic variation provides strong evidence that variants in addition to rs1800588 influence HDL-C levels and also suggests that different LIPC variants influence HDL-C levels and HDL particle size differentiation.

Population diversity and GWAS-based genetic variants for BMI: The PAGE Study. *K.E. North[1, 12], M. Fesinmeyer[2], M.D. Ritchie[3], N. Francescini[1], P. Buzkova[4], U. Lim[5], M. Quibrera[1], M. Gross[6], K. Glenn[3], S. Buyske[7], C. Kooperberg[2], C.S. Carlson[2], R. Li[8], C.A. Haiman[9], L.R. Wilkens[5], L.L. Marchand[5], R.L. Prentice[2], L.H. Kuller[10], L. Hindorff[8], J. Manson[11], C. Chen[2], U. Peters[2].* 1) Dept Epidemiology, Univ North Carolina, Chapel Hill, NC; 2) Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 4) Department of Biostatistics, University of Washington, Seattle, WA; 5) Cancer Research Center of Hawaii, Honolulu, HI; 6) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 7) Department of Statistics & Biostatistics, Rutgers University, Piscataway, NJ; 8) Office of Population Genomics, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 9) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 10) Department of Epidemiology, University of Pittsburgh, Pittsburgh, PA; 11) Department of Medicine, Harvard Medical School, Boston, MA; 12) Carolina Center for Genome Sciences, Univ North Carolina, Chapel Hill, NC.

The successes of genome-wide association studies (GWAS) in mapping loci that influence complex traits advance our understanding of genomic influences on common diseases. Translation of such knowledge into clinical and public health applications requires exploration of these associations in different ancestral groups. The NHGRI-supported 'Population Architecture using Genomics and Epidemiology (PAGE)' consortium of population-based studies accomplishes this by investigating the epidemiologic architecture of well-replicated genetic variants associated with complex traits. PAGE is comprised of CALiCo (Causal Variants Across the Life Course, a consortium of ARIC, CARDIA, CHS, and SHFS), EAGLE (Epidemiologic Architecture for Genes Linked to Environment, with participants from National Health and Nutrition Examination Surveys), Multiethnic Cohort, and Women's Health Initiative studies. We selected twenty putative body mass index (BMI) related SNPs identified by prior GWAS in European and European American populations, and genotyped each SNP in a diverse sample of up to ~70,000 subjects representing European American (N=39,421), African American (N=14,573), Mexican American (N=7,317), Asian and Pacific Islanders (N=3,236), and American Indian (N=7,317) individuals. We compared allele frequencies between ancestry groups and examined each SNP for departure from Hardy-Weinberg equilibrium within each subpopulation. The association between each SNP and BMI was analyzed stratified by PAGE site and self-identified race using additive genetic models and linear regression (mixed models for family relatedness), and adjusting for age and current smoking status specific for each sex strata. Results were combined across study but within ancestral groups using fixed effects meta-analysis techniques. Interestingly, some well established genetic variants did not replicate in any population we considered (for example, rs2815752 in NEGR1). However, several SNPs did replicate in most of the populations, for example rs7498665 in SH2B1 demonstrated a significant effect ($P < 0.05$) in all but the Mexican American subpopulation. Given known differences in allele frequencies and linkage disequilibrium patterns across ancestral groups, our findings suggest a complex architecture of BMI and the need for considering genetic, cultural, and environmental population differences in interpreting the increasing body of genetic associations emerging from well-replicated GWAS.

Comparative genomics and functional analysis of coronary artery disease associated chromosome 9p21 region. *H. Ongen, T. Kyriakou, A. Goel, M. Farrall, H. Watkins, J. Peden.* Department of Cardiovascular Medicine, Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom.

Several independent genome wide association studies (GWAS) identified a 53 kb region on chromosome 9p21 that is associated with coronary artery disease (CAD), which is the most supported association to arise from CAD GWAS to date. Recent studies in mouse knockout models and human cell lines suggest that this region harbours elements that act in *cis*- and potentially have a regulatory role in the expression of neighbouring genes *CDKN2A* and *CDKN2B*. Phylogenetic footprinting and phylogenetic shadowing (a comparative genomics approach using only closely related sequences) have successfully identified conserved enhancer elements. Here we report phylogenetic footprinting and novel phylogenetic shadowing experiments designed to identify enhancer elements in this 9p21 CAD associated region. The information that would be gained by sequencing additional primates for the phylogenetic shadowing experiment was assessed by simulation of the sensitivity of detecting known functional elements as defined by the ENCODE project. These simulations ascertained that the addition of Colobus monkey, Owl monkey, and Dusky titi sequences to publicly available primate sequences increases accuracy. Orthologous bacterial artificial chromosome (BAC) clones for the 9p21 region from these three primates were sequenced using the 454 sequencing technology. 11 primate specific conserved elements (PSCEs), ranging from 80 bp to 431 bp, were predicted within the 9p21 region. Of these 11 PSCEs, 5 were prioritised for functional analysis based on putative histone modifications, DNase hypersensitive sites, and transcription factor binding sites as reported by the ENCODE project. In addition, another 8 mammalian conserved elements (MCEs) were identified within the publically available 34 species alignments due to their deep conservation and supporting functional evidence from ENCODE. Of these 8 MCEs, 4 have recently been independently assayed for functional activity and one was reported to be an enhancer. Ongoing work includes cloning the 5 PSCEs and 8 MCEs in luciferase reporter vectors so that their enhancer activity can be assayed in primary endothelial and smooth muscle cell cultures.

A New Genetic Factor Influencing Pleoitropically Body Mass Index and Venous Thrombotic Risk Identified by Means of GWAS. *J.C. Souto[1], D.A. Tregouet[2], A. Buil[3], N. Saut[5], A. Martinez-Perez[3], M. Germain[2], S. Lopez[3], J. Fontcuberta[1], L. Almasy[4], P. Morange[5], J.M. Soria[3].* 1) Dept Hematology, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain; 2) INSERM, UMRS 937; Université Pierre et Marie Curie, Paris, France; 3) Unit of Genomics of Complex Diseases. Research Institute Hospital de la Santa Creu i Sant Pau, Barcelona, Spain; 4) Department of Population Genetics, Southwest Foundation for Biomedical Reseach, San Antonio, Texas, USA; 5) INSERM, UMRS 626, Université de la Mediterranée, Marseille, France.

Body mass index (BMI) is an independent risk factor for myocardial infarction, obesity and type 2 diabetes. In addition, recent data relate BMI and obesity with venous thromboembolic (VTE) risk. However, it is unknown if this relationship is due to common genetic causal factors. No one of the several human genetic loci associated with obesity or BMI have been involved in VTE risk. Methods: In order to identify genetic determinants of BMI, we conducted a genome-wide association study by analyzing 317000 single nucleotide polymorphisms (SNPs) in the GAIT study, composed of 398 individuals belonging to Spanish extended pedigrees with unexplained thrombophilia. Those SNPs showing significant p-values with BMI ($p<0.0001$) were replicated in the French cohorts of the MARTHA Project (419 patients with venous thrombosis and 1228 healthy controls) Results: Several SNPs in the same region of chromosome 1 associated with the BMI. The strong p-value was $p = 0.000007$. The same SNP showed a significant association with VTE in the French cohort ($p = 0.026$). A haplotype within this region also associated with thrombotic risk (OR 2.72, CI 1.7 - 4.2; $p = 0.00001$). Both, the SNP and the haplotype are located in a gene previously related to obesity. Conclusions: We have found a genetic determinant of the BMI that is pleiotropically related with venous thrombosis risk. The proposed research strategy (genomic search by means of a family study plus replication in a case/control study, using populations with different backgrounds) can be very helpful in the genetic analysis of many other complex traits and diseases. Our result suggests the existence of a common genetic basis between obesity and VTE, which would be clinically relevant.

Interaction between Monoamine Oxidase A Gene Polymorphism and Childhood Emotional Abuse on Susceptibility to Early Atherosclerosis: A Twin Study. *J. Yang[1], V. Vaccarino[2], J. Zhao[1].* 1) Biostatistics and Epidemiology, University of Oklahoma HSC, Oklahoma City, OK; 2) Emory Univ, Atlanta, GA.

Background: A functional promoter polymorphism in MAOA has been implicated as a moderating factor in the relationship between childhood trauma and adult behavior or mental disorders, which often co-occur with cardiovascular disease (CVD). However, no previous study has examined the role of MAOA in preclinical atherosclerosis. Hypothesis: MAOA genotype is implicated in preclinical atherosclerosis and childhood trauma moderates the association between MAOA polymorphism and early atherosclerosis. Methods: We genotyped the MAOA polymorphism in a sample of 169 middle-aged male twin pairs drawn from the Vietnam Era Twin Registry. Childhood trauma, before age 18, was measured with the Early Trauma Inventory and included physical, emotional and sexual abuse and general trauma. Preclinical CVD was assessed by flow-mediated dilation (FMD) using ultrasound. Generalized estimating equation models were used to test main and interactive effects of MAOA genotype and each domain of childhood trauma on FMD, controlling for coronary risk factors. Results: General trauma was the most prevalent childhood trauma (27.5%), followed by physical abuse (21.1%), emotional abuse (17.5%) and sexual abuse (11.1%). For MAOA, five repeated sequences were identified. Based on differential transcription efficiency, twins were assigned to low activity group (2R, 3R or 5R), or high activity group (3.5R or 4R). There was no significant evidence for a main effect of MAOA genotype or childhood trauma on early atherosclerosis. However, we identified a significant interaction between MAOA genotype and emotional abuse on early atherosclerosis ($p = 0.02$), independent of multiple covariates. In the absence of emotional abuse, low activity alleles protected against subclinical CVD (mean FMD value: 6.24 in low activity group vs. 4.61 in high activity group), but the presence of emotional abuse reversed this association (mean FMD value: 4.17 in low activity group vs.5.26 in low activity group). Conclusion: This study provides the first evidence that an interaction between MAOA gene polymorphism and childhood emotional abuse influences the susceptibility for early atherosclerosis, independent of traditional cardiovascular risk factors.

Genome-wide association study of intracranial aneurysm identifies new loci. *K. Yasuno[1,2], K. Bilguvar[1,2], R.P. Lifton[2,3], M. Gunel[1,2], The Genetics of Intracranial Aneurysm Consortium.* 1) Dept Neurosurgery and Neurobiology, Yale Univ Sch Med, New Haven, CT; 2) Dept Genetics, Yale Program on Neurogenetics, Yale Center for Human Genetics and Genomics, Yale Univ Sch Med, New Haven, CT; 3) Howard Hughes Medical Institute and Dept Internal Medicine, Yale Univ Sch Med, New Haven, CT.

Saccular intracranial aneurysms are balloon-like dilations of the intracranial arterial wall; their hemorrhage commonly results in severe neurologic impairment and death. We recently reported a genome-wide association study including 2,075 cases and 6,952 controls that identified 3 significant loci with odds ratios ranging from 1.24 to 1.36 (Bilguvar et al., Nat Genet 40, 1472-7, 2008). This analysis had limited power and explained only a small fraction of the risk of intracranial aneurysm. In order to increase the power to detect new intracranial aneurysm loci, we conducted a second genome-wide association study with discovery and replication cohorts from Europe and Japan comprising 5,891 cases and 14,181 controls with ~832,000 genotyped and imputed SNPs across discovery cohorts. We identified three new loci showing strong evidence for association with intracranial aneurysm in the combined data set, including intervals on 18q11.2 ($P=1.1\times10^{-12}$), on 13q13.1 ($P=2.5\times10^{-9}$) and on 10q24.32 ($P=1.2\times10^{-9}$). Odds ratios for these new loci were from 1.20 to 1.29. We also confirmed prior associations near SOX17 (8q11.23-q12.1; $P=1.3\times10^{-12}$) and CDKN2A/B (9p21.3; $P=1.5\times10^{-22}$). It is noteworthy that several putative risk genes play a role in cell-cycle progression, potentially affecting proliferation and senescence of progenitor cell populations that are responsible for vascular formation and repair. We will also present results from further follow-up study for 14 regions that showed less significant association with intracranial aneurysm in the discovery cohort.

716/W

Ancestral missense mutations in TMEM43 cause arrhythmogenic right ventricular cardiomyopathy in outbred populations. *T. Young[1], A.F.M. Haywood[1], N. Merner[1], P. Syrris[3], V. Booth[2], J. Houston[1], W. McKenna[3], K.A. Hodgkinson[1].* 1) Faculty of Medicine, Memorial University, St. John's, NL, Canada; 2) Faculty of Science, Memorial University, St. John's, NL, Canada; 3) The Heart Hospital, 16-18 Westmoreland Street, London, United Kingdom.

Background: Arrhythmogenic right ventricular cardiomyopathy (ARVC/D) is considered a common cause of sudden death in the young. ARVC is genetically heterogeneous with 8 identified genes, most of them structural components of the cardiac desmosome. In 2008, we reported that an autosomal dominant form, ARVD5, was due to a missense mutation (S358L) in a highly conserved transmembrane domain of TMEM43, a gene of unknown function. Previous studies across 15 unrelated ARVD5 families of Newfoundland ancestry showed that the S358L variant resided on a shared (ancestral) haplotype and that the median age to death in untreated males was 40 years. The purpose of this study was to determine the role of TMEM43 mutations in outbred populations. Methods and Study Population: We recruited 5 patients from 2 clinical sites in Canada and 151 from the UK, and performed bidirectional, complete gene sequencing of TMEM43. We identified several amino acid substitutions in highly conserved domains of TMEM43. Results: One variant was a c.934C>T, R312W change in 4 clinically affected UK patients from three unrelated families. In one family, the variant segregated with subjects manifesting minor clinical anomalies and was absent in subjects with completely normal cardiac testing. The R312W variant was reported in 4/500 controls in The ARVD/C Genetics Variants Database (www.arvcdatabase). However, it is predicted to be deleterious using bioinformatics software, and like the founder S358L variant, lies within the highly conserved transmembrane domain of the TMEM43 protein. Interestingly, when we compared disease haplotypes between unrelated UK families, we discovered that the R312W variant resided on an identical haplotype suggesting that this is a potentially lethal ancestral mutation in the UK population. Conclusions: We speculate that a portion of sudden death in the population is due to recent, relatively rare, variably penetrant alleles in TMEM43. Pursuing family and population-based evidence improves our ability to distinguish lethal alleles from benign variants. This distinction is clinically relevant as implantable converter device (ICD) therapy for primary prevention in both sexes and secondary prevention in males significantly improves survival in S358L subjects. We are seeking other patients with a clinical diagnosis of ARVC or a related disorder to improve our ability to identify potentially lethal mutations using a similar approach.

Epilogue: Association of APOCIII and APOAV gene with Coronary Artery Disease. *V. BHUPESH KUMAR[1], S. NAIK[2], V. KUMAR[3], SUBASH[4], S. DAYAKAR[1,5], M. D. SADHNANI[1].* 1) CLINICAL BIOCHEMISTRY, IGHGD, OSMANIA UNIVERSITY, HYDERABAD, ANDHRA PRADESH, INDIA. EMAIL: bhupeshkumar_v@rediff.com; 2) HEART INSTITUTE, APOLLO HEALTH CITY, JUBILEE HILLS, HYDERABAD, ANDHRA PRADESH, INDIA; 3) DEPARTMENT OF NEPHROLOGY, CHRISTIAN MEDICAL COLLEGE, VELLORE-632 004, TAMILNADU, INDIA; 4) DEPARTMENT OF CARDIOLOGY, DURGABAI DESHMUKH HOSPITAL AND RESEARCH CENTRE, ANDHRA MAHILA SABHA[AMS], UNIVERSITY ROAD, HYDERABAD- 500 044, ANDHRAPRADESH, INDIA; 5) APOLLO HOSPITALS EDUCATIONAL AND RESEARCH FOUNDATION, APOLLO HEALTH CITY, JUBILEE HILLS, HYDERABAD-500033, ANDHRAPRADESH, INDIA.

Background: Coronary artery Disease (CAD) in India is associated with high morbidity and mortality tends to be more severe and effects a younger age group compared to the west. The genes governing lipid transport and metabolism have always been considered as classical risk factors for CAD. Aim and Design of study: The aim of the study is to examine the association of polymorphisms in two Apolipoprotein genes APOCIII (C3238G), and APOAV (T1131C) in Myocardial infarction (MI) subjects compared with healthy volunteers. The SNPs were selected on the basis of their function and published evidence about their potential role in MI to their association with CAD. Methods: Genomic DNA is extracted from blood samples obtained of 150 MI subjects and 300 healthy volunteers following both inclusive and exclusive criteria. DNA samples were genotyped for C3238G, variant using PCR-RFLP assay and then DNA samples followed by genotyping T1131C variant using ARMS-PCR assay. Result and Conclusion: The C3238G SNP of APOCIII (S2 allele) tend to have high plasma Lipid concentrations was shown a risk factor in MI subjects when compared with healthy volunteers. The rare allele T1131C (CC allele) is also associated with elevated lipids levels. The Haplotypes analysis performed for APOAV and ApoCIII SNPs indicated significant differences (P.001) in distribution. Most significantly, a risk haploptype S2/C was obtained (P.001) and was associated with increased lipid. Key words: APOC3/A5- Apolipoprotein C3/A5, SNP- Single Nucleotide Polymorphism, ARMS-PCR- Amplification Refractory Mutation System.

Model free Linkage Analysis of cIMT in the Jackson Heart Study. *S.G. Buxbaum[1], L. Ekunwe[1], E. Fox[2], D.F. Sarpong[1], G. Evans[3].* 1) Jackson Heart Study, Jackson State Univ, Jackson, MS; 2) Jackson Heart Study, University of Mississippi Medical Center, Jackson, MS; 3) Wake Forest University, Winston-Salem, NC.

The Jackson Heart Study is a longitudinal study of 5301 African Americans in the Jackson, MS metropolitan area. Nested within the JHS is a family study. While the targeted age bracket for the overall study population was 35-84 years, inclusion of adult relatives of the indexed families brought down the lower limit of the age bracket to ≥ 21 years. 374 autosomal microsatellite markers were used to conduct a linkage analysis of carotid intima-media thickness (cIMT) using data from 1091 full sibs and 305 half sibs.

Due to the prevalence of CVD among African Americans, furthering the understanding of the genetics underlying CVD is likely to be of benefit. A measure of subclinical atherosclerosis, the mean intima-media thickness of the carotid artery segments was determined by B-mode carotid ultrasonography.

Model free linkage analysis was conducted in the SIBPAL program in the S.A.G.E. package. Two IMT measures were analyzed: sum45_1, a maximum likelihood estimate of average far wall cIMT at the optimal angle of interrogation across the right and left common, bifurcation and internal carotid arteries and CCA45_1, a maximum likelihood estimate of average right and left common carotid far wall cIMT across circumferential views collected at anterior, lateral and posterior angles of interrogation. Both measures were estimated to be 29% heritable based on full sib correlations in FCOR in S.A.G.E..

Particularly strong evidence for linkage was found on chromosome 19p13. A multipoint analysis of CCA45_1 gave a LOD score of 5.7 and a singlepoint analysis gave a LOD of 5.1 at the same marker. At the same locus, sum45_1 also had a peak and a multipoint LOD score of 2.5 and a singlepoint LOD of 2.9.

Chromosome 3 also had significant linkage with sum45_1 (LOD=4.3) at 108 cM, but not with CCA45_1. Suggestive linkage was found on chromosome 12, but only with CCA45_1 (LOD=2.5). Singlepoint and multipoint LOD scores of 4 and higher were found on chromosome 18 using CCA45_1, while the highest LOD score for sum45_1 on chromosome 18 was 2.63 at the p arm telomere.

A Novel Locus For Dilated Cardiomyopathy Maps To Chromosome 20q12. *G. Guo[1], C. Hayward[2], A. Keogh[2], P. Macdonald[2], D. Fatkin[1,2].* 1) Molecular Cardiology Program, Victor Chang Cardiac Research Institute, Sydney, NSW, Australia; 2) St Vincent's Hospital, Darlinghurst, NSW, Australia.

Dilated cardiomyopathy (DCM) is a heart muscle disorder characterized by dilation and contractile dysfunction of left and/or right ventricles that is a major cause of morbidity and mortality. Approximately 20-30% of cases of DCM have a positive family history suggesting a genetic etiology. Despite the considerable genetic heterogeneity demonstrated to date in familial DCM, the majority of families do not have mutations in any of the known disease genes. We have identified a three-generation Australian family (38 members, 11 affected) with autosomal dominant inheritance of DCM. A genome-wide (10 cM) linkage analysis was performed followed by 5 cM and fine mapping. A disease-causing interval was identified on chromosome 20 between markers D20S872 and D20S96 (~10 cM) by parametric and non-parametric analyses using ANALYZE and GENEHUNTER programs. The maximum LOD score 4.34 at $\theta = 0$ was shown at marker D20S107 by two-point analysis and a LOD score 4.35 was shown by multi-point analysis (penetrance = 0.9). Twenty candidate genes including ACSS2, APBA2BP, CTNNBL and STK4 in the interval have been screened, however a disease-causing mutation has not yet been identified. Elucidation of the molecular mechanisms underpinning familial DCM may provide a basis for new approaches to disease prevention and treatment.

Quantitative Trait Loci for Brain Natriuretic Peptide Concentration among African Americans at the Jackson Heart Study. *S.K. Musani[1], S.G. Buxbaum[2], R.S. Vasan[3], A. Bidulescu[4], H.A. Taylor[1,2], E.R. Fox[1].* 1) University of Mississippi Medical Center, 2500 North State Street, Jackson MS 39216; 2) Jackson State University, Jackson MS; 3) Boston University, Boston MA; 4) Morehouse School of Medicine, Atlanta GA.

Statement of Purpose: The level of serum Brain Natriuretic Peptide (BNP) concentration is determined by cardiac pressure and volume overload. Further, BNP concentration has been found to be correlated with severity of heart failure. The purpose of this study is to investigate the extent of interindividual variation in plasma BNP levels among African Americans using microsatellite markers. Methods: We studied 1,300 Jackson Heart Study participants (mean age 55±12 years, 63% women) who underwent routine echocardiography and testing for serum BNP concentration. Sex specific multivariable models and Haseman-Elston regression were used to estimate polygenic heritability. We also performed multipoint marker linkage analysis using data from 402 microsatellite markers typed in 1,300 participants belonging to 264 families. Summary of Results: Age and echocardiographic variables respectively, accounted for 45% and 33% variation in log BNP concentration in men and women, respectively. We observed multivariable polygenic heritability of 0.237. Multipoint linkage analysis revealed regions of significant linkage to log BNP on chromosome 5q15-q21 (LOD score 3.73), and suggestive linkage on chromosomes 7q36 (LOD score 2.22) and distal 16p (LOD score 2.78). The significant QTL on chromosome 5q15-q21 is located near Proprotein convertase subtilin / kexin type 1 (PCSK1) gene that has been reported to be associated with body mass index. Conclusion: In this community-based sample, additive genetic effects explained moderate proportion of variation in brain natriuretic peptide levels. Additional analyses targeting significant linkage peak may provide more information about the genetic loci that regulate BNP levels in African Americans.

721/W

Gene x environment interaction analysis reveals association of *APOE4* genotype with adiposity in children of lower cardiorespiratory fitness. *J. Ellis[1], A-L. Ponsonby[1,2], A. Pezic[1], E. Williamson[1], J. Cochrane[2], J. Dickinson[2], T. Dwyer[1,2].* 1) Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 2) Menzies Research Institute, University of Tasmania, Hobart, Tasmania, Australia.

The plasma protein apolipoprotein E, encoded by the gene *APOE*, plays a well established role in lipid metabolism. There are three isoforms of ApoE, ε2, ε3 and ε4, which are encoded by three alleles, E2, E3, and E4. Evidence derived from animal models suggests that ApoE4 may be protective against increased adiposity, however this has not been thoroughly investigated in human populations. We examined the association of *APOE* genotype with BMI and other measures of adiposity, including truncal fat mass and waist circumference, among 8 year old children from the Tasmanian Infant Health Study. 290 children were genotyped for the E2, E3 and E4 alleles of *APOE*. As expected, overall *APOE* genotype was associated with lipid profile, especially low density lipoprotein cholesterol (LDL-C, $p < 0.001$). We also found that overall *APOE* genotype was associated with adiposity (eg BMI: $p = 0.01$). When we dichotomized the genotype groups into E2-containing and E4-containing, we found that the association with adiposity was specific to the E4 allele with adiposity lower in the E4-containing group (BMI: Mean difference -0.90 kg/m^2; 95% CI -1.51, -0.28; $p = 0.004$). Adjustment for potential confounders including age, sex, lipids, insulin and glucose did not alter the association. We then considered the role of sex, physical activity and cardiorespiratory fitness (CRF) as effect modifiers of the BMI-*APOE4* association. *APOE4* was associated with lower BMI only in those who were below the median for CRF (high fitness mean BMI difference 0.07 kg/m^2, 95% CI: -0.6, 0.7, $p = 0.83$; low fitness mean BMI difference -1.8 kg/m^2, 95% CI: -2.7, -0.8, $p < 0.001$ (adjusted for age and sex); interaction $p = 0.002$). We conclude that *APOE4* is related to lower childhood adiposity. *APOE* has not previously been identified as an adiposity determinant in humans. We demonstrated that consideration of the 'environment' in which the gene is expressed (in this case cardiorespiratory fitness level) may yield novel findings related to the genetic architecture of complex traits including adiposity.

722/W

Exome sequencing in a large dislipidemic family identifies candidate genes for phospholipid transfer protein activity on chr. 19p. *E.A. Rosenthal[1], J. Ronald[1], R. Rajagopalan[1], G. Wolfbauer[5], J.J. Albers[4,5], J. Brunzell[6], M.J. Rieder[2], D.A. Nickerson[2], E.M. Wijsman[1,2,3], G.P. Jarvik[1,2].* 1) Division of Medical Genetics, Department of Medicine, Univ Washington, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Department of Biostatistics, University of Washington, Seattle, WA; 4) Department of Pathology,University of Washington, Seattle, WA; 5) Northwest Lipid Metabolism and Diabetes Research Laboratories, Department of Medicine, University of Washington, Seattle, WA; 6) Department of Medicine, Division of Metabolisn, Endocrinology, and Nutrition, University of Washington, Seattle, WA.

We combined next generation exome sequencing with quantitative trait linkage analysis in large families to identify genes for lipid traits. In contrast to simple Mendelian traits, where a simple model can be used to narrow candidate mutations to a single causal variant, complex oligogenic traits, such as lipid disorders, present additional challenges to gene discovery. Such challenges include multiple underlying genes, each with multiple alleles having different effect sizes, frequency distributions, and modes of inheritance. The use of large families is expected to reduce genetic heterogeneity, because fewer variants are expected to segregate within a family than in a population. Furthermore, large families allow for the estimation of the effect size of specific variants since the identical coding variant can be observed multiple times. Sequence data allows for simultaneous analysis of multiple linkage signals due to multiple traits in the same families. In this analysis, we focus on phospholipid transfer protein activity (PLTPa), a trait implicated in atherogenesis. We analyzed four large multigenerational pedigrees (F1-F4, N=466) ascertained for familial combined hyperlipidemia (FCHL), using multiallelic STRs, cardiovascular disease chip SNPs, and whole exome sequence data. Linkage analysis was carried out with the MCMC-based programs Loki, which employs an oligogenic model and can include SNPs as covariates, and with lm_markers from MORGAN, which provides parametric lod scores. Notably, we did not detect linkage to, nor find any exomic variation at, the *PLTP* structural locus on chr. 20. However, we detected linkage between PLTPa and the *LDLR* region of chr. 19 in family F1 (lodmax= 3.2). Exome sequences of 11 selected individuals in family F1 revealed 311 variant sites at 104 genes and 4 open reading frames under the linkage peak. Prioritization of these sites was based on cosegregation of the variant allele with PLTPa. Further prioritization of genes was based on biological factors including expression profile and GO terms; prioritization of variant sites within genes was based on evolutionary conservation score, mutation type, and predictive effect. Using this strategy, we identified mutations in three genes, excluding *LDLR*, for further analysis. Details of these variants will be presented.

Hunting for Novel Dilated Cardiomyopathy Genes using Haplotype Sharing and Exome Sequencing. *R.J. Sinke[1], A. Pósafalvi[1], P.A. van der Zwaag[1], J. Bergsma[1], F. van Dijk[1], D.J. van Veldhuisen[2], K. van Spaendonck-Zwarts[1], G. te Meerman[1], R.M.W. Hofstra[1], M.P. van den Berg[2], J.P. van Tintelen[1], J.D.H. Jongbloed[1].* 1) Department of Genetics, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands; 2) Department of Cardiology, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands.

Background: Idiopathic Dilated cardiomyopathy (DCM) is a heritable, monogenic disorder in one-third of cases and is characterized by dilation and impaired contraction of the left ventricle. DCM is genetically highly heterogeneous and ≥40 genes are known to be involved. Mutations in these genes can be identified in around 30% of index-patients. To identify novel DCM genes we used an approach in which the Haplotype Sharing Test (HST) and exome sequencing were combined. Haplotype sharing has been shown to be a powerful tool for identifying candidate regions and disease-causing genes. Moreover, exome sequencing was shown to be effective in the identification of novel genes in monogenic disorders.

Methods: To localize novel DCM genes, 250K SNP genotyping was used to identify shared haplotypes between patients from a single pedigree. The HST was applied to (I) a family with 6 DCM patients and (II) a family with 3 DCM patients and 1 patient with reduced left ventricular function, yet not fulfilling formal DCM criteria. To subsequently identify the corresponding disease genes, exome sequencing using DNA of the probands of both families was performed.

Results: The HST revealed a shared haplotype of 71 cM on chromosome 15, containing ~600 genes in family I and a 46 cM haplotype on chromosome 9, containing ~475 genes in family II. Upon exclusion of known DCM genes within these regions, exome sequencing revealed several potentially pathogenic variants in both families. Carriership analysis in family members, healthy controls and mutation analysis in our DCM cohort is in progress.

Conclusions: We identified potentially pathogenic variants in candidate regions in two DCM families. Our results show that using a combined approach of the HST and exome sequencing is highly promising in identifying mutations in novel genes underlying inherited cardiomyopathies.

724/W

Genome-wide Linkage and Positional Candidate Gene Study of Blood Pressure Response to Dietary Potassium Intervention: The GenSalt Study. *T.N. Kelly[1], J.E. Hixson[2], D.C. Rao[3], H. Mei[1], T.K. Rice[3], C.E. Jaquish[4], L.C. Shimmin[2], K. Schwander[3], C. Chen[1], D. Liu[5], J. Chen[6], C. Bormans[2], P. Shukla[2], N. Farhana[2], C. Stuart[2], P.K. Whelton[7], D. Gu[6], J. He[1,8].* 1) Dept Epidemiology, Tulane Univ, New Orleans, LA; 2) Dept Epidemiology, Univ of Texas, Houston, TX; 3) Div Biostatistics, Washington Univ, St. Louis, MO; 4) Division of Prevention and Population Sciences, NHLBI, Bethesda, MD; 5) National Laboratyory of Medical Molecular Biology, Institute of Basic Medical Sciences, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China; 6) Cardiovascular Institute and Fuwai Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, and Chinese National Center for Cardiovascular Disease Control and Research, Beijing, China; 7) Office of the President, Loyola University Health System and Medical Center, Maywood, IL; 8) Dept Medicine, Tulane Univ, New Orleans, LA.

Genetic determinants of blood pressure (BP) response to potassium, or potassium sensitivity, are largely unknown. We conducted a genome-wide linkage scan and positional candidate gene analysis to identify genetic determinants of potassium sensitivity. A total of 1,906 Han Chinese participants took part in a 7-day high-sodium followed by a 7-day high-sodium plus potassium dietary intervention. BP measurements were obtained at baseline and following each intervention using a random-zero sphygmomanometer. Significant linkage signals (LOD>3) for BP responses to potassium were detected at chromosomal regions 3q24-q26.1, 3q28, and 11q22.3-q24.3. Maximum multipoint LOD scores of 3.09 at 3q25.2 and 3.41 at 11q23.3 were observed for absolute diastolic (DBP) and mean arterial (MAP) responses, respectively. Linkage peaks of 3.56 at 3q25.1 and 3.01 at 11q23.3 for percent DBP response and 3.22 at 3q25.2, 3.01 at 3q28, and 4.48 at 11q23.3 for percent MAP response were also identified. AGTR1 SNP rs16860760 in the 3q24-q26.1 region was significantly associated with absolute and percent systolic (SBP) responses to potassium (p-values= 0.0008 and 0.0006, respectively). Absolute SBP responses (95% CI) for genotypes C/C, C/T, and T/T were: -3.71 (-4.02, -3.40), -2.62 (-3.38, -1.85), and 1.03 (-3.73, 5.79) mmHg, respectively; and percent responses (95% CI) were: -3.07 (-3.33, -2.80), -2.07 (-2.74, -1.41), and 0.90 (-3.20, 4.99), respectively. Similar trends were observed for DBP and MAP responses. Genetic regions on chromosomes 3 and 11 may harbor important susceptibility loci for potassium sensitivity. Furthermore, the AGTR1 gene was a significant predictor of BP responses to potassium intake.

725/W

Low frequency and rare variant analysis of serum lipid levels. *K. Rehnström[1], A. Day-Williams[1], I. Surakka[2], J. Kettunen[2], T. Esko[3], C. Ladenvall[4], M. Mangino[5], A-K. Petersen[6], J. Eriksson[7], L. Groop[4], MR. Järvelin[8], A. Metspalu[3], O. Raitakari[9], V. Salomaa[10], T. Spector[5], E. Wichmann[6], L. Peltonen[1], E. Zeggini*[1], S. Ripatti*[2] on behalf of the ENGAGE consortium.* 1) Wellcome Trust Sanger Institute, Hinxton, Hinxton, United Kingdom; 2) Institute for Molecular Medicine Finland, FIMM, Helsinki, Finland; 3) Estonian Genome Project of University of Tartu, Tartu, Estonia; 4) Department of Clinical Sciences, Diabetes and Endocrinology, University Hospital Malmö, Lund University, Malmö, Sweden; 5) Department of Twin Research and Genetic Epidemiology, King's College London, St. Thomas' Hospital Campus, London, UK; 6) Institute of Medical Informatics, Biometry and Epidemiology, Ludwig-Maximilians-Universität, Munich, Germany; 7) University of Helsinki, Department of Public Health, Helsinki, Finland; 8) Department of Epidemiology and Public Health, Imperial College London, UK; 9) University of Turku and Turku University Hospital, Turku, Finland; 10) National Institute for Health and Welfare, Helsinki, Finland.

Numerous common genetic factors affecting serum lipid levels have been identified in GWAS. However, these variants only explain part of the heritability of these traits, and it is becoming increasingly clear that low frequency and rare variants also play a role in lipid traits. Here, we have used available genome-wide SNP data from 8 datasets from the ENGAGE consortium (DGI, Estonian biobank, Genmets, HBCS, KORA, Young Finns Study, NFBC 1966 and TwinsUK) cohorts totalling >17,000 individuals to examine the role of low frequency/rare variants (MAF<0.05) affecting blood lipid levels (HDL-C, LDL-C, total cholesterol (TC) and triglycerides (TG)). Low frequency variants are typically discarded from analysis because of low power to detect effects with single-point analysis. We followed a locus-specific approach and tested for an accumulation of low frequency variants within genes. Results were combined across cohorts using p value-based meta-analysis allowing for differences in the direction of effect. The number of genes with 3 or more rare variants per cohort resulting in meta-analysis p<0.0001 was 12, 15, 13 and 16 for TC, LDL-C, HDL-C and TG respectively. None of these loci have previously been identified in GWA studies of common variants. Unsurprisingly, there was overlap between genes with rare variants affecting TC and LDL-C, in keeping with hits from previous GWAS using common variants. The most significant result for LDL was obtained in the PVR gene on chr19 (p=4*10-6 for LDL-C and p=7*10-5 for TC) and AKAP6 (p=6*10-6 in LDL-C and p=9*10-6 in TC). The p-value threshold for genome-wide significance correcting for the 23192 tests performed is 2.2*10-6 leaving our results just outside genome-wide significance. The results need to be followed up by rigorous quality control of the genotyping quality of the variants contributing to the signals. Although GWAS platforms are strongly biased toward common SNPs, we show that they can also be used to identify association with low frequency/ rare variants. Data provided by large-scale sequencing studies will further help clarify the role of low frequency and rare variants affecting lipid traits. The next step of this study will be to pursue in silico replication. Further, a similar analysis will be performed in 1000genomes-imputed data.

726/W

Evaluation of Targeted Enrichment Strategies for Next Generation Sequencing of Cardiomyopathy Associated Genes. *S. Dames[1], J.D. Durtschi[1], J. Stephens[1], B. Funke[3], H.L. Rehm[3], K.V. Voelkerding[1,2].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT, USA; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT, USA; 3) Department of Pathology, Harvard Medical School, Cambridge, MA, USA.

Background: Targeted multigene enrichment is a bottleneck for implementing next generation sequencing based diagnostic panels. Enrichment strategies can generally be classified as amplification or hybridization capture based. This study compares enrichment and sequencing results using long range PCR (LRPCR) and FEBIT (Lexington MA) array capture for genes associated with hypertrophic cardiomyopathy (HCM). Array capture technologies for targeted enrichment are an attractive alternative to PCR based methods since they streamline workflow, and nullify amplicon/allele drop out. **Methods**: 9 genes associated with HCM were enriched by LRPCR and FEBIT capture. A previously assayed control and 2 Coriell samples with short read archive (SRA) data were sequenced. A comparison of LRPCR amplicon normalization was also performed using gel purification and equimolar pooling versus SequalPrep (Invitrogen, Carlsbad CA). 76 base-length reads from Illumina GA IIX platform (San Diego CA) were analyzed using CLCbio (Cambridge MA) and DNASTAR (Madison WI) alignment software. RefSeq genes were used for sequence alignment of enriched libraries. Additional filtering of FEBIT sequencing data was performed by whole-genome alignment. **Results**: Analysis of the previously sequenced control (Illumina GAII; Sanger verified) reported no novel exonic variants between LRPCR enriched samples. Furthermore, no exonic false positives/negatives were found in any of the 9 genes. One gene associated with HCM, *MYH6*, was excluded from the panel due to homology with *MYH7* (51% gDNA; 80% mRNA). Analysis of the FEBIT sequence data showed co-capture of the *MYH6* gene, introducing false *MYH7* variants. Filtering of the FEBIT sequence data by whole genome alignment reduced the number of false variants observed in *MYH7*, but did not remove all false variants in other HCM genes not previously observed due to gDNA co-capture. The specificity of LRPCR for enrichment allowed for optimal alignment without the requirement of filtering, which dilutes coverage and may lead to aberrant variant calls. Analysis of SRA data for the Coriell samples is underway to determine variant correlation. **Conclusions**: FEBIT is an attractive technology but is limited by co-capture for HCM gene enrichment. LR-PCR offers greater target specificity, but is nontrivial in design, workflow, and implementation. We are extending this work using RainDance technology as an alternative enrichment strategy versus LRPCR with blinded HCM samples.

727/W

Genome-wide association for anatomic coronary artery disease. *G.W. Beecham[1], K.L. Hamilton[1], P. Goldschmidt-Clermont[2], M.A. Pericak-Vance[1], D. Seo[1].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Miller School of Medicine, University of Miami, Miami, FL.

BACKGROUND Coronary heart disease is the leading cause of death in the United States, with atherosclerosis of the coronary arteries (CAD) being the major underlying etiology. Patients with CAD are more likely to suffer a myocardial infarction or sudden cardiac death. CAD is highly heritable, but there have been few genetic studies of anatomic CAD and the knowledge of CAD genetics is limited. To further determine the etiology of anatomic CAD, we have performed the first genome-wide association study of CAD, using our dataset of 2,000 cardiac catheterization patients. **METHODS** Each patient received cardiac catheterization and was assigned a CAD burden index which measures their overall anatomic CAD burden based on size and location of coronary lesions. Data were generated using the Affymetrix SNP array 6.0 platform for 900,000 SNPs. Extensive quality controls tests were performed to ensure the integrity of the data, including sample filters, SNP filters, and EIGENSTRAT methods to correct for population substructure. We tested for association using linear regression using the PLINK software package, and included smoking, cholesterol, blood pressure, age, sex, and two vectors describing the population substructure of the sample. **RESULTS** The first 1,050 samples are currently available for analysis. Among them, we detected strong association ($p < 0.00001$) at 9 SNPs on 6 different chromosomes, in 7 different genes. One SNP met a conservative Bonferroni threshold for genome-wide multiple testing correction (p-value = 0.05/782,000=6x10-8). This SNP was rs10206951 (p-value=2.6x10-8) on chromosome 2 near the CREB1 gene (cAMP responsive element binding protein). It is also located near the Kruppel-like factor 7 (KLF7) a gene previously associated with type 2 diabetes, and as such proves to be an interesting candidate. Another associated SNP, rs2786157 (7.3x10-7), located in the chitinase, acidic gene (CHIA), a gene that is expressed in pulmonary epithelial cells and is associated with asthma. The additional 1,000 samples are being genotyped and will be included in the final analysis. **CONCLUSION** These signals are being further investigated in a larger dataset. An additional 1,000 samples are currently being genotyped and will be used to confirm these signals. These data provide promising results that may lead to further insights into the genetics of anatomic coronary artery disease.

A Genome-Wide Association Study Uncovers a QTL of Adiponectin on CDH13 Which Predicts Cardiometabolic Outcomes. *C. Chung[1], T. Lin[2,3], J. Chen[4,5], H. Chang[6], H. Leu[4], H. Ho[7], C. Ting[7], S. Sheu[2,3], W. Tsai[8], J. Chen[8], S. Lin[5], W. Pan[1].* 1) Inst Biomedical Sci, Academia Sinica, Taipei, Taiwan; 2) Division of Cardiology, Dept of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 3) Dept of Internal Medicine, Faculty of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Cardiovascular Research Center, National Yang-Ming University, Taipei, Taiwan; 5) Dept of Medical Research and Education, Taipei Veterans General Hospital, Taipei, Taiwan; 6) Center of General Education, Hsuan Chuang University, Hsinchu, Taiwan; 7) Taichung Veterans General Hospital, Taichung, Taiwan; 8) College of Medicine, National Cheng Kung University, Tainan, Taiwan.

The plasma adiponectin levels, a potential upstream and internal facet of metabolic diseases and cardiovascular diseases, have a reasonably high heritability. it has not been carefully examined upon whether other novel genes may influence the variation of adiponectin level and the roles of these genetic variants on subsequent clinical outcomes. Therefore, we aimed not only to identify novel variants modulating plasma adiponectin but also investigate whether these variants are associated with adiponectin related metabolic traits and cardiovascular diseases. We conducted a genome-wide association study (GWAS) on adiponectin levels by using genotypic information derived from the Illumina HumanHap550 SNP chip in 382 young-onset hypertensive (YOH) subjects to identify the quantitative trait loci associated with the adiponectin levels. The culpable SNP variants for lowered adiponectin were then tested for their association with risk of metabolic syndrome, type 2 diabetes mellitus(T2DM), and stroke in an independent community-based prospective cohort, the CardioVascular Disease risk FACtors Two-township Study (CVDFACTS)(n=3350). The SNP (rs4783244) most significantly associated with adiponectin levels was located in the intron 1of CDH13 gene in the first stage (p value=1.42x10-8). We further replicated and confirmed the association between rs4783244 and plasma adiponectin levels in an additional 559 YOH subjects (p value=6.87x10-17). This same risk allele at CDH13 was also associated with higher risks of metabolic syndrome, T2DM (in male) (OR=3.25,p=0.02) ,and stroke (OR=2.13; p= 0.002). These findings may broaden our understanding of the mechanisms modulating adiponectin levels and their roles in the development of cardiometabolic diseases.

Introduction: While the presence of coronary artery disease (CAD), as measured by angiography, is present in the majority of myocardial infarction (MI) cases, there are many individuals who do not develop MI despite having considerable coronary atherosclerosis. We hypothesized that some genetic risk for plaque rupture and MI is distinct from that which relates to development of atherosclerosis. Methods: We performed a meta-analysis across eight genome-wide (~2.3 million genotyped and imputed SNPs) association studies (GWAS) of CAD in European ancestry participants who were phenotyped through coronary angiography. In order to identify loci that predispose to MI in the setting of angiographic CAD (AngCAD; at least one coronary artery with >50% stenosis), we compared patients with AngCAD and MI (AngCADMI+, N=5,783) to those with AngCAD but no MI (AngCADMI-, N= 3,644). Using the DAVID Functional Annotation Tool, we examined enrichment for certain functional themes for genes with SNPs with suggestive association (P<0.0001) with AngCADMI+ compared to all genes on the Affymetrix 6.0 array. Results: Our top finding (described elsewhere) for association with AngCADMI+ was for SNPs at the ABO locus, a glycotransferase gene. Using DAVID, we observed enrichment for certain functional themes, including cell adhesion (enrichment score = 1.81, p=0.01) and immunoglobulins (enrichment score = 1.7, p= 0.0001), as well as fibronectins (enrichment score = 2.13, p=0.0001), and glycoproteins and genes with N-linked glycosylation sites (enrichment score 1.59, p=0.008). Loci (e.g, including 9p21) and pathways (e.g., lipid and fatty acid biosynthetic processes) previously implicated in CAD by GWAS were not enriched in AngCADMI+ patients. Conclusion: Genetic predisposition to MI in the setting of atherosclerosis may be distinct from that associated with the development of atherosclerosis. Genes that encode proteins involved in cell-cell adhesion and glycomic modifications may modulate plaque rupture and MI. These findings suggest potential novel therapeutic avenues for prevention and treatment of plaque rupture and MI.

Eight genetic loci associated with variation in lipoprotein-associated phospholipase A2 (Lp-PLA2) mass and activity and CHD: Meta-analysis of genome-wide association studies from five community-based studies. *H. Grallert[1], JC. Bis[2], A. Dehghan[3,4], M. Barbalic[5], C. Lu[6], J. Baumert[1], RB. Schnabel[6], K. Rice[7], JCM. Witteman[3,4], RP. Tracy[8,9], W. Koenig[10], EJ. Benjamin[6], CM. Ballantyne[11] on behalf of the CHARGE inflammation working group.* 1) Institute of Epidemiology, Helmholtz Zentrum Munchen, Neuherberg, Germany; 2) Cardiovascular Health Research Unit and Department of Medicine, University of Washington, Seattle, WA; 3) Department of Epidemiology, Erasmus University Medical Center, Rotterdam, The Netherlands; 4) Member of the Netherlands Consortium on Healthy Aging; 5) Genetics Center, University of Texas Health Science Center, Houston, Texas, USA; 6) National Heart, Lung, and Blood Institute's and Boston University's Framingham Heart Study, Framingham, MA; 7) Department of Biostatistics, University of Washington, Seattle, WA, USA; 8) Department of Pathology, University of Vermont College of Medicine, Burlington, VT; 9) Department of Biochemistry, University of Vermont College of Medicine, Burlington, VT; 10) Department of Internal Medicine II-Cardiology, University of Ulm Medical Center, Ulm, Germany; 11) Section of Atherosclerosis and Vascular Medicine, Baylor College of Medicine, Houston, Texas.

Background: Lipoprotein-associated phospholipase A2 (Lp-PLA2), is an enzyme that generates pro-inflammatory and pro-atherogenic compounds in the arterial vascular wall, Lp-PLA2 may represent a therapeutic target in coronary heart disease (CHD). Methods: We sought to investigate genetic loci related to Lp-PLA2 mass or activity by conducting meta-analyses of genome-wide association (GWA) findings from 5 population-based studies as part of the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium, comprising 13,664 subjects. Results: In meta-analysis, two loci (PLA2G7, CETP) were associated with Lp-PLA2 mass, with rs1805017 in PLA2G7 as strongest signal ($p=2.4\times10^{-23}$, log Lp-PLA2 difference per allele (beta): 0.043). Six loci were associated with Lp-PLA2 activity (PLA2G7, APOC1, CELSR2, LDLR2, ZNF259, SCARB1), among which the strongest signals were at rs4420638, near the APOE-APOC1-APOC4-APOC2 cluster ($p=4.9\times10^{-30}$, log Lp-PLA2 difference per allele (beta): -0.054). There were no significant gene-environment interactions of these 8 top SNPs and age, sex, body mass index or smoking status in relation to LP-PLA2 mass or activity. Moreover, in an additional analysis, four loci (APOC1, CELSR2, LDLR, ZNF259) were significantly associated with cardiovascular outcome (APOC1: $p=9.2\times10^{-11}$, beta= 0.301). Conclusions: We report the first genome-wide meta-analysis for SNPs associated with Lp-PLA2 activity and mass. Whereas levels of Lp-PLA2 mass and activity were associated with the gene coding for this protein, Lp-PLA2 activity was also strongly associated with genetic variants related to low-density lipoprotein cholesterol levels and CHD. Further studies are needed to assess whether and how Lp-PLA2 concentrations are causally involved in atherogenesis.

Genome-wide association study of Kawasaki disease. *J. Kim[1], K. Kim[2], Y. Park[1], I. Park[3], J. Lee[1], Korean Kawasaki Disease Genetics Consortium.* 1) Asan Institute for Life Sciences, University of Ulsan College of Medicine, Seoul, Korea; 2) Genome Research Center, Asan Medical Center, Seoul, Korea; 3) Department of Pediatrics, University of Ulsan College of Medicine, Asan Medical Center, Seoul, Korea.

Kawasaki disease (KD) is an acute self-limited vasculitis of infants and children, manifested by fever and signs of mucocutaneous inflammation. Coronary artery aneurysms develop in approximately 15 to 25% of untreated and 3 to 5% of treated children and may lead to myocardiac infarction, ischemic heart disease or sudden death. Although its etiology is largely unknown, epidemiologic data suggest the importance of genetic factors in susceptibility to KD. To identify genetic variants influencing KD susceptibility, we performed a genome-wide association study (GWAS) in 186 Korean KD patients and 600 healthy controls. Eighteen and twenty-five genomic regions with one or more sequence variants were associated with KD and KD with coronary artery lesions (CALs), respectively ($P < 1 * 10^{-5}$). Of these, only one locus was replicated in 266 children with KD and 600 normal controls (rs527409, odds ratio (OR) = 2.90, 95% confidence interval (95% CI) = 1.85 - 4.54, $P_{combined} = 1.46 * 10^{-6}$) and another one locus was replicated in 86 KD patients with CALs and 600 controls (rs7604693, OR = 2.70, 95% CI = 1.77 - 4.12, $P_{combined} = 2.00 * 10^{-6}$). We also performed replication study in Taiwanese population. Further fine-mapping of the candidate genes is needed to identify causative variants for KD susceptibility.

Genome-wide association study to identify the susceptible genes for Kawasaki disease. *T.J. Lai[1, 2], M.W. Lin[3], C.H. Lin[4, 6], S.F. Tsai[4, 6], K.S. Hsieh[5], K.P. Weng[5], C.C. Shih[1, 7], L.P. Ger[2], C.J. Tseng[1, 2].* 1) Institute of Clinical Medicine, National Yang-Ming University, Taipei, Taiwan; 2) Department of Medical Education and Research, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan; 3) Institute of Public Health and Department of Public Health, National Yang-Ming University, Taipei, Taiwan; 4) Genome Research Center, National Yang-Ming University, Taipei, Taiwan; 5) Department of Paediatric Cardiology, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan; 6) National Health Research Institutes, Miaoli, Taiwan; 7) Division of Cardiovascular Surgery, Taipei Veterans General Hospital, Taipei, Taiwan.

Kawasaki disease (KD) is the most common cause of pediatric acquired heart disease of an unknown etiology. Epidemiologic data suggest that KD is triggered by unidentified infections in genetically susceptible children. To identify the susceptible genes involved in KD in Han-Chinese of Taiwan population, we performed a genome-wide association study (GWAS) with a total of 112 KD cases and 58 healthy controls. All cases were diagnosed using the criteria for KD according to the Japanese Kawasaki Disease Research Committee and recruited at the Kaohsiung Veterans General Hospital (KVGH), Taiwan. Controls were recruited from two junior high schools in the KSVGH community. The GWAS was used to screen 346,110 SNPs in 86 cases and 10 controls by use of the Illumina HumanHap370 BeadChip and 1,016,423 SNPs in 26 cases and 48 controls by use of the Illumina HumanOmnil BeadChip. The SNPs with following three criterions were excluded from analyses: (1) call rate<95%, (2) missing data rate>5% for SNPs with a minor allele frequency<1%, and (3) p-value of Hardy-Weinberg disequilibrium test$<10^{-7}$. In addition, only 206,176 overlapping SNPs of the two GeneChips were further analyzed by use of both allelic and recessive-dominant models. We initially identified 26 SNPs/loci ($10^{-10}<P<10^{-3}$), which contain novel and known SNPs/loci. Imputation of the non-overlapping SNPs in two GeneChips for further analyses and a SNP-replication study by Sequenom-based genotyping assay are in preparation for the coming 60th Annual ASHG Meeting.

Genome-wide association studies in coronary artery disease (CAD) have so far focussed on populations of European ancestry and have detected common variants with odds ratio of about 1.12 or greater. The variants discovered to date explain a small proportion of the predicted genetic risk. We report a prospective meta-analysis of four large unpublished genome-wide association studies of CAD susceptibility.

The discovery stage comprised four participating GWAS studies with a total of 15,418 cases and 15,067 controls matched for country of origin, all typed on high-density Illumina arrays: PROCARDIS (5720 European cases), HPS (2704 European cases), PROMIS (4253 South Asian cases) and LOLIPOP (2741 South Asian cases). After quality control, data for 574,911 SNPs with frequency ≥1% were entered into a fixed effects meta-analysis to combine the results of the individual studies for all overlapping SNPs. Heterogeneity between studies was assessed using standard techniques. The primary analysis examined the associations of SNPs with CAD in: (i) all four studies in combination; (ii) the two European Studies; and (iii) the two South Asian studies.

Previously reported susceptibility loci were confirmed (e.g. 9p21.3: $p<10^{-28}$; 1p13.3: $p<10^{-11}$). Although examples were identified where there were significant differences in haplotype frequency and/or effect size, there was little evidence for either European or Asian specific associations. Thus we did not find evidence for fundamental differences in genetic susceptibility to explain the excess risk of CAD in South Asian populations.

Potential novel associations from the meta-analysis were tested by genotyping 50 SNPs from 35 loci in an independent replication sample comprising about 19,000 cases and 14,000 controls, predominantly of European origin. A number of novel associations of genome-wide significance were identified, some with associated expression QTLs in a panel of relevant tissues. These findings implicate pathways not previously identified through GWAS findings. The effect sizes of the novel variants were all small, suggesting that a large number of small effect common variants contribute to CAD susceptibility.

Korea.

Coronary artery disease (CAD) is the most common form of heart disease and the leading cause of death worldwide. Multiple genetic factors and environmental exposures have been shown to affect pathogenesis of coronary artery disease (CAD) together. The etiology contributing to CAD pathogenesis are different between Asian and European populations. Recently genetic variants contributing to CAD have been identified through Genome-wide association (GWA) studies in the European population. In this study, we conducted a two-stage GWA analysis of CAD to identify Asian-specific genetic variants influencing CAD in East Asian populations. In the discovery stage, we carried out SNP genotyping for 2,123 cases of individuals with CAD and 2,690 gender-matched controls of healthy individuals using Affymetrix Genome-wide Human SNP array 6.0 platform. The logistic regression model (1 d.f.) with adjustment for age and gender was used to analyze the association. In the replication stage, 16 SNPs were tested in 812 cases of CAD and 4,422 gender-matched controls of Japanese population using TaqMan assay. After combining the GWAS and replication samples for 16 SNPs, we identified three new loci associated with CAD at 12q24, 13q12 and 4q12.

Genomic strategies to identify functional noncoding sequences in loci associated with cardiovascular diseases. *J.M. Westlund, S. Smemo, I. Aneas, N.J. Sakabe, M.A. Nobrega.* University of Chicago, Chicago, IL.

Genome-wide Association Studies (GWAS) routinely identify noncoding loci associated with complex traits, raising the possibility that variation in long-range cis-regulatory elements might lead to disease risk. Technologies to identify and experimentally validate these putative long-range regulatory sequences are, therefore, key steps in the follow-up of GWAS. We carried out a strategy to identify regulatory variation associated with increased risk to cardiovascular diseases in loci emerging from GWAS. Using ChIP-seq, we profiled the chromatin states and binding sites for a number of transcription factors and transcription co-factors in mouse hearts, generating a comprehensive transcription regulation map in an organ that lacks cell types amenable to routine culture in vitro. Using a combination of comparative genomics, open chromatin marks and binding sites of transcription factors and co-activators, we uncovered a number of candidate cis-regulatory sequences in loci associated with various cardiovascular diseases, such as SCN5A, SCN10A, TBX5, TBX3, PITX1, KCNQ etc. These putative regulatory sequences either harbor SNPs associated with cardiovascular traits or are in LD with associated SNPs. To test the regulatory potential of these candidate sequences, in vivo, we cloned each DNA sequence in a GFP reporter vector, injected these constructs in zebrafish eggs and evaluated the resulting transgenic zebrafish for GFP expression in the heart. Our data demonstrates that several of our candidate regulatory sequences possess in vivo heart specific enhancer properties. Combined, our results describe a strategy for the functional follow-up of GWAS implicating noncoding loci in disease etiology and identify functional noncoding sequences in loci associated with cardiovascular disorders.

A genome-wide gene-based association study identifies SLC4A4, WWOX and COMMD7 as hypertension susceptibility genes in a Han Chinese population. *H.-C. Yang[1], L.-J. Liang[1,3], K.-M. Chiang[2,4], G. Thomas[6], B. Tomlinson[7], S. Cherny[8], Y. Gu[8], T.-H. Lam[9], J.-W. Chen[5], W.-H. Pan[2].* 1) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 3) Graduate Institute of Biomedical Electronics and Bioinformatics, National Taiwan University, Taipei, Taiwan; 4) School of Public Health, National Medical Defense Center, Taipei, Taiwan; 5) National Yang-Ming University School of Medicine and Taipei Veterans General Hospital, Taipei, Taiwan; 6) Public Health, Epidemiology and Biostatistics, School of Health and Population Sciences, University of Birmingham, Birmingham, UK; 7) Department of Medicine and Therapeutics, Chinese University of Hong Kong, Hong Kong; 8) Genome Research Centre, Hong Kong University, Hong Kong; 9) School of Public Health, Hong Kong University, Hong Kong.

Hypertension [OMIN #145500] is a complex disorder with high prevalence and social impact all over the world, especially in industrialized regions. This study conducts the first genome-wide gene-based association scan for hypertension in a Han Chinese population. By analyzing genome-wide SNP data of ~400 matched pairs of young-onset hypertensive patients and normotensive controls genotyped with the Illumina HumanHap550-Duo BeadChip, 100 susceptibility genes of hypertension are identified and then validated by permutation tests. In addition to differential allelic distributions, 17 of the 100 genes also exhibit differentially expressed distributions in case and control groups. These genes provide a good molecular signature for a classification of hypertensive patients and normotensive controls. Among the 17 genes, SLC4A4 encoding the Electrogenic Sodium Bicarbonate Cotransporter 1 Protein and WWOX encoding the WW Domain-Containing Protein are not only identified by our gene-based association scan and gene expression analysis but also replicated by a gene-based analysis of the Hong Kong Hypertension Study. Previous mouse experiments have suggested that SLC4A4 is associated to decreased body weight/size and abnormal ion homeostasis and WWOX is associated to hypoglycemia and hyperphosphatemia. In addition, a novel hypertension gene COMMD7 encoding COMM Domain-Containing Protein 7 is replicated by a gene-based analysis of the WTCCC Hypertension Study. Identification of these genes benefits to enrich a collection of hypertension genes thereby to unravel complex development etiology of hypertension in Han Chinese populations.

We performed an admixture mapping analysis for systolic and diastolic blood pressure (SBP, DBP) followed by association analysis in 6302 unrelated African-Americans in the CARe consortium. We identified 5 genome regions (P <0.001) harboring genetic variants contributing to inter- individual blood pressure variation. In follow-up association analysis in these 5 regions, , we identified 4 loci associated with SBP and one associated with DBP which were significant after correcting for multiple comparisons (P £5×105). Further analysis suggested that there are 9 independent SNPs contributing to the phenotypic variation observed in the admixture mapping analysis. These 9 SNPs were carried forward for replication analysis in multiple large independent African-American samples (Women's Health Initiative, Maywood, GENOA and HUFS) as well as one Nigerian sample, with a total sample size of 12,153. Meta-analysis of the replication cohorts identified evidence of a novel variant on chromosome 5 as being associated with SBP and DBP (P £0.0015). The genes near the variant include SUB1, PDZD2, NPR3, MTMR12. Our results suggested admixture mapping can be fruitful for detecting genetic variants underpinning complex traits such as blood pressure.

738/W

Association of Potassium Channel Genes, KCNK3 and KCNK9, with Blood Pressure and Serum Levels of Potassium and Aldosterone. *J. Jung[1], G. Eckert[2], W. Tu[2], JH. Pratt[2].* 1) Med & Molec Gen, Indiana Univ Sch Med, Indianapolis, IN; 2) Dept. of Medicine, Indiana Univ Sch Med, Indianapolis, IN.

The epithelial sodium channel (ENaC) in the kidney's distal nephron is the final and perhaps the most important site for reabsorption of sodium and for establishing levels of blood pressure (BP). The principal regulator of ENaC is aldosterone which is secreted by the adrenal zona glomerlosa (ZG) under the synergistic influences of angiotensin II and potassium. We performed association studies for two genes highly expressed in ZG, KCNK3 and KCNK9, that encode for the potassium channels TASK-1 and TASK-3, respectively. Both were shown in mouse knock-out models to restrain aldosterone secretion. Subjects (n=286; 127 males and 159 females) were from a cohort of healthy African Americans (AA) adolescents with mean ages of 15 years old (range of age: 5-25 yr). BP was measured semi-annually for up to 20 years; levels of potassium and aldosterone as well as the ratio of aldosterone to renin (ARR) were measured cross-sectionally. Seventy-four tag SNPs for KCNK9 and 20 for KCNK3 were selected using Tagger with R2 =80% and MAF >10%. Population-based association studies identified 10 SNPs that associated with BP (4 with p<0.01; 6 with p<0.05) and of these 4 SNPs (rs888345, rs2545462, rs3824281, rs3780037) associated with serum K (p=0.006). rs888345 also associated with serum aldosterone and ARR (p=0.003 and 0.01, respectively). No significant associations with KCNK3 were observed. The findings suggest that variations in TASK-3 affect sodium retention and in turn BP in young and healthy AA, a group at increased risk for salt-sensitive hypertension.

739/W

A large mutation screen in the German LIANCO cohort identified *SREBF1* and *SREBF2* as hypercholesterolemia-associated genes. *N. Plume[1, 2, 3], E. Milz[1, 2, 3], I. Gouni-Berthold[4], W. Krone[4], H. Berthold[5], B. Wollnik[1, 2, 3].* 1) Institute of Human Genetics, University Hospital Cologne, Cologne, Germany; 2) Center for Molecular Medicine Cologne (CMMC), University of Cologne, Cologne, Germany; 3) Cologne Excellence Cluster on Cellular Stress Responses in Aging-Associated Diseases (CECAD), University of Cologne, Cologne, Germany; 4) Department of Internal Medicine II, University of Cologne, Cologne, Germany; 5) Lipid Clinic at the Interdisciplinary Metabolism Center, Charite University Medicine Berlin, Virchow Clinic Campus, Berlin, Germany.

Familial hypercholesterolemia (FH) is a highly prevalent autosomal dominant disorder and the high cholesterol level in affected individuals is a major risk factor for coronary artery disease (CAD) and myocardial infarction. We initiated a molecular study of 200 cases from the German LIANCO (Lipid-Analytic-Cologne) cohort with the aim (i) to determine the *LDLR* mutation spectrum (ii) to identify molecular modifiers of cholesterol levels in *LDLR*-caused FH, and (iii) to find novel FH causing genes. Sequencing of *LDLR* revealed a mutational spectrum of known (34) and novel (7) heterozygous mutations, predominantly missense, but also nonsense and splice-site mutations as well as small deletions and insertions. Using MLPA we found 4 large deletions within the *LDLR* gene. Interestingly, one heterozygous mutation, c.1-188C>T, was identified within the predicted *LDLR* promoter region we could clearly demonstrate a reduced ability for transcriptional activation. Only one patient carried the p.R3500Q hot-spot mutation in *ApoB100*, whereas no alterations were found in *PCSK9* and *SCARB1*. We also tested the nonsense SNPs rs10491178 in *ABCA10* and rs328 in *LPL* in all mutation positive patients but could not observe a clear genotype-phenotype correlation. In order to identify novel hypercholesterolemia associated genes, we sequenced the transcription factors *SREBF1* and *SREBF2* for mutations in our mutation-negative patients. Interestingly, we found one novel nucleotide substitution in both, *SREBF1* and *-2*, respectively. The c.G2435A substitution is located in exon 13 of *SREBF1* and is predicted to cause an amino acid change from arginine to glutamine at position 812. The putative mutation in *SREBF2* was found in exon 14 (c.G2554A) and changing the glycine at position 852 to arginine. Both alterations were not found in 200 control chromosomes. We are currently investigating the functional effect of both mutations via Luciferase Activity Assay, Cleavage Efficiency Assay and Co-Immunoprecipitation of wild-type and mutant SREBF1 and SREBF2 with SCAP. In summary, we could show that *LDLR* mutations are present in the German LIANCO cohort. Moreover, we identified *SREBF1* and *SREBF2* as putative novel hypercholesterolemia causing genes. Our data indicate that transcriptional activation of *LDLR* is essential for normal cholesterol levels and that mutations in the *LDLR* promoter as well as the transcriptional regulators SREBF1 and SREBF2 underlie hypercholesterolemia.

Candidate gene association study of frailty in older community dwelling women. *Y-Y. Ho, Q-L. Xue, A.M. Mattenini, W. Yao, A. Chakravarti, D.E. Arking, L.P. Fried, J.D. Walston, M.D. Fallin.* Johns Hopkins University, Baltimore, MD.

Frailty is a late-life syndrome of vulnerability to adverse health outcomes that is characterized by muscle weakness and increased inflammatory pathway activation. Evidence suggests that these variations may play important roles in frailty susceptibility. We hypothesized that variations in genes related to inflammation and muscle maintenance associate with frailty in older adults, and tested this hypothesis in candidate gene association study in older community dwelling women. Subjects were participants in a cohort study on the development of disability, aged 70-79, and Caucasian. Frailty defined as a three-level outcome was assessed using a validated assessment method that includes grip strength, walking speed, physical activity, weight loss, and fatigue. Genotypes were obtained for 1364 SNP markers across 134 candidate genes related to inflammation and muscle biology using the Illumina Genotyping platform. Likelihood ratio tests were performed for each SNP adjusting for age using multinomial logistic regression model. Individual SNPs within MTR (rs10925235, rs4659725, rs1770449, rs2297967, rs10802569, rs1050993), CASP8 (rs3769827, rs6747918, rs2037815), FN1 (rs7567647), RIPK1 (rs9405191) loci were associated with frailty before adjustment for multiple comparisons (p value < 3 x10-3). These genes are related to DNA methylation, apoptosis, and inflammation biology. Although no conclusions can be drawn for this data given small number of genotypes, and as the SNPs from the top 20 hits do not exceed the genome wide significant p value of 0.0004, these genotypes may provide further insights into the pathways that may underlie the development of frailty and late-life decline.

741/W

Association analysis of coronary artery disease loci with the Metabochip array. *P. Deloukas[1], K. Stirrups[1], S. Potter[1], S. Hunt[1], S. Edkins[1], C. Langford[1], P.S. Braund[2], A. Balmforth[3], A.S. Hall[3], M.I. McCarthy[4], G. Dedousis[5], M. Sandu[1,6], N.J. Samani[2], Wellcome Trust case Control Consortium.* 1) Wellcome Trust Sanger Inst, Cambridge, UK; 2) University of Leicester, Leicester, UK; 3) Leeds Institute of Genetics, Health and Therapeutics, Leeds General Infirmary, Leeds, UK; 4) WTCHG, University of Oxford, Oxford, UK; 5) Harokopio University, Athens, Greece; 6) Department of Public Health & Primary Care, Strangeways Research Laboratory, University of Cambridge, UK.

Following an initial round of GWAS, large scale meta-analyses of common disease phenotypes including coronary artery disease (CAD) have led to the identification of multiple loci reaching genome wide significance (p 5 10^{-8}). In parallel, such analyses yielded additional loci with moderate evidence of association. A custom iSELECT array harbouring ~196,000 markers, the Metabochip, was designed to undertake both fine mapping in loci of confirmed association and extensive replication of the weaker signals for several cardiometabolic traits. For CAD, marker content (~23,000 SNPs) was supplied from a meta-analysis of over 22,000 CAD cases and 67,000 controls of European descent (CARDIOGRAM). Markers for fine mapping were selected from dbSNP and the 1000 Genomes (August 2009). We have genotyped over 6500 CAD cases and 8000 controls with the metabochip array so far. The presence of a large fraction of low frequency variants (3 - 0.1%) on the metabochip along-side common ones complicates genotype calling. We analysed an initial set of 3000 cases (BHF collection) and 5000 UK controls using three calling algorithms GenCall, Illuminus and GenoSNP. Close to 93% of all SNPs have a call rate ≥99%, any calling algorithm, with circa 55,000 markers being non polymorphic or having an AF < 0.1%. Most SNPs (93%) are over 99.8% concordant among all genotype calling algorithms. After data QC, tests of self association in both the case and control series found no significant background association for markers with AF ≥1.5%. Preliminary analysis of the 3000 CAD cases vs 5000 controls indentified an excess of association signals with over 180 having p < 10^{-5}. As expected most of these SNPs fall within the regions of confirmed association with 11 such loci providing initial insights to fine mapping. The strongest signal was obtained in the ANRIL locus on chromosome 9p21 with the lead SNP been rs10757278 (p < 6.4 10^{-5}). At least one locus, ADAMTS7 on chromosome 15 has evidence of two independent signals - r^2 with the lead SNP <0.2. In five of the 11 loci the emerging lead SNP was novel derived from the 1000 genomes data set. In addition to expanding analysis to all of the above cohorts to increase power we are typing 2000 CAD patients and 2000 controls from South Asia to explore transethnic fine mapping. An international effort to analyse over 20,000 CAD cases and 40,000 controls is underway testing replication of the weaker signals identified in Cardiogram.

Characterization of a new dominant Marfan-like phenotype by deep whole genome sequencing. *S. Scherer[1,3,5], D. Milewicz[2], S. LeMaire[4,5], I. Volguina[4,5], L. Palmero[4,5], M. Bainbridge[1,5], J. Reid[1,5], D. Muzny[1,5], J. Coselli[4,5], R. Gibbs[1,3,5].* 1) Human Genome Sequencing Center; 2) Division of Medical Genetics, University of Texas Health Science Center at Houston Houston, TX; 3) Department of Molecular and Human Genetics; 4) Texas Heart Institute at St. Luke's Episcopal Hospital; 5) Baylor College of Medicine Houston, TX.

Various defects in the transforming growth factor-beta (TGF-β) signaling pathway give rise to a number of well-described phenotypes, including hereditary hemorrhagic telangiectasia (HHT), Marfan syndrome (MFS), Loeys-Dietz syndrome (LDS), and familial thoracic aortic aneurysms and dissections (FTAAD). We recently demonstrated the utility of using whole genome sequencing (WGS) to identify causative allelic variants in recessive Charcotte Marie Tooth disease [Lupski et al. 2010 NEJM]. Here, we extend these methodologies to determine the mutation underlying a unique, dominantly inherited vascular phenotype. Deep, WGS SOLiD sequencing was used to characterize the genome of a Caucasian female proband that presented with a dilated aorta and underwent aortic root and arch replacement at age 17. The proband has features of MFS (arched palate, arachnodactyly, a positive thumb sign and mild scoliosis), LDS (dilatation and tortuousity of large arteries) and HHT (arteriovenous malformations requiring treatment and atypical telangiectasias). Sequencing of the known genes for these disorders failed to reveal any disease-causing mutations. The proband's mother also underwent aortic root replacement surgery and displays the same phenotype as her daughter and similarly affected two first cousins; there is no evidence of consanguinity in the family. Preliminary light coverage sequencing identified a heterozygous nonsense mutation in exon 62 of the FBN2 gene, which was validated and present in all affected family members. Analysis of deep sequencing results, variant validation and genotyping data are ongoing as we seek to extend these protocols to the clinical setting.

743/W

Targeted capture and massively parallel sequencing in pediatric cardiomyopathy: development of novel diagnostics. *M. Tariq[1], T. Lee[1], P. Putnam[2], S. Kindel[1], C. Jamison[2], M. Keddache[3], SM. Ware[1,3].* 1) Division of Molecular Cardiovascular Biology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Division of Biomedical Informatics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 3) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Pediatric cardiomyopathy is a genetically heterogeneous disease associated with significant morbidity. Although identification of cause is important for management, therapy, and screening of at risk family members, molecular diagnosis has been difficult due to the large number of causative genes, high rate of private mutations, and cost of testing. The aim of this study was to determine the utility of array-based targeted sequence capture coupled to massively parallel sequencing for diagnosis of pediatric cardiomyopathy. A custom 385K NimbleGen sequence capture array containing 110 genes and providing 99.9% coverage of the exons of interest was used to screen 3 patients with cardiomyopathy. The sensitivity and specificity of the custom array was >99% as determined by comparison to a subset of 31 genes subjected to long range PCR-based next-generation sequencing, Sanger sequencing validation of all missense variants, and genotyping using the Illumina Infinium Omni1 array. On the custom array, 99.73% of the total targeted regions were captured and sequenced at >10X coverage, allowing reliable variant calling in all patients. Variant analysis identified 146 non-synonymous missense variants and 6 indels in 26 genes including 43 missense and 1 indel in patient 1, 41 missense and 3 indels in patient 2, and 62 missense and 2 indels in patient 3. The functional pathogenicity of all the non-synonymous variants were analyzed through the bioinformatic tools Polyphen, SIFT and PANTHER. This study demonstrates the digenic or oligogenic pattern of inheritance in pediatric cardiomyopathy. Comparison of the performance of targeted sequence capture vs. PCR-based enrichment methods demonstrate that former is more sensitive and efficient although more costly. This study attests to the importance, robustness and performance of array-based sequence capture technology followed by massively parallel sequencing as a promising and comprehensive tool for the genetic screening of cardiomyopathies.

ANRIL, the non coding RNA in the Coronary Artery Disease associated 9p21 locus has trans-effects on gene expression and a potential regulatory role. *T. Kyriakou, A. Goel, H. Ongen, J. Peden, H. Watkins.* Department of Cardiovascular Medicine,Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Genome-wide association studies have identified a 53kb haplotype block in the 9p21 region associated with risk of diverse cardiovascular diseases. This locus overlaps with ANRIL, a non coding RNA gene of unknown function and genomic architecture. Using RT-PCR and RACE-PCR we identified alternative transcription start and end sites and multiple alternative spliced transcripts differentially expressed between different tissues and cell lines. siRNA oligonucleotides were designed against a constitutively expressed exon and against the last exon of all transcripts identified . siRNA oligonucleotides were transfected in a primary endothelial cell model (Human Umbilical Vein Endothelial Cells). Total RNA from transfected cells was used to assess global changes in gene expression using microarray technology. Analysis of changes in global expression levels was performed using PARTEK software and after a false discovery rate (FDR) correction of 0.05 approximately 200 genes were perturbed more than 50% and almost 90 genes had more than 2-fold altered levels of expression after the knock-out when compared with controls. The majority of the top 20 affected genes are involved in cell cycle regulation. Interestingly, CDKN2B, a neighboring gene that overlaps with the first intron of ANRIL and previously associated with expression levels of ANRIL was found to be significantly upregulated. In contrast, it has previously been reported that expression levels of CDKN2B were found to be drastically down regulated in a mouse model when the 9p21 syntenic region was knocked out. Our data demonstrate that ANRIL has a role to play in regulating the expression of number of different genes in different cellular pathways and does so by acting in trans.

745/W

Fatty acid desaturase 1 (FADS1) transcripts are associated with insulin sensitivity and are controlled by a local expression quantitative trait locus (eQTL). *J.N. Hellwege[1], S.K. Das[2], N.K. Sharma[2], A.K. Mondal[2], S.C. Elbein[2].* 1) Molecular Genetics and Genomics, Wake Forest University, Winston-Salem, NC; 2) Internal Medicine- Endocrinology, Wake Forest University Health Sciences, Winston-Salem, NC.

Fatty acid desaturase 1 (FADS1) is a delta-5 desaturase involved in the essential omega-3 and omega-6 fatty acid metabolic pathways. SNPs in the FADS1 gene have been shown previously to be associated with polyunsaturated fatty acids (rs174547, rs174537, rs174548), fatty acid serum levels (rs174546), total cholesterol levels (rs174548), and recently fasting glucose levels and possibly abnormal insulin secretion. However, the function of these noncoding variants on FADS1 transcript levels, or the role of these transcript levels has not been examined. We examined FADS1 transcript levels in adipose and muscle from 62 individuals chosen for extremes of insulin sensitivity (31 insulin resistant, 31 insulin sensitive). FADS1 was 1.59 fold reduced in insulin resistant muscle (q value 0.88%) and 1.67-fold reduced in insulin resistant adipose (q value 0.96%). Intronic SNP rs174550 was associated with FADS1 transcript levels in two different liver studies ($p<0.0001$), but did not reach significance ($p<0.001$) in either muscle or adipose from these 62 individuals. To further explore the role of GWAS associated SNPs in transcript expression, we genotyped SNPs rs174548 and rs174550 in 498 individuals including 153 who provided subcutaneous adipose and 146 with skeletal muscle biopsy samples. The two SNPs were in strong linkage disequilibrium in Caucasians ($r^2 = 0.89$) but not in African Americans ($r^2 = 0.015$). SNP rs174550 was associated with FADS1 expression in skeletal muscle ($p = 0.0002$, dominant model), even with adjustment for age, gender, and ethnicity. However, neither SNP was associated with insulin sensitivity among the 498 individuals with detailed assessments by frequently sampled intravenous glucose tolerance test. Among individuals with biopsies, adipose FADS1 transcript levels were negatively correlated with AUC insulin levels from the oral glucose tolerance test ($p = 0.014$). We show that FADS1 expression in both muscle and adipose tissue is associated with insulin sensitivity and that intronic SNP rs174550 is associated with FADS1 expression in both liver and skeletal muscle. FADS1 has multiple splice forms that are now under evaluation, and may explain tissue specific differences. Markedly different allele frequencies in African Americans and Caucasians suggest that FADS1 may be primarily a European risk locus, acting as a local eQTL in liver and muscle.

746/W

Investigating the association of MGP promoter polymorphisms with coronary artery disease and their effect on gene expression. *M. Keramatipour[1], P. Ahmadi[1], M. Abiri[1], S. Sadeghian[2], M. Pedram[1].* 1) Department of Medical Genetics, School of Medicine, Tehran University of Medical Sciences, Tehran, Iran; 2) Department of Cardiology, Tehran Heart Center Hospital, Tehran University of Medical Sciences, Amirabad St., Tehran, Iran.

Coronary Artery Disease (CAD) is a major cause of death worldwide including Iran. Positive family history among patient points to the significance of genetic elements in the risk of CAD. Two single nucleotide polymorphisms (SNPs) at -7 (rs1800801) & -138 (rs1800802) positions on Matrix- Gla Protein (MGP) gene have been suggested to play a role in susceptibility towards CAD. Such a role is possibly due to the effect of these SNPs on the level of gene expression. This study aims to investigate the association of these SNPs with CAD in Iranian population and their possible effect on MGP gene promoter activity in vitro. To achieve these goals, a population based genetic association study is being conducted on appropriate groups of patients and controls on the basis of their clinical assessments and angiographic reports. Analysis of the preliminary data obtained from genotyping 150 cases and 150 controls shows an excess of A allele at position -7 and T allele at position -138 among patients. The observed differences are not significant at this point, but genotyping of proposed sample size is not complete yet. On the other hand, four appropriate vectors that express GFP under the control of different haplotypes of MGP promoter have been constructed. To assess the effects of haplotypes on promoter activity, vectors were transfected into the Hek293 cells and relative expression of GFP was quantified. Analysis of data using Student's T-test, revealed that G-7A SNP has a significant effect on promoter activity in cultured cells. Presence of nucleotide A in -7 position resulted in 12% increase in promoter activity ($p<0.002$). T-138C SNP did not show a significant change in promoter activity ($p>0.7$). The maximum mean activity of the promoter was seen with A-T haplotype while the minimum activity appeared by G-T haplotype. By the way, statistically the most significant difference in promoter activity is seen between vectors containing A-C and G-T haplotypes ($p<0.0005$). less significant differences in promoter activity were shown between A-T and G-T haplotypes as well as A-T and G-C haplotypes ($p<0.05$).

747/W

A common variant of beta3-adrenergic receptor gene and pregnancy-induced hypertention in Japan. *G. Kobashi[1,5], H. Yamada[2], A. Hata[3], K. Ohta[1,3,4], H. Minakami[4], N. Sakuragi[4], H. Tamashiro[5], S. Fujimoto[6], Hokkaido PIH Epidemiological Study Group.* 1) Research Center for Charged Particle Therapy, National Institute of Radiological Sciences, Chiba, Japan; 2) Dept. of Obstetrics and Gynecology, Kobe University Graduate School of Medicine; 3) Dept. of Public Health, Chiba University Graduate School of Medicine; 4) Dept. of Obstetrics and Gynecology, Hokkaido University Graduate School of Medicine; 5) Dept. of Global Health and Epidemiology, Hokkaido University Graduate School of Medicine; 6) Sapporo Maternity-Women's Hospital.

Pregnancy-induced hypertention (PIH), major cause of maternal morbidity and mortality, is considered to be a multifactorial disease resulting from an interaction among several factors including lipolysis and obesity. Beta3-adrenergic receptor (B3AR) is mainly expressed in brown and white adipose tissues and is considered to be responsible for thermogenesis, lipolysis, insulin sensitivity and body weight gain, and was reported to be associated with non-insulin dependent diabetes mellitus. Recently, an association between a common variant, Trp64Arg of the B3AR gene and manifestation of PIH was suggested in its pathogenesis, however, it has been yet confirmed. In the present study, we genotyped and analyzed the variant and other genetic and environment risk factors in order to confirm the association in the Japanese subjects. Seventy-nine Japanese primiparous patients with PIH including preeclampsia, protein uric type of PIH, were matched with 158 Japanese normal pregnant controls according to age and parity. Informed consent for the study was obtained from every subject. Genotypings of variants including Trp64Arg of the B3AR gene were carried out using PCR-RFLP methods after extraction of genomic DNA from 1.0 ml of whole blood samples. Differences were statistically analyzed by the chi-square test (degree of freedom=1). Fisher's exact test was used when an observed number was £ 5. In the allelic frequencies of Arg64, a mutant type of the B3AR gene, there were no significant differences between the cases and controls (15.8% in PIH and 16.1% in controls). Furthermore, no significant differences were found in the subgroup analyses using the other PIH risk factors such as prepregnancy body mass index, family history of hypertension, M235T of angiotensinogen gene, Glu298Asp of the endothelial nitoric oxide synthase gene and some lifestyle factors. The present result suggests that the Trp64Arg variant of the B3AR gene is not associated with PIH in the Japanese women.

748/W

Evaluation of three molecular mechanisms for altered *MMAB* transcript level at a locus associated with high density lipoprotein cholesterol (HDL-C). *M.P. Fogarty[1], M.L. Bucholovich[1], K.J. Gaulton[1], Y. Li[1,2], K.L. Mohlke[1].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Biostatistics, University of North Carolina, Chapel Hill, NC.

Liver eQTL studies and our hepatocyte RNA and protein expression imbalance studies showed that an HDL-C-associated locus on chromosome 12 is also associated with higher levels of *MMAB*. Our goal is to determine the underlying SNP(s) and molecular mechanisms affecting *MMAB* transcript level. We hypothesize that a SNP(s) acting at this locus likely has a subtle effect (~20%) on *MMAB* transcript synthesis or stability and we are exploring 3 potential mechanisms for this effect. First, we tested whether HDL-C associated SNP rs877710, located in the *MMAB* 3'UTR, affects targeting by miR-564. The G allele of rs877710 is predicted to weaken the target site for miR-564 and thus increase *MMAB* expression levels. Using a dual luciferase reporter vector and 293T cells, we demonstrated that in the presence of miR-564, the G allele of rs877710 demonstrated a 16% weaker repression of luciferase activity compared to the C allele (P=.002), suggesting preferential binding to the C allele. Additional studies will test whether miR-564 results in decreased endogenous *MMAB* expression in liver cells. Second, to assess whether a regulatory SNP acts in *cis* to affect transcript synthesis, we tested SNPs for allele-specific enhancer activity in HepG2 cells. We used linkage disequilibrium data obtained from HapMap and the 1000 Genomes Project to identify 63 SNPs in r^2>.7 (CEU) with highly HDL-C associated SNP rs2338104, and we identified 3 associated SNPs located in potential regulatory elements based on evidence of open chromatin, histone modifications and predicted transcription factor binding. Preliminary results showed that of 57 SNPs screened to date, six leading SNPs display >1.5-fold allele-specific enhancer activity in the direction expected. Additional experiments are needed to verify the magnitude and significance of allele-specific differences. Third, rs2287180 (r^2=.22 with rs2338104) disrupts a predicted splicing enhancer and has been implicated in alternative splicing of *MMAB* leading to decreased expression in the expected direction. rs2287180 genotypes in our human hepatocyte cohort (n=89) will be used to evaluate the relative contribution of this decrease on overall *MMAB* transcript level. Taken together, these results provide suggestive evidence for more than one mechanism that may alter *MMAB* transcript level. Identification of a molecular mechanism for altered *MMAB* expression may guide functional studies to determine how variants at this locus influence HDL-C.

749/W

Differential gene expression and enhancer use are correlated with asymmetries in epigenetic modification within the developing heart. *S. Smemo, I. Aneas, N. Sakabe, M. Nobrega.* Human Genetics, University of Chicago, Chicago, IL.

The mammalian heart is heterogeneous in form and function, and understanding those differences has been at the center of cardiac research for centuries. In modern times this has been carried out at the genetic level, with a multitude of differences in gene expression, including many genes encoding transcription factors, being described and correlated with chamber identity, structure, function and disease. Nonetheless, it is not fully resolved how these transcriptional asymmetries, evident at even the very early stages of morphogenesis, are established and maintained. One hypothesis, pursued here, is that chromatin accessibility is modulated independently within the developing heart via epigenetic modification, thereby potentiating or excluding expression of specific genes. To study this we have performed transcriptional profiling by RNA-seq on isolated left and right ventricles of embryonic mice and correlated the findings with ChIP-seq against H3K27me3, a mark of closed chromatin associated with gene repression. Furthermore, by performing ChIP-seq in left and right ventricles for H3K4me1, a chromatin modification associated with enhancers, and p300, a chromatin-binding coactivator found at active enhancers, we have extended this hypothesis to include differential usage of transcriptional enhancers.

Association study, KCNE1, polymorphisms, non-familial atrial fibrillation(AF), potassium channel. *A.R. Park[1], D.-J. Shin[1,2], H. J. Hwang[3], N.-H. Son[1], K.-B. Lee[1], J.-W. Im[1], E.-S. Shin[4], J.-E. Lee[4], H.-N. Pak[3], M.-H. Lee[3], S.-S. Kim[3], Y. Jang[1,3].* 1) Yonsei Cardiovascular Genome Center, Seoul, Seodaemun-ku, Korea; 2) Yonsei University Research Institute of Science for Aging, Seoul, Korea; 3) Division of Cardiology, Yonsei University College of Medicine, Seoul, Korea; 4) DNA Link, Inc, Seoul, Korea.

Slowly activating delayed-rectifier potassium currents in the heart are produced by a complex protein with alpha and beta subunits composed of the potassium voltage-gated channel KQT-like subfamily, member 1 (KCNQ1) and the potassium voltage-gated channel Iks-related family, member 1 (KCNE1), respectively. Recent studies have been proposed to play a mechanistic role in non-familial Atrial fibrillation (AF). We preformed a case-control study to evaluate the presently controversial question of whether KCNE1 gene polymorphisms are associated with AF in Koreans. We studied a sample population of 754 Koreans, comprising of 400 controls and 354 cases with AF, which were recruited from Cardiovascular Genome Center in Korea. We analyzed 8 single nucleotide polymorphisms (SNPs) of KCNE1 genes (rs2834485, rs3453, rs13050198 and rs41314067, rs1805127, rs2236608, rs2834502, rs4817669). All subjects were genotyped for these polymorphisms by single base primer extension assay using the SNaPShot assay. The distribution of allele for rs2834485 and rs2834502 was significantly different between the patients with AF and the controls in female group (P=0.0197) and male group (P=0.0379), respectively. Logistic regression analysis represented that KCNE1 rs2834485 T carriers were significantly associated with AF under a dominant model (CT+TT/CC; OR, 0.535; confidence interval (CI), 0.313-0.913; P=0.0219), rs2834502 A carriers were significantly associated with AF under a dominant model (AA+AG/GG; OR, 0.661; confidence interval (CI), 0.447-0.977; P=0.0379). In haplotype analysis, the dominant model of haplotype AAG and recessive model of haplotype AA was shown to predisposing effect significantly in females (OR, 2.318; confidence interval (CI), 1.138-4.721; P=0.0205) and males (OR, 1.541; confidence interval (CI), 1.040-2.285; P=0.0313), whereas haplotype CAA-GATAA decreased the risk of AF by 46% (OR, 0.536; confidence interval (CI), 0.288-0.997; P=0.0491) under a dominant model in female subjects. These findings suggest that KCNE1 gene polymorphisms are associated with non-familial Atrial fibrillation in Koreans. Further investigations should be performed to analyze association of these polymorphisms with non-familial Atrial fibrillation in other genes and conducted to evaluate the functional role of these genes as a genetic contributor.

751/W

A common polymorphism in the NOTCH1 gene is associated with calcific aortic valve stenosis. *V. Ducharme[1], N. Gaudreault[1], P. Pibarot[1], P. Mathieu[1], Y. Bossé[1,2].* 1) Centre de recherche Institut universitaire de cardiologie et de pneumologie de Québec, Laval University, Quebec, Canada; 2) Laval University Hospital Research Center (CRCHUL), Quebec, Canada.

Calcific aortic valve stenosis (AVS) is the most frequently acquired valvular heart disease affecting 1-2% of the population older than age 65 years. It is characterized by pathological remodeling and calcification of the aortic valve cusps, which eventually lead to left ventricular outflow track obstruction. Genetic studies in few multi-generation families have provided compelling evidence that functional DNA variants at the NOTCH1 locus result in aortic valve anomalies and severe valve calcification. Whether genetic variants in that gene contribute to AVS in the population at large still remain to be determined. A total of 14 genetic variants surrounding the NOTCH1 gene were genotyped in 467 patients with severe AVS and tricuspid valve morphology. Genotyping was carried out using the Illumina BeadXpress platform. SNPs were selected to document the previously rare mutations associated with AVS, but also to capture the common genetic variation within this locus. Allele frequencies of common SNPs for patients with AVS were compared to a share control group (Illumina iControlDB, n=3294). The mutation R1107X, previously associated with AVS in an autosomal-dominant mode of inheritance with complete penetrance, was detected in one patient. The mutations R1279H and V2285I were detected in 19 and 15 heterozygotes, respectively. In contrast, two additional missense mutations (T596M and R938Q) as well as a frameshift mutation (H1504del) were not detected in our AVS population. A common polymorphism (rs13290979) located in intron 2 was significantly associated with AVS (minor allele frequencies: 32% cases and 38% controls, p = 0.001). This study suggests that multiple rare variants and a common polymorphism in the NOTCH1 locus confer susceptibility to AVS. The prevalence of the rare variants in healthy controls and replication of the common variant in an independent population warrant further investigation.

752/W

Fine mapping of loci associated with low-density lipoprotein cholesterol (LDL-C) via candidate gene sequencing and large scale genotyping. *A. Mulas[1], B. Li[2], C. Sidore[1,2], H.M. Kang[2], S. Sanna[1], S. Najjar[3], E. Lakkata[3], M. Uda[1], F. Cucca[1], D. Schlessinger[4], G.R. Abecasis[2], R. Nagarja[4], SardiNIA project.* 1) Istituto di Neurogenetica e Neurofarmacologia, CNR, Monserrato, 09042 (CA), Italy; 2) Center for Statistical Genetics, Ann Arbor, University of Michigan, MI, USA; 3) Laboratory of Cardiovascular Science, Intramural Research Program, National Institute on Aging, National Institutes of Health, Baltimore, USA; 4) Laboratory of Genetics, National Institute on Aging, Baltimore, MD, USA.

Lipoprotein levels are a risk factor for cardiovascular diseases, the leading cause of morbidity and mortality in developed countries. Several studies have shown that low-density lipoprotein cholesterol (LDL-C) is associated with increased risk of coronary artery disease, a connection that is emphasized by the fact that all genetic variants associated with increased LDL-C also increase the risk of coronary artery disease. Our previous genome-wide association studies of >8,000 subjects identified a number of loci associated with LDL-C levels, including both previously reported and newly implicated loci. To further understand the genetic contributions of both common and rare variants to the LDL-C level, we sequenced exons and flanking regions of 9 genes at associated loci in 256 unrelated Sardinian individuals with either extremely low or high LDL-C levels, along with 120 HapMap samples. Among all variants identified, 71% (81/121) nonsynonymous and 56.3% (40/71) synonymous mutations have frequencies below 1%. In addition, two frame shift (in *APOB*) and two truncation mutations (in *PCSK9*) were identified. Comparisons between high LDL-C and low LDL-C groups showed that rare coding variants are enriched in one of the two groups for a set of genes (*APOB*, *LDLR*, *PCSK9*, *SORT1*). To increase the power to detect associations, we imputed all the variants detected by sequencing in a subset of the cohort (N=4,305) and successively genotyped those in the entire SardiNIA sample (N=5,543).Among all tested variants, 11 showed a pvalue $<10^{-4}$, including six that have not previously been associated with LDL-C variation, as for example a very rare non-synonymous variant on the *LDLR* gene (MAF 0.005), that explains 0.5% of the total variance of LDL-C levels in Sardinia ($p<10^{-6}$). Evidence for association typically increased as we moved from the sequence of extreme individuals to imputation of a subset of the cohort to direct genotyping of the entire sample. For example, at the APOE-005012 (MAF=0.037) non-synonymous mutation association started at $2x10^{-4}$, increased to $2x10^{-8}$ after imputation, and to $4x10^{-33}$ when using the complete set of genotypes. Overall, these results identify a novel set of common and rare variants in LDL associated genes, and suggest that sequencing coding regions in extreme individuals followed by large scale imputation and genotyping are efficient designs for detecting potentially causative variants and increase the variance explained for these traits.

Is E-selectin Gene S128R Polymorphism Associated with Incidence or Severity of Kasawaki Disease? *S. Toshihiko, K. Hideo, N. Kazuhisa, M. Hideki, M. Hiroyuki.* Nagasaki University Hospital, nagasaki-shi nagasaki-ken, Japan.

Background: Kawasaki disease (KD) is an acute systemic vasculitic syndrome in childhood of unknown etiology, and development of coronary arterial lesions (CAL) is the most critical prognostic factor of KD. E-selectin, which intermediates between vascular endothelial cells and inflammatory cells, has been shown to increase in blood during the acute stage of KD. Interestingly, p.S128R polymorphism (rs5361) of E-selectin gene has been associated with the incidence of adulthood coronary artery diseases (e.g., myocardial infarction) in which vasculitic process is recognized as an important etiological factor. Therefore, we hypothesized that the polymorphism of E-selectin gene might be associated with incidence of KD or development of CAL in KD. Methods: Genomic DNA was extracted from peripheral blood of 176 patients with KD (61 with and 115 without CAL) and 305 controls. E-selectin genotypes was determined by melting curve method using intercalating dye with real-time PCR. The genotype distribution was assessed using the Chi-square test. Experimental procedures were approved by the Committee for the Ethical Issues on Human Genome and Gene Analysis in Nagasaki University. Results: R allele frequencies were 0.0454 and 0.0344 in KD and control, respectively (OR 1.33 [95% CI, 0.68 - 2.59]). On the other hand, R allele frequencies in KD with and without CAL were 0.0410 and 0.0478, respectively (OR 0.85 [95% CI, 0.28 - 2.50]). Discussion: This study was unable to prove association of p.S128R polymorphism of E-selectin gene with the incidence of KD or development of CAL in KD, although we cannot rule out the possibility that the sample size was not large enough to detect existent but subtle association. Therefore, further studies are warranted to identify single nucleotide polymorphisms (SNPs) in genes that are associated with both coronary artery diseases in adulthood and KD in childhood, including another SNP in E-selectin gene, G98T in 5'UTR area (rs1805193). 754/W

Sex and age differential genetic effect of chromosome 9p21 on atherosclerosis. *P.C. Tsai[1], H.F. Lin[2,3], R.T. Lin[2,3], G.T. Khor[2], S.H. Juo[1,4].* 1) Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 2) Department of Neurology, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 3) Department of Neurology, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Department of Medical Genetics, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan.

Purpose: Chromosome 9p21 has recently been shown to be a risk region for a broad range of vascular diseases. Carotid intima-media thickness (IMT) and plaque are independent predictors for vascular diseases. We aimed to test for the association between 9p21 and stroke, MI and subclinical phenotypes (IMT and plaque) in a Chinese population residing in Taiwan. **Methods:** We enrolled 687 stroke patients, 425 MI patients and 1377 stroke- and MI-free volunteers as health controls. Carotid segment-specific IMT and plaques were examined among the 1083 control subjects. Three commonly used SNPs (rs1333040, rs2383207, and rs1333049) were genotyped and genetic effects were tested for each SNP and haplotype. Further subgroup analysis was performed to explore sex-specific and age-specific association. Permutation was used to correct for multiple testing. **Results:** Multivariate permutation analyses demonstrated that carriers of the T allele of SNP rs1333040 was significantly associated with thicker common carotid artery (CCA) IMT (p = 0.042) and MI (p=0.045), but not for stroke (p=0.280). The risk G allele of SNP rs2383207 was associated with higher ICA IMT (p = 0.010) and MI (p=0.002), but not for stroke (p=0.097). Carriers of the C allele of SNP rs1333049 was found to be significantly associated with thicker ICA IMT (p = 0.026) and the greater risk for the presence of carotid plaque (OR=1.55 for heterozygous carriers; OR= 1.65 for homozygous carriers). Haplotype analysis showed a global p value of 0.265 for stroke, 0.032 for MI, 0.015 for ICA IMT, and 0.067 for the presence of carotid plaque. Further analyses showed the significant association for IMT and plaque only existed in men, and for MI only in young subjects (less than 65 years old). **Conclusions:** Chromosome 9p21 had a significant association with carotid atherosclerosis and myocardial infarction but not stroke. Furthermore, such genetic effect was in a gender-specific and age-specific manner in the Chinese population.

755/W

Stem Cell Regulatory Genes Associated with the Racial Differences in the Promotion of Coronary Artery Disease by Tobacco Smokers. *L.R. Yanek[1], D.M. Becker[1], L.C. Becker[1], R.C. Levitt[2,3,4].* 1) Johns Hopkins Medical Institutions, Baltimore, MD; 2) Department of Anesthesiology, Miller School of Medicine, University of Miami, Miami, FL; 3) Hussman Institute of Human Genomics, Miller School of Medicine, University of Miami, Miami, FL; 4) Miami Veterans Healthcare System, Miami, FL.

Background: Coronary artery disease (CAD) is clustered strongly in families and associated with risk factors, including tobacco smoke exposure. Recent evidence suggests that biologic variability in stem cell mediated vascular repair may play an important role in CAD. We hypothesize that functional polymorphisms in stem cell regulatory genes underlie the promotion of CAD by tobacco smoke in susceptible individuals. To investigate this, we analyzed for association between CAD and a panel of 7 candidate genes involved in the regulation of stem senescence that may affect stem cell mediated vascular repair. **Methods:** The GeneSTAR study population was ascertained from families via a proband who experienced an early onset (prior to age 60) cardiovascular event, and included apparently healthy siblings (n=1140; 49% Blacks; 51% Whites) who completed baseline screening. Incident CAD was assessed by follow-up questionnaires and confirmed by medical records. Self-reported smoking status was confirmed by exhaled CO. Genotype data were generated using the Illumina Human 1M Beadchip; 116 SNPs in Blacks and 106 SNPs in Whites were analyzed. Data integrity was ensured with extensive quality controls including sample and SNP filters. Racial groups were analyzed separately to control for population substructure. Mixed effects models implemented in SAS were used to conduct candidate gene association analyses under an additive model. Analyses were adjusted for age, sex, smoking, eigenvector(s) for within race population stratification, and familial clustering and a SNP*smoking interaction term was included in the models. **Results:** Preliminary analyses indicate significant differences between racial groups and associations between CAD with SNPs in stem cell regulatory genes. WNT2 (rs10487362, P=0.0007), WNT2B (rs12138754, P<0.0004), and MDM2 (rs3730613, P<0.001) were associated with CAD in Blacks. Only WNT2B (rs3790604, P<0.04) and WNT10A (rs10177996, P<0.05) were potentially associated with CAD in Whites. A SNP*smoking interaction was found for CDKN1A (rs3176321, P<0.004 Whites), and HMGA2 (rs7967476, P<0.004 Blacks). **Conclusions:** These data indicate for the first time that the stem cell regulatory genes may be implicated in the promotion of incident CAD by tobacco smoke. Associations may differ by racial background. These findings suggest that smoking may have its impact on CAD by altering stem cell mediated vascular repair.

Allele-specific regulatory activity of variants associated with human high-density lipoprotein cholesterol level at the *GALNT2* locus. *T.S. Roman[1], A.F. Marvelle[1], K.J. Gaulton[1], M.P. Fogarty[1], A.J. Gonzalez[1], Y. Li[1,2], K.L. Mohlke[1].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Biostatistics, University of North Carolina, Chapel Hill, NC.

Genome-wide association studies have identified SNPs within intron 1 of the *GALNT2* gene that are strongly associated with human high-density lipoprotein cholesterol (HDL-C) levels, although the molecular mechanism responsible for this association remains unknown. *GALNT2* encodes an N-acetylgalactosaminyltransferase important for O-linked oligosaccharide biosynthesis, and may influence HDL-C level by modifying proteins involved in cholesterol transfer or processing. SNPs in strong linkage disequilibrium (r^2>.8, HapMap and 1000 Genomes Project CEU) with the reported HDL-C -associated SNPs span ~15 kb of intron sequence, and resequencing of the *GALNT2* exons did not identify other variants likely to explain the association signal. We hypothesize that one or more of the intron 1 variants have an allele-specific regulatory effect on gene expression. Eight variants are located in regions with evidence of regulatory function based on open chromatin and histone modification data generated in HepG2 cells. We used dual-luciferase assays to test these variants as possible allele-specific enhancers of transcriptional activity in HepG2 cells. A 780-bp region containing one haplotype showed a 15-fold increase in transcriptional activity compared to a control vector containing only a minimal promoter. An alternate haplotype showed a 3-fold further increase in enhancer activity. This increase was observed for alleles associated with increased HDL-C level. To determine which of the four variants in the haplotype might be responsible for this increased activity, we created additional haplotypes by site-directed mutagenesis. Preliminary results suggest that at least two of the SNPs (rs4846913 and rs2144300) contribute significantly and additively to differential transcriptional activity. Electrophoretic mobility shift assays are being used to evaluate evidence of differential protein binding at these SNPs. Notably, the direction of allele-specific haplotype enhancer activity we observed in HepG2 cells contrasts a recent report that *Galnt2* knockdown in mouse liver increased plasma HDL-C levels, suggesting that rs4846913 and rs2144300 do not act directly to influence *GALNT2* expression. Successful identification of the molecular mechanism underlying the genome-wide association signal would provide insight into the variants' role in *GALNT2* activity, and may lead to a greater understanding of the biological processes that help regulate human HDL-C metabolism.

A de novo terminal deletion of 10q26.3 associated with poor attention, developmental delay, and ataxia with normal cerebellum on MRI. *C.L. Goldsmith[1], A. Doja[2], K.M. Boycott[1].* 1) Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) Neurology, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

The phenotype associated with terminal deletions of 10q is variable but reported features include developmental delay/learning disability/mild to moderate mental retardation, speech and language delay, poor attention, strabismus and distinctive facial features in the context of normal growth and good health. We report a 6 year-old girl who presented to the neurogenetics clinic at the age of 3 years of age with global developmental delay, poor coordination, and ataxia. MRI showed no abnormality of the posterior fossa. Standard investigations for ataxia were unrevealing. A high-resolution (105 K) comparative genomic hybridization microarray identified a deletion of the terminal 4.6 Mb of the long arm of chromosome 10, within cytogenetic band 10q26.3. This finding was confirmed by FISH analysis. The parents were tested and this is a de novo change. There are approximately 40 genes in the deleted interval. A small number of children reported with deletions in this region have poor balance/wide-based gait (AJMG 2009; 149A:669-680) and further investigation of two of these children demonstrated vestibular anomalies. These two children had an overlapping deletion which included the HMX2 and HMX3 genes and haploinsufficiency was proposed as the mechanism based on previous reports that Hmx2/Hmx3 knockout mice have vestibular anomalies. The deletion in the patient reported here is distal and does not include these two genes; CT of the inner ear is pending. Our findings suggest that there may be other genes involved in coordination/gait/ataxia in 10qter.

758/T

Down syndrome with bilateral absence of cochlear nerves, a previously unreported association. *N. Leonard[1], T. Uwiera[2], A. Kanigan[3], R. Bhargava[3].* 1) Department of Medical Genetics, University of Alberta, Edmonton, AB, Canada; 2) Department of Surgery, University of Alberta, Edmonton, AB, Canada; 3) Department of Radiology, University of Alberta, Edmonton, AB, Canada.

Individuals with Down syndrome are prone to hearing loss, most often conductive in nature. Sensorineural hearing loss, usually mild-moderate in severity, is seen in 4-20% of cases. We report a unique case of a child with Down syndrome with bilateral absence of the cochlear nerves, a previously unreported association. Following parental concerns raised over possible hearing loss, a 6 month old boy with Trisomy 21 had an audiologic assessment that identified bilateral profound sensorineural hearing loss. Auditory brainstem responses confirmed lack of responses. Otoacoustic emissions were absent in both ears and tympanometry was normal. A workup began to determine cochlear implantation candidacy. A high resolution CT scan showed significantly narrowed cochlear apertures raising the concern of absence of cochlear nerves bilaterally. There were normal appearing cochleae. The lateral semicircular canals and vestibules were mildly enlarged. The middle ear was normal. Additional imaging on MRI demonstrated the absence of the cochlear branches of the vestibulocochlear nerves bilaterally. The pregnancy was uncomplicated except for delivery by cesarean section for maternal hypertension for the 43 year old gravida 1 mother. He had treated hypothyroidism and no health concerns. In particular there were no concerns for diabetes, infection, hyperbilirubinemia, hypoxia, prematurity, pigmentation, olfaction or vision. Physical exam was in keeping with Down syndrome. There was no family history of consanguinity, neuropathies, hearing loss or health concerns. The family opted to decline genetic testing for hearing loss. In the literature, histopathology and radiology reports indicate numerous middle ear abnormalities that can be seen in Down syndrome. For inner ear abnormalities, there are reports of inner ear dysplasia in individuals with Down syndrome, the most common feature being generalized hypoplasia of the inner ear structures. There are reports of cochlear nerve canal hypoplasia and internal auditory canal stenosis or duplication, but no case of absent cochlear nerves (Blaser 2006). To date, this is the first report of an individual with Down syndrome having absence of the cochlear nerves. Profound sensorineural hearing loss in a child with Down syndrome should prompt MRI imaging to look for absence of the cochlear nerves as cochlear implantation is contraindicated in this setting. Ref: Blaser S, et al. Laryngoscope. 2006 Dec;116(12):2113-9.

BACKGROUND: Polymicrogyria (PMG) is a malformation of brain cortical development. Common clinical features include seizures, developmental delay, oromotor dysfunction and motor disabilities. PMG is a clinically and etiologically heterogenous condition. It can be attributable to environmental causes, single gene disorders with various patterns of inheritance, or chromosomal rearrangements, usually sporadic. AIMS: To report the clinical phenotypes and genetic data of several subtypes of PMG and establish genotype-phenotype correlations. METHODS: Search of our brain malformation databases at the MNH/I and HUDERF hospitals, and inclusion of all types of PMG, except those associated with schizencephaly and confirmed congenital CMV/toxoplasmosis infections; detailed review of medical records; karyotype and FISH 22q11; CGH and/or SNP microarray of genomic DNA. RESULTS: We enrolled 24 patients: 11 symmetric bilateral perisylvian polymicrogyria (BPP), 2 asymmetrical BPP, 4 unilateral right PMG, 3 unilateral left PMG, and 4 bilateral posterior PMG. A 22q11 deletion was found in one patient with unilateral right PMG. The brain MRI showed an associated large contralateral frontal heterotopia. He presented with congenital mitral valve stenosis, congenital left hemiparesis, facial dysmorphism, and moderate mental retardation. A 2p13.3-p16.3 duplication was found in a patient with symmetric BPP. He presented with neonatal global hypotonia, feeding difficulties, and delayed psychomotor development. At the age of 10 years, physical examination revealed mild facial dysmorphic signs, mental retardation, severe language delay, attention deficit helped by methylphenidate, and growth deficiency treated with growth hormone. CONCLUSIONS: The inheritance of PMG is heterogeneous. Our observations confirm that PMG, including right-sided PMG, is associated with deletion 22q11 (DiGeorge) syndrome; however, the association of a large contralateral frontal heterotopia is unusual. Altogether this suggests asymmetrical gene(s) expression between the hemispheres. Phenotypic comparison with previously published patients harboring other types of proximal 2p duplications shows a subgroup of patients with BPP sharing a common locus narrowed to 2p16.1-p16.3.

760/T

47,XX,iso(18p) Case History. *j. martinez[1], i. briceno[1,2], m. brigmon[1], a. venegas[2].* 1) Universidad de La Sabana, Bogota, Colombia; 2) Pontificia Universidad Javeriana, cra 7 numero 40-52.

Sixteen year old patient with, moderate mental non progressive deficiency and attending a school for the mentally handicap, a friendly and loquacious personality, no relevant diseases history, menarche at thirteen years, during the physical examination the only signs were: a thoracic kyphosis of 50 degrees and a lumbar lordosis of 8 degrees and hypoplasia of the fourth and fifth toes of the right foot. Kariotype revealed 47 XX+mar Microarray DNA analysis by Affimetrix SNP 6.0: showed that the marker corresponds to an isochromosome eighteen from p 11.21 a pter. Diagnosis: 47, XX iso 18p. Conclusion: This case is evidence that additional short arm of Chromosome 18 produces a mild clinical manifestation in contrast to the short arm of chromosome 18.

A Heterozygous 3q24-q25 Deletion in a Patient with the C Syndrome. *A. Nakatomi[1], T. Kondou[2], A. Mori[2], O. Shimokawa[4], Y. Sasaki[4], N. Harada[4], T. Shimoji[3], M. Fukuda[2], T. Matsumoto[1], H. Moriuchi[1].* 1) Dept Pediatrics, Nagasaki Univ, Nagasaki city, Japan; 2) Division of Developmental Disabilities,The MISAKAENOSONO MUTSUMI,Isahaya city,Japan; 3) Okinawa Prefectural Nanbu Medical Center & Childrens Medical Center,Okinawa,Japan; 4) Cytogenetic Testing 2nd.Group,Molecular Genetic Testing Dept,Clinical Laboratory Center,Mitsubishi Chemical Medience Corporation,Nagasaki city,Japan.

The C (Opitz Trigonocephaly) syndrome (OMIM #211750) is characterized by severe mental retardation, trigonocephaly and such characteristic facies as broad dental alveolar ridges, epicanthal folds, broad depressed nasal bridge and abnormal external ears. Brain and heart anomalies have also been associated with it. Mutations of CD96, located on 3q13.13, have been reported in a form of the C syndrome (Kaname et al, 2007). Furthermore, cytogenetic abnormalities of chromosome 3 or 4 have been found in patients with the C or C-like syndrome (Preus et al, 1975; Sargent et al, 1985; McGaughran et al, 2000; de Ravel et al, 2009), suggesting genetic heterogeneity for the C syndrome. We here present a C syndrome patient with brain anomaly who had an interstitial 3q deletion, del(3)(q24q25.3). The patient, a 6-year-old girl, was born by unrelated parents after uneventful pregnancy and delivery. There was no significant family history. Poor weight gain and mild motor retardation were noted during infancy. Her verbal development had been remarkably delayed: she had not spoken even a word until now. Since 3 years of age, she had been awake at night, screaming and hitting her head against the wall, and had been clinging to specific sounds, mimicking autistic spectrum disorder. She had trigonocephaly, broad dental alveolar ridges, long philtrum and epicanthus. Neurologically, ataxic gait and hyperreflexia of the lower limbs were noted. The blood cell counts and biochemical examinations revealed no abnormality. Brain MRI detected hypoplasia of cerebellum (Dandy-Walker variant) and brain stem and delayed myelination of periventricular white matter. CD96 gene analysis revealed no mutation. Chromosomal and genomic copy number analyses with high resolution SNP array interpreted the karyotype of the patient as 46,XX,del(3)(q24q25.3).-arr3q24q25.31(148,242,205-158,030,540)×1. According to the Genome Browser of database of genomic variants (build 36 assembly: http://projects.tcag.ca/cgi-bin/variation/gbrowse/hg18/), the 9.7-Mb deletion contains 57 RefSeq genes including the following OMIM disease genes, ZIC4, ZIC1, USH3A, MME, AGTR1, CP, P2RY12, SLC33A1, GMPS and HPS3, none of which has never been associated with the C syndrome. Interestingly, ZIC1 and ZIC4 genes were responsible to Dandy-Walker malformation. Further investigation of the deleted area is warranted to clarify the genetic basis of the C syndrome phenotypes and brain anomalies including Dandy-Walker malformation.

762/T

17q21.2ter microduplication and 20p13ter deletion in a dysmorphic girl with microcephaly, abnormal cerebellum and absence-like events. *C. Vinkler[1,2], R. Shuvalov[2], T. Lerman-Sagie[2], S. Kivity[2], M. Michelson-Kerman[1,2], D. Lev[1,2].* 1) Inst Med Gen, Wolfson Med Ctr, Holon, Israel; 2) Metabolic- Neuro-genetic Clinic Wolfson Medical Center, Holon, Israel.

Partial duplication of the terminal portion of the long arm of chromosome 17, is a rare but well recognized disorder. The syndrome is characterized by variable degrees of mental retardation, growth retardation, microcephaly, a large spectrum of dysmorphic features including, frontal bossing, flat nasal bridge, bulbous nose, long philtrum, wide mouth, thin upper lip, cleft palate, low-set ears, short neck, and anomalies of the limbs, heart, CNS and the urogenital system. . We describe a girl with 17q21.2ter duplication and monosomy 20p13ter who presented with a complex clinical manifestations including significant brain malformation and absence-like events. She is the third child of healthy consanguineous parents of Georgian- Jewish origin. She had a brother who was born with multiple congenital anomalies who died at the age of three weeks and another 10y old healthy brother. The mother had two spontaneous abortions . At the age of 19 m she had severe developmental delay and growth retardation. On examination she had microcephaly and dysmorphic features including, frontal bossing, flat nasal bridge, bulbous nose, long philtrum, thin upper lip, bifid uvula, low-set ears, short neck, low posterior hairline and proximal limb shortness. Right after birth, she had PFO and PDA that closed spontaneously. Brain MRI revealed a short and thick corpus callosum, enlarged forth ventricle, dysplasia of the cerebellar vermis and abnormal structure of the cerebellum. At the age of three years, her parents complained that she had up to 30 absance-like events per day. There was no correlation with EEG changes neither when awake nor during sleep. Microarray CGH showed a 15Mb17q21.2ter duplication and 600kb 20p13ter deletion. Her mother was found later to carry a balanced translocation 46,XXt(17;20)(q21;p13). CNS involvement in patients with 17q duplication has been previously described. Structural changes involving both the vermis and the cerebellar hemispheres may well be associated with 17q duplication in this child. However, the absence-like events have not been described yet in this disorder. They may represent epilepsy without EEG changes because of its deep hemispheric origin (e.g. inferior mesiofrontal).They may be either a new feature in this syndrome or associated with the partial monosomy 20p found in this case.

Ring Chromosome 21 and Cleft Palate a Case Report and Possible Candidate Gene for Orofacial Clefting Phenotype. *I. Briceno, M. Brigmon, J.C. Martinez.* Faculty of Medicine, Universidad de La Sabana, Chia, Colombia.

We report a case of a feminine child who is the product of a second controlled pregnancy ended preterm (36 weeks) by cesarean delivery, who also incurred a premature rupture of membranes. At birth, the child weighed 2100g, height of 47cm; she was diagnosed early with an atrial septal defect that required several hospital stays until surgical correction at 4 years of age. During her care in pediatrics, a genetic evaluation was solicited because of the following phenotypical findings: brachycephaly, oblique palpebral fissures, poor language skills, and small size. During the clinical genetic evaluation, the positive genetic findings were as follows: flat occiput, bilateral epicanthus, bilateral palpebral fissures, broad nasal bridge, microcephaly, hypertelorism, surgical correction of cleft palate, extremities with bilateral syndactyly in II and III toe, and bilateral shortening of the V finger. Parent comments that language skills had improved with cleft palate correction and the patient received myringotomy in the right ear to help hearing loss and language development. Our case report also had generalized seizures until about 2 years of age and the necessity of surgical correction of thoracic scoliosis at 12 years. Also, We preformed a G band karyotype that found a ring chromosome 21. After a copy number variation based on whole genome analysis we found a chromosomal deletion of 21q 22.2-gter which could be a possible candidate gene for the orofacial clefting phenotype. After an exhaustive literature review, we found that this is only the 2nd case report of ring chromosome 21 with craniofacial abnormalities such as cleft palate and a unique case for study.

INTRODUCTION. A genetic disorder is caused by abnormalities in genes or chromosomes. While some diseases, such as goldenhar are due in part to genetic disorders, they can also be caused by environmental factors. Most disorders are quite rare and affect one person. A single gene disorder is the result of a single mutated gene. There are about 4000 human diseases caused by single gene defects. Single gene disorders can be passed on to subsequent generations, however, may affect inheritance patterns. The mendelian alteration have been reported as recessive, dominant and X-linked inheritance. A great variety of genetic and non genetic disorders have been described in this study, such as Cornelia de Lange, Dextrocardia, Kabuki, Duchenne Muscular Dystrophy (DMD), Achondroplasia, Mucopolysacharidossis, Albinism, Osteogenesis Imperfecta, Neurofibromatosis, Down, Criduchat, Turner, Klinefelter, Cystic Fibrosis, Marfan, Fetal Alcohol, Moebius, Ectodermic dysplasia, Goldenhar, Beckwith wiedemann, Williams, Arthogryposis, Epiolia. MATERIAL AND METHODS. A wide study was performed in this hospital since 1992 to 2010, where cytogenetic (6480 Caryotypes performed), Iontoforesis and metabolic studies (MS) among others have been performed, in order to obtain a diagnosis, for a better treatment. 2370 metabolic studies performed, where 102 clinical cases were associated to different inborn errors of metabolism (IEM). CONCLUSIONS. The IEM due to metabolic error for a protein or enzyme absence were observe a similar incidence (4.3%) a that already reported. In relation to chromosome aberration a great variety of mutation were observed, however the most frequent chromosome aberrations as down, turner and klinefelter syndromes among others have been invited for a multidisciplinary meeting during the year, especially for Genetic Counseling. For example, achondroplasia is typically considered a dominant disorder, but children with two genes for achondroplasia have a severe skeletal disorder that achondroplasics could be viewed as carriers, similar as DMD where molecular studies are performed to females (mother and sisters) since it is a X-linked disease. The porpoise of these meetings are to obtain an earlier multidisciplinary medical evaluation for a genetic diagnosis, and a better medical and therapeutic treatment to offer a better quality of life for the different patients according to their genetic disease.

765/T

Genetic Dosage Compensation in a Family with Velo-cardio-facial/ DiGeorge/22q11.2 Deletion Syndrome. *A.A. Alkalay[1], T. Guo[2], C. Montagna[2], C. Digilio[3], B. Marino[4], B. Dallapiccola[5], B. Morrow[2].* 1) Obstetrics and Gynecology, Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY; 2) Department of Genetics, Albert Einstein College of Medicine, Bronx, NY; 3) Medical Genetics, Bambino Gesù Hospital, Rome, Italy; 4) Department of Pediatrics, La Sapienza University of Rome, Rome, Italy; 5) Department of Medicine, Viale Regina Margherita, Rome, Italy.

Cytogenetic studies of a male child carrying the 22q11.2 deletion common in patients with velo-cardio-facial/DiGeorge syndrome revealed an unexpected rearrangement of the 22q11.2 region in his normal appearing mother. The mother carries a 3 Mb deletion on one copy and a reciprocal, similar sized duplication on the other copy of chromosome 22q11.2 as revealed by fluorescence in situ hybridization and array comparative genome hybridization analysis. The most parsimonious mechanism for the rearrangement is a mitotic non-allelic homologous recombination event in a cell in the early embryo soon after fertilization. The normal phenotype of the mother can be explained by the theory of genetic dosage compensation. This is the second documented case of such an event for this or any genomic disorder. This finding helps to reinforce this phenomenon in a human model, and has significant implications for genetic counseling for future children.

766/T

BRAF Gene Mutation Associated With Intraoral Giant Cell Granulomas. *S. Beiraghi, V. Leon-Salazar, A.K. Thurmes, W.S. Looman, G.C. Anderson.* University of Minnesota School of Dentistry, Minneapolis, MN.

Cardio-Facio-Cutaneus Syndrome (CFCS; MIM 11550) is part of five syndromes with overlapped phenotype caused by mutations in genes encoding various components of the Ras/Mitogen-Activated Protein Kinase (RAS/MAPK) pathway. CFCS is characterized by a heterogeneous autosomal dominant transmission pattern, a distinctive facial dimorphism, mental retardation, global developmental delay, heart defects, and ectodermal abnormalities. Although not rare, there are few reports about multiple giant cell lesions (MGCL) associated with mutations in the RAS/MAPK pathway. Here we report CFCS with intraoral MGCL and xantho granuloma lesions in a patient with BRAF gene mutation. A 5.8 year-old boy born to nonconsaguineous parents at 36 weeks gestation with polycythemia and multiple congenital anomalies including macrocephaly, submucous cleft palate, stenotic ear canals, left ptosis and exotropia, supravalvular pulmonary stenosis, bilateral cryptorchidism, dysplastic right kidney and hydronephrosis. Significant growth and development delays, including short stature, expressive and receptive language delays, and conductive hearing loss, chronic generalized eczema, especially in the facial area, chronic ear infection, plagiocephaly, lymphedema, xantogranulomas, and bilateral expansible jaw cysts (MGCL) were part of the phenotype. Genetic testing revealed that he carries one copy of a sequence variant (1406 G>A) in the BRAF gene. Since the RAS/MAPK genes has been associated with dysregulation in oncogenesis and the presence of Xantho granulomas, this patient is tested every 3 months for leukemia.

767/T

Solitary median maxillary central incisor (SMMCI) syndrome in a pediatric patient. A case report, Hospital para el Niño Poblano, México. *D. Sanchez-Lopez[1], J.M. Aparicio-Rodriguez[2], N.G. Hernandez-Trejo[1], L. Bueno-Garcia[1].* 1) Odontopediatrics; 2) Medical Genetics , Hospital para el Niño Poblano, Puebla, Puebla, Mexico.

INTRODUCTION. Solitary median maxillary central incisor syndrome known as SMMCI, is a rare and complex disorder consisting of different mainly midline defects of development. This is secondary to vary intra uterine factor(s) between the 35th-38th day(s) from conception. It's incidence is about 1:50,000 live births. It has been suggested that missense mutation in the SHH gene (I111F) at 7q36 may be associated with SMMCI. This syndrome tooth differs from the normal central incisor, in that the crown form is symmetric; it develops and erupts precisely in the midline of the maxillary dental arch in both primary and permanent dentitions. It has been also observed nasal malformation (choanal atresia, midnasal stenosis or congenital pyriform aperture stenosis) associated with SMMCI. The presence of an SMMCI tooth can be part of a nervous central system anomaly like holoprosencephaly, severe to mild mental retardation, congenital heart disease, cleft lip and/or palate and less frequently, microcephaly, hypopituitarism, hypothyroidism, hypotelorism, strabismus, esophageal and duodenal atresia, cervical hemivertebrae and scoliosis, kidney malformation and ambiguous genitalia. MATERIAL, METHODS AND CASE REPORT. A 3 years old female patient was evaluated at the departments of estomatology and genetics, she is the 5th child of a normal family. A 35 years old mother and 40 years old father. The patient was evaluated at ortopedics to discard an osseous dysplasia. However due to the short stature of the patient, was sent to endocrinology for Human Hormone Evaluation. Hematury and proteinury was observed in urine laboratory sample, a kidney ultrasound was requested to discard kidney malformation. A caryotype was requested by genetics since different chromosomes aberrations had been reported, such as triple XXX syndrome, 7q-, 18p- and 22q. CONCLUSION. Diagnosis should be made by eight months of age, but can be made at birth and even prenatally at 18-22 weeks from the routine mid-trimester ultrasound scan. Medical management depends upon the different individual anomalies present. Short stature may require growth hormone (GH) therapy, as the case in this study, which will start GH treatment. Same as neurology with early rehabilitation therapy if necessary. The department of odontopediatrics will provide a multidisiciplinary treatment with orthodontic, prosthodontic and oral surgical treatment, to ensure a better quality of life for the patient.

768/T

Clinical heterogeneity in a family with a small microduplication of chromosome 22q11.2. *J.D Weisfeld-Adams[1,2], I.K. Gadi[3], L. Mehta[1].* 1) Gen & Genomic Sci, Mount Sinai Med Ctr, New York, NY; 2) Department of Pediatrics, Mount Sinai Med Ctr, New York, NY; 3) LabCorp, Center for Molecular Biology and Pathology, Research Triangle Park, Durham, NC.

The chromosome 22q11.2 region is commonly involved in nonallelic homologous recombination (NAHR) events. Microduplications of 22q11.2, usually involving a 3 Mb or 1.5 Mb region, are thought to be approximately half as common as the microdeletion syndrome involving the same genomic region. Clinical features decribed in affected individuals are variable and show overlap with the 22q11.2 microdeletion syndrome. Previously reported clinical features associated with larger microduplications in this region have included dysmorphic facial appearance, velopharyngeal insufficiency, congenital heart disease, and immunologic defects. We report an 8 month old boy who presented for genetics evaluation because of microcephaly and mild developmental delay. Prenatal history was unremarkable, with spontaneous delivery at term. Head circumference at birth was 31.5 cm (<3rd centile) and at 8 months was 41.7 cm (<3rd centile). Other findings included hypertelorism, left-sided cryptorchidism and developmental dysplasia of the left hip. At 8 months, gross motor development was delayed with inability to sit unsupported. Array CGH (Affymetrix Genome-Wide Human SNP Array 6.0) revealed a novel 438 Kb interstitial duplication at 22q11.21, involving TBX1. The same duplication was confirmed by FISH in the patient's mother and a sister. The mother is described as having a history of anxiety disorder, but had normal head size and was a college graduate. The sister had delayed motor milestones, walking at 22 months. She is described as having normal development at 2 years of age. None of the three carriers of the duplication has any documented cardiac issues, renal anomalies or any significant medical problems. This family demonstrates the clinical heterogeneity observed in microduplications of 22q11.2, and further illustrates the difficulty in providing prognostic information and accurate genetic counseling to families where this finding is detected. The described microduplication is the smallest reported in the literature to date.

769/T

Clinical Reports and Further Delineation of the 14q32 Deletion Syndrome. *E.L. Youngs[1], J.A. Hellings[1], M.J. Dasouki[2], M.G. Butler[1].* 1) Departments of Psychiatry & Behavioral Sciences and Pediatrics, University of Kansas Medical Center, Kansas City, KS 66160; 2) Department of Pediatrics, University of Kansas Medical Center, Kansas City, KS 66160.

Individuals with deletions of the chromosome 14q32 region are rare. The focus of our report is to describe additional subjects with de novo 14q32 deletions and compare with 11 individuals ranging in age from 1 day to 33 years described in the literature with proximal and distal breakpoints within the 14q32 band. We report two subjects (8 month old female and 18 year 6 month old female) with 14q32 deletions using chromosomal microarray hybridization to delineate the cytogenetic findings. Our older female presented at birth with a small appearing jaw, large tongue, high-arched palate with a bifid uvula, horizontal nystagmus, optic nerve hypoplasia, hypotonia and a 14q32 deletion. Bilateral sensorineural hearing loss was detected by 2 years of age along with developmental delay. Strabismus was corrected at 5 years of age. Hyperactivity and behavioral problems (OCD, depression, anxiety, impulsivity) were noted by 8 years of age. At 18 years of age, her growth parameters were within normal range. Her face was long and narrow with a high forehead, downslanting palpebral fissures, blepharophimosis, epicanthal folds, a flattened, wide nasal bridge, short nose with anteverted nares and a long appearing pointed chin. She had a bifid uvula, high-arched palate and digital findings. Her full scale IQ was 74; verbal IQ was 71 and performance IQ was 81 (WAIS-III) at 18 years. Her 4.16 Mb deletion (102.21 to 106.37 Mb from pter) extending from 14q32.32 to qter identified by microarray analysis contained approximately 50 genes. Our second female presented at 8 months with severe hypotonia and failure to thrive, global developmental delay, dysmorphic facial features, congenital heart disease and a cat-like cry. Her 6.1 Mb deletion of the 14q32.2-q32.31 region occurred from 95.58 to 101.77 Mb from pter. The following list of commonly occurring physical anomalies reported in subjects with the 14q32 deletion including our subjects in order of frequency is: broad philtrum (8/9 subjects), broad and flat nasal bridge (8/9), thin upper lip (5/6), hypotonia (9/11), telecanthus (8/11), high-arched palate (8/11), blepharophimosis (6/9), malformed helices (5/8), small mouth (5/9), pointed chin (5/10), strabismus (5/10) and downslanting palpebral fissures (4/9). Individuals with ring chromosome 14 were excluded in our analysis as these subjects frequently present with seizures, visual problems and retinal abnormalities not generally seen in the 14q32 deletion subjects.

770/T

Deletion 3q22.3q23: Blepharophimosis-ptosis-epicanthus inversus syndrome (BPES) and spastic diplegia, speech delay and penile skin anomalies. *S. Zahanova[1], B. Labieniec[2], H. Verdin[3], B.F. Meaney[4], J.-C. Wang[5], E. De Baere[3], M.J.M. Nowaczyk[4,5].* 1) DeGroote School of Medicine, McMaster University, Hamilton, Ontario, Canada; 2) School of Medicine, Jagiellonian University, Krakow, Poland; 3) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 4) Dept. Pediatrics, McMaster University, Hamilton, Ontario, Canada; 5) Dept. Pathology and Molecular Medicine, McMaster University, Hamilton, Ontario, Canada.

BPES is an autosomal dominant disorder affecting craniofacial development and presenting with specific eyelid abnormalities. Premature ovarian failure and internal genital anomalies are found in a subgroup of female patients. BPES is caused by mutations of the *FOXL2* gene located at 3q23; only 10% of BPES cases are caused by interstitial deletions of 3q. We report a boy who presented with classic facial features of BPES, who also had a webbed penis noted at birth. There was no separation of the skin on ventral aspect of the penis and the scrotum; the skin was fused. At age two he presented with speech delay, and articulation problems persisted to after age 4. The patient also had gross motor delay and spastic diplegia; upper motor neuron dysfunction was documented. Molecular testing for hereditary spastic paraplegias SPG 3A, 4, 6, 7, 8, 17 and 31 were negative; brain and spine MRIs were normal. His karyotype was 46,XY,del(3)q(22.3-23), and BAC probe RP11-54801 was deleted on FISH analysis. Whole-genome oligonucleotide array demonstrated a 4.7 Mb deletion at chr3:139,354,104-144,013,999. MLPA also confirmed the *FOXL2* deletion, and showed that the deletion spans the *ATR* gene; this is a relatively large deletion. The genital anomalies observed in our patient have not been reported in male patients with BPES, although premature ovarian failure and internal genital anomalies are observed in females with BPES type I. Spasticity and developmental delay, observed in a number of BPES deletion patients, in addition to the dystonia seen in our patient, may be due to haploinsufficiency of *MRPS22,* a skeletal muscle mitochondrial protein, located in proximity to *FOXL2*. It has also been hypothesized that mental retardation and growth delay in BPES patients with large deletions is due to haploinsufficiency for *ATR*, a gene associated with autosomal recessive Seckel Syndrome. Although an unrelated genetic condition or an alternate disease mechanism cannot be ruled out in our patient, to date we do not have an adequate explanation for his neurologic presentation and the penile anomalies.

771/T

Third case of limb reduction defect in a patient with Jacobsen 11q distal deletion syndrome. *B. Hall.* University of Kentucky, Lexington, KY.

Finger and toe abnormalities such as clinodactyly, syndactyly, and short fingers are common in Jacobsen's syndrome. Limb deficiency has been reported only twice and in both instances the deficiency was distal, unilateral, and involved a single limb. One case was in a 34 year-old male with a missing distal right forearm with 4 nubbin-like digits attached to the remaining forearm. The other instance involved a 37 week gestation female who was missing the anterior half of her left foot. I report a third case of Jacobsen's syndrome to more firmly establish this limb reduction defect association. The girl was a 41 week gestation product of an uncomplicated pregnancy who was born to a 33 year-old G2P2 mother. The child had normal birth parameters and mild thrombocytopenia (60,000-80,000 platelets) for the first twenty-four hours. She had a hypoplastic right hand with nubbins for fingers 3 and 4 and hypoplastic 2nd and 5th fingers. Additional abnormalities included multiple thoracic hemivertebra, VSD, and accessory left nipple. On standard karyotype she had deletion 11q23.3-qter, but on ARRAY the deletion was 11q24.2-qter. The two literature cases showed deletions in the same region although one was a terminal mosaic deletion involving 11q24.1 and the second an 11q24-qter deletion. All 3 cases showed unilateral, distal, and single limb reduction defects. Only one of the two literature cases showed any prolonged thrombocytopenia. Over 80% of Jacobsen patients have thrombocytopenia and some researchers have theorized it to be the causative factor in the limb reduction defects via fetal hemorrhage/ vascular disruption. The gene (s) for the thrombocytopenia is at 11q24.3. At this point no limb development gene has been located in the 11q24-pter region to explain the limb reduction defects. In any regard limb abnormalities including limb deficiencies are common in terminal 11q deletions.

772/T

Natural history of Down syndrome patients in Japan: a questionnaire investigation. *T. Kondoh[1], K. Morifuji[4], T. Matsumoto[4], H. Nakane[5], E. Tsukada[3], M. Fukuda[1], M. Doi[2], H. Motomura[2], S. Honda[6], H. Moriuchi[2].* 1) Dept Pediatrics, Misakaenosono Mutsumi, Isahaya, Japan; 2) Dept Pediatrics, Nagasaki University Hospital, Nagasaki, Japan; 3) Genetic Counseling Unit, Nagasaki University Hospital, Nagasaki, Japan; 4) Dept Nursing, Nagasaki University School of Health Science, Nagasaki, Japan; 5) Dept of Occupational Therapy, Nagasaki University School of Health Science, Nagasaki, Japan; 6) Dept Public Health, Nagasaki University School of Medicine, Nagasaki,Japan.

[Background] Down syndrome (DS) is the most common chromosomal aberration. Its incidence has been increasing from one of every 932 live births in 1975 to one of every 583 live births in 2005, and its life expectancy has been elongated in Japan. Nevertheless, the natural history of Japanese DS patients remains obscure. [Materials and Methods] Study subjects were all DS patients who were sixteen years or older who lived in Nagasaki Prefecture. A small proportion included those in neighboring prefectures. A total of 1,300 questionnaires were delivered to their families and institutional caregivers. Questionnaire investigation was performed in 2-fold: one for the families to clarify chronological changes as well as current conditions, and the other for caregivers to assess current conditions supplementing the former. [Results and Discussion] We collected 551 questionnaires from 269 families and 282 caregivers. Based on this investigation and Nagasaki prefectural census data, morbidity of DS was 0.47 in 1,000 persons aged 16-64 years and the average life span was 57.8 years old. While younger DS patients live along with their families at home, the proportion of those who live in institutes increased with age: 55% in early 30's and 100% in late 50's and 60's. Only a minority in young age groups could talk fluently, and difficulties in language function increased with age: approximately 30% of DS patients in 40's had lost verbal communication skill. As for daily activities, those who needed help all the time were less than 10% in the late 10's and early 20's, but increased to around 30% in 30's and to around 40% in 50's and 60's. Among DS patients aged 27-44 years, there was little difference in the ability to move between those at home and those in institutes; however, the latter had more difficulties in verbal communication and daily activity than the former. Most DS patients appeared to be the most active physically and intellectually before and around 20 years old. Physiological aging signs started to develop in the late 20's. 75% of DS patients consulted with hospitals. 23% of DS patients had operations. Major psychiatric problems included disturbance of skills in daily lives, defects of memory, general mental disability, language dysfunction, personality disorders, depression, delusion, panic disorder and anxiety disorder. Further investigations are warranted to clarify characteristics of the natural history of Japanese DS patients.

773/T

Novel Clinical Manifestations in Pallister-Killian Syndrome: Comprehensive Evaluation of 26 Affected Individuals and Review of all Previously Reported Cases. *A. Wilkens, L. Conlin, M. Kaur, L. Campbell, M. Deardorff, M. Jackson, N. Spinner, I. Krantz.* Children's Hospital of Philadelphia, Philadelphia, PA.

Pallister-Killian Syndrome (PKS) (OMIM # 601803) is a rare, multi-system developmental disorder caused by tetrasomy 12p that exhibits tissue-limited mosaicism. The spectrum of clinical manifestations in PKS is wide and although almost universally described as a severe disorder with multiple congenital anomalies and severe to profound cognitive involvement, recent reports have described a milder phenotype. We report the clinical findings of 26 individuals with PKS who were all evaluated at family meetings of the PKS Foundation, or during a clinical genetics evaluation at The Children's Hospital of Philadelphia. All subjects were enrolled under an IRB-approved protocol of informed consent. Consented individuals filled out a medical history survey and all available records obtained were reviewed by the genetics team. Dysmorphologic examinations were performed on all subjects and neurological and developmental examinations were conducted on a subset. These cases were then compared to the 152 cases of PKS reported in the medical literature. Index and reference cases without cytogenetic confirmation or with variant chromosomal abnormalities involving 12p were excluded. Several novel clinical characteristics of our cohort were identified. Among our patient cohort, several previously unreported clinical features were observed including a high prevalence of dermatoglyphic whorls, philtral skin extending into vermilion border of the upper lip and posterior ear pits. In addition, our patients demonstrated greater variability in cognitive outcomes compared to patients reported in the literature. Advanced molecular SNP and CGH array-based techniques which can detect low levels of mosaicism in blood without the requirement of a skin biopsy has improved diagnostic capabilities, even in the absence of a suspected PKS clinical diagnosis. However not all patients can be diagnosed using blood-based testing and recognition of the clinical phenotype is critical. Such higher resolution molecular technologies have also aided in the identification of patients with variable 12p chromosomal rearrangements in probands with overlapping PKS phenotypes, which has allowed for the delineation of a PKS critical region within chromosome 12p. This report expands and defines the clinical phenotype of PKS, highlights the highly variable expressivity of this disorder, and discusses the impact of array-based cytogenetic analysis on diagnosis and counseling.

Deletion 3p syndrome and phenotypic change with age: an adult case report. *N. Davalos[1,4], I.J. Garcia-Gonzalez[1], V.M. Anguiano-Alvarez[1], J.L. Villarreal-Salgado[2], G.H. Galicia-Hernandez[1], C.A. Galvan-Diaz[3], A.M. Franco-Martinez[1], A.R. Rincón-Sanchez[5].* 1) Inst Human Genetics, Univ Guadalajara, Guadalajara, Mexico; 2) Hospital Regional de Zona "Valentín Gómez Farías", ISSSTE, Cirugia reconstructiva, Zapopan, Mexico; 3) Centro De Investigación Biomédica De Occidente IMSS, Guadalajara, Mexico; 4) Hospital Regional de Zona "Valentín Gómez Farías", ISSSTE Servicio de Genética, Zapopan, Mexico; 5) Instituto de Enfermedades Crónico Degenerativas, CUCS, UdeG;, Guadalajara, Mexico.

Introduction: The deletion of the short arm of the chromosome 3 is a rare disorder characterized by growth failure, psychomotor and mental retardation and craniofacial anomalies and less commonly others cardiac, renal and gastrointestinal malformations. Case report: The propositus is male reported at the age of 20 months for the presence of congenital malformation and hypotonia. The karyotype was 46,XY,del(3p26). Currently he is 18 years old and exhibits evidence of phenotype changes no characteristics of the syndrome at pediatric ages. Physical examination revealed a height of 167 cm, weight of 47 kg. He is normocephalic with triangular face, malformed ears, low frontal hairline; low nasal base and bridge, absent and long philtrum, full inferior lip, narrow and high arched palate; hypotrophyc limbs, hands with cutaneous syndactyly and bilateral clinodactyly in the fifth finger. Neurological examination is normal. Discusion: The deletion 3p syndrome it has a characteristic phenotype, nevertheless a few adult cases were reported. The patient shows some physical findings not compatible with the syndrome and could be age-related. Other are more associated with the extension of the deletion. Conclusion: This syndrome presents a strong connection between the severity of the disease and the portion of the deletion. The previous statement justifies the importance of delimit the affected chromosomic area with molecular characterization and the phenotype-genotype correlation. We also consider the existence of a phenotypic variability that is related with the age in this syndrome.

775/T

A *de novo* deletion of 12p12.1 partially overlapping the *SOX5* gene in a patient with developmental delay and hypotonia. *M. Gorre[1], J. Kim[1], S. Gunn[1], W. Burdo-Hartman[2], K. Hovanes[1].* 1) CombiMatrix Diagnostics, Irvine, CA; 2) Spectrum Health, Grand Rapids, MI.

Here we describe a 20 month old female referred to the neurodevelopmental clinic due to global developmental delays. Her mother reports that she sat at 6 months of age, crawled at 8-9 months of age, and has only progressed to standing and cruising now. She only says a few consonant sounds. She holds her hand in fisted position with her left thumb is in a cortical position. Her rate of weight gain has been slow as well. MRI showed her to have bilateral optic nerve hypoplasia and a small pars intermedia cyst in the pituitary. She was born at term and weighed 7 pounds and 6 ounces and there was no alcohol, drug or tobacco use during the pregnancy. Her mother has a past history of having a stillbirth and a miscarriage. The family history is significant for a maternal uncle who had Friedreich's ataxia and died at about 40 years of age and her mother who had speech delay as a child. Her weight is 9.52 kg (305th%), length is 85.1 cm (75-90th%), head circumference is 45.2 cm (10th%), and her weight for length is at the 3rd%. Her head is normocephalic and fontanels are closed and sutures are approximated. Pupils are equal round and reactive to light and extraocular muscles are intact. Ears are well formed, nose is bulbous, and teeth are normal. Neck is supple without lymphadenopathy, lungs are clear, heart has a regular rate and rhythm, abdomen is soft, and bowel sounds are normal. Extremity examination reveals long tapering fingers with a cortical left thumb. Neurologically, she has decreased strength and muscle mass. Her tone is decreased except at her left thumb. She can bear some weight on her legs and she was interactive and gave eye contact. Oligonucleotide array comparative genomic hybridization (aCGH) revealed the patient to have a 1 Mb deletion of 12p12.1. A search for genes in the deleted region revealed partial deletion of a single annotated gene -- the *Sry-related HMG box 5* (*SOX5*) gene, a member of the Sox D subfamily of genes. *SOX5* codes for a transcription factor whose long transcript is expressed in the brain and cartilage during embryonic development in mice and humans and is thought to play a role in neuronal and skeletal development. Failure to detect the same deletion in parental samples suggests that this is a de novo event. This is the first reported case of a de novo deletion affecting the *SOX5* gene in a patient with developmental delay and hypotonia suggesting a potential genotype/phenotype correlation.

Ambiguous genitalia in a patient with a genetic diagnosis, 46,XX/46,XY chimera: A Case Report at the Hospital Para el Niño Poblano, Mexico. *F. Cuellar-López[1], J.M. Aparicio-Rodriguez[2,6], M.L. Hurtado-Hernandez[3], C. Carrillo-Gonzalez[4], M. Barriento-Perez[4], H. Tovar-Gonzalez[5].* 1) Pediatric Urology; 2) Genetics; 3) Cytogenetics; 4) Endocrinology; 5) Psychology, Hosp Para el Nino Poblano, Puebla, Mexico; 6) Estomatology, Benemerita Universidad Autonoma de Pueblña, Mexico.

INTRODUCTION. The phenotypic spectrum of 46,XX/46,XY chimeric cytogenetics results is variable. It ranges from normal male or female genitalia to different degrees of ambiguous genitalia. Chimerism results from the mixure of two different zygotes in a single embryo, whereas mosaicism results from a mitotic error in a single zygote. Here, we report on a case of chimerism (46,XX/46,XY) in a pediatric patient, Clinical examination revealed ambiguous genitalia, female external genitalia with a small tissue similar to a small penis. During cytogenetic diagnosisit was observed the presence of 46,XX and 46,XY cell lines in 47%/53% respectively. Diferent cases of chimerism have been reported by Hunter et al., 1982; Freiberg et al., 1988; Pinhas-Hamiel et al., 2002; Simon-Bouy et al., 2003; Chen et al., 2005. In 1962, Gartler et al. described the first case of chimerism. Since then, about 30 cases have been reported in the literature. MATERIAL AND METHODS. After undergoing cytogenetic studies in a pediatric patient referred to medical genetics, two different cells lines (46,XX [47%] and 46,XY [53%]) were observed in blood cell culture. Karyotyping after G banding was performed according to standard procedures on cultured blood cells, venous blood sampling and peripheral blood lymphocytes. 100 hundred metaphases were studied in order to estimate the percentage of each cell line. DNA was extracted from peripheral blood cells. RESULTS. Karyotypes obtained confirmed the presence of 2 cell lines from 100 cells examined (46,XX [47] and 46,XY [43]). A multidisciplinary medical meeting was performed to discuss whether the patient could be surgically transformed as female or male with a genitalia modification. It was concluded taking in considerations the cell line percentage and the best sexual future function for the patient, that it could be better to perform a surgery for a female rather than male. It was discussed with the family whom agreed on this decision. The earlier cytogenetic and urologic diagnosis is very important in these patients in order to obtain the best quality of life. De Novo Deletion and Duplication of the _SMC1A_ gene at Xp11.2. *ES. Goh[1], G. De Veber[2], DJ. Stavropoulos[3], D. Chitayat[1].* 1) Division of Clinical & Metabolic Genetics, The Hospital for Sick Children, Toronto, ON, Canada; 2) Division of Neurology, The Hospital for Sick Children, Toronto, ON, Canada; 3) Cytogenetics Laboratory, Department of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, ON Canada.

Microarray analysis has become part of clinical practice in screening patients with mental retardation and or congenital anomalies. However, Buysse *et al.*, showed that in a population of 703 patients with mental retardation and/or congenital anomalies who had undergone 44K oligonucleotide array, 11% was found to have causal copy number variants, while 21% showed changes of unknown significance. Thus, information obtained by microarray analysis often presents a challenge in interpretation.

We report two probands with multiple congenital anomalies and findings of copy number variation in the Xp11.2 region. Case 1 is a female with facial dysmorphism including hypertelorism, hypoplastic supraorbital ridges, left cleft lip and palate, bilateral overlapping 2nd and 3rd digits with camptodactyly, hypotonia and poor suck. At 2 months of age she developed intractable seizures which resulted in her death. She had a *de novo* deletion at Xp11.2 including a partial deletion of exons 19-25 in the *SMC1A* gene. Case 2 is a male born with missing right fibula, short bent tibia with subcutaneous spur, equinus right foot with limitation of ankle joint movement and oligodactyly with 3 toes (great toe, 2nd and 3rd). The left lower limb was unremarkable. He has a maternally inherited duplication of Xp11.2 in the same region. The *SMC1A* (OMIM 300040) gene is located at Xp11.2 and is reported to escape X-inactivation. It is associated with a variant of Cornelia de Lange (CdLS) which is characterized by mild facial features such as a prominent nose with lack of synophrys or arched eyebrows, mild developmental delay and absence of major congenital structural anomalies or limb reduction defects (Deardorff *et al.* 2007). We compare the recent literature on the cases of *SMC1A*-associated CdLS as well as copy number variation at Xp11.2. To our knowledge, case 1 represents the largest deletion known affecting *SMC1A* only and case 2 is the smallest duplication of the Xp11.22, including the *SMC1A* gene reported in the literature. We postulate based on the phenotype of these two cases that the pathogenic mechanism of *SMC1A* is not due to a gene dosage effect but rather due to defects in dominant negative function of the gene.

Neurocognitive spectrum in boys with the fragile X premutation. *S.W. Harris[1,2], A. Schneider[1], N. Russo[3], C. McKown[3], D. Alderson[3], M. Lipton[3], P. Hagerman[1,4], F. Tassone[1,4], R.J. Hagerman[1,2].* 1) MIND Institute, Univ of California Davis, Sacramento, CA; 2) Department of Pediatrics, University of California Davis, Sacramento, CA; 3) Rush NeuroBehavioral Center, Skokie, IL; 4) Department of Biochemistry and Molecular Medicine, University of California Davis, Davis, CA.

Background/Purpose

We are conducting a study regarding profiles of cognitive involvement in young males with the fragile X premutation, and are interested in the neucognitive profile of these children, including autism features, memory, and social-emotional functioning.

Methods

To date we have done a comprehensive neurocognitive assessment with 10 boys between 8 and 15 years of age (mean= 11.2 + 2.1) who have the fragile X premutation. We assessed cognitive ability using a Wechsler intelligence scale (either WISC-IV or WASI), and we also used the Autism Diagnostic Observation Schedule (ADOS) to assess characteristics of autism spectrum disorders. Additional measures were completed to assess social-emotional and theory of mind abilities, including subtests from the CASL (pragmatic judgment), NEPSY-II (theory of mind and affect recognition), and the TOPS (problem solving), as well as memory abilities. We also completed several research measures to assess social-emotional functioning, including computerized measures of affect processing of both faces and postures. Molecular data is being collected on each subject as well, including mRNA and protein (utilizing the updated ELISA method).

Results

The subjects assessed showed a wide range of cognitive abilities. Full scale IQ (FSIQ) scores ranged from 51 to 141 (mean= 93 + 25) and classification utilizing the ADOS showed that several of the subjects were classified as within the autism spectrum. Interestingly, two of the subjects were diagnosed with Asperger's syndrome, and this has not been reported previously in boys with the premutation. We will also report on results of memory and social-emotional functioning of the subjects assessed to date, including results from some of the standardized measures and research paradigms used to assess these children. We will also present data on correlations between these clinical measures and the molecular data for these subjects.

779/T

Whole genome FAIRE analysis reveals regions of chromatin fluctuations in Angelman syndrome deletion versus 15q interstitial duplication autism. *X. Wang[1], N. Urraca[2], W. Taylor[3], L.T. Reiter[1,2].* 1) Dept Anatomy and Neurobiology, UTHSC, Memphis, TN; 2) Dept Neurology, UTHSC, Memphis, TN; 3) Molecular Resource Center, UTHSC, Memphis, TN.

The q arm of human chromosome 15 contains several low copy repeat (LCR) regions which predispose segment 15q11.2-q13 to non homologous allelic recombination events resulting in copy number changes for the intervening genes. Maternally inherited deletion events at this locus result in the neurological disorder Angelman syndrome (AS) when they include the human *UBE3A* gene, while the reciprocal interstitial duplications of the locus surrounding *UBE3A* give rise to milder phenotypes that include autism when maternally derived. To provide a framework from which to initiate the identification of transcripts that show variable expression in the presence of decreased (AS) or increased (dup15) levels of UBE3A we used lymphoblast cell lines from a class II AS deletion and a class II int dup15 subject for analysis by whole genome Formaldehyde-Assisted Isolation of Regulatory Elements (FAIRE). We identified signals on all chromosomes that showed enriched FAIRE signals indicative of increased regional gene expression and a decrease in chromatin condensation. We scanned 10kb segments for regions where the average FAIRE signal showed opposing patterns in AS deletion vs dup15 cell lines. We found 189 regions where FAIRE signals were enriched in one direction or the other depending on the deletion or duplication on 15q. Some regions undergoing changes in chromatin conformation included autism associated loci on 1q21.1 and 16p13.1. We also found signal differences in genes: 1) *ASTN1* (1q25.2) a neural migration gene; 2) *NFX2* (Xq22.1) an FMRP interacting protein that regulates Nxf1 mRNA stability in neuronal cells and; 3) *CNTNAP2* (7q35-q36) a gene encoding Caspr2, a member of the neurexin family linked to autism with language impairment. The number of pericentromeric reads on chromosomes 1, 2, 6 and 10 was over represented in FAIRE treated dup15, but unchanged in these same regions in AS deletion. Although this could be an artifact generated by the repetitive nature of these regions, it could also indicate a general loss of chromatin compaction in 15 duplication subjects. These regions may contain genes that are regulated at the chromatin level by upstream changes in *UBE3A* expression and are therefore good candidates for expression studies to identify molecular changes that result in both AS and int dup15 autism. The combination of gene expression data and promoter region specific FAIRE signal analysis may reveal new gene networks involved in both AS and autism.

780/T

MECP2 Duplication with Left Ventricular Apical Trabecular Cardiomyopathy. *C.A. Bay[1], C. Cottrill[2], N. Soares[3], B.D. Hall[1], T. Bonilla[1], A. Rutherford[1].* 1) Clinical/Biochemical Gen, University of Kentucky, Lexington, KY; 2) Community Pediatric Cardiology, University of Kentucky, Lexington, KY; 3) Developmental Behavioral Pediatrics, University of Kentucky, Lexington, KY.

We have observed a 15 year old caucasian male followed since childhood with severe cognitive delays, and ataxia. Dysmorphic features include epicanthal folds and flat malar bones. Family tree is consistent with X-linked recessive inheritance. Previous karyotype, Angelman studies, and Fragile X testing were negative. Cardiovascular monitoring documented arrhythmias which responded to medication. The finding of left ventricular apical trabecular cardiomyopathy prompted reappraisal and consideration of Barth syndrome. He did not have neutropenia. Sequencing of TAZ gene did not identify a mutation. Chromosomal Microarray documented a duplication within Xq28. Duplication size is a minimum of 0.890 Mb, and includes both MECP2 gene, and FLNA, but does not include TAZ. We believe this patient, who is clinicallly consistent with MECP2 duplication, to be the first reported MECP2 duplication patient with left ventricular trabecular cardiomyopathy. Recent reports have documented cardiovascular abnormalities in patients with an Xq28 duplication including both MECP2 and FLNA, but those abnormalities did not include left ventricular apical trabecular cardiomyopathy. This type of cardiomyopathy can be seen in Barth syndrome, also found at Xq28. We suggest that cardiovascular abnormalities may be an important clinical feature of MECP2 duplication. Left ventricular apical trabecular cardiomyopathy could represent a broader spectrum of the observed cardiovascular features when the Xq28 duplication includes MECP2 as well as FLNA. Alternatively, in our patient Tafazzin function might be impaired due to epigenetic factors associated with the proximity of the TAZ gene to the duplicated Xq28 segment.

781/T

Identification of pathogenic copy number variants and of a novel single-gene deletion on syndromic obesity. *C.S. D'Angelo, I. Kohl, C.P. Koiffmann.* Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of São Paulo, Rua do Matão 277, sala 204/209 CEP 05508-900, São Paulo, SP, Brazil, Financial Support: FAPESP, CEPID-FAPESP, CNPq.

The impact over the ascertainment of rare copy number variants (CNVs) in cohorts with extreme phenotypes in addition to congenital malformations and/or developmental delay (DD) has been recently appreciated with the discovery of deletions at 16p11.2 as a new highly penetrant form of human obesity. In an ongoing research on syndromic obesity we sought for pathogenic CNVs in patients with negative testing for PWS with array genomic hybridization (AGH). We found several CNVs of *de novo* occurrence: a deletion of chromosomes 2p25.3, 6q16.1q21, 7q22.1q22.3, 12q15q21.1 and Xp22.13p22.12, a duplication of chromosomes 14q11.2 and Xq28, and an unbalanced translocation between chromosomes 3p26.3 and 11q22.3. Obesity in monosomy 6q16 is related to the hemizygosis of *SIM1*. Several presumed obesity-associated genes were mapped to the genomic intervals of the remaining CNVs. To evaluate the contribution of these CNVs to syndromic obesity, we developed a synthetic MLPA probemix containing probes to each of these genomic intervals. With the same purpose, we synthesized another probemix based on the observation of rare CNVs that were recurrent in patients with obesity-associated phenotypes listed on the DECIPHER. Besides, we performed 100 K Affymetrix GeneChip® array in combination with CNAT (v4.0) and CNAG (v3.0) on a select group of 11 patients with obesity and negative testing for Smith-Magenis syndrome. Thus far, we have found two unrelated patients out of 38 screened by MLPA with *de novo* deletions at 2q37, and apparently pathogenic CNVs in three of the patients tested with SNP arrays: a *de novo* single-gene deletion at 14q12 (~600 kb), a *de novo* duplication at 12q21.32q23.1 (~12 Mb), and a duplication at 20q11.1q11.2 (~2 Mb). The deletions at 2q37 encompass at least 4 genes assigned as candidates for obesity in 2q37 monosomy syndrome. The deletion at 14q12 covers the entire coding region of *PRKD1*. This gene is usually deleted in patients with 14q12 microdeletion syndrome. No benign CNVs have been assigned to *PRKD1* and we found two patients with DD and overlapping deletions within this gene on the DECIPHER. The remaining CNVs affect several genes with important signaling functions, such as *DUSP6* and *DUSP15*. The use of AGH has increased the recognition of new syndromic forms of obesity, and is a potential source for understanding the etiology of common obesity as well. We present our preliminary data towards the identification of novel obesity-associated genomic *loci*.

Paternal UPD14 diagnosed by whole genome array: clinical and radiological features. *B.E. Mucha-Le Ny[1], J.M. Kalish[1], N.B. Spinner[2], E.H. Zackai[1], L.K. Conlin[2].* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA.

The introduction of single nucleotide polymorphism (SNP) array analysis allows the direct diagnosis of uniparental disomy (UPD) even when UPD is not initially suspected. We report two patients referred for array analysis, who were diagnosed with paternal uniparental disomy of chromosome 14. Patient 1 presented at birth with bony abnormalities including "coat hanger" ribs and bony spurs emanating from the mental protuberance of the mandible and calcaneus. She died at 8 weeks of age secondary to respiratory distress. Patient 2 had a milder phenotype with only mild respiratory distress exacerbated by upper airway infections. Whereas the chest was only slightly bell-shaped on X-ray imaging, she exhibited similar bony spurs as patient 1 on the mandible and the calcaneus. Patient 1 had isodisomy of chromosome 14 based on homozygosity for the entire chromosome 14 on SNP array analysis. She had a normal 46,XX karyotype. Parental genotyping confirmed paternal isodisomy and these findings together indicate that UPD 14 arose by monosomy rescue. Presumably, this occurred secondary to maternal non-disjunction resulting in a nullisomic egg with subsequent duplication of the paternal chromosome 14. SNP array analysis of patient 2 revealed mosaic trisomy 14 in 20-25% of peripheral blood cells which was confirmed by chromosomal analysis. The presence of runs of homozygosity near the centromere and telomere indicated uniparental disomy in the diploid cell line which parental genotyping revealed was paternal. The uniparental disomy in this patient is both iso- and heterodisomic. In this case, UPD arose by trisomy rescue presumably secondary to nondisjunction in paternal meiosis with subsequent loss of the maternal chromosome. Clinically, these cases both demonstrate bony spurs, a previously unreported skeletal feature associated with paternal UPD 14. To our knowledge, this is the first report of calcaneal spurs in a genetic disorder and anterior bony spurs from the mandible have previously only been seen in frontometaphyseal dysplasia. These cases illustrate the heterogeneity both in the mechanism of formation of the UPD, as well as clinical heterogeneity, which may be explained in part by the mosaic trisomy for chromosome 14 in patient 2, in contrast to the pure paternal UPD 14 in patient 1. These cases highlight the utility of SNP array analysis to both diagnose UPD and to provide information about the mechanism by which these occur.

783/T

Accomulation of Iron in Mitochondria in Friedreich Ataxia may damage the mtDNA in this patients. *S. Sanjarian[1], M. Shafa shariat panahi[2], Z. Nourmohammadi[1], M. Naseroleslami[1], M. Houshmand[2,3].* 1) Science & Research branch Islamic Azad University, tehran, Iran; 2) National Institute of Genetic Engineering and Biotechnology , Tehran,Iran; 3) Special Medical Center,tehran, Iran.

Introduction:Friedreich ataxia is an autosomal recessive neudegenerative disorder caused by decreased expression of protein frataxin. The expansion of polymorphic GAA triplet repeat in the first inton may be caused by decreased frataxin expression by interfering with transcription. Frataxin deficiency leads to excessive free radical production and dysfunction of chain complexes. FRDA characterized by gait and limb ataxia, lower limbs areflexia, loss of joint position, cardiomyopathy, scoliosis. material and methods:We studied the frequency and the length of (GAA)(n) repeat in 25 Iranian patients (16 females and 9 males) from unrelated families (control= 50).DNA from each patient was extracted and frequency and length of (GAA)(n) repeat was analyzed using a long-range polymerase chain reaction (PCR) test. Also we investigated impact of GAA size on neurological findings, age of onset and disease development. In order to identify polymorphic sites and genetic background, the sequence of two hyper variable regions (HVR-I and HVR-II) of mtDNA was obtained from FA patients harboring GAA tri nucleotide expansions. We have found 13 mutations (T8614C,T8598C,C8684T, A8701G, G8994A, A9024G, G8251A, A8563G,G8584A, A3505, T3335C and G3421A) in tRNALeu and ND1 and tRNALys and ATPase gene in 20 patients and 80 control by PCR analysis. In other study in order to determine the exact number of GAA repeats in FRDA gene we used Fragment analysis. fragment analysis was used to investigate genotype and phenotype correlation. For this reason expand long PCR was used for amplification. We believed that fragment analysis is more helpful for: a) Carrier detection (even most patients are consanguinity marriage) b) Genotype and phenotype analysis. Results:Homozygous GAA expansion was found in 21 (84%) of all cases. In four cases (16%), no expansion was observed, ruling out the diagnosis of Friedreich's ataxia. Our results showed that the rate of D-loop variations was higher in FA patients than control (P<0.05). Only A9024G was reported for the first time. Fragment analysis determine exact number of GAA repeats and the result confirm that there was a significant inverse correlation between the average of two expansion size and age of onset of symptoms. Discussion:1) Because of Iron accumulation in mitochondria, it may damage to mtDNA. 2) for genotype phenotype correlation fragment analysis is a best method.

THE IMPORTANCE OF BIN-AURAL HEARNESS ON THE COGNITIVE DEVELOPMENT IN PEDIATRIC PATIENTS WITH UNILATERAL MICROTIC ATRESIA IN RELATION TO THE AUDITIVE REHABILITATION. *A.Diaz. Romero[1], Y. Peñaloza-Lopez[2], J.M. Aparicio-Rodriguez[3], S.I. Assia-Robles[4].* 1) Audiology, Hospital para el Niño Poblano; 2) Neurophisiology, Instituto Nacional de Rehabilitacion; 3) Genetics; 4) Pediatrics, Hospital para el niño Poblano.

Microtia also called microtia-anotia, is a congenital deformity where the pinna (outer ear) is very small and underdeveloped (microtia) or absent (anotia). It can be unilateral (one side only) or bilateral (affecting both sides). It occurs in 1 out of about 8,000-10,000 births. In unilateral microtia, the right ear is founded more often. It is known that microtia can have different phenotipical degrees; Grade I: A slightly small ear with identifiable structures and a small but present external ear canal. Grade II: A partial or hemi-ear with a closed off or stenotic external ear canal producing a conductive hearing loss. Grade III: Absence of the external ear with a small vestige structure and an absence of the external ear canal and ear drum conductive hearing loss. Grade IV: Absence of the total ear or anotia. Unilateral deafness was not generally considered a serious disability before the nineties; it was thought that the afected person was able to adjust to it. In general, there are very good advantages to gain from an intervention to enable hearing in the microtic ear, especially in bilateral microtia. Patients with untreated unilateral hearing loss are eight to ten times more likely not to hear. However, with unilateral deafness often require years of speech therapy. Aural atresia is commonly associated with microtia. Atresia occurs because patients with microtia may not have an external opening to the ear canal, though the cochlea and inner ear are usually present. The grade of microtia is in relation to the development of the middle ear. Microtia is found isolated, but may occur in conjunction with hemifacial microsomia, Goldenhar Syndrome or Treacher-Collins Syndrome. Microtia1,2 can cause difficulties with life. It is also occasionally associated with syndromes as mentioned before that can cause, kidney problems, and jaw problems, and more rarely, heart defects and vertebral deformities. It is important the highly experienced audiologist for a better evolution of thge patient. It must be difficult that many surgeons believe that ear canal reconstruction is unnecessary and over complicated and that very good hearing is possible with modern hearing aids which can be hidden under the skin. Microtia eitology has been associated to vascular deficiency that is in relation to sporadic cases rather than inherited. Several teratogens have been associated as Talidomida, retinoic acid, alcohol and diabetes.

785/T

Spondylospinal thoracic dysostosis, a new case with the longest survival. *L. Becerra-Solano[1,2], D. Morales-Mata[2], E. Monroy-marquez[2], L. Chacon-Alcaraz[2], Y. Rufino-Serralde[2], J. García-Ortiz[1], M. Ramirez-Dueñas[1].* 1) Div Genetica, CIBO-IMSS, Guadalajara, Jalisco, Mexico; 2) CRIT Chihuahua, Fundación México.

In 1997, Johnson et al. described the Spondylospinal thoracic dysostosis (STD, OMIM 601809) in two related sibs with dwarfism, short thorax, and curved spine; fusion of the vertebrae and spinal process; multiple pterygium and arthrogryposis. They postulated an autosomal recessive mode of inheritance and considered this entity as a lethal condition due to stillbirth of one patient and early death of the second one. Clinical report. A female patient 15 years-old, was evaluated by dwarfism, severe dorsal lordosis, and multiple pterygium. She was product of the second uneventful pregnancy from healthy non consanguineous parents (mother 41 and father 39 years-old). She was delivered by cesarean section. At birth her weight was 2850 g (10-25 centile), no Apgar score was recorded but spontaneous cry was referred. Psychomotor development was notoriously delayed. Physical examination: Height 93 cm (-3 centile), weight 23.2 cm (-3 centile), OFC 54 cm (70 centile); dolichocephaly, bitemporal narrowing, high forehead, left facial hemi-hypoplasia, up-slant palpebral fissures, telecanthus, high nasal bridge and broad nasal base, anteverted nares, short columella, thick lips, short lingual frenulum, micrognathia; posteriorly rotated ears; short neck with hyperextension, short and wide thorax; external genitalia pubic hair Tanner 4 and hypoplastic labia majora; upper limbs with limitation of extension and pronosupination due to elbow pterygium, and partial cutaneous syndactyly; lower limbs in abduction with popliteal pterygium, both patella were not palpable, overlapping of second over first toes, and bilateral brachydactyly of 4th and 5th toes. X-ray examination and 3D reconstruction showed: advanced pneumatization of paranasal sinuses; short and wide thorax, crowded and gracile ribs; multiple fusions of vertebral bodies and spinal processes, hyperextension of cervical-dorsal column and lumbar hyperlordosis (both angle of approximately 90=BA); narrow hip, hypoplastic and vertically placed pelvic bones, wide pubic simphysis, and the presence of a hole on the central portion of iliac bones; also fusion of carpal and tarsal bones were appreciated. Discussion. STD is a rare MCA entity mainly characterized by vertebral defects, thoracic anomalies, and multiple pterygium. Here, we described a female patient of 15 years of age, whom probably would be considered as the eleventh case of this entity and interestingly the one with a longer survival period.

786/T

Fibular Aplasia in Acro-Cardio-Facial Syndrome: expanding phenotypic spectrum in search for causative gene(s). *D. Niyazov[1], R. Monier[1], L. Finger[1], H. Ginsberg[1], A. Kenney[2], B. Canzoneri[3].* 1) Dept Pediatrics, Ochsner Clinic Foundation, New Orleans, LA; 2) Dept Radiology, Ochsner Clinic Foundation, New Orleans, LA; 3) Dept Maternal & Fetal Medicine, Ochsner Clinic Foundation, New Orleans, LA.

Acro-cardio-facial syndrome (ACFS) is a rare disorder which includes split-hand/foot malformation (SHFM), cleft lip/palate (CL/P), cardiac defects, dysmorphic features, genital anomalies and mental retardation. To our knowledge, only 6 cases have been published to date. We report a new patient with the characteristic features of ACFS, and bilateral fibular aplasia which has not been previously described. The male proband was born with unilateral CL/P, hypoplastic left heart and atrial septal defect, single umbilical artery and lower limb deformities. His karyotype on amniocytes was negative. In addition, he had sparse scalp hair, dysmorphic facies and ears, unilateral CL/P, hypoplastic nipples and genitalia with bilateral cryptorchidism. His multiple lower limb anomalies included an absent left hallux, SHFM of the right foot with absent right toes T3-4, severe bilateral limb shortening and equinovarus deformities. The patient died at 6 days of life from cardiac complications. Postmortem xray revealed the right anterior femural bowing, bilateral fibular aplasia, absence of the 3rd and 4th rays on the right and the 4th ray on the left. Total body MRI with 3D reconstruction revealed no anomalies in the brain or abdomen. His 105K oligo array was negative and the TP63 gene is currently being sequenced. Etiology of ACFS is currently unknown. To our knowledge, fibular aplasia (FA) as seen in our patient, has not been previously described in ACFS. FA or FA with ectrodactyly may be a part of the phenotypic spectrum of ACFS which can help identify more genes important in limb patterning. For instance, the TP63 gene has been implicated in ectrodactyly, ectodermal dysplasia and CL/P syndrome (EEC). The proband had SHFM, hypoplastic nipples and toenails, sparse scalp hair, and CL/P. Genital anomalies have also been reported in EEC. While cardiac anomalies are rare the TP63 mutation R298Q was reported in a patient with arrhythmogenic right ventricular cardiomyopathy and a possible role of the TP63 in the heart development was explored. This gene encodes 6 protein isoforms and is highly expressed in many organs including the heart. It may enhance the ability of cardiac tissue to resist mechanical stress by promoting the stable assembly of desmosomal adhesive complexes. In conclusion, discovery of additional anomalies in ACFS may aid in identification of causative gene or interaction of several genes variably affecting multiple organ systems.

787/T

Association of Lactotransferrin Gene Polymorphisms with Risk of Aggressive Periodontitis. *C. Chou[1,2], F. Kuo[1,2], C. Brooks[3], C. Huang[1], J. Burmeister[3], H. Schenkein[3], S. Diehl[1,2].* 1) Health Informatics, UMDNJ-School of Health Related Professions, Newark, NJ; 2) Center for Pharmacogenomics and Complex Disease Research, UMDNJ-New Jersey Dental School, Newark, NJ; 3) Clinical Research Center for Periodontal Diseases, School of Dentistry, Virginia Commonwealth University, Richmond, VA.

Periodontitis, an inflammatory disorder of the periodontium caused by microorganisms, is one of the most common oral infectious diseases. Aggressive periodontitis (AgP) is further subdivided as generalized (GAgP) or localized (LAgP) and affects 2% of the African American population after puberty and may lead to premature tooth loss. Lactotransferrin (LTF) is a protein present in saliva with bactericidal function and can inhibit bacterial growth and attachment to epithelial cells. LTF can also inhibit cytokine production through interference with NF-kB activation, a primary cause of inflammation. Thus, it is reasonable to believe LTF gene may be involved with the development of periodontitis. This work aims to investigate the association between polymorphisms of the LTF gene and aggressive periodontitis. A total of 428 African American subjects were recruited from the Richmond, Virginia area. One hundred and eighteen subjects with GAgP, 112 with LAgP and 198 healthy controls were genotyped for four single nucleotide polymorphisms (SNPs) in the LTF gene by using TaqMan genotyping assay (Applied Biosystems). One SNP is located in the 5' region, and three are non-synonymous SNPs that alter the amino acid coded in the mature protein. The difference in the genotype frequencies between patients and controls was calculated under dominant, recessive and additive model by Fisher's exact test and the Armitage trend test. To control for potential confounding effects, gender, age and smoking status were included as covariates in logistic regression analyses. Statistical analyses were performed using SAS software. SNP rs1126478 that codes for a Lys/Arg polymorphism showed evidence of association with LAgP under dominant and additive models (p=0.019 and p=0.021, respectively). The Lys allele was more common in cases, indicating this variant may be associated with increased risk of this disease. No association was found between any of the evaluated LTF polymorphisms and GAgP. Further investigations including with functional studies of gene and proteins, are needed to support this conclusion. Supported by the Foundation of UMDNJ and NIDCR grants DE13102 and DE016057.

ALX3 gene is not associated with the syndrome of midline facial defects, callosal agenesis, basal encephaloceles, and eye anomalies. *R.G. Quiezi, A. Richieri-Costa, S.P Barros, L.A. Ribeiro.* Genetics, Hospital for Rehabilitation of Craniofacial Anomalies/USP, Bauru, Brazil.

Frontonasal dysplasia (FND) is the hallmark of several syndromes involving the frontonasal process that includes: isolated frontonasal dysplasia, acrofrontofacionasal dysostosis 1, acrofrontofacionasal dysostosis 2, frontofacionasal dysplasia, oculoauriculofrontonasal syndrome, among other related conditions. One of the syndromes within this spectrum comprises of the syndrome of midline facial defects, callosal agenesis, basal encephaloceles, and eye anomalies. It has been described under different eponyms, most commonly the morning glory syndrome. The anomalies observed in the present condition are embryological related, occurring in the same critical period of time, most likely during the early induction of the forebrain, resulting in anomalies involving frontonasal process, midfacial structures as well as the primordium of the eyes. Several genes are known to exert effects during this period resulting in different craniofacial anomalies. Up to now there is no evidence of any particular gene involved in etiology of the reported condition within the FND spectrum. The chromosome 1 interval contained a strong candidate gene, ALX3; related to the aristaless gene in Drosophila. This gene, located in band 1p13.3, encodes the ALX homeobox 3 transcription factor, a member of the Paired class of homeodomain proteins. Previous studies of the murine ortholog, Alx3, had demonstrated strong expression in the frontonasal mesenchyme. Although the phenotype of Alx3_/_ mice was normal, a cleft face occurred when these homozygotes were additionally mutant for the paralogous gene Alx4. Mutations in ALX3 have been found in patients with frontorhiny phenotype. We amplified each of the four exons of ALX3 and subjected the products to DNA sequencing in 8 patients presenting midline facial defects, callosal agenesis, basal encephaloceles, and eye anomalies. No sequence variation was identified in this analysis. We conclude that ALX3 mutations are not associated with the reported condition within the FND spectrum. Grants: CNPq (307595/2008-0).

Epistasis between Folate Genes contributes to the Genetic Risk for Non-syndromic Cleft of the Hard Palate. *M. Rubini[1], M. Ferrian[1], C. Baluardo[1], L. Marullo[1], D. Balestra[1], S. Bruni[1], E. Calzolari[1,2], A. Franchella[2].* 1) Dip. MSD Sez. Genetica Medica, Universita' di Ferrara, Ferrara, Italy; 2) Dip. Riproduxzione e Accresciment6o, Az. Ospedal. Sant'Anna, Ferrara, Italy.

During embryogenesis folate metabolism is a critical component for the development of orofacial structures, especially for those deriving from neural crests. Cleft palate only (CPO) and cleft lip with/without cleft palate (CL/P) are common congenital malformations with an overall birth prevalence of 1:700. Most of orofacial clefts are non-syndromic (NS-OFCs), and are considered disorders of multifactorial origin. Epidemiologic evidence indicate that folic acid (FA) supplementation during early pregnancy significantly reduces the risk for NS-OFCs, while association studies suggest that the risk for NS-OFC is influenced by polymorphisms in genes of folate metabolism and transport. It is generally accepted that altered metabolic balance of folate in the embryo, resulting from interaction between functional variants in folate genes and B vitamins bioavailability, could contribute to the risk for NS-OFCs. The genetic basis of folate unbalance underlying NS-OFC is likely to be the outcome of complex epistatic interactions, rather than be due to single gene variants. So far very little is known about the etiology of non-syndromic CPO (NS-CPO), but a number of evidence suggest that In order to track down the network of gene-gene interactions that could lead to folate unbalance and contribute to the risk for NS-CPO we have studied a wide panel of polymorphisms in genes of folate metabolism in a group of NS-CPO nuclear families of Italian origin (Italcleft study). Using Multifactorial Dimensionality Reduction (MDR) we identified a redundant interaction between variants in MTRR and MTHFS genes. This epistasis was specific for cases with cleft of the hard palate (CPH), and was associated with a significant increased risk. This evidence suggests that cleft of the hard palate and cleft of the soft palate should be considered conditions with different etiology, and that folate unbalance could be a specific pathogenetic component of cleft of the secondary palate. Our results, if confirmed in an independent study, would support the hypothesis that complex epistatic interactions between variants in folate genes contribute to the pathogenesis of non-syndromic cleft of the hard palate, and pave the way toward new preventive and diagnostic measures for this congenital malformation.

Association of CARD8 with IBD in Koreans. *K. Song[1], H. Kim[1], M. Hong[1], S. Yang[2].* 1) Dept Biochem & Molec Biol, Univ Ulsan Col Medicine, Seoul, Korea; 2) Dept. Internal Medicine, Univ Ulsan Col Medicine, Seoul, Korea.

Caspase recruitment domain (CARD)-containing protein 8 (CARD8) is an attractive candidate risk gene for IBD because of its location within inflammatory bowel disease (IBD) locus and its role as a nuclear factor (NF) kappaB inhibitor. A recent report that NOD-2 mediated signaling is negatively regulated by CARD8 in intestinal epithelial cells supports its candidacy for IBD susceptibility gene. However, previous studies have yielded mixed results in the association of a CARD8 nonsynonymous SNP, rs2043211, which changes a cysteine residue to a stop codon at amino acid 10, with IBD in Caucasians. The aim of this study was to test the genetic association of the CARD8 nonsynonymous SNP rs2043211 with Korean ulcerative colitis(UC) and Crohn's disease(CD) patients. We tested rs2043211 of CARD8 in 659 UC, 632 CD, and 687 healthy controls. Rs2043211 showed 5.5 % difference in allele frequency between the UC and control groups, while the difference between the CD and control groups was 1.2%. Logistic regression analysis revealed that rs2043211 was associated with UC significantly. The odds ratio of the rare stop allele homozygote (TT) in comparison with the combined genotype of AA and AT was 1.54 (95% CI, 1.17 - 2.04, P = 0.002). Our data suggests that the CARD8 variants might play a role in the pathogenesis of IBD in the Korean population.

791/T

Recurrent left atrial myxomas in female patients with Carney complex: a genetic cause of multiple strokes in young adults that can be prevented. *G. Briassoulis[1], MS. Popovic[2], P. Xekouki[1], N. Patronas[3], V. Vukomanovic[2], V. Kuburovic[2], M. Keil[1], CA. Stratakis[1].* 1) NICHD, SEGEN,National Institutes of Health, Bethesda, MD; 2) Mother and Child Healthcare Institute New Belgrade, Serbia; 3) Department of Radiology, Clinical Center, National Institutes of Health, Bethesda, MD, USA.

Background: Intracardiac myxomas in the autosomal dominant syndrome Carney complex (CNC) are significant causes of cardiovascular morbidity and mortality through embolic stroke and heart failure. The genetic, clinical and laboratory characteristics of CNC-related strokes from atrial myxomas have not been described before. The PRKAR1A gene is mutated in more than 60% of the cases of CNC. Methods and Results: We studied patients with strokes and cardiac myxomas that were hospitalized in our institution and elsewhere out of a total of more than 500 patients with CNC worldwide: a total of 7 patients with 16 recurrent atrial myxomas and more than 14 episodes of strokes were indentified. Neurological deficits were reported; in one patient, an aneurysm developed at the site of a previous stroke. All patients were female, most of them had presented with Cushing syndrome and all had additional tumors or other CNC manifestations. Although there was a trend for patients being overweight and hypertensive no other abnormalities or risk factors were identified. A total of 5 patients (71%) had a PRKAR1A mutation. All detected mutations (c418_419delCA, c.340delG/p.Val113fsX15, c.353_365del13/p.Ile118fsX6, c.491_492delTG/p.Val164fsX4, c.177+1G>A) were located in exons 3-5 and introns 2-3, and all led to a non-sense PRKAR1A mRNA. Conclusions: Among CNC patients, recurrent atrial myxomas that lead to multiple strokes appear to primarily develop in female patients. Cushing syndrome may be a risk factor that increases the possibility of multiple strokes (Cushing syndrome is more frequent among females with CNC). Early identification of a female patient with CNC either through the application of the diagnostic criteria or through PRKAR1A sequencing (genetic testing) is of paramount importance for the early diagnosis of atrial myxomas and the prevention of strokes.

792/T

Multisynostotic Osteodysgenesis (Antley-Bixler Syndrome). Three years follow-up in a new patient with a very severe form due the mutation c.870G>T (W290C) in the exon IIIa of FGFR2 gene. *M.L. Giovannucci Uzielli[1, 2], G. Scarselli[1], L. Di Medio[2], N. Dayan[2], D. Nannini[2], S. Guarducci[3], E. Gambineri[1].* 1) Dept Paediatrics, Univ Florence, Viale G. Pieraccini 24, 50139, Firenze, Italy; 2) Genetic Science, Piazza G. Savonarola 11, 50132 Firenze, Italy; 3) Meyer Children's Hospital, Viale G. Pieraccini 24, 50139 Firenze, Italy.

Antley-Bixler syndrome (ABS), first described in 1975 in a patient with craniosynostosis, midfacial hypoplasia, arachnodactyly, radiohumeral synostosis and femoral bowing, is a very rare condition. With now a little more than 50 published cases, ABS has evolved as a clinical entity over the past three decades. The clinical and RX phenotype has expanded to include many other characteristic abnormalities, and more or less severe phenotype, often responsible for early death. The proband was born at 34 weeks EGA from a 28year-old woman. Healthy non-consanguineous parents, and a normal brother. Amniocentesis revealed 46,XY normal male. Polyhydramnios from the second trimester, was not well investigated. Several examinations with ultrasounds only revealed bilateral fetal exophthalmos at 33 weeks gestation. Delivery was by C-section. Initial examination at birth, and postnatal clinical and RX studies revealed a severe abnormal phenotype: multiple, premature craniosynostosis, increased biparietal diameter, midfacial hypoplasia, depressed nasal bridge, bilateral choanal stenosis, and severe proptosis. The extremities had, and still have, multiple joint contractures, more severe in the elbow due to radiohumeral synostosis. Three, consecutive, craniotomies with craniofacial correction, were not able to control the progressive exophtalmos, and to improve the breathing: ocular globe was enucleated at age two years, and tracheotomy, performed few days after birth, is still essential. Intellectual and social performances are not assessable. Steroidogenesis and Sterol metabolism are normal. The external genitalia are normal. The mother didn't use Fluconazole during the pregnancy. By direct sequencing of the Fibroblast Growth Factor Receptor 2 (FGFR2) gene, we identified the mutation c.870G>T (W290C) in the exon IIIa.

793/T

A familial case of Goltz-Gorlin syndrome. *L. Wong-Ley[1 2], S. Hernández-Córdova[1], E. Lechón-López[1], M. Messina-Robles[1 2], J. González-Zapata[1 2], M. Pérez-Nuño[2], L. Medina-Carrillo[1 2], A. Flores-García[2].* 1) Dept Gen, SSN-IMSS, Tepic, Mexico; 2) Dept Gen, UAN, Tepic, México.

In 1960 (1), Gorlin and Goltz gave a complete description of the Goltz-Gorlin syndrome (OMIM #305600). A systemic dysplasia of mesodermal and epidermal structures characterized by underdevelopment of the dermal connective tissue and various anomalies in the ocular and skeletal systems. (2). In 2007 mutations in the PORCN gene were found to be causative in Goltz-Gorlin syndrome (3), presents a quite variable estimated prevalence, which goes from 1 in 57.000 to 1 in 256.000 habitants (4). The present report is that of three women with the syndrome, a 29-year-old female, her 50-year-old mother and her daughter deceased to the birth. The three patients had similar clinical symptoms, phenotype characterized by microcephaly, protruding ears with thin pinnae, small orbits with overriding eyelids, microphthalmia, agenesis of the incisors, sensorineural and conductive hearing loss, upper extremities with bilateral syndactyly and camptodactyly, lower limbs with bilateral clinodactyly and ectrodactyly, lobster-clawing with equinovarus deformity. Linear areas of dermal hypoplasia, linear hypopigmentation with dermal hypoplasia, telangiectasias, dysplasia of the hair and nails, mental retardation and inguinal hernias. Examination of the cardiovascular and respiratory system was normal. All the haematological and biochemical studies carried out were normal. X-ray examination showed several skeletal malformations such as hypoplasia of the craniofacial skeleton, winged shoulder, pectus excavatum, defects of segmentation of the vertebrae, dorsal scoliosis and lumbar kyphosis. Chromosome analyses were normal females (46,XX). The genealogical analysis showed autosomal-dominant or sex linked dominant mode of inheritance. There were no other affected relatives. A diagnosis familial Goltz-Gorlin syndrome was made on the basis of clinical and imaging findings. The intention of this paper is to present three cases of Goltz-Gorlin syndrome, diagnosed in the dermatology, gynecology y genetics department of the Civil Hospital of Tepic, Nayarit, México. A Silver-Russell syndrome patient with 22q13.3 deletion and H19-DMR epimutation. *E. Nishi[1], S. Mizuno[1], K. Yamzawa[2], T. Ogata[2].* 1) Department of Pediatrics, Central Hospital, Aichi Human Service Center, Kasugai, Japan; 2) Department of Molecular Endocrinology, National Research Institute for Child Health and Development, Tokyo, Japan.

Introduction 22q13.3 deletion syndrome (MIM606232) is characterized by overgrowth, muscle hypotonia, severe speech retardation, and autism-like behavioral features, whereas Silver-Russell syndrome (SRS, MIM180860) is characterized by pre- and postnatal growth retardation, relative macrocephaly, muscle hypotonia, difficulty in suckling, and body asymmetry. Here we report a girl with SRS who has chromosome 22q deletion and H19-DMR epimutation. Patient This Japanese female patient was conceived naturally without any remarkable family history. In 34 weeks of gestation, asymmetrical IUGR was indicated. She was born at 37 weeks of gestation with a height of 40.5 cm (-3.8SD), a weight 1,342 g (-3.8SD), and a cephalic circumference 32.0 cm (-0.5SD). Relative macrocephaly, triangular face, short clinodactyly of the bilateral fifth fingers, muscle hypotonia, right hydronephrosis, and leg length discrepancy were observed at birth. Tube feeding was required during the neonatal period. At 2-year-and-4-month-old, her height is 77.5 cm (-3.0SD), weight 6.03 kg (-4.3SD), and cephalic circumference 45.8 cm (-1.0SD). Both cervical and sitting positions remain incomplete, and she crawls on her back. Severe speech delay has been noted, and severe psychomotor retardation is present. G-banding stain showed 46,XX,del(22)(q13.3q13.3). Subtelomere FISH analysis did not identify any chromosomal disturbances including 22q. A CGH array (Agilent, 244 k) test showed a decrease in the copy number of 22q13.2 to q13.33, suggesting that intra-arm deletion at approximately 7 Mb involving SHANK3. In addition, she was diagnosed with SRS based on the clinical symptoms. Methylation analysis revealed H19-DMR hypomethylation, whereas maternal uniparental disomy for chromosome 7 was not identified. Discussion To our knowledge, no case of SRS with 22q13.3 deletion has reported thus far. Although 22q13.3 deletion and H19-DMR epimutation appear to develop independently, a relationship between these two events remains to be elucidated. In our case, symptoms characteristic of SRS were marked at birth, and subsequently severe language development retardation characteristic of 22q13.3 deletion syndrome has become apparent since 2 years of age. In view of the fact that the site of deletion involves SHANK3 gene which is associated with autism spectrum disorders, further developmental follow-up is required.

795/T

Craniotelencephalic Dysplasia. A rare and unusual form of Dysplasia of Frontal Bone. *G. Scarselli[1], L. Di Medio[2], E. Gambineri[1], N. Dayan[2], D. Nannini[2], M.L. Giovannucci Uzielli[1, 2].* 1) Dept Pediatrics, Univ Florence, Firenze, Firenze, Italy; 2) Genetic Science, Florence, Italy.

Craniotelencephalic Dysplasia (OMIM 218670) was firstly described in 1958 by Daum, LeBeau and Minuit in an infant with protrusion of the frontal bone, craniosynostosis, encephalocele, and mental retardation. A second patient with a similar appearance, but no encephalocele, was described in 1964 by Jabbour and Taybi, and the term craniotelencephalic dysplasia was suggested. In the literature we only found three other reports, by G.R. Hogan (1969), Holmes et al (1972), and Gorlin et al. (2001). All described patients were newborns. Here we report a new patient observed since the birth and periodically studied by a 17 years multidisciplinary follow-up. At birth, this patient, a female, showed protuberance of frontal bone, and premature closure of sagittal, coronal, and metopic sutures, corrected by multiple surgery operations. Staturo-ponderal and psychomotor development were quite normal. Of special interest are now the dental problems with progressive, abnormal, placement, shape, and size of teeth. The intellectual development is within the average, but the girl expresses, especially in the last two years, psychosocial discomforts, in spite of the very good results of multiple aesthetic surgery reconstructions. No genes were until now associated with this disorder. A suggestion to the mutational analysis of EFNB1 in our patient, originates from the observation of vertical splitting and striping of the nail of first toe: this clinical aspect is typically described in Craniofrontonasal dysplasia (CFNS), a well known genetic disorder caused in the majority of patients by mutations of EFNB1 gene. The mutational analysis of this gene, often deleted, as part of contiguous gene deletions is in progress. High resolution cytogenetic analysis of G-banded metaphases (550-750 bands) from peripheral blood lymphocytes revealed a normal 46,XX karyotype.

796/T

Follow-up and Management of Young-Simpson Syndrome. *K. Enomoto[1], N. Furuya[1], M. Adachi[2], S. Mizuno[3], Y. Yamanouchi[4], M. Masuno[4], T. Kondoh[5], K. Kurosawa[1].* 1) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 2) Division of Endocrinology and Metabolism, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Pediatrics, Aichi Prefectural Colony Central Hospital, Kasugai, Aichi, Japan; 4) Kawasaki University of Medical Welfare, Okayama, Japan; 5) Institute for The Handicapped, Mutsumi Home, Misakaeno-sono, Nagasaki, Japan.

Young-Simpson syndrome (YSS) is a rare congenital multi-system disorder, characterized by hypothyroidism, facial dysmorphic features including blepharophimosis, congenital heart defects, and mental retardation. Following the first report by Young and Simpson [1987], many cases with similar symptoms have been reported. Although there is a case with parental consanguinity [Bonthron et al., 1993], suggesting autosomal recessive (AR) inheritance, almost all the cases with YSS are sporadic. In addition, there are few distinct chromosomal aberrations associated with YSS. To date, the underlying genetic defect remains unresolved. The clinical classification or diagnostic criteria of this rare condition is also unsettled. To refine the long-term development and phenotype in YSS, we report clinical findings in 5 individuals (4 males and a female) presenting just typical features of YSS. They are ranging in age 2 months to 20 years. All of them present hypothyroidism requiring levothyroxine replacement and severe mental retardation, especially speech delay. All 4 male patients present bilateral cryptorchidism and micropenis. Ptosis and blepharophimosis were obvious in the neonatal period, so that parents were not able to confirm their babies' eyes open at all. Hypotonia and feeding difficulty in early infancy are common features. Skeletal complications including contracture, dislocation, and deformation of lower limbs are common to our cases. 18-year-old male patient has been requiring several operations for ankle joint deformations and femoral head osteonecrosis. As information about orthopedic complications and problems during the neonatal period of YSS is so limited, the long-time follow-up and the management are important for health and quality of life (QOL) in YSS. These observations support the idea that YSS is a distinctive entity and a recognizable disorder of newborn.

797/T

Ectodermal Dysplasia, Vertebral Anomaly, Hirschsprung Disease, Growth and Mental Retardation: A Clinical Report of a Boy with BRESEK Syndrome. *S. Mizuno[1], M. Oshiro[2], M. Seishima[3], N. Okamoto[4], Y. Makita[5], N. Wakamatsu[1].* 1) Dept Pediatrics, Central Hosp, Aichi Human Service Ctr, Kasugai, Japan; 2) Dept Pediatrics, Ogaki Municipal Hosp, Ogaki, Japan; 3) Dept Dermatology, Ogaki Municipal Hosp, Ogaki, Japan; 4) Dept Clinical Genetics,Osaka Medical Ctr and Research Institute for Maternal and Child Health, Izumi, Japan; 5) Education Center, Asahikawa Medical College, Asahikawa, Japan.

We present the case of a boy with multiple anomalies, including Hirschsprung disease and specific features of the skin, vertebrae anomaly and mental/growth retardation. The patient's gestalt and combination of multiple malformation are rather similar to previously reported BRESEK syndrome. We report this congenital malformation complex as an established syndrome. The patient was born to healthy parents without consanguinity. The pregnancy was complicated with mild oligohydramnios. He was born at 38 weeks and weighed 1996g. He exhibited generalized alopecia with absence of scalp hair, eyebrows, and eye rashes. He had malformed large ears and an inferiorly curved penis and bifid scrotum. The testicles was not palpated. He experienced persistent constipation, and Hirschsprung disease was confirmed by rectal biopsy. Congenital scoliosis in this patient was attributable to an hemivertebrae. Brain imaging revealed dysmorphology of the gyrus in the fronatal and parietal lobes. Right kidney of the patient was small. The entire skin constantly desquamated and erythematous. Skin biopsy revealed a reduced number of hair follicles and units and excessive keratinization. The patient exhibited a moderate to severe delay in psychomotor development. Intractable epilepsy persited in his infancy. Genetic analysis: G-banded chromosome analysis and genome-wide subtelomere FISH analysis did not show any chromosomal rearrangements. Mutation analysis of *ZEB2*, causative gene for Mowat-Wilson Syndrome, was performed on genomic DNA from the patient and no mutation was detected. No copy number changes were found in the genome of the patient using array CGH analysis. Discussion: Our present case is assumed to be identical to the second case by Reish. Reish et al. used the acronym BRESEK /BRESHECK to denote the following findings in their patients: brain anomalies, retardation, ectodermal dysplasia, skeletal deformities, Hirschsprung disease, ear/eye anomalies, cleft palate/cryptorchidism, and kidney dysplasia/hypoplasia. Although this combination is specific, only 3 articles concerning this syndrome could be retrieved in PubMed search. Simultaneous occurrences of Hirschsprung disease, Vertebrae anomaly, Ectodermal dysplasia, Retardation of Growth and Mentality are the main features for this syndrome. The standard CGH-array analysis did not reveal any changes in the copy number within the genome of the patient. Further case reports will help in delineating this disorder.

798/T

Associated malformations in cases with neural tube defects. *C. Stoll, B. Dott, Y. Alembik, M-P. Roth.* Faculte de Medecine, Strasbourg, France.

Infants with neural tube defects (NTDs) may have other associated congenital defects. The reported incidence and the types of associated malformations vary between different studies. The purpose of this investigation was to assess the prevalence of associated malformations in a geographically defined population. The prevalences at birth of associated malformations in infants with NTDs were collected between 1979 and 2008 on all infants born in the area covered by the registry of congenital anomalies of Northeastern France in 402,532 consecutive births. Of the 441 infants with NTDs born during this period, representing a prevalence at birth of 10.9 per 10,000, 20.4 % had associated malformations. The associated cases were divided into recognized syndromes, chromosomal: 11 cases (2.5%) and non chromosomal: 23 cases (5.2%), and non recognized syndromes, multiply malformed: 55 cases (12.5%). Associated malformations were more frequent in infants who had encephalocele (36.8 %) than in infants with anencephaly (11.5 %) or infants with spina bifida (23.8 %). Malformations in the face (oral clefts), in the musculoskeletal system, in the renal system, and in the cardiovascular system were the most common other anomalies. In conclusion the overall prevalence of malformations, which was one in five infants, emphasizes the need for a thorough investigation of infants with NTDs. A routine screening for other malformations especially facial clefts, musculoskeletal, renal and cardiac anomalies may need to be considered in infants with NTDs, and genetic counseling seems warranted in most of these complicated cases.

799/T

Replication of genome wide association findings for Cleft Lip and Palate a role for variants in MAFB, VAX1 and PAX7 in Asian populations. *S. Suzuki[1,2,3], ML. Marazita[4,5], ME. Cooper[4], E. Dragan[1], A. Butali[1], M. Mansila[1], N. Nagato[2], Y. Suzuki[2], T. Niimi[2], M. Yamamoto[3], G. Ayanga[8], T. Erkhembaatar[8], H. Furukawa[2], K. Minami[2], H. Imura[2], K. Fujiwara[2], J. L'Heureux[1], K. Durda[1], AC. Lidral[1], JC. Murray[1,6,7].* 1) Dept of Pediatrics, Univ Iowa, Iowa City, IA; 2) Division of Research and Treatment for Oral and Maxillofacial Congenital Anomalies, School of Dentistry, Aichi-Gakuin University, 2-11 Suemori-Dori, Chikusa-Ku, Nagoya 464-8651, Japan; 3) Faculty of Psychological and Physical Science, Aichi-Gakuin University; 4) Center for Craniofacial and Dental Genetics, and Dept of Oral Biology, and Dept of Human Genetics, Univ of Pittsburgh, Pittsburgh, PA; 5) Dept of Psychiatry, Univ of Pittsburgh, Pittsburgh, PA; 6) Dept of Pediatric Dentistry, Epidemiology and Biology, univ of Iowa, Iowa City, IA; 7) College of Nursing, University of Iowa, Iowa City, IA; 8) Maternal and Children's Health Research Center Hospital, Ulaanbaatar, Mongolia.

Nonsyndromic cases of cleft lip with or without cleft palate (NSCL/P) and cleft palate only (NSCPO) are among the most common human birth defects caused by both genetic and environmental factors and/or by their cross talks. Recent genome-wide association studies discovered multiple loci such as MAFB, VAX1 and PAX7 associated with NSCL/P. In order to replicate the association of these genes in other populations, we used independent case-parents samples from Mongolia (204 case-parents trios) and Japan (98 case-parents trios). We genotyped single nucleotide polymorphisms (SNPs) in or near VAX1, MAFB and PAX7 using TaqMan assays which were performed used in GWAS study by Beaty, T. et al. (2010). Transmission disequilibrium tests were performed using the Family Based Association Test and PLINK programs. In Mongolian trios, potential candidate gene makers showed significant association (VAX1, rs7078160, p=5.32E-05, and MAFB, rs13041247, p=0.00108). In Japanese trios, one marker showed significant association (VAX1, rs 7078160, p=0.00511). This study suggests that VAX1 and MAFB are either directly or indirectly involved in the etiology of NSCL/P in Asian populations. This replication study further supports the role of common causative genes among different populations.

800/T

An array-based approach to detect copy number changes in *SHOX* and other stature-associated genes in children with idiopathic short stature. *J. Keefe[1], P. Crotwell[2], S. Kirmani[1], G. Velagaleti[3], A. Lteif[1], L. Davis-Keppen[2], A. Karmazin[2], E. Thorland[1].* 1) Mayo Clinic, Rochester, MN; 2) Sanford Clinic USD Genetics Laboratory, Sanford Children's Hospital, Sioux Falls, SD; 3) Pathology Department, University of Texas Health Sciences Center, San Antonio, TX.

Idiopathic short stature (ISS) is defined as apparently isolated short stature with no other obvious clinical signs. Short stature is a developmental, multifactorial condition with a strong genetic background involving several genes. One such gene is the short-stature homeobox containing gene (*SHOX*) which maps to the pseudoautosomal region on chromosome Xp. The true frequency of *SHOX* gene mutations, including deletions of the coding region and deletions of upstream and downstream coding elements, in ISS is not known. It was our aim to utilize array comparative genomic hybridization (aCGH) technology to create a 'short stature' chip targeting the *SHOX* gene and other pertinent stature-related genes to gain a better understanding of the frequency of copy number changes contributing to short stature in ISS patients. An Agilent custom 8x60k array was designed to interrogate the *SHOX* gene and its regulatory regions, the Xp/Yp pseudoautosomal region, and 108 other genes implicated in short stature with high-density probe coverage. Following IRB approval and informed consent, the blood samples of 200 ISS patients are being collected. These patient samples are being tested using the custom aCGH chip and relevant copy number changes will be analyzed. Currently, there is no consensus on which subset of patients with ISS should be offered genetic testing. This study will allow us to determine the frequency of copy number changes in patients with ISS and help determine an appropriate testing algorithm for the evaluation of these patients.

Building up a genetic approach of nonsyndromic orofacial clefts in Alagoas, Brazil. *M.I.B. Fontes[1], V.L. Gil-da-Silva-Lopes[2], K.M. Santos[1], J.I. Vieira-Filho[1], F.S. Anjos[1], I.L. Monlleo[1,3], Alagoas' Cleft Team.* 1) Departament of Pediatrics, State University of Alagoas, Maceio, Alagoas, Brazil; 2) Departament of Medical Genetics, University of Campinas, Campinas, Sao Paulo, Brazil; 3) Clinical Genetics Unit, University Hospital Federal University of Alagoas, Maceio, Alagoas, Brazil.

There are regional disparities in public healthcare for patients with orofacial clefts in Brazil. This situation is much worse in poorest states such as Alagoas. There is just one clinical genetics unit and clinical geneticist for 3 million of inhabitants in this region and none specialized centre for orofacial cleft care. This study profiles nonsyndromic orofacial clefts (NSOC) of patients from this area. From September to December 2009, 53 families with NSOC were preliminarily seen by clinical geneticists. Data were collected through a pre-tested clinical protocol. Fisher Test was used for statistics with p-value<0.05. Age ranged from 0-31 years, sexual ratio was 1:1. Cleft lip with or without palate amounted to 84.9% while cleft palate, 15.1%. Rate of parental consanguinity and familial recurrence were 7.5% and 28.3%, respectively. Mother's age at birth ranged from 14-42 years. Level of instruction of 75% of mothers ranged from illiterate to primary school. In 15% of the families proband was a single child. In the remaining cases, patient was the first child and sibling was significantly smaller. Results suggest that the birth of a child with NSOC might have played a rule in reproductive decisions of these families although they had never benefited from genetic evaluation and counseling. Except for sexual ratio, results on clinical and genetic characteristics corroborate the literature. These data would be useful for the planning of genetic care for patients with orofacial clefts in Alagoas. Financial Support: FAPEAL, FAPESP.

Hypophosphatemic rickets, two unrelated case reports and review of the literature. *G.H. Galicia Hernandez[1], V.M. Anguiano-Alvarez[1], I.J. Garcia-Gonzalez[1], J.F. Michel Monrroy[4], J. Fonseca Cárdenas[4], R. Minerva Martínez[5], N.O. Davalos[1,2,3].* 1) Biologia Molecular, Instituto de Genética Humana Dr. Enrique Corona, Guadalajara, Guadalajara, Mexico; 2) Doctorado de Genética Humana, CUCS, Universidad de Guadalajara; 3) Servicio de Genética, HRVGF ISSSTE Zapopan, Jalisco; 4) Ortopedia y traumatología, HRVGF ISSSTE Zapopan, Jalisco; 5) endocrinología,HRVGF ISSSTE Zapopan, Jalisco.

INTRODUCTION: Hypophospatemic rickets (HR) is characterized by osseus hypomineralization, secondary to the increased expression of phosphatonins , especially FGF23, which acts in the sodium and phosphate cotransporters of the proximal convoluted tubule, inducing phosphaturia. HR exhibits AD, AR or X-linked inheritance patterns. OBJECTIVE: To present two compatible HR case reports, its osseous complications and adverse medical events. Case report: We present two unrelated familial cases, HR compatible. Proposita 1: A 7.6-year-old girl with disproportional short stature, genu varum, gait difficulties, asymmetric thorax; actually presenting normocalcemia, normophosphatemia, phosphaturia, calcitriol deficiency and secondary hyperparathyroidism. Proposita 2: 15-year-old girl with surgical antecedents, the first one in order to correct bilateral tibia deformity at age 3, and genu varum correction surgery at age 5; actually presenting genu varum recidivation, normocalcemia, hypophosphatemia, and phosphaturia. CONCLUSIONS: Due to functional complications in HR, early diagnosis and treatment is necessary, based in growth curves as well as serum values of phosphorus, calcitriol, alkaline phosphatase, and others, in order to offer an optimal medical care and prevent secondary osseous deformities.

803/T

Patients with heterozygous deletion of *NRXN1*α present with variable phenotypes from mental retardation, developmental delay, seizures, cardiac conduction defects to apparently normal phenotype. *K. Hovanes[1], J. Kim[1], M. Gorre[1], N. Shur[2], C. Harini[2], S. Gunn[1], D. Niyazov[3].* 1) Dept Gen, CMDX CombiMatrix Diagnostics, Irvine, CA; 2) Rhode Island Hospital, Providence, RI; 3) Pediatrics, Ochsner Clinic Foundation, New Orleans, LA.

We present *NRXN1* gene deletions in two unrelated patients with developmental delay and in four members of another family with variable phenotypes. Our first patient, a 5-year-old male, was evaluated for global developmental delay and seizures. The onset of his seizures was at the age of 13 months with frequency of 20-40 seizures per day. His evaluation at 5 years of age revealed mixed receptive and expressive language delays with obsessive compulsive behavior and had repetitive and hand flapping activities. Our second patient was a 3-year-old male with language delay and autistic features. These two patients were evaluated by array comparative genomic hybridization (aCGH) which revealed an approximately 255 Kb deletion of *NRXN1* (*Neurexin 1*) gene on chromosome 2p16.3. Parental analyses for these patients are pending. Two brothers, age 23 and 20, from the third family were also found to have a similar deletion in *NRXN1*. The older brother had motor and language delays. He also had advanced second degree atrioventricular (AV) block. He has profound mental retardation due to anoxic brain injury that he suffered during a prolonged cardiac arrest. His younger brother had normal development but required speech therapy at age 5 and was diagnosed with ADHD. Their 16-year-old sister had normal development but required special education classes until the 5th grade due to learning disability and currently struggles with dyslexia. The younger brother and sister also have second degree AV block. Both brothers were tested by aCGH and found to have a *NRXN1* gene deletion similar to the one found in the two patients mentioned above. FISH analysis revealed the same deletion in the mother and the sister. However, the mother, who is a licensed professional nurse, denied any history of developmental delay or learning disabilities. The deletion seen in these three families encompasses the promoter and part of the coding sequence of the neurexin1α without affecting the neurexin1β transcript. *Neurexin 1* has been a candidate gene for schizophrenia and autism spectrum disorder. Recently, Zahir et. al. reported a *de novo* heterozygous deletion of 320 kb affecting neurexin1α in a patient with vertebral, cognitive and behavioral abnormalities. Here we report three additional families with similar deletions affecting the neurexin1α transcript suggesting that haploinsufficiency of this transcript presents with significant variable phenotype and incomplete penetrance.

804/T

AN EXERCISE IN DIAGNOSING PROTEUS SYNDROME. *R.M. Minillo, C. Mcheletti, M.A.P. Ramos, A.B.A. Perez, V.F.A. Meloni, M.C.P. Cernach, F.T. Lima, D. Brunoni.* Universidade Federal de São Paulo (UNIFESP), São Paulo, Brazil.

INTRODUCTION: Proteus syndrome (PS), (OMIM %176920), is a rare genetic disease with unknown etiology and highly variable expression. No intraexonic mutations were identified, indicating that neither PTEN nor GPC3 was likely to have a major role in the etiology of the disease (Thiffault et al., 2004). The diagnosis criteria must be applied carefully in order to its confirmation, classify patients at risk and allow molecular and evolution evaluation. OBJECTIVE: Analyze the difficulty and complexity in confirming the diagnosis of PS as well as its differential diagnosis. MATERIALS AND METHODS: Retrospective analysis by chart review of 30 patients of Centro de Genética Médica of Universidade Federal de São Paulo with initial diagnostic hypothesis of PS, trying to apply the diagnosis criteria properly and check the complementary exams ordered during the investigation. RESULTS: PS was confirmed in 6 patients (20%;). Six patients (20%;) presented only macrodactyly and 7 patients (23,3%), hemihypertrophy (isolated, with hemangiomas or macrodactyly), still without final diagnosis, being that 10 were younger than 1 year old and needed periodic revaluations because of its progressive course. The diagnosis of PS was discarded in 11 patients (36,7%), (1 with encephalocraniocutaneous lipomatosis, 2 with Klippel-Trennaunay syndrome, 1 with macrolipodistrophy, 2 with lipomatosis, 1 with linfangiomatosis, 1 with hemifacial hemihypertrophy, 1 with Mafucci syndrome, 1 with vascular malformation and 1 with epibulbar dermoid). The exams of each patient were tabbed and their contribution to diagnosis was analyzed. CONCLUSION: PS is often associated with missed diagnosis and applying the diagnosis criteria is not always easy. It is important to highlight the correct investigation and the importance of periodic revaluations of oligosymptomatic patients so that the proper differential diagnosis is made, which requires a real diagnosis exercise in many instances.

805/T

MOMO Syndrome with holoprosencephaly and cryptorchidism: Further dilineation of the new obesity syndrome. *S. Sharda, I. Panigrahi, R. Marwaha.* Pediatrics, Advanced Pediatric Centre,PGIMER, Chandigarh, India.

There are multiple genetic disorders with known or unknown etiology grouped under obesity syndromes. Inspite of having multisystem involvement and often having a characteristic presentation, the understanding of the genetic causes in majority of these syndromes are still lacking. The common obesity syndromes being Bardet-Biedl syndrome Prader-Willi syndrome, Alstrom syndrome ,Cohen syndrome, Albright's hereditary osteodystrophy ,Carpenter syndrome, Rubinstein-Taybi syndrome, Fragile X syndrome and Börjeson-Forssman-Lehman syndrome. The list is ever increasing with new syndromes being added on. A recent addition is MOMO syndrome, with about five such cases being reported in the literature. Expanding the spectrum of clinical features, we report the first case of MOMO syndrome from India. The hitherto undescribed association with the lobar variant of holoprosencepahaly and cryptorchidism and the rarity of the syndrome prompted us to document this case. Key words: Obesity syndrome, MOMO, cryptorchidism holoprosencephaly.

806/T

Genetic risk factors for neonatal hyperbilirubinemia in North Indian population. *P.K. Tiwari[1], A. Kumar[1,3], A. Bhutada[1], R. Agarwal[1], R. Raman[2,3].* 1) Department of Pediatrics, IMS, Banaras Hindu University, Varanasi, Uttar Pradesh, India; 2) Department of Zoology, Faculty of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India; 3) Centre for Genetic Disorders, Faculty of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India.

Introduction: Jaundice is a common problem in newborn babies in first few days of life. In severe, untreated cases, it leads to the risk of bilirubin encephalopathy or kernicterus. The cause of neonatal hyperbilirubinemia (NNH) is multifactorial. There is a wide variation in the prevalence of NNH in different ethnic groups, suggesting the influence of genetic factors. Genetic factors may influence bilirubin metabolism by increasing bilirubin production and/or diminished bilirubin conjugation. It has been established that variants of bilirubin metabolism controlling genes, viz, Uridinediphosphate glucuronosyl transferase1A1 (UGT1A1), Solute carrier organic anion transporter family, member 1B1 (SLCO1B1) and Glucose -6-phosphate dehydrogenase (G-6-PD) may predispose to NNH. Objective: To understand the contribution of genetic variants of UGT1A1, SLCO1B1and G-6-PD genes to the etiology of NNH. Methods: A prospective case-control study was conducted, which included 247 newborns as cases (total serum bilirubin ≥15 mg/dl) and 278 newborns as controls (total serum bilirubin < 15 mg/dl). Polymorphisms of above mentioned genes were genotyped by PCR-RFLP, SSCP and DNA sequencing. Statistical analysis has been done by using SPSS, version 16.0. Results and conclusions: In our study NNH was significantly associated with certain polymorphisms of UGT1A1 gene such as G211A variant (OR= 3.03, 95%CI=1.06-8.63), enhancer region polymorphism -G3279T (OR=2.5, 95%CI=1.5-4.3) and TATA box polymorphism (TA)6®(TA)7 of promoter region (OR=1.5,95%CI=1.06-2.13).We did not observe any association between NNH and polymorphisms of CAT box, C686A, C1091T and T1456G. Similarly polymorphisms in coding region of SLCO1B1 gene did not appear to contribute to NNH as the occurrence of variants was comparable between the cases and controls. For G-6-PD gene Mediterranean mutation (C563T) was found in only 2 female (heterozygous) neonates with hyperbilirubinemia and 1 male (hemizygous) control neonate, suggesting infrequent occurrence of this mutation in this region of India. It is concluded that variants of UGT1A1 gene contribute significantly to NNH in Indian population.

The identification of SNPs associated with facial morphological traits in a genome-wide association study. *L. Paternoster[1,2], A.M Toma[3], C. Wilson[3], A.I. Zhurov[3], J. Kemp[2], G. Davey Smith[1,2], B. St Pourcain[2], G. McMahon[2], P. Deloukas[4], S.M. Ring[2], N. Timpson[1,2], S. Richmond[3], D.M. Evans[1,2].* 1) MRC CAiTE, University of Bristol, Bristol, United Kingdom; 2) Social Medicine, University of Bristol, Bristol, United Kingdom; 3) Department of Applied Clinical Research & Public Health, Cardiff University, Cardiff, United Kingdom; 4) Wellcome Trust Sanger Institute, Cambridge, CB10 1SA, United Kingdom.

Craniofacial morphology is highly heritable (with the easier to measure traits showing higher heritability) but very little is known about which individual genes are involved. We have carried out the first genome-wide association study (GWAS) of facial morphology to identify single nucleotide polymorphisms (SNPs) for facial characteristics.

Three-dimensional facial images of 2185 15 year-olds with genome-wide data from the Avon Longitudinal Study of Parents and Children (ALSPAC) were obtained using two high resolution Konica/Minolta laser scanners. The images were aligned and 21 key facial landmarks identified. The 3-D coordinates of these landmarks were used to derive linear distances and angular measurements. In addition, the lip morphology was categorized according to size, shape and features. We carried out genome-wide association analyses on these measures using imputed genome-wide data in MACH2QTL.

We have several exciting associations that meet $p<5x10^{-8}$, including SNPs near FAM44B, ISX, SIX2 and AQP4. The most promising of these was in a region on chromosome 2 that showed association with the nasion-mid-encanthion distance (the distance from the nasal root to the midpoint of the line made by the inner eye fissures). The top SNP in this region was rs7559271 ($p=2x10^{-10}$), which is in the PAX3 gene. This gene is known to play a role in Waardenburg syndrome and craniofacial-deafness-hand syndrome, both of which have distinct facial clinical features. We will now genotype this SNP (and others which reached $p<5x10^{-8}$) in a further 2500 ALSPAC 15 year-olds with facial data and DNA extracted and attempt to replicate these findings (results of this will be presented).

Serum iron parameters indicate the availability of and the demand for iron. This is the first meta-analysis of genome-wide association studies (GWAs) on soluble transferrin receptor (sTfR). This parameter is regarded as a more reliable index of iron deficiency in anemia, compared to other serum iron parameter such as ferritin which may be disproportionately influenced by inflammation or neoplasia. The meta-analysis of five GWAs on sTfR and ferritin serum levels revealed a novel association to the *PCSK7* locus on chromosome 11. Additionally, two genes, *TMPRSS6* and *HFE*, which are known to be associated with iron parameters such as free iron, ferritin or transferrin, have also been found to be associated with sTfR. The association with the *PCSK7* locus was the most significant (rs236918, $p = 1.1 \times 10^{-27}$) suggesting that proprotein convertase 7, the gene product of *PCSK7*, is involved in sTfR generation and/or iron homeostasis.

809/T

Replication study of the recently identified rheumatoid arthritis susceptible polymorphisms: a case-control study. *T. Suzuki[1,2], K. Ikari[1], Y. Toyama[2], A. Taniguchi[1], H. Yamanaka[1], S. Momohara[1].* 1) Inst Rheumatology, Tokyo Women's Med Univ, Tokyo, Japan; 2) Dept of Orthopedic Surgery, Keio Univ, Tokyo, Japan.

Background. Recently a large-scaled meta-analysis of genome-wide association studies (GWAS) and replication studies identified novel rheumatoid arthritis (RA) risk loci in European descent populations; SPRED2 (rs934734), ANKRD55 (rs6859219), C5orf30 (rs26232) (1). The aim of this study was to validate the association between these reported loci and susceptibility to RA in a Japanese population.

Methods. The present study is part of a RA cohort project with an enrollment of nearly 5000 patients established by the Institute of Rheumatology, Tokyo Women's Medical University (IORRA). All the RA patients fulfilled the American College of Rheumatology 1987 revised criteria for RA. DNA samples of 1504 RA patients were obtained from IORRA study and 752 population-based control DNA samples were obtained from the DNA collection of Health Science Research Resources Bank (Osaka, Japan), which was entrusted by Pharma SNP consortium (Tokyo, Japan). Tested SNPs on the genes were selected based on the published studies. Genotyping was performed using the TaqMan assay according to the manufacture's instructions (Applied Biosystems, Japan). The Chi-square test was used for the case-control study.

Results. We failed to genotype rs6859219 using the TaqMan assay. No significant differences were observed in allele frequencies of the two SNPs between cases and controls (rs934734 [P=0.86, OR=1.01, 95%CI=0.84-1.16], rs26232 [P=0.50, OR=1.05, 95%CI=0.83-1.10]. Our data could not support the evidence of association between these SNPs and RA.

Conclusion. Although strong association was found in European descents, these reported susceptibility genes analyzed here are not associated with RA susceptibility in a Japanese population. The result suggests that the SNPs may be associated with RA susceptibility in a specific ethnic group.

Double methylation disorder: Beckwith-Wiedemann and Angelman syndromes in two patients. *L. Randolph[1], D. Wong[1], J. Waterson[2], J. Schoof[3], J. Johnson[3].* 1) Div Med Gen, Childrens Hosp, Los Angeles, Los Angeles, CA; 2) Children's Hospital Oakland, Oakland, CA; 3) Medical Genetics, Shodair Hospital, Helena, MT.

The concept of a multiple methylation disorder was recently proposed in both IVF and other pregnancies, (J Med Genet 2006;43:902-7). Our lab (JJ) analyzes both SNRPN and LIT1 methylation and found two patients with abnormal imprinting at both loci, but with different mechanisms Pt1 is a 3-y.o. F referred to genetics for DD and protruding tongue. She was born to a 31-y.o. G3 P2-3 woman with type I DM and preeclampsia after a naturally conceived pregnancy. Gestation was 34 wks, BW 4020 g and HC 34.5 cm, LGA with a normal head size. She had facial asymmetry, macroglossia, hand flapping and easy laughter. Methylation testing for BWS showed mosaic hypomethylation of LIT1, with a methylation index of .20. Uniparental disomy (UPD) studies for chromosome 11 were normal, indicating that she likely has a mosaic imprinting defect of LIT1. msPCR for SNRPN showed an MI of .08, consistent with Angelman syndrome (AS), similar to Southern blot results showing a faint methylated allele. UPD studies for chromosome 15 were normal. FISH for SNRPN has not yet been done. Pt2 was a 2 m.o. female infant seen by genetics at 2 d. age for suspected BWS. She was born at 30 6/7 wks to a 26-y.o. G1. Omphalocele and polyhydramnios were diagnosed prenatally. BW was 2.46 kg (>97th), length 49 cm (>97%) HC 29 cm (50%). She had hemihyperplasia and a globular pancreas. She died at two months of age. LIT1 msPCR showed an MI of .22, , and UPD 11 studies showed an average paternal/maternal allele ratio of 3.9, consistent with approximately 59% of cells being isodisomic for paternal alleles. Pt1, with signs of both syndromes, has a presumed mosaic imprinting defect of LIT1 resulting in BWS, and an almost complete lack of methylation of SNRPN, consistent with AS and a possible imprinting defect. The coincidence of the two syndromes, produced possibly by imprinting defects is unusual. More unusual is the same syndrome combination in Pt2, but produced by a different mechanism, mosaic UPD for two different paternal chromosomes, indicating a possible predisposition to post-zygotic non-disjunction. We report these patients to raise awareness of multiple imprinting syndromes in the same patient, with multiple mechanisms potentially responsible. We suggest that patients with atypical clinical presentations of BWS and other maternal hypomethylation disorders be tested for other methylation disorders.

811/T

The heritability of the common foot disorders, hallux valgus and pes cavus, in elder men and women: The Framingham Study. *Y. HSU[1], J. Jordan[2], LA. Cupples[3], DP. Kiel[4], M. Hannan[4].* 1) Molecular & Integrative Physiological Sciences Program, Harvard School Public Health, Boston, MA; 2) University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Dept. Biostatistics, School of Public Health, Boston University, Boston, MA; 4) Hebrew SeniorLife, Boston, MA.

Foot disorders, including hallux valgus, pes planus, pes cavus, lesser toe deformities, are common among adults, affecting approximately 20-60% of Americans and are increasingly linked to chronic mobility limitations and disability. Although genetic predisposition to foot disorders has been suspected, we are aware of only one study that reported family history of patients with hallux valgus, and this study concluded that this foot deformity may be inherited through an autosomal dominant transmission. To date, no linkage, candidate gene association, GWAS or heritability studies have been performed. Utilizing the pedigree structure in the Framingham Study, we estimated overall and gender-specific heritability of hallux valgus and pes cavus (our most common and least common foot disorders) by a standard quantitative genetic variance-components model implemented in the Sequential Oligogenic Linkage Analysis Routines (SOLAR) package. Foot disorders were assessed using the validated Foot Assessment Clinical Tool that captures the main features of common foot disorders. Briefly, trained clinical examiners conducted a physical examination of a participant's feet, collected data on medical history, plantar pressures using a computerized mat, and administered risk assessment questionnaires. The structural foot disorders were indicated as present or absent based on an atlas of pictorial depictions of each foot disorder. For example, hallux valgus was defined as the angular deviation of the hallux with respect to the first metatarsal bone toward the lesser toes at 15° or more, and appears as a medial bony enlargement of the first metatarsal head. The prevalence of Hallux Valgus was 31% in these participants (675 Hallux Valgus cases with available pedigree information). The overall heritability (h2) was 0.39 for women and 0.38 for men. For individuals < 60 years of age, the heritability was 0.89. The prevalence of pes cavus was only 7% (154 cases with available pedigree information). The heritability was 0.68 for women and 0.20 for men. For individuals < 60 years of age, the heritability was 0.99 for women and 0.63 for men. In summary, we found that hallux valgus and pes cavus are highly heritable, especially for younger adults. Genome-wide association analyses on three independent studies (including the Framingham Study) are planned to identify potential genetic determinants for these common foot disorders.

A genome-wide scan for quantitative trait loci that regulate canine skull shape. *J.J. Schoenebeck[1], A.M. Byers[1], J.W. Fondon III[2], L. Lin[3], A.R. Boyko[3], C.D. Bustamante[4], R.K. Wayne[5], E.A. Ostrander[1].* 1) Cancer Genetics Branch, National Human Genome Research Institute, Bethesda, MD; 2) Department of Biology, University of Texas at Arlington, Arlington, TX; 3) College of Veterinary Medicine and Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 4) Department of Genetics, Stanford School of Medicine, Stanford, CA; 5) Department of Ecology and Evolutionary Biology, University of California, Los Angeles, CA.

An understanding of how gene products interact during development could lead to better diagnosis and treatment for individuals with craniosynostoses. However, the compendium of molecular machinery that dictates cranioskeletal morphology remains poorly defined. Dogs display tremendous intraspecific cranioskeletal variation, making them an appealing model for the identification of genetic regulators of skull shape. Using a microscribe digitizer, we collected coordinate data from 53 landmarks on 192 skulls of dogs and wild canids and analyzed skull shape variation using MorphoJ software (Klingenberg lab). Our data reveals three principal components (PCs) that cumulatively explain 68% of symmetrical variance seen across 61 dog breeds. The first PC explains snout length, a feature that differs prominently among brachycephalic (short-snouted) and dolichocephalic (long-snouted) breeds of dogs. Genome-wide scans using both breed averages for PC1 and binary status (case/control) reveal that regions on chromosomes 1, 5, and 26 are highly associated with snout length (best uncorrected quantitative associations: $P = 4.99 \times 10^{-43}$, 3.00×10^{-49}, and 1.65×10^{-46} respectively). PC2 explains variation, predominantly in the neurocranium and width of the snout, that distinguishes brachycephalic and molosser breeds from toy breeds. Quantitative associations using PC2 reveal a single, highly significant association on the X chromosome (best uncorrected SNP: $P = 2.28 \times 10^{-67}$). Together, our data begin to reveal how multiple genetic loci converge to generate the tremendous skull shape variation seen in domestic dogs. With the eventual identification of causal variants, we hope to relate our findings to human symmetric craniosynostoses.

A wide range of ophthalmologic anomalies are part of the broad holoprosencephaly spectrum. *D.E. Pineda Alvarez[1], B.D. Solomon[1], J.Z. Balog[1], D.W. Hadley[1], B.P. Brooks[2], E. Roessler[1], M. Muenke[1].* 1) Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) National Eye Institute, National Institutes of Health, Bethesda, MD.

Holoprosencephaly (HPE) is the most common disorder of the developing forebrain in humans, characterized by failure of cleavage of the cerebral hemispheres; additionally, it is accompanied by a spectrum of midline craniofacial anomalies such as cyclopia at the most severe end of the spectrum to mild hypotelorism, single central incisor, and flat nasal bridge, at the milder end. Besides obvious ocular anomalies easily apparent on physical exam, other eye findings have not been described formally within the HPE spectrum. One central cause of HPE is functional alterations of the Sonic Hedgehog signaling pathway. SHH is a well known morphogene that regulates several processes during organogenesis, including the forebrain, limbs, and eyes. For instance, SHH inhibits PAX6 in the midline in order to maintain the development of the optic cups in the lateral planes, and also regulates PAX2, an important molecule for normal eye development. Loss of PAX2 function causes cobolomatas and retinal anomalies in animal models. Thus, alterations in the SHH pathway are expected to cause alterations of the normal development of the eye. From our large cohort of over 1000 patients with HPE, we have evaluated ocular changes in patients carrying mutations or deletions in SHH (n = 203 patients), SIX3 (n = 141 patients), TGIF (n = 56), and ZIC2 (n=42). While cyclopia and extreme hypotelorism are relatively common in patients with severe HPE, other subtle findings were noted in patients with microform or mild HPE. Coloboma was reported in 4% (18/449) of our patients, with mutations representing all studied genes, 44.5% of patients with colobomas had no brain anomalies. Congenital ptosis was found in 1.3% (6/449) of the patients, most of whom had only subtle microforms of HPE (5/6). Except for a mother with microform HPE due to a ZIC2 mutation, only patients with SHH mutations had ptosis. Nine of 10 individuals (including patients with mutations in SHH, SIX3, TGIF, and ZIC2) with identified mutations in HPE-associated genes who were evaluated by an NIH ophthalmologic geneticist familiar with the condition were found to have subtle ocular anomalies. These anomalies include microcornea, microophthalmia, thinning of the cornea, subtle defects of the pigmentation of the retina, optic nerve cupping, and ocular position anomalies were noted. The results suggest that some subtle ocular anomalies could be used to predict HPE-associated mutations in otherwise unaffected individuals.

814/T

Crossed segment hemihyperplasia and constitutional epigenotypes. *M.I. Van Allen[1,2], G. Hulait[1,2], T. Oh[1,2], M.S. Peñaherrera[1], W.P. Robinson[1].* 1) Dept Med Gen, Univ British Columbia, Vancouver, BC, Canada; 2) Provincial Medical Genetics Programme B.C. Children's and Women's Health Centre Vancouver, B.C. Canada.

Crossed segment hemihyperplasia is an unusual finding in idiopathic hemihyperplasia (IH) and in Beckwith Wiedemann syndrome (BWS). Buek et al (2008) reported on the epigenotypes of 73 IH and 110 BWS patients, only one case (1/183) had crossed segment hemihyperplasia, suggesting that it is an infrequent finding. IH and BWS result from various genomic changes in molecular alterations of 11p15, including paternal uniparental disomy (UPD) and alterations of methylation of two imprinting centers at 11p15:ICR1(*H19*) and ICR2 (KCNQ10T1). We present two cases with crossed segment hemihyperplasia found to have constitutional mosaicism of epigenetic events. These rare cases shed light on the timing of mechanisms of genomic imprinting inducing parental-specific gene expression. ***Case (1)*** presented at 10 weeks old with crossed segment body asymmetry, Lt tongue hyperplasia, an ear tag and pit, and BWt 4220 gm. He had Lt face > Rt, Lt side tongue >> Rt, and limb segment measurements Rt upper arm > Lt, Rt forearm < Lt, Rt hand length < Lt. His leg length measurements were consistently Rt > Lt. The soft tissue circumferences were consistently Rt > Lt for all limb segments. There was no organomegaly. Molecular study results were consistent with mosaic paternal isodisomy for 11p14.3-pter in ~25-30% of cells and hypomethylation of ICR2. ***Case (2)*** presented at 7 months old with Rt tongue and face hyperplasia, occipital flamus nevus, and BWt 4128 gm. Limb segment lengths were variable with Lt forearm > Rt, Lt palm > Rt, Rt thigh > Lt, Rt lower leg > Lt. The circumferences varied with the Lt upper arm > Rt, Lt forearm < Rt, Lt thigh < Rt, Lt calf > Rt. There was no organomegaly. Molecular studies identified borderline low methylation at *H19/IGF2* ICR1 consistent with mosaicism for an imprinting mutation or mosaic UPD11p15.5 below our detection limits. Our cases have molecular changes typical of other cases of IH and BWS with unilateral hemihyperplasia, consistent with the same underlying mechanism, rather than another cause, for crossed segment hemihyperplasia. Epigenetic mechanisms play major gene-regulatory roles in development, differentiation and disease. The finding of crossed segment hemihyperplasia suggests that epigenetic events occurred prior to determination of Rt/Lt sidedness, most likely during secondary reprogramming and establishment of parental imprints in the pre- and post-implantation blastocyst.

815/T

Association analysis of the Class-II Division-2 (CIID2) malocclusion with *RUNX2*, *RUNX3*, *PAX9*, *MSX1* and *AXIN2*. *L.A. Morford[1, 2], T.J. Coles[2, 3], M.D. Wall[4], M.W. Morrison[4], D.W. Fardo[5], K.S. Kula[4], J.K. Hartsfield Jr.[2, 3, 6].* 1) Dept Oral Health Practice, Univ Kentucky College of Dentistry, Lexington, KY; 2) Hereditary Genomics Laboratory, Center for Oral Health Research, Univ Kentucky College of Dentistry, Lexington, KY; 3) Dept Oral Health Science, Division of Orthodontics, Univ Kentucky College of Dentistry, Lexington, KY; 4) Dept of Orthodontics and Oral Facial Genetics, Indiana Univ School of Dentistry, Indianapolis, IN; 5) Dept of Biostatistics, Univ Kentucky, College of Public Health, Lexington, KY; 6) Dept of Medical and Molecular Genetics, Indiana Univ School of Medicine, Indianapolis, IN.

Objectives: Development of the dental/skeletal Class II Division 2 (CIID2) malocclusion is a heritable trait. Multiple tooth anomalies, including hypodontia of maxillary incisors and/or third molars, coincide with the CIID2 phenotype at a higher frequency than observed with other dental/skeletal malocclusions. This study sought to determine whether five genes that influence incisor and third molar development, namely *RUNX2*, *RUNX3*, *PAX9*, *MSX1* and *AXIN2*, could influence the development of CIID2 in the presence or absence of hypodontia. Our null-hypothesis states there is no association of SNPs near or within these candidate genes and CIID2 (in the presence or absence of hypodontia). **Methods:** Both Indiana University and The University of Kentucky IRBs approved this study. Ninety-four Caucasian CIID2 subjects (31 with hypodontia) were compared to eighty-nine Caucasian non-CIID2 control subjects without hypodontia. Clinical exam, photographs, models, radiographs and saliva were collected and analyzed for all subjects. SNPs within or near the *RUNX2* (rs1406846, rs6930053), *RUNX3* (rs6672420), *PAX9* (rs8004560, rs1955734), *MSX1* (rs12532, rs3821949) and *AXIN2* (rs7591, rs2240308) genes were genotyped utilizing either Applied Biosystems Taqman ® or Roche SimpleProbe ® technology. A chi-square analysis was used to evaluate the potential association of CIID2 (in the presence and absence of hypodontia) and each SNP genotype. **Results:** All SNP alleles were in Hardy-Weinberg equilibrium. Assuming a co-dominant mode of inheritance, a marginal association was identified between CIID2 (in the presence and absence of hypodontia) and *RUNX2* rs6930053 ($p=0.09$) when compared to non-CIID2 controls. No association of rs6930053 was identified for CIID2 subjects with hypodontia of any permanent tooth or with hypodontia of one or more non-third molars, when compared to CIID2 subjects without hypodontia. **Conclusions:** The data suggest that *RUNX2* rs6930053 (or genetic loci in linkage-disequilibrium with *RUNX2*) plays a role in CIID2 development but not in the coincidental hypodontia. Studies are ongoing to expand the number of subjects being examined for SNPs from all five genes. **Supported by:** Indiana University Bixler Fund for Research in Genetics & Education, and the University of Kentucky E. Preston Hicks Endowed Chair.

816/T

Role of interleukin-28B polymorphisms in the treatment of Taiwanese patients with hepatitis C virus genotype 1 infection. *M.S. Wu[1], C.F. Haung[3], M.L. Yu[3], S.H. Juo[1,2].* 1) Department of Medical Genetics, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 3) Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung, Taiwan.

Purpose: Interleukin 28B (IL28B) encodes interferon-λ3 on chromosome 19 and had been referred to be involved in the suppression of hepatitis C virus (HCV) replication. Several genome-wide studies had showed that single nucleotide polymorphisms (SNPs) at IL28B were related to the treatment response in HCV genotype 1 (HCV-1) patients. Our goal was to confirm whether SNPs at IL28B are associated with HCV-1 infection treatment response in a Taiwanese population. **Methods:** We enrolled a total of 473 HCV-1 Taiwanese treatment-naïve patients who received pegylated interferon plus ribavirin combination therapy in Kaohsiung Medical University Hospital (KMUH). Five tagging SNPs were selected. Genotyping was determined by using the Taqman 5 nuclease assay (Applied Biosystems). **Results:** Among the five candidate SNPs (rs8105790, rs8099917, rs4803219, rs8109886, and rs10853728) at the IL-28B, rs8099917, rs4803219 and rs8105790 were noted to be in very strong linkage disequilibrium with each other ($r2=0.94$-0.96). Sex, age, body weight, baseline HCV viral loads were adjusted in the statistical analysis. SNPs rs8105790 TT genotype, rs8099917 TT genotype, rs4803219 GG genotype, rs8109886 CC genotype and rs10853728 CC genotype were associated with a rapid virological response of Hepatitis C virus infection. (RVR, seronegativity of HCV RNA at treatment week 4, $p=0.00007$, $p=0.00008$, $p=0.00003$, $p=0.0002$, and $p=0.0247$ respectively) and also associated with an sustained virologic response of Hepatitis C virus infection. (SVR, seronegativity of HCV RNA throughout 24 weeks of post-treatment follow-up, $p=0.00001$, $p=0.000098$, 0.000005,0.0001,and 0.0044 respectively) **Conclusion:** SNPs at IL28 were associated with treatment responses in HCV-1 patients in Taiwanese.

Complex I deficiency in Persian multiple sclerosis patients. *S. Ardalan Khales[1], S. Ardalan Khales[1], M. Houshmand[2].* 1) Medical Genetic Laboratory of Special Medical Center, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology, Tehran, Iran.

Complex I deficiency in Persian multiple sclerosis patients S. Ardalan Khales1, S. Ardalan Khales1, M. Houshmand2 1)Medical Genetic Laboratory of Special Medical Center, Tehran, Iran 2)National Institute for Genetic Engineering and Biotechnology, Tehran, Iran Multiple sclerosis (MS) is an immunological inflammatory disease of the central nervous system. Until now, little attention has been paid to the contribution of mitochondrial respiratory chain enzyme activities to MS. We showed a biochemical defect in complex I activity may be involved in pathogenesis of MS and also point mutation occurred in mtDNA might be involved in pathogenesis of MS. So in this study we sequenced mitochondrial complex I subunit in MS patient (ND1-ND6). No pathogenic mutations were found in our patient's. We conclude that it may mitochondrial nuclear subunit of complex I gene play roll in MS patient. Keywords: Multiple sclerosis; Mitochondrial complex I; Mitochondrial DNA.

The association of VEGF C-634G polymorphism with diabetic retinopathy: a meta-analysis. *H. Chen[1,2], W. Chen[1], C. Pang[1], M. Zhang[1,2].* 1) Joint Shantou International Eye Center, STU/CUHK, Shantou, GUangdong, China; 2) Department of Ophthalmology and Visual Sciences, the Chinese University of Hong Kong, Hong Kong, China.

Purpose: To investigate the association of *vascular endothelial growth factor (VEGF)* gene polymorphism with diabetic retinopathy (DR). Methods: A meta-analysis was performed. Literatures reporting the association of *VEGF* C-634G polymorphism with DR was searched in PubMed and EMBASE. Allele and genotype frequencies of *VEGF* C-634G polymorphism were extracted. The statistical analysis was performed using Reviewer Manager comparing the allelic distributions between (1) any DR and control; (2) proliferative diabetic retinopathy (PDR) and diabetes without retinopathy (DC); (3) non proliferative diabetic retinopathy (NPDR) and DC; (4) PDR and NPDR. Results: Totally 9 reported studies were retrieved. There was statistical significant difference in the distributions of *VEGF* C-634G polymorphism between any DR and DC (OR = 1.13, 95% CI 1.01-1.26, P=0.04). The G allele is more frequent in NPDR than in DC (OR=1.61, 95% CI 1.23-2.10, P=0.0005). However, it is less frequent in PDR than in NPDR (OR= 0.76, 95% CI=0.57-1.01, P=0.06). There is no different of the G allele frequency in PDR and DC (OR=1.02, 95% CI 0.87-1.18, p=0.85). Conclusion: The *VEGF* C-634G polymorphism is more frequency in NPDR patients than in PDR and diabetes without retinopathy patients.

819/T

Neurocristopathies in DiGeorge Syndrome. *A. Myers[1], V. Schroeder[2], M. Dasouki[3].* 1) Department of Pediatrics, University of Nebraska-Creighton, Omaha, NE; 2) Department of Pediatrics, University of Kansas Medical Center, Kansas City, KS; 3) Departments of Pediatrics and Internal Medicine, University of Kansas Medical Center, Kansas City, KS.

DiGeorge Syndrome is a well-established multiple congenital anomalies syndrome usually caused by a 3-5Mb deletion within the 22q11.2 chromosomal region. Other phenotypes caused by this microdeletion include Velo-Cardial-Facial, Conotruncal Anomaly Face Syndrome, and Opitz G/BBB Syndrome. Deletions at 22q11.2 have been associated with craniofacial abnormalities, congenital heart disease, palatal abnormalities, hypoparathyroidism, and developmental delays. Labyrinthine malformation has been described only in one individual with DiGeorge syndrome. TBX1 (a gene within the 22q11.2 microdeletion region) is required for mouse inner ear morphogenesis and proper neural crest migration. In addition, Hirschprung disease has been reported in association with DiGeorge syndrome in a few patients, suggesting a locus for Hirschprung disease within the 22q11.2 region. Typically, Hirschprung disease is recognized as a polygenic and isolated neurocristopathy. However, it is frequently associated with congenital central hypoventilation syndrome (CCHS) caused by PHOX2B gene mutations. Recently, the PHOX2B gene was linked to Hirschprung disease in Chinese patients. Patient one (AO) presented with speech and developmental delays, PDA, and bilateral labyrinthine abnormalities. She was diagnosed with DiGeorge syndrome based on the presence of a 2.81 Mb deletion in the 22q11.2 region found on aCGH analysis. Patient two (LN) had congenital heart disease and polyhydramnios diagnosed prenatally. After birth, he was diagnosed with Tetralogy of Fallot, Hirschprung disease, and congenital central hypoventilation syndrome. His blood karyotype was normal while a deletion in 22q11.2 was found by FISH analysis. Sequencing of his PHOX2B gene showed an abnormally expanded polyalanine repeat. Both patients were diagnosed with DiGeorge syndrome and neurocristopathies. Given these clinical presentations and the known role of TBX1 in mouse inner ear development, the labyrinthine malformation appears to be explained by the 22q11.2 deletion. On the other hand, the PHOX2B mutation found in the second patient separates Hirschprung disease and CCHS from DiGeorge syndrome. While neurocristopathies cause a myriad of anomalies in patients with DiGeorge syndrome, the exact molecular basis of their pathogenesis needs to be delineated.

The Psychiatric and Neurocognitive Manifestations in 1q21.1 Deletion Syndrome. *E. Chow[1,2,3], A. Ho[1], T. Aidan[3], D. Skidmore[3], C. Morel[4].* 1) Clinical Genetics Service, Centre for Addiction & Mental Health, Toronto, Ontario, Canada; 2) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 3) IWK Health Centre, Halifax, Nova Scotia, Canada; 4) Fred A. Litwin Family Centre in Genetic Medicine, University Health Network / Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada.

Background: The 1q21.1 Deletion Syndrome (1q21.1DS) is a recently identified microdeletion syndrome with a variable phenotype. It has an estimated prevalence of ~0.4% in the general population. Cognitive and psychiatric manifestations have been reported in this syndrome but few details are available. Method: We have ascertained two unrelated families with 1q21.1DS. A total of 7 individuals in these two families (5 adults and 2 children) have been identified with 1q21.1DS on microarray testing. We systematically assessed them for psychiatric and neurocognitive phenotypes. Results: High rates of psychiatric conditions were identified in the 7 affected individuals. Every affected individual, except the youngest who is only 6 years old, has suffered from at least one psychiatric disorder: 4 subjects were treated for attention deficit hyperactivity disorder, 4 suffered from a major depressive disorder, 2 had alcohol abuse, and one suffered from psychotic disorder not otherwise specified. No autism or autism spectrum disorder was found. Intellect ranged from normal to moderate intellectual disability. Median full-scale IQ was 65, median verbal IQ was 71, and median performance IQ was 74. Verbal IQ was lower than performance IQ in all subjects tested. One subject was diagnosed as having dyslexia in school and another subject had a Verbal-Performance IQ difference of 21 points in favor of performance IQ on testing. Verbal comprehension and reading skills were particular weaknesses, while perceptual organization, abstraction and mental flexibility were relative strengths. Conclusions: A high rate of psychiatric conditions is associated with 1q21.1DS. 1q21.1DS may also be associated with weaknesses in verbal abilities and a relatively lower verbal IQ. Early assessment and intervention for neuropsychiatric manifestations are recommended for individuals with 1q21.1DS.

Lipomatous cortical dysplasia with lipoma of the corpus callosum associated with an Xp deletion. *R. Regan[1], L. Baker[2], J. Conroy[1], V. Donoghue[2], M. Mullarkey[3], N. Shah[1], N. Murphy[2], S. Ennis[1], S.A. Lynch[3].* 1) School of Medicine and Medical Science, Univ College Dublin, Dublin 4, Ireland; 2) Temple Street Children's Hospital, Dublin 1, Ireland; 3) National Centre for Medical Genetics, Our Lady's Children's Hospital, Dublin 12, Ireland.

We report a 4 year old girl with a de novo 13.7Mb deletion on Xp who has lipomatous cortical dysplasia with lipoma of the corpus callosum. Antenatal ultrasound scans had initially revealed ventriculomegaly and a fetal magnetic resonance imaging (MRI) scan revealed a soft tissue mass in the region of the corpus callosum. Post-natal MRI confirmed the diagnosis of a lipomatous cortical dysplasia with agenesis of the corpus callosum. Karyotype analysis showed a deletion on the short arm of chromosome X. Chromosomal replication studies using a thymidine analogue (BrdU) and methylation analysis of DNA at the androgen insensitivity locus showed non-random X inactivation. Fine mapping studies carried out with the Illumina 1M SNP array confirmed the deletion spanned Xp22.31 to Xp22.12. Cytogenetic abnormalities have not previously been described with this malformation, although this may be attributed to selection bias. At four years of age, the girl remains clinically well with no evidence of seizure activity or headache. She has normal growth.

822/T

Phenotypic manifestations of copy number variation in chromosome 16p13.11. *S.C Sreenath Nagamani[1], A. Erez[1], P. Bader[2], S.L Lalani[1], D.A Scott[1], F. Scaglia[1], S.E. Plon[3], C.H. Tsai[4], T. Reimschisel[5], E. Roeder[6], A.D. Malphrus[7], P.A. Eng[1], P.M. Hixson[1], S.L. Kang[1], P. Stankiewicz[1], A. Patel[1], S.W Cheung[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Parkview Hospitals, Fort Wayne, IN, USA; 3) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 4) Division of Clinical Genetics, Children's Hospital, Aurora, CO, USA; 5) Department of Pediatrics, Vanderbilt University School of Medicine, Nashville, USA; 6) Department of Pediatrics, University of Texas Health Science Center, San Antonio, TX, USA; 7) Division of Pediatric Neurology, Baylor College of Medicine, Houston, TX.

The widespread clinical utilization of array comparative genome hybridization, has led to the unraveling of many new copy number variations (CNV). While some of these CNVs are clearly pathogenic, the phenotypic consequences of others, such as those in 16p13.11 remain unclear. Whereas deletions of 16p13.11 have been associated with multiple congenital anomalies, the relevance of duplications of the region is still being debated. We report detailed clinical and molecular characterization of ten patients with duplication and four patients with deletion of 16p13.11. We found that patients with duplication of the region have varied clinical features including behavioral abnormalities, cognitive impairment, congenital heart defects and skeletal manifestations such as hypermobility, craniosynostosis and polydactyly. These features were incompletely penetrant. Patients with deletion of the region presented with microcephaly, developmental delay and behavioral abnormalities as previously described. One patient with deletion presented with Wilms' tumor. The CNVs were of varying sizes and were likely mediated by non-allelic homologous recombination between low copy repeats. Our findings expand the repertoire of clinical features observed in patients with CNV in 16p13.11 and strengthen the hypothesis that this is a dosage sensitive region with clinical relevance.

823/T

A novel familial 11p15.4 microduplication associated with developmental delay and hypercalcemia, likely secondary to an increased copy number of the OVHC2 gene involved in calcium ion binding. *N. Shur[1], D. Abuelo[1], S. Gunn[2], N. Golova[1], C. Harini[1], J. Quintos[1], E. Sofos[3], K. Hovanes[2].* 1) Rhode Island Hospital, Providence, RI; 2) Combimatrix Diagnostics, Irvine, CA; 3) Alpert Medical School at Brown University, Providence, RI.

We evaluated a seven-year-old boy with intellectual disability and seizures in genetics clinic. He was the six pound product of an uncomplicated term pregnancy born via repeat C-section to a 30 year-old mother and 24-year-old father. He appeared healthy until three months of age, when he was hospitalized for pneumonia. Soon after, developmental delays were noted. He walked at age 2, said his first words at around 3, and spoke in sentences at age six. Recently, he was hospitalized at a psychiatric institution for aggressive behavior. Family history was positive for significant medical problems in his father and siblings. The father and two younger brothers (age 4 and 6) all had developmental delay and familial hypocalciuric hypercalcemia (discovered through screening because of that diagnosis in the paternal grandfather). The 6-year-old also had an atrial septal defect, a seizure disorder, hernias, and kidney stones. An 8-year-old brother who did not have hypercalcemia had mild learning problems. Our patient's mother had learning disabilities and seizures. On physical examination, his weight and height were greater than the 95th percentile, and his head circumference was 52.5 cm (90th percentile). He was large for age and had a round face. Dysmorphic features included high arched eyebrows with synophorus, large posteriorally rotated ears, a long smooth philtrum, an overbite, and high palate. Calcium level was normal. Oligonucleotide array comparative genomic hybridization (aCGH) revealed a single copy number gain of approximately 2.3 Mb in the 11p15.4 region. His mother's aCGH result was negative for this duplication. The father and 8-year-old brother have not yet been tested. His six-year-old brother carried the same 11p15.4 duplication. The duplicated region seen in these two brother's genome spans 31 genes (6,904,229-9,243,447) and includes the ovochymase 2 (OVCH2) gene involved in calcium binding, which could explain the hypercalcemia in some family members with the duplication. A literature review showed only one other case of a patient with an overlapping, albeit larger, duplication. He had pharmacoresistant epilepsy, profound intellectual disability, and dysmorphisms. Our case represents a novel familial microduplication syndrome of chromosome 11p15.4 with variable expression of features that include developmental delay, dysmorphic features, and hypercalcemia.

Developing neurocognitive profiles of patients with recently reported CGH abnormalities. *G.C. Gowans, P.L. Brock, K.E. Jackson, S.D. Tomchek, L.L. Sears, E.R. Markham, A.M. Allard, Y.S Senturias, R.H. McChane, T.L. Erwin, K.M. Goodin, A. Asamoah, J.H. Hersh, P.G. Williams.* WCEC, Pediatrics, Univ Louisville, Louisville, KY.

Behavioral and developmental phenotypes are well recognized for a variety of genetic conditions, e.g. Down syndrome, Fragile X syndrome, Williams syndrome, Turner syndrome and 22q11.2 deletion syndrome. Comparative genomic hybridization (CGH) analysis with increasing resolution has resulted in detection of much smaller chromosome duplications and deletions. Physical and medical manifestations of some of these newly described CGH anomalies are beginning to emerge. We describe cognitive and behavioral assessments of selected CGH anomalies that we are developing through a multidisciplinary approach to patient evaluation that include not only geneticists and genetic counselors, but developmental pediatricians, child psychologists, child psychiatrists, speech therapists, occupational therapists and physical therapists. Our research at the Weisskopf Child Evaluation Center is currently focused on patients with the chromosome 1q21.1 deletion and duplication syndromes. However, we plan to similarly assess other conditions beginning with the chromosome 22q11.2 duplication syndrome.

825/T

Growth in Chilean infants with chromosome 22q11 microdeletion syndrome. *G.M. Repetto, M.L. Guzman, A.R. Puga, J.A. Justiniano.* Human Genetics, Clin Alemana- Univ Desarrollo, Santiago, Chile.

Chromosome 22q11.2 deletion syndrome (del22q11) is the most common known microdeletion syndrome, with an estimated frequency of 1/4000 to 1/6000. Though most patients share a deletion of similar size and location, the phenotypic variability among them is substantial. Growth failure is frequently described in patients with del22q11, and it is unclear whether this is an intrinsic manifestation of the syndrome or it is secondary to other medical problems, such as the presence of congenital heart disease (CHD) or endocrine deficiencies. We evaluated growth during infancy (newborn to 3 years of age), measured as weight and height, in a group of Chilean patients with del22q11. Data was collected through review of medical records, and compared with World Health Organization (WHO) growth curves, routinely used in the country for growth assessment in the pediatric population. In addition, we compared the findings between patients with and without CHD. Longitudinal measurements during infancy were obtained from 139 patients. Weight for age was below the 10th percentile of WHO curves in 86 of them (62%), and height for age was below the 10th percentile in 82 patients (59%). Only 2 patients had height/age above the 90th percentile, and the majority of remaining patients had measurements between the 10th and the 50th percentiles. Fifty two patients (37.4%) had CHD, all of them surgically repaired. We found no evidence of statistically significant differences in height or weight for age when comparing patients with or without CHD (p value of 0.07, Fisher's exact test). None of the patients had hypothyroidism or evidence of growth hormone deficiency. Although potentially biased due to its retrospective nature and lack of standarized measurements, our results show that the majority of Chilean patients with del22q11 in this study have growth in height and weights below the 10th percentile, at least during the first 3 years of life. Additionally, there was no evidence of association between growth pattern and presence of CHD or hormone deficiencies, suggesting that the findings may be due to direct effects of the deletion. Funded by Fondecyt-Chile grant #1100131.

Deletion of *MAP2K2*: A possible novel mechanism for RASopathies? *M. Nowaczyk[1], S. Zeesman[1], K.A. Rauen[2].* 1) Dept Pathology & Pediatrics, McMaster Univ, Hamilton, ON, Canada; 2) 3Dept. of Pediatrics, Division of Medical Genetics, University of California, San Francisco, San Francisco, CA.

The Ras/mitogen-activated protein kinase (MAPK) pathway is essential to embryonic development. Germline mutations of genes encoding components of this pathway have been described in a group of conditions referred to as RASopathies (which include, among others, Noonan (NS), and cardiofaciocutaneous (CFC) syndromes). RASopathies are characterized by craniofacial and cardiac defects, ectodermal anomalies, variable degrees of cognitive defects and of growth disorders. MEK2 (encoded by MAP2K2) is activated by Raf and in turn activates ERK1/2, the final effectors of the Ras/MAPK pathway. Activating mutations of MEK2 have been reported in patients with CFC which comprises NS-like facies, moderate-severe neurocognitive impairment, hyperkeratotic skin lesions, and sparse, curly hair and absent eyebrows, and heart defects. We report an 11 year old boy with a 1.5 Mb deletion in 19p13.3, which includes MAP2K2, who has clinical features suggestive of dysregulation of the Ras/MAPK pathway. He has macrocephaly, bicuspid aortic and dysplastic mitral valve, cardiac rhythm abnormalities, severe eczema with hyperkeratosis and nail dysplasia combined with severe developmental delay. His facial features include a triangular face with tall forehead, down slanting palpebral fissures, thick nasal tip, underdeveloped cheekbones, tall and prognathic chin, thin upper and thick lower vermilion border; his ears are small with abnormal antihelices, and posteriorly rotated. He has a history of severe GE reflux with recurrent aspiration pneumonias which required Nissen funduplication and G-tube feeding. He requires nighttime CPAP for obstructive sleep apnea. He has lymphopenia of unknown etiology. He has advanced bone age. BAC-based chromosomal microarray detected deletion of clone RP11-454N6 at 19p13.3. Haploinsufficiency of other Ras/MAPK components resulting in phenotypic effects reminiscent of RASopathies have been reported recently. Individuals with deletions including ERK2 present with craniofacial and cardiac anomalies, microcephaly, and developmental deficits; deletions ERK3 are associated with autism, and facial and cardiac anomalies. Deletion of MAP2K2 may produce similar effects during development and organogenesis. Our patient's phenotype may be a result of a dysregulation of the Ras/MAPK pathway caused by haploinsufficiency of MAP2K2. This is the first report of deletion of MAP2K2 associated with a phenotype suggestive of a RASopathy.

827/T

22q11.2 deletion syndrome: Three unexpected diagnoses through Single Nucleotide Polymorphisms (SNP) microarray in a four month period. *M. Ronningen Johnson[1], C. Dinsmore[1], A. Bytyci Telegrafi[1], D. AS Batista[2], M. Gunay-Aygun[1], R.D. Cohn[1], A. Hamosh[1].* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Pathology Department, Johns Hopkins University, Baltimore, MD.

22q11.2 deletion syndrome is a common genetic condition with a current prevalence of 1/2000-1/4000 births. With the advent of SNP microarray technology, diagnoses of subtle and non-classic presentations are being made in individuals whose clinical features are not consistent with the clinical description of this condition. From 12/2009 to 4/2010 we evaluated three individuals with unanticipated diagnoses of 22q11.2 deletion syndrome. The first patient is a 12 year-old female who presented to the genetics clinic with a history of autism and hyperflexibility. A bifid uvula and hypertelorism were observed. An echocardiogram showed an aortic root measurement on the high end of normal (2.70 cm, z-score = 1.9) and was otherwise unremarkable. TGFBR1/2 sequencing and a SNP array were pursued. TGFBR1/2 was negative. The SNP array showed an interstitial deletion at 22q11.21 (2.68-2.73 Mb). The second diagnosis was made in a two day old male in the newborn nursery with prenatally diagnosed right multi-cystic dysplastic kidney, left hydronephrosis and hydroureter. Karyotype and SNP array were sent by the newborn nursery and a genetics consult was requested for questionable dysmorphic features. An echocardiogram showed only a small patent foramen ovale. Examination revealed no dysmorphic features. The karyotype was 46,XY and the SNP array showed a 2.6 Mb deletion of 22q11.2 deletion. The third case involved a genetics consult for a 2 month-old male on the GI service due to poor feeding and dysmorphic features. An echocardiogram showed a moderate atrial septal defect, and the examination revealed petite facial features, mild micrognathia, overfolded helices and an intact but highly arched palate. The karyotype was 46,XY and the SNP array diagnosed 22q11.2 deletion syndrome (2.58 Mb). These patients illustrate the broad phenotypic variability of 22q11.2 deletion syndrome and represent cases that would have been undiagnosed or diagnosed later without the utilization of SNP microarray technology. While 22q11.2 deletion syndrome is a common and well described genetic condition, these cases show that clinical examination alone may not identify all affected individuals. We anticipate that SNP array technology will result in an increasing number of diagnoses, spectrum expansion, and that prevalence estimates may rise.

828/T

Two identical cases of dup(16)(p13.3->p13.11); a new microduplication syndrome? *R. Pasion[1], B. Rush[1], S.S. Brooks[3], C. Botti[3], M. Holt[4], J. Tepperberg[1], S. Schwartz[1], R.D. Burnside[1], I. Gadi[1], V. Jaswaney[1], H. Risheg[2], E. Keitges[2], P. Papenhausen[1].* 1) Laboratory Corporation of America RTP, NC; 2) Laboratory Corporation of America Seattle, WA; 3) Department of Pediatrics, UMCNJ-Robert Wood Johnson Medical School, New Brunswick, NJ; 4) Blythe Family Health Clinic, Blythe, CA.

We present two patients referred for whole genome SNP microarray (Affymetrix 6.0). Both individuals have an identical 3.377 Mb interstitial duplication of 16p13.3->p13.11 (11,946,847-15,323,999). Patient 1 is a three year old male who was born at 25 weeks gestation, weighing 745 grams. Neonatally, he was in the NICU for 86 days due to respiratory distress, apnea, bradycardia, anemia and jaundice. Currently, he is non-dysmorphic, has global developmental delays, tip toe walks with an abnormal gait, and has significant language delays with only 2 words. He has slightly autistic behavior, but has not had a formal evaluation for autism. Patient 2 is a 12 year old female who was born at 32 weeks gestation, weighing 2353 grams, and was hospitalized neonatally for three weeks. She is non-dysmorphic, with cognitive and social delays. She also has a history of significant language delay, with no sentences until 7 years of age. While neither patient is dysmorphic, both demonstrate prematurity, significant speech delays, global developmental delays, and mild behavioral issues. The 3.377 Mb interval contains 8 OMIM annotated genes and numerous refseq genes. No previously reported cases of this duplication have been published. However, the duplicated interval encompasses the distal portion of the recently described 1.5Mb 16p13.1 microdeletion/microduplication, which is associated with a predisposition to autism, mental retardation, behavioral problems and speech delays. The deletion is more clearly implicated to be causal whereas significance of the duplication is unclear. Two candidate genes, NTAN1 and NDE1, have been hypothesized as contributing to the phenotype of the 1.5 Mb duplication. The NTAN1 candidate gene is included in the both the 3.377 Mb and 1.5 Mb duplications. Shared phenotype between the two microduplications includes speech delays and absence of dysmorphic features. Behavioral problems in individuals with the 1.5 Mb duplication appear to be more severe than the larger duplication, perhaps related to the duplication of NDE1 in the smaller duplication. The identical duplication in both patients and a similar phenotype further implicates duplication of the NTAN1 candidate gene in contributing to developmental and speech delays and the 3.377 Mb duplication may define a new duplication ASD related syndrome region.

829/T

Microdeletions and microduplications of 2q23.1 involving the *MBD5* gene. *E.A. Repnikova[1], A. Bailes[1], A. McKinney[1], A. Brock[1], C. Deeg[1], L. Erdman[1], J. Gordon[1], C. Weber[1], D. Bartholomew[1,3], K. Manickam[1,3], D. Lamb Thrush[1,3], S. Reshmi[1,2], C. Astbury[1,2], R.E. Pyatt[1,2], J. Gastier-Foster[1,2,3].* 1) Laboratory Medicine, Nationwide Children's Hospital, Columbus, OH; 2) Department of Pathology, Ohio State University, Columbus, OH; 3) Department of Pediatrics, Ohio State University, Columbus, OH.

Haploinsufficiency of the *MBD5* gene (methyl-CpG domain binding protein) is believed to be the primary cause of the features associated with the 2q23.1 microdeletion syndrome, which include microcephaly, intellectual disabilities, severe speech impairment, and seizures. The *MBD5* gene encodes several alternatively-spliced transcripts that are expressed in the cerebellum, muscle, heart, pancreas, and kidney. In all previously reported cases, deletions ranged in size from 200 kb to more than 4 Mb (which contained multiple genes including all the *MBD5* isoforms). Duplication of the 2q23.1 region is extremely rare (only four cases have been reported) with sizes ranging from 4-5 Mb and most are visible by standard cytogenetic analysis. In this study, we report the molecular and clinical characterization of two patients with alterations in the *MBD5* gene detected by oligonucleotide array comparative genomic hybridization. The first patient presented with developmental and speech delay. We identified a *de novo* 240 kb deletion which contained only the 5'UTR of the long *MBD5* transcript but did not disrupt shorter isoforms. A previous report described two siblings with 400 kb deletions that also contained a portion of only the *MBD5* long isoform 5'UTR. Similarly, these patients had developmental and speech delay and stereotypic behavior. However, all the previously reported deletion cases, including our case, involving only the long *MBD5* transcript lacked other features characteristic of the 2q23.1 microdeletion syndrome. Our second patient presented with a mild Angelman-like phenotype including mild developmental delay and seizures. She also exhibited motor tics and skin picking behavior. In this patient, we detected an approximately 600 kb duplication in chromosome 2q23.1 which included the majority of the *MBD5*, as well as *EPC2* (a member of the polycomb protein family, involved in heterochromatin formation), a portion of *KIF5C* (a neuron-specific kinesis family member) and *MIR1978*. To our knowledge, submicroscopic duplications at 2q23.1 have not been previously reported. These cases suggest that the *MBD5* gene may play an important role in pathogenesis involving deletions and duplications of the 2q23.1 region.

830/T

Chromosome 1q21.2 microdeletion in a child with phacomatosis pigmentovascularis type IIIb. *J. Stone[1], W.R. Heymann[2], S.M. Manders[2], R.E. Schnur[1].* 1) Genetics/Pediatrics, Cooper University Hospital/Robert Wood Johnson Medical School, Camden, NJ; 2) Dermatology/Internal Medicine, Cooper University Hospital/Robert Wood Johnson Medical School, Camden, NJ.

Phacomatosis pigmentovascularis (PPV) refers to a group of disorders with congenital nevoid pigmentary and vascular skin lesions, +/- systemic anomalies. The underlying genetic etiology remains elusive, but PPV is thought to represent post-zygotic somatic mutation/mosaicism, given the segmental distribution of lesions, sporadic occurrence, and discordance in MZ twins (e.g., Moutray et al. 2010). PPV is classified based on the type of cutaneous abnormalities. Type IIIb PPV includes speckled lentigines/nevus spilus, vascular lesions and systemic anomalies. We report an 8 year-old boy with PPV type IIIb and a 77.6 kb chromosome 1q21.2 deletion detected by microarray analysis. He has mild learning disability and craniofacial variations (hypertelorism, high arched palate). Pigmented lesions include segmental lentigines on a background of increased pigment (nevus spilus) and pigmentary clumping of the irides. Several lesions cross the midline. Vascular lesions include portwine stains, conjunctival telangiectasias and a hemangioma of the right temporoparietal region. He also has left leg hemihyperplasia, pelvic tilt and scoliosis. MRI showed low-lying cerebellar tonsils at the level of the foramen magnum, a venous anomaly, hypoplastic frontal sinuses, and a posterior location of the conus medullaris without tethered cord. He also had hepatomegaly with a relatively small spleen. Parental karyotypes, performed previously, were normal. Mother does not have the 1q21.2 deletion by microarray analysis; paternal testing is pending. The microdeletion contains two OMIM genes, *ENSA* and *MCL1*. *MCL1*, a member of the *BCL2* gene family, may function as a cell growth regulator/anti-apoptotic agent. Could hemizygosity of *MCL1* contribute to the dysregulation of melanocytic and endothelial cell growth that comprises the PPV phenotype? Also, *ADAMTSL4* lies only ~4 kb centromeric to the deletion and is part of a gene family involved in angiogenesis, cell adhesion and CNS patterning. In summary, our patient has the first reported chromosome anomaly associated with PPV. Genes within chromosome 1q21.2 may underlie PPV. Overt chromosomal or gene mosaicism may not be the underlying mechanism as has been assumed, but localized factors during embryogenesis or a "second hit" mechanism may underlie the patchy distribution of PPV lesions. We suggest that other children with PPV be screened with microarray and sequencing of *MCL1* and *ADAMTSL4* as candidate PPV genes.

831/T

Interstitial deletion of the 6q16.3q21 chromosomal region: report on a new patient and review of the literature. *J. Puechberty[1,2], A. Schneider[2], M. Tournaire[2], M. Girard[2], C. Coubes[1], L. Pinson[1], E. Haquet[1], AM. Chaze[2], M. Vincent[1], G. Lefort[2], P. Sarda[1,2], D. Geneviève[1], P. Blanchet[1].* 1) Centre de Référence Anomalies du Développement et Syndromes Malformatifs, Département de Génétique Médicale, CHRU Arnaud de Villeneuve, Montpellier, France; 2) Laboratoire de Génétique Chromosomique, Département de Génétique Médicale, CHRU Arnaud de Villeneuve, Montpellier, France.

We report on an interstitial 6q16.3q21 deletion in an 8.5-year-old girl. The patient was referred to our Department of Medical Genetics because of psychomotor delay of undefined origin associated with developmental delay and dysmorphic features. The prenatal period was marked by moderate intrauterine growth retardation. Clinical examination found facial features (prominent forehead, high arched eyebrows, slight bilateral ptosis with downslanting palpebral fissures, slightly elongated face, macroglossia, cup-shaped ears), body and facial asymmetry, abnormal asymmetric skin pigmentation, ligament hyperlaxity, hypermetropia and strabismus. She presented with psychomotor delay (developmental delay, delayed walking, ataxia, delayed language, hypotonia), and echolalia. She had a friendly and amiable behavior. Skeletal X-ray study revealed delayed bone age (18 months at 5 year-old), 11 pairs of ribs, delayed ischio-pubic bone ossification, coxa valga, thin diaphyses. Psychomotor development was improved through appropriate medical care and supportive educational management. Initial blood chromosome studies using standard cytogenetic methods (RHG and GTG banding) at a 550 band level were interpreted as normal. Microarray analysis (SNP 6.0 Affymetrix) subsequently showed a 4.85 Mb interstitial deletion of the long arm of chromosome 6 (6q16.3q21). To date, less than one hundred 6q deletions have been reported and are subdivided in three cytogenetic groups (proximal, middle and terminal). Constitutional middle deletions of the long arm of chromosome 6 are rare chromosomal events with around 20 patients reported in the literature. We compare the phenotype observed in our patient to the phenotype observed in the patients with overlapping deletions reported in the literature and discuss candidate genes linked to the features described in patients with 6q16.3q21 deletion.

832/T

A family with microdeletion at 2q14 associated with IUGR, OFC at the 2nd%, cognitive impairment and hypercoagulability. *J. Richer, M. Lines, J. McGowan-Jordan, K. Boycott.* Med Gen, CHEO, Ottawa, Canada.

The proband was born following a pregnancy complicated by gestational diabetes on diet, maternal cigarette smoking (1 pack/day) to a mother on Novolox for a prior history of phlebitis. He was born at $37^{6/7}$ weeks gestational age. Birth weight was 2050g (<3rd%), length 47cm (10th%) and head circumference 30.8cm (<3rd%). At 5 months of age he had been admitted 4 times for failure to thrive. Dysmorphic features included: 2 posterior hair whorls, frontal upsweep, medial eyebrow flaring, mild telecanthus with bilateral epicanthal folds, depressed nasal bridge and long philtrum with thin upper vermillon . He re-presented at 3 years of age with significant development delay with impulsive and aggressive behaviors. Head circumference was 2nd%, weight 5th% and height 10-25th%. His mother required special education since grade 2 and had been unable to retain employment for 15 years. Her head circumference was 52 cm (2nd%) and she had a history of multiple thrombotic events for which she is now on warfarin. Three siblings had normal birth weights, head circumferences and early developmental milestones within normal limits, the fourth sibling had IUGR (birth weight at 36 weeks of 1786g, <3rd%), severe developmental delay with a head circumference at the 2nd%. At 3 years of age, microarray (Baylor, oligonucleotides V8.0) showed a maternally inherited 2 megabase deletion at 2q14.3. The deletion was also present in the affected brother and was absent in the 3 unaffected brothers. In the neonatal period, the proband had a normal brain MRI, echocardiogram and karyotype (500-550 bands). This region contains 2 genes of clinical importance: BIN1 and PROC. Haploinsufficiency of PROC causes protein C deficiency thereby explaining the hypercoagulability in this family. BIN1 is a highly conserved gene in mammalian and alternative splicing leads to the expression of 2 isoforms: amphiphysin 2, primarily expressed in muscle, and amphiphysin 2a (amph2a) which is mainly expressed in brain (particularly at nodes of Ranvier). Amph2a forms heterodimers with Amph1 forming a complex which is required in the endocytic recycling pathway and is evolutionarily conserved from worms to mammals. Knock-out mouse for amph1 show cognitive deficits and a higher rate to sudden death due to paroxysmal seizures. Our findings suggest that haploinsufiency of BIM1 may lead to dosage imbalance between amph2a and amph1 and explain our patients' cognitive deficits and microcephaly.

833/T

Interstitial deletion of 3q22-q25 in associated with multiple congenital abnormalities, growth retardation and intellectual disability. *E.C. Tan[1], E.C.P. Lim[1], B. Cham[2], L.K. Ching[1], I.S.L. Ng[2].* 1) KK Research Centre, KK Women's & Children's Hospital, Singapore; 2) Genetics Service, KK Women's & Children's Hospital, Singapore.

Interstitial deletions on the long arm of chromosome 3 are very rare, and most of the few recorded cases involved 3q12 - 3q21. More common abnormalities involving chromosome 3 are structural rearrangements, translocations and mutations in FOXL2 which have been associated with blepharophimosis, ptosis, and epicanthus inversus syndrome (BPES). In this report, we describe a boy with normal karyotype. He was born at term by normal delivery. He had low birthweight of below 2.5 kg. His length at birth was 45 cm and his occipito-frontal circumference was 30 cm. Clinical examination at 8 years of age showed severe growth retardation with height, weight and occipito-frontal circumference all below the 3rd centile. Dysmorphism in this patient include turricephaly, ptosis, bilateral microphthalmia, low-set ears, micrognathia, overlapping fingers and rocker bottom feet. Other abnormalities include cleft palate, moderate ventral septal defect, small patent ductus arteriosus, absent right kidney, and bilateral inguinal hernia. The non-BPES-associated abnormalities are probably the result of abnormalities in genes other than FOXL2. Array-CGH analysis revealed an interstitial deletion from 3q22.1 to 3q25. This deletion was confirmed by qRT-PCR. The chromosomal region deleted in this patient provides candidate genes for molecular genetic studies related to the phenotypic presentations.

834/T

The 12q14 microdeletion syndrome : description of a new case without osteopoikilosis. *L. Telvi[1], L. Boutaud[1], O. Brichet[2], A. Coussement[1], JM. Dupont[3], G. Viot[4], C. Bellesme[2].* 1) Cytogenetics Laboratory, Hosp St Vincent de Paul, Paris, France; 2) Department of Pediatric Endocrinology, Hosp St Vincent de Paul, Paris, France; 3) Cytogenetics Laboratory, Hosp Cochin, Paris, France; 4) Genetics Department, Hospital Cochin, Paris, France.

Recently, the microdeletion of 12q14 region has been reported as a new chromosomal syndrome (Merten,2007). The phenotype of these patients was defined with mental retardation, short stature, dysmorphia and osteopoikilosis. We report a nine-years-old boy with mental retardation, dysmorphic features, unusual hyperactivity and short stature. The genital examination showed cryptorchidia and small penis. At nine-years-old he had no speech and showed an unusual hyperactivity. The patient had a phenotypically normal brother. The karyotype with RHG banding of the patient was found normal. By using Cytochip Bac Arrays v20 Bluegnome (Amplitech) we identified a microdeletion at 12q14. The RP11-366L20 and RP11-109N1 probes was used with FISH analysis and confirm the deletion. The size of the deletion was 5.8 Mb (linear position 60,290,737-66,163,925). The karyotype of the parents was found normal with absence of 12q14 deletion after FISH analysis. Few cases was described to date with 12q14 microdeletion (Merten & al, 2007; Mari & al, 2009; Buysse & al, 2009). The patient described did not showed osteopoikilosis and/or skin manifestions caracteristic of Buschke-Ollendorff syndrome after squeletal X-rays, ultrasound examination and RMI. The LEMD3 gene of our patient was found deleted. However, LEMD3 gene was described as implicated with ostepoikilosis and/or skin manifestations caracteristic of Buschke-Ollendorff syndrome. The relationship of LEMD3 deletion with the absence of osteopoikilosis in this case is discussed.

835/T

A patient with Williams-Beuren syndrome and multicystic kidney disease with deletions at 7q11.23 and 17q12. *L. Cohen[1], J. Samanich[1], Q. Pan[2], A. Ludtke[3], L. Mehta[3], R. Marion[1].* 1) Williams Syndrome Center, Division of Genetics, Department of Pediatrics, Children's Hospital at Montefiore, Bronx, NY; 2) Dept. of Pathology, Montefiore Medical Center, Bronx, NY; 3) Dept. of Genetics & Genomic Sciences, Mount Sinai School of Medicine, NY, NY.

The Williams-Beuren syndrome (WBS) is a complex genomic disorder entailing distinctive facial dysmorphisms, cardiovascular abnormalities (predominantly supravalvular aortic stenosis [SVAS]), intellectual disabilities, unusual behavioral features, and a specific cognitive profile with considerable variability. Additional symptoms include endocrine abnormalities, renal anomalies and connective tissue weakness. We report a monozygotic twin patient with WBS who presented with multicystic kidneys in the newborn period, and, in addition to the typical WBS deletion at 7q11.23 (detected by FISH), was found to have a de novo 1.7 Mb deletion in the 17q12 region on microarray comparative genomic hybridization (array CGH). Prenatal history was significant for the patient's co-twin being diagnosed with bilateral multicystic dysplastic kidneys and anhydramnios. A selective termination of the co-twin was performed at 23 weeks gestation. In the prenatal period, the patient herself had intrauterine growth retardation and single umbilical artery. At birth, she was symmetrically small (<3%). Facial features were suggestive of WBS and FISH revealed the typical deletion at 7q11.2. Echocardiogram showed mild bilateral peripheral pulmonic stenosis with no significant SVAS. Renal sonograms showed small kidneys with bilateral tiny cysts. Neonatal course was otherwise uncomplicated. While renal anomalies are reported in WBS, the severe renal involvement in the patient's twin and her own presentation are unusual. Hence, array CGH using a custom designed Agilent 44K oligonucleotide microarray with 50kb resolution in targeted regions was performed. In addition to the 1.3Mb deletion on 7q11.2, a second deletion at 17q12 was detected. Karyotype and array CGH on parents were normal. Review of literature shows that deletion of chromosome 17q12, encompassing the HNF1beta gene, is associated with cystic renal disease and is the first recurrent genomic deletion associated with maturity onset diabetes of the young (MODY5). In addition, two cases of Mayer-Rokitansky-Kuster-Hauser syndrome with identical deletions on chromosome 17q12, including TCF2 and LHX1 genes, have also been described. It is likely that the additional 17q12 deletion has played a role in modifying the phenotype in our patient. This case highlights the importance of using array CGH in the clinical setting to uncover the etiology of atypical findings in individuals with known microdeletion syndromes.

836/T

Microdeletions within the "Imprinting region 2" on 11p15 identify a variant of the Beckwith-Wiedemann syndrome at risk for cardiac arrythmia. *G. Neri[1], F. Gurrieri[1], M. Zollino[1], G. Marangi[1], D. Orteschi[1], R. Pietrobono[1], M.G. Pomponi[1], A. Camporeale[2], F. Bellocci[2].* 1) Inst Di Gen Medica, Univ Cattolica, Rome, Italy; 2) Istituto Di Cardiologia, Univ Cattolica, Rome, Italy.

Beckwith-Wiedemann syndrome (BWS) is a relatively common genetic overgrowth condition, characterized by clinical variability and genetic heterogeneity. Cardinal features include macroglossia, omphalocele, and macrosomia. Psychomotor retardation is uncommon and familial recurrence rare. BWS is caused by genetic or epigenetic alterations of two imprinting domains (ICR1 and ICR2) on 11p15, ICR2 being involved in most cases. Hypermethylation in ICR1 is associated with BWS, whereas hypomethylation of the same region is associated with Silver-Russel syndrome (SRS), a condition characterized by growth delay. Abnormalities of ICR2 include loss of methylation of KvLQT1-AS or point mutations of CDKN1C, both occurring on the maternal allele. We here report on two unrelated females , aged 16 and 19 years respectively, both carrying a 11p15 microdeletion involving ICR2. The deletion spanned about 900 kb in the first case, including CDKN1C, KCNQ1 and additional 15 flanking genes. The size of the deletion in the second patient was 200 kb, encompassing the entire KCNQ1OT1 antisense transcript (AS), and exons 11-16 of KCNQ1. Both patients presented with an atypical BWS phenotype, including mild mental delay in the first patient [Zollino et al, J Med Genet, 2009], a long QT syndrome in the second and overgrowth and facial dysmorphisms in both. The long QT syndrome was responsible for a cluster of life-threatening ventricular fibrillation episodes, needing an urgent implant of intra-cardiac defibrillator. In this patient loss-of-function mutation of KCNQ1 is likely responsible for the long QT trait, although the severity of clinical presentation may be due to additional mutations either in the remaining KCNQ1 allele or in other genes known to cause long QT. Interestingly, the ICR2 deletion in patient 2 was inherited from the mother, who carries the same alteration on the paternal allele. The mother has minor physical anomalies, short stature and long QT. The first patient was re-called and checked for a long QT, which she did not have. Nonetheless, patients in which ICR2 is deleted should be monitored for long QT syndrome. Both patients were counselled that a 50% recurrence risk of BWS expected in the offspring.

837/T

Immune deficit in a cohort of 90 patients with 22q11 deletion. *M. PEREZ, P. SARDA, E. HAQUET, A. SCHNEIDER, G. LEFORT, D. GENEVIEVE.* Medical Genetics, Arnaud de Villeneuve Hospital, Montpellier, France.

The 22q11 deletion causes the most common microdeletion syndrome. During a period of five years, the Montpellier Reference Center for Developmental Abnormalities and Malformative Syndromes has coordinated the multidisciplinary management of 90 patients aged from a few months to 45. Ear-nose-throat (ENT) infections are particularly frequent during the first years of life for children. ENT infections in children have multiple origins, associating inner and middle ear abnormalities, pharyngeal and velar abnormalities and " transitory" immune deficit. CD4 lymphocytes and CD8 lymphocytes deficits probably play a role in these infections in the young child. To investigate the immunologic constitution of patients we characterized the T-cell deficiency in the follow-up of patients with 22q11 deletion. CD4 levels (number/mm3 and percentage) normalize for the majority of patients before the age of 8. CD8 lymphocytes levels (number/mm3 and percentage) remain low until the age of 15, as opposed to what is reported in the literature. In most patients, the immune deficit improves with time, therefore CD4 and CD8 lymphocytes levels do not need to be regularly measured once normalized, unless a clinical problem appears. Autoimmune disorders are more frequent in the group of patients with 22q11 deletion (10%). Many patients who were properly vaccinated do not achieve immunity for certain vaccinations. With advancing age it is thus important to check residual antibody levels after certain vaccinations (polio, tetanus, diphtheria, hepatitis, mumps for men and rubella for women).

838/T

Paternal duplication 15q11-q13 results in sleep problems, anxiety and abnormal EEG patterns. *N. Urraca[1], J. Cleary[2], E. Pivnick[3], K. McVicar[3], V. Brewer[3], R. Thibert[4], L.T. Reiter[1,3].* 1) Department of Neurology, UTHSC, Memphis, TN; 2) Department of Speech and Language Pathology, University of Memphis, Memphis, TN; 3) Department of Pediatrics, UTHSC, Memphis, TN; 4) Department of Neurology, Mass General Hospital, Boston, MA.

The widespread use of clinical microarrays has substantially increased the detection rate of 15q11-q13 interstitial duplication cases. In most cases the duplication is de novo, however there are few familial cases. Although the majority of duplications in this region are maternal in origin, some cases of paternally transmitted 15q duplication have been reported with a presumably normal phenotype since unaffected mothers have transmitted paternally derived duplication chromosomes to their affected children. A few paternal cases have been reported with speech delay and behavior problems. Here we report for the first time a father with a paternal duplication who transmitted to both his son and daughter. Both children and the father had macrocephaly (>97%), an asymmetric face due to unilateral relaxed nasal labial fold, and mild unilateral eyelid ptosis. They also shared the following features: downslanting of palpebral fissures, prominent infra-orbital creases, upturned, short nose, mildly elongated philtrum, thin upper lip, round, moon-like face and mild orofacial hypotonia. The son had radiological signs of Chiari I malformation. In addition he also had a pineal gland cyst. The daughter had a voracious appetite since infancy. ADOS/ADI-R testing indicated that the son meets the criteria for autism, however his sister does not. Both children had normal awake EEG's with excessive bi-frontally predominant 18-22Hz beta activity throughout the recording, which may be characteristic of int dup 15. The father and both children have sleep problems and showed signs of anxiety. Pediatric polysomnogram showed abnormal sleep architecture in both children. Molecular analysis indicated a class II duplication in all three individuals of paternal origin. The majority of int dup 15 cases detected are maternal in origin; this is most likely due to the coincidence of autism with maternal duplications. Although clinically neither sibling clearly fit an autism diagnosis, the male proband did meet the minimal criteria for autism on the ADOS. Further evaluation must be conducted on this family and others with paternal 15q duplication syndrome, including a special emphasis on sleep evaluation, evidence of anxiety, EEG features and detailed physical description. These investigations may help to establish as well as distinguish the unique characteristics of paternal 15q duplications from the more common maternal 15q duplications that cause autism.

839/T

Refinement of the interstitial microdeletion in chromosome 6q25 associated with mental retardation. *A.B. Ekici[1], J. Hoyer[1], C. Petsch[1], I. Göhring[1], A. Rauch[1,2], A. Reis[1].* 1) FAU Erlangen-Nuremberg, Institute of Human Genetics, Erlangen, Germany; 2) University Zurich, Institute of Medical Genetics, Zurich, Switzerland.

Interstitial deletions of chromosome 6q are very rare findings. Deletions range from 0.3 Mb to several megabases spanning multiple chromosomal bands. Some associated clinical features are commonly seen including mental retardation, hypotonia and facial dysmorphism, while others like microcephaly, brain malformation, micrognathia, hearing loss, hernia and heart malformation are only seen in some cases. The high clinical variability is explained by the large divergence in the overlap and gene coverage of the deletions. We report on a 28 month old infant with normal female karyotype, mental retardation (MR), facial dysmorphism, strabismus alternans, plagiocephaly, hyperopy and body measurements on 10th centile. After exclusion of known aberrations with various commercial MLPA-kits, Angelman Syndrome with methylation specific PCR and Rett Syndrome (MECP2 point mutations) we conducted a genome-wide analysis of copy number variation (CNV). We performed molecular karyotyping in the patient and both parents with high density Affymetrix Genome-Wide Human SNP 6.0 microarrays. In addition to a paternally inherited 121 kb duplication on chromosome 12 we detected a de novo deletion of 2.3 Mb on chromosome 6q25. This deletion encompasses only 5 known genes and lies within the previously reported deletion region. We hypothesize that haploinsufficiency for a gene within the 2.3 Mb deleted region may impair normal development. In order to identifying the phenocritical gene we are screening these five positional candidates for point mutations in 144 patients with moderate to severe MR from our MRNET-cohort. To date we found a sequence alteration in one of the genes, highly expressed in brain. One patient of our screening cohort showed an exonic 11 bp deletion leading to a frameshift resulting in a premature stop codon, which would shorten the protein by 58 amino acids. Sequencing of both parents to prove de novo origin of the mutation is ongoing as well as mutation analysis in further patients and controls. This study is part of the German Mental Retardation Network (www.german-mrnet.de).

840/T

Intragenic deletion of the *AUTS2* gene in patients with mental retardation, autistic behaviour and dysmorphic features. A new microdeletion syndrome. *E.A. Sistermans[1], E. Voorhoeve[1], G. Beunders[1], B. van der Zwaag[2], H.Y. Kroes[2], S. Vergult[3], G. Mortier[4], B. Menten[3], S. Gana[5], J.J. Saris[6], M. van der Mespel[1], D. Linders[1], A. Nieuwint[1], J.M. van de Kamp[1], S. Groffen[1], M.M. Weiss[1].* 1) Dept Clinical Genetics, VU University Medical Center, Amsterdam, The Netherlands; 2) Dept Medical Genetics, University Medical Center Utrecht, The Netherlands; 3) Center for Medical Genetics, Ghent, Belgium; 4) Dept Medical Genetics, Antwerp University, Edegem, Belgium; 5) Genetica Medica, Pavia, Italy; 6) Dept Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands.

Disruption of the *AUTS2* gene on 7q11.2 has been described in five patients with a translocation with one of the breakpoints in 7q11.2 by Kalscheuer et al. (2007) and Sultana et al. (2002). These findings suggested that rearrangements of *AUTS2* cause mental retardation and/or autism. We here present three patients with (partial) deletions of *AUTS2* detected by array CGH (Agilent 180k oligo-array), and an additional patient with a translocation disrupting *AUTS2*. One patient lacks the 3' end of the gene, which is likely to result in inactivation of *AUTS2* only. This patient has mental retardation, and shares several distinct dysmorphic features described in the translocation patients, confirming that aberrations of the *AUTS2* gene are causative for MR and/or autism. This new microdeletion syndrome is unique in that it is more often caused by translocations than by "pure" microdeletions. Furthermore, the gene is located close to the Williams-Beuren syndrome critical region on 7q11.23, and deleted in rare patients with larger non-standard deletions (including one of our patients). It is very likely that deletion of *AUTS2* will add to the phenotype in these patients. Functional studies are currently performed to assess the biological role of AUTS2, which is highly expressed in fetal and adult brain.

841/T

Parathyroid gland dysfunction in a cohort of 90 patients with 22q11 deletion. *P. Sarda, M.J. Perez, G. Lefort, E. Haquet, A. Schneider, D. Genevieve.* Dept Med Gen, Arnaud de Villeneuve Hosp, Montpellier, herault, France.

The 22q11 deletion causes the most common microdeletion syndrome. During a period of five years, the Montpellier Reference Center for Developmental Abnormalities and Malformative Syndromes has coordinated the multidisciplinary management of 90 patients aged from a few months to 45. 35% of the subjects had hypocalcemia, half in the neonatal period and for the other patients hypocalcemia was diagnosed after the first year of life. 6% of the patients developed hypocalcemia after puberty or at adult age. The diagnosis of late-onset hypocalcemia in 15% of the patients implies the organization of a regular calcemia monitoring at all age. In the population with normal calcemia, the level of calcium showed a progressive decrease with age (y=-0.0026x + 2.38). Ionized calcium was always low (1.15 +/- 0.1 mmol/l , normal between 1.20 and 1.35), which was probably responsible for the cramps the patients presented. PTH levels in blood are low but seem to be of little interest for the follow up of these patients (PTH for patients with normal calcemia : 17.3 +/- 8.3 pg/ml versus 14.9 +/- 8.3 pg/ml for patients with hypocalcemia). The results we observed concerning the risk of late-onset hypocalcemia suggest that the monitoring of calcemia should not be neglected. The frequency and the method of follow-up still need to be defined as well as the therapeutic regimen and its management. We suggest a check-up every 2 years for patients with 22q11 deletion. However this raises the problem of patient accessibility and participation.

842/T

Functional and cellular characterization of human Retinoic Acid Induced 1 (RAI1) mutations associated with Smith-Magenis Syndrome. *P. Carmona-Mora[1], C.A. Encina[2], C.P. Canales[1], J. Molina[2], L. Cao[1], J.I. Young[1, 2, 3], K. Walz[1, 2].* 1) Dr. John T. Macdonald Foundation Department of Human Genetics, John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine Miami, Florida, USA. 1501 NW 10th Avenue Miami, FL 33136; 2) Centro de Estudios Científicos, CECS, Valdivia, Chile. Arturo Prat #514, Valdivia, Chile; 3) Centro de Ingeniería de la Innovación (CIN), CECS, Valdivia, Chile. Arturo Prat #514, Valdivia, Chile.

Smith-Magenis Syndrome is a contiguous gene syndrome with a birth prevalence estimated at 1/25,000. The clinical phenotype includes craniofacial abnormalities, brachydactyly, self injurious behavior, sleep abnormalities and mental retardation. The dosage sensitive gene causative of SMS has been identified: the Retinoic Acid Induced 1 (RAI1). Little is known about the function of human RAI1. We generated the full-length cDNA of the wild type protein and four mutated forms: RAI1-HA Q1562R, RAI1-HA S1808N, RAI1-HA 2687delC and RAI1-HA 3103delC, three of them previously associated with SMS clinical phenotype. Molecular weight, subcellular localization and transcription factor activity of the wild type and mutant forms were studied by western blot, immunofluorescence and luciferase assays respectively. The wild type protein and the two missense mutations presented a higher molecular weight than expected, localize to the nucleus and activate transcription of reporter gene. The frameshift mutations generated a truncated polypeptide with transcription factor activity but abnormal subcellular localization. Besides, we have generated two different C-terminal halves of the RAI1 protein (1038aa-end and 1229aa-end). Both were able to localize into the nucleus but have no transactivation activity. With this work, we demonstrate that the human wild type protein has transcription factor activity, and is able to localize to the nucleus. Moreover, it is possible to define a transcription factor domain within the first 1034 aa and that the nuclear localization signals reside in the second half the protein. Our results indicate that transcription factor activity and subcellular localization signals reside in two separate domains of the protein and both are essential for the correct functionality of RAI1. The pathogenic outcome of some of the mutated forms can be explained by the dissociation of these two domains.

843/F

Branchio-oculo-facial syndrome: Inner and middle ear malformations. *M. Carter[1], S. Blaser[1], W. Meschino[2], B. Papsin[1], W. Reardon[3], R. Klatt[1], R. Babul-Hirji[1], J. Milunsky[4], D. Chitayat[1].* 1) Hospital for Sick Children, Toronto, ON, Canada; 2) North York General Hospital, Toronto, ON, Canada; 3) Our Lady's Hospital for Sick Children, Crumlin, Dublin, Ireland; 4) Center for Human Genetics, Boston University School of Medicine, Boston, Massachusetts, USA.

Branchio-oculo-facial syndrome is an autosomal dominant disorder of the first and second pharyngeal arches. The main features of this syndrome are cutaneous defects in the cervical, infra-auricular and/or supra-auricular region; ocular anomalies; and characteristic craniofacial features including dolichocephaly, malformed pinnae, broad nasal tip, pseudocleft, up-slanting palpebral fissures, and cleft lip with or without cleft palate. Other common findings are conductive hearing loss, prematurely gray hair, ectopic dermal thymus, and scalp cysts. Recently, the gene responsible for BOFS was identified as TFAP2A (Milunsky, 2008). The gene is expressed in cranial neural crest cells and their derivatives including the mesenchyme of the medial and lateral nasal prominences and the maxillary prominence. We report middle and inner ear abnormalities in three individuals with mutation-proven BOFS. Patient 1 is a 13-year old boy with bilateral cleft lip and palate, malformed pinnae, congenital conductive hearing impairment, and bilateral cervical skin defects. Temporal bone (TB)-CT showed deficient long process of the right incus, bony atresia plate covering left oval window, and mild prominence of the left vestibular aqueduct. Patient 2 is 10-year old boy with moderate bilateral conductive hearing impairment, nasolacrimal duct stenosis, myopia, and skin defects superior to the malformed pinnae bilaterally. TB-CT showed mildly prominent vestibular aqueduct on the left and small bone islands. Patient 3 is an 11 year old girl previously reported as an infant by Raveh et al. (2000). She has mixed conductive and sensorineural hearing impairment, with narrow external auditory canals, cochlear dysplasia, small horizontally-oriented semicircular canals and small bone islands. She has right-sided facial nerve palsy and CT revealed an accessory facial nerve canal with an ectopic origin on the right side. Hearing impairment in individuals with BOFS is common and variable. The majority of described individuals have conductive hearing impairment due to malformed ossicles and/or external canal stenosis/atresia. A sensorineural component to the hearing impairment is increasingly being reported. Sophisticated computed tomography of the temporal bone has revealed inner ear malformations in three reports of patients with BOFS (Raveh 2000, Tekin 2009, and Stoetzl 2009). Our study further delineates the variety of inner and middle ear abnormalities associated with BOFS.

844/F

The low-frequency hearing loss: a mexican family. *E. Hernandez Gomez[1], L. Hernandez Gomez[2], S. Juarez Garcia[3], D. Gomez Torres[4].* 1) Biology, Facultad de Estudios Superiores Iztacala, Mexico; 2) Dept Audiologia Instituto Nacional de Rehabilitacion Mexico; 3) Dept Neuropsicologia Instituto Nacional de Rehabilitacion Mexico; 4) Instituto Nacional de Rehabilitacion Mexico.

The low-frequency hearing loss is genetically heterogeneous, caused by mutation of WFS1 gene located in 5q31. It has been observed in parent families. The hearing loss usually begins in the first decade of life, being non-syndromic and postlingual. Which may progress to profound hearing loss. Audiometric studies show an apical initial, probably a result of endolymphatic hydrops caused by alterations in the stria vascular sclerosis secondary to labyrinthine. Present the case of a Mexican family where the father of four male children have bilateral hearing loss for low frequencies, detected between 11 and 16 years old, There are no previous medical history, hearing loss, exposure to noisy environment or use ototoxic in 5 patients. Physical examination is normal in five patients. The audiometric study on five patients were observed for low frequency hearing loss. Speech audiometry in the five cases was sensory. Tympanometry was observed in two curves A of Jerger and 3 with curves As stapedial reflex absent bilaterally in all patients. Caloric tests in 1 patient is reported with areflexia, 1 with hyporeflexia and 3 patients are normal. Computed tomography normal in all patients. Corroborate the clinical cases with hereditary hearing loss for low frequencies and are similar to the results presented in other studies, only pending the molecular studies give us a definitive diagnosis.

845/F

Congenital deafness diagnosed by custom molecular microarray (ARRAY CGC): A new rapid and cost-effective approach. *P. Rendeiro[1], L. Lameiras[1], A. Lopes[1], L. Dias[1], L. Nunes[2], J. Saraiva[3], A. Fortuna[4], M. Cunha[5], M.H. Carreiro[6], M. Rosa[7], J. Sá[1,3], S. Almeida[1,2], A. Palmeiro[1], P. Tavares[1].* 1) Cytogenetics, CGC Genetics (www.cgcgenetics.com), Porto, Portugal; 2) Centro Hospitalar de Lisboa Central, EPE, Lisboa, Portugal; 3) Hospital Pediátrico de Coimbra EPE, Coimbra, Portugal; 4) Instituto Nacional de Saúde Dr. Ricardo Jorge, IP, Porto, Portugal; 5) Centro Hospitalar Trás-os-Montes Alto Douro EPE, Vila Real, Portugal; 6) Hospital Professor Doutor Fernando Fonseca EPE, Amadora, Portugal; 7) Hospital Garcia de Orta EPE, Almada, Portugal.

Introduction: Congenital hearing loss/deafness is the most common birth defect and the most prevalent sensorineural disorder in developed countries but currently only a minority of genes is included in genetic diagnostics. Genetic factors are considered to cause more than 50% of the cases of congenital deafness in children. Genetic deafness can be inherited, as an autosomal dominant, autosomal recessive, or X-linked recessive trait, as well as by mitochondrial inheritance. Over 400 genetic syndromes that include deafness have been described. Moreover, in some syndromes deafness may appear as the first symptom, while other pathological manifestations may have a later onset during development. Molecular testing is a vital asset to complement the differential diagnosis between nonsyndromic and syndromic hearing loss. Method: Using a custom microarray panel (Arrays CGC - Patent Pending) that contains 312 point mutations, identified in 31 main genes involved on congenital deafness it is possible to identify the molecular basis of the most common forms, both syndromic and nonsyndromic. Results: The samples analyzed were obtained from an already scrutinized population, so the most common genetic alterations were already excluded. We analyzed 110 cases and in 24 we detected mutations or sequence variants on CDH23, GJB2, GJB3, MYO1A, MYO7A, OTOF, SLC26A4 and WFS1 genes. Turnaround time was one week after DNA extraction. Conclusion: The usual diagnostic approach only analyses few genes. With this approach we can drastically increase the number of genes/mutations analyzed maintaining accuracy but reducing turnaround time. This approach greatly enhances genetic diagnostics, allowing early decision-making process in patient management as well as new epidemiologic data.

The Oculocutaneous Albinism Natural History Study at the National Institutes of Health. *D.R. Simeonov[1], B.P. Brooks[2], C.C. Brewer[3], W.M. Zein[2], C.K. Zalewski[3], T.D. Ngugyen[4], M. Huizing[1], W.A. Gahl[1], D.R. Adams[1].* 1) NHGRI, National Institutes of Health, Bethesda, MD; 2) NEI, National Institutes of Health, Bethesda, MD; 3) NIDCD, National Institutes of Health, Bethesda, MD; 4) Clinical Center, National Institutes of Health, Bethesda, MD.

Introduction: Autosomal recessive oculocutaneous albinism (OCA) causes low vision, hair, skin and eye hypopigmentation, and skin ultraviolet-light sensitivity in 1:18,000 newborns. Approximately 85% of OCA is caused by defects in one of four known genes: *TYR*, *OCA2*, *TYRP1* and *SLC45A2*, leaving a substantial minority of OCA cases without molecular confirmation. The pathogenic potential of many individual variants of the known genes has yet to be quantified. Key aspects of the natural history and cellular biology of OCA also remain to be elucidated.

Methods: The NIH OCA Natural History Study is actively recruiting individuals and families with OCA to participate in a 3-5 day evaluation at the NIH Clinical Center in Bethesda, Maryland. Participants are clinically evaluated at the NIH, focusing on comprehensive evaluation of the visual system with an attempt to uncover clinically relevant endpoints, and evaluation of hearing, auditory processing abilities, and low-vision adaptation. Functional assays are being developed to assess the pathogenic potential of individual mutations in known genes.

Results: Forty individuals have been recruited to date. Demographic and preliminary molecular data are presented along with examples of functional assessment of DNA variants.

Conclusions: The careful collection of clinical data, genetic data and cell biological data for persons with albinism has the potential to yield new albinism-related genes, new biological insights and novel therapeutic targets. Medical providers are encouraged to provide information about the study to their patients with albinism.

In Silico and Experimental Analysis of a Novel Intronic *LMNA* DNA Variation Implicated in Limb Girdle Muscular Dystrophy Type 1B and Dilated Cardiomyopathy. *B.W. Darbro[1], E.M. Cox[1], A.A. Stence[1], B.M. Cabuay[3], K.D. Mathews[2], P.L. Nagy[1,4], S.A. Moore[1].* 1) Department of Pathology, University of Iowa, Carver College of Medicine, Iowa City, IA; 2) Departments of Pediatrics and Neurology, University of Iowa, Carver College of Medicine, Iowa City, IA; 3) Department of Internal Medicine, University of Iowa, Carver College of Medicine, Iowa City, IA; 4) Department of Pathology, Columbia University Medical Center, New York City, NY.

Mutations in the *LMNA* gene encoding lamins A and C result in a wide variety of dominant disorders known as laminopathies that include the striated muscle phenotypes limb-girdle muscular dystrophy type 1B (LGMD1B) and dilated cardiomyopathy (DCM). We identified a four-generation family with a novel sequence variant in *LMNA* (c.639+1 G>A) and clinical features of both LGMD1B and DCM. The variably expressed familial phenotype includes increased creatine kinase levels, muscle weakness, and, in some family members, severe cardiomyopathy leading to heart transplant or death. Muscle biopsies in adult members of the second generation revealed mild dystrophic pathology. Cultured fibroblasts from affected family members had increased nuclear blebbing, a feature common to a variety of laminopathies. The *LMNA* sequence variant segregated with affected family members and is present in three currently asymptomatic members of the third generation. To confirm that the novel sequence variation affects proper pre-mRNA splicing, a thorough in silico analysis of the mutation using several online computational tools was performed and predicted improper splicing that would lead to the formation of a premature stop codon (r.635_639del, p.Ser212ArgfsX4). This prediction was confirmed through the use of mutation specific RT-PCR studies in cultured fibroblasts. These data indicate that this novel *LMNA* change is pathogenic and consequently responsible for the LGMD1B and DCM phenotypes seen in this family. Clinical experience with this family affirms that patients with autosomal dominant LGMD should be screened for cardiac abnormalities and mutations in *LMNA*. Furthermore, when novel DNA variants are discovered by gene sequencing, proper in silico analysis can provide valuable clues to mechanisms of pathogenicity and guide confirmatory testing.

848/F

Delineation of novel phenotypes and the identification of new disease genes from United Arab Emirates. *L. Al-Gazali[1], N.A. Akawi[2], S. Ben-Salem[2], B.R. Ali[2].* 1) Dept Pediatrics, Faculty of Medicine and Health Sciences, UAE University, Al Ain, Abu Dhabi, United Arab Emirates; 2) Dept Pathology, Faculty of Medicine and Health Sciences, UAE University, Al Ain, Abu Dhabi, United Arab Emirates.

The local inhabitants of the United Arab Emirates (UAE) are ethnically diverse with ancestries from the south and north of the Arabian Peninsula, Persia, Baluchistan and East Africa. In addition, the majority of the current 5 million inhabitants are expatriates from the Asian subcontinent, Middle Eastern, African and European countries. Despite this admixture of populations, intermarriages between the groups are still rare, with consanguineous marriages within the UAE local and other Arab populations still the norm, leading to the formation of population isolates and indeed the appearance of recessive conditions. Like other regional populations, the UAE has high frequencies of blood disorders including beta and alpha thalassemias, sickle cell disease and glucose-6-phosphate dehydrogenase (G6PD) deficiency. In addition, some other genetic disorders are relatively common in the UAE including cystic fibrosis, deafness, Joubert syndrome and Meckel syndrome. Furthermore, numerous rare congenital malformations and metabolic disorders caused by defects in recessive genes have also been reported. Clinical characterization of phenotypes of patients with recessive disorders from the UAE led to the delineation of rare and new conditions. In addition, molecular studies led to the discovery of a significant number of disease genes. In this paper, we will present the novel phenotypes observed in the UAE and we list the conditions and disease genes identified. Examples include new disorders like BNAR caused by mutations in FREM1 gene, CHIME-like syndrome caused by mutations in SRD5A3 gene, AR cutis laxa type IIB caused by mutations in PYCR1 gene and well established disorders like Hennekam syndrome caused by mutations in CCBE1 gene, Joubert syndrome caused by mutations in INPP5E gene and Crisponi syndrome caused by mutations in CRLF1 gene.

849/F

The D538H mutation in ENPP1 is associated with generalized arterial calcification of infancy and pseudoxanthoma elasticum. *G. Baujat[1], S. Hadj-Rabia[2], M. Le Merrer[1], B. Bader-Meunier[3], N. Boddaert[4], C. Gay[5], G. Guest[6], K. Lambot[4], A. Linglart[7], L. Martin[8], F. Tazarourte[9], Y. Nitschke[10], F. Rutsch[10].* 1) Department of Genetics, Necker Hospital, AP-HP, Paris, France; 2) Department of Dermatology, Necker Hospital, AP-HP, Paris, France; 3) Department of Pediatric Immunology and Rheumatology, Necker Hospital, AP-HP, Paris, France; 4) Department of Pediatric Radiology, Necker Hospital, AP-HP, Paris, France; 5) Department of Pediatrics, Saint Etienne University, Saint Etienne, France; 6) Nephrology Unit, Necker Hospital, AP-HP, Paris, France; 7) Department of Pediatric Endocrinology, Saint Vincent de Paul, AP-HP, Paris, France; 8) Department of Dermatology, Angers University Hospital, Angers, France; 9) Pediatrics Unit, CH, Montreuil, France; 10) Department of Pediatrics, Muenster University Children's Hospital, Muenster, Germany.

Generalized arterial calcification of infancy (GACI) is an autosomal recessive disorder characterized by diffuse vascular and periarticular soft tissue calcifications, frequently leading to death in early infancy. A few patients present with a milder phenotype and hypophosphatemic rickets. This disorder is due to mutations in ENPP1 in most cases. Pseudoxanthoma elasticum (PXE) is another autosomal recessive multisystem disorder characterized by ectopic mineralization and fragmentation of elastic fibers of connective tissues, including skin, vascular walls, and the eye. Classic PXE results from mutations in the ABCC6 gene. We report a boy with a unique phenotypic overlap between PXE and GACI. He presented with neonatal periarticular and arterial calcifications, which completely resolved during childhood. However, ectopic calcification in both kidneys and eyes developed, associated with hypophosphatemic rickets. He lost his hearing due to stapedo-vestibular ankylosis and showed diffuse angiomatomateous skin lesions. The diagnosis of PXE was confirmed by histology and immunohistochemistry from a skin lesion at the age of 10 years. Sequence analysis of ABCC6 revealed no mutation, while the patient was demonstrated to carry the ENPP1 mutation p.D538H in exon 16 on both alleles. This particular overlapping phenotype between PXE and GACI appears to be associated with a better prognosis than classical GACI, with spontaneous resolution of vascular calcifications, but with severe hypophosphatemic rickets and hearing loss. Our case study confirms that GACI and PXE may have more similarities than previously thought. Since ABCC6 was recently discussed as the causative gene in a case of GACI without mutations in ENPP1 (Am J Med Genet 152A:118-123; 2010), we demonstrate here that, conversely, ENPP1 may be involved in some cases of PXE in the absence of ABCC6 mutations. This emphasizes that ENPP1 and ABCC6 are probably involved in the same molecular pathway.

850/F

Case Report: Fraternal twins with Kniest dysplasia. *E. Carter[1], P. Brill[3], C. Raggio[1], J. Davis[1,2].* 1) Ctr Skeletal Dysplasias, Hosp Special Surgery, New York City, NY; 2) Div. Human Genetics, New York-Presbyterian Hospital, Weill Cornell Medical College, New York City, NY; 3) Pediatric Radiology, New York-Presbyterian Hospital, Weill Cornell Medical College, New York City, NY.

Kniest dysplasia is characterized by short trunk and limbs, kyphoscoliosis, midface hypoplasia, hearing loss, and severe myopia. Some individuals have cleft palate and/or club feet. Dominant mutation of *COL2a1* is causative. Severity varies, with severely-affected individuals dying from respiratory failure after birth and mildly-affected individuals having mild short stature, scoliosis and/or craniofacial findings. Adult height ranges from 106-145cm. We present 14-month-old dizygotic twins, conceived with assistance (IVF) using germ cells from both parents. The 36-yr-old mother (G1P2) is 5'3" tall with a history of polycystic ovarian syndrome. The 37-yr-old father is 6' tall. No consanguinity, no family history of skeletal dysplasia or metabolic bone disease. Prenatal history significant for bed rest from 23wks gestation, gestational diabetes, and blood pressure fluctuations. The twins were born at 34 wks gestation (10 days past EDD). Twin A (male) weighed 4lbs5oz and was 16.75" long at birth. He spent 3wks in the NICU with respiratory problems, a grade 1 germinal matrix hemorrhage and GE reflux. Developmental milestones are delayed. At 1yr height was in the 0.01 percentile. Radiographic evaluation of his pectus deformity showed abnormal vertebrae, leading to genetics referral and a full skeletal survey which we interpreted as Kniest dysplasia. Ophthalmology evaluation within normal limits. No hearing problems. He is normocephalic with prominent eyes, hypertelorism, anteverted nares with normal bridge, no cleft palate. Rhizomelic, no bowing of the limbs. Twin B (female) weighed 4lbs2oz and was 18" long at birth. She has had no medical problems or developmental delay. At 14mos a skeletal survey revealed similar findings to her brother's. Height at 14mos was 26" (0.09 percentile) and weight 20lbs14oz (26th percentile). Regular facial features, hypertelorism. Some bowing of her lower extremities, no pectus deformity. Radiographically, Kniest is distinguishable from other type II collagenopathies by coronal clefts of the vertebrae and dumbbell-shaped femora. Dysplastic epiphyses and metaphyses. Platyspondyly, some wedging and anterior beaking. Shortened tubular bones with narrowed joint spaces. In summary, this is a set of dizygotic twins with Kniest dysplasia, first identified at 14mos of age when twin A underwent radiographs for evaluation of a pectus deformity. Molecular genetic analysis of *COL2a1* is pending. Paternal mosaicism is possible.

851/F

Fractures in children with neurofibromatosis type 1. *J. George-Abraham[1], E. Schorry[1], S. Allen[2], M. Rieley[1], H. Kalkwarf[1], L. Martin[1], D. Viskochil[2], D. Stevenson[2].* 1) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) University of Utah School of Medicine, Salt Lake City, UT.

Neurofibromatosis type 1 (NF1) is an autosomal dominant genetic disorder affecting many different body systems including the musculoskeletal system with bony abnormalities occurring in up to 1/3 of patients. There is a growing body of evidence supporting the idea of an underlying bony dysplasia predisposing individuals with NF1 to orthopedic complications, which include dystrophic scoliosis, tibial dysplasia, and bone cysts. Several studies have documented osteopenia in both children and adults with NF1, with bone mineral densities (BMD) about 1 standard deviation below the mean compared to control groups. However, the significance of this degree of osteopenia in relationship to fracture incidence is not well elucidated, particularly in children. We undertook a retrospective study to determine incidence and types of fracture in children with NF1, ages 5-20 years using a standardized questionnaire. Patients with known tibial pseudoarthrosis were excluded from the analysis. We surveyed 98 individuals with NF1 from two multidisciplinary NF centers and compared to 74 controls without NF1 of similar ages and gender as the NF1 individuals. Data collected included numbers and types of fractures, dietary calcium intake, and physical activity levels. The fracture incidence for the NF1 group was 29.6% versus 20.3% in the control group. Further, NF1 individuals with fractures had a higher incidence of multiple fracture sites and occurrences (44.4% and 36%, respectively) than the controls with fractures (21.4% and 14.3%, respectively). NF1 individuals with fractures also exhibited a significantly lower age at fracture compared to control individuals with fractures ($p = 0.01$). Our data suggest that fracture incidence is higher in young NF1 individuals in comparison to healthy controls. We are currently evaluating additional factors (dietary, exercise, BMD) which could contribute to fractures in NF1 children.

852/F

Mutations in FKBP10 cause Bruck syndrome type I and Osteogenesis Imperfecta type III. *B.P. Kelley[1,2], F. Malfait[3], L. Bonafe[4], D. Baldridge[1], S. Symoens[3], A. Willaert[3], N. Elcioglu[5], L. Van Malderghem[6], C. Verellen-Dumoulin[7], Y. Gillerot[7], D. Napierala[1], D. Krakow[8], P. Beighton[9], A. Superti-Furga[4], A. De Paepe[3], B. Lee[1,2].* 1) Human and Molecular Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute, Chevy Chase, MD; 3) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 4) Division of Molecular Pediatrics, Centre Hospitalier Universitaire Vaudois, 1011 Lausanne, Switzerland; 5) Department of Pediatric Genetics, Marmara University Medical Faculty, Istanbul, Turkey; 6) Centre de Genetique Humaine, Universite de Liege, Liege, Belgium; 7) Center for Human Genetics, Cliniques Universitaires St Luc and University of Louvain Medical School, Brussels, Belgium; 8) Medical Genetics Institute, Cedars-Sinai Medical Center, David Geffen School of Medicine at UCLA, Las Angelas, CA; 9) Division of Human Genetics, University of Capetown, Observatory, 7925 South Africa.

Osteogenesis imperfecta (OI) is a heritable disorder of connective tissue characterized by bone fragility and alteration in synthesis and post-translational modification of type I collagen. Autosomal dominant OI is caused by mutations in the genes (COL1A1 or COL1A2) encoding the chains of type I collagen. Bruck syndrome is a recessive disorder featuring congenital contractures in addition to bone fragility; Bruck syndrome type 2 is caused by mutations in PLOD2 encoding collagen lysyl hydroxylase, while Bruck Syndrome type 1 has been mapped to 17q12 but the gene has remained elusive so far. Recently, the molecular spectrum of OI has been expanded with the description of the mechanistic basis of a unique post-translational modification of type I collagen, i.e., 3-prolyl-hydroxylation. Three proteins, cartilage-associated protein (CRTAP), prolyl-3-hydroxylase-1 (P3H1, encoded by the LEPRE1 gene), and the prolyl cis-trans isomerase Cyclophilin-B (PPIB) form a complex that is required for fibrillar collagen 3-prolyl-hydroxylation and mutations in each gene have been shown to cause recessive forms of OI. Recently, an additional putative collagen chaperone complex, composed of FKBP10 (also known as FKBP65) and SERPINH1 (also known as HSP47), has also been shown to be mutated in recessive OI. Here, we describe five families with OI-like bone fragility in association with congenital contractures who all had FKBP10 mutations. Given the previous mapping of Bruck syndrome type 1 to the chromosomal region containing FKBP10, we conclude that FKBP10 mutations are the cause of Bruck syndrome type 1.

853/F

FATCO Syndrome: A Case Report. *M.G. Lopez-Cardona[1,2], A. Del Toro-Valero[1], D. Carmona-Navarro[1], J. Fonseca[2].* 1) Dpto Biologia Molecular y Genomica, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) Hospital Regional "Dr. Valentin Gomez Farias", ISSSTE, Zapopan, Jalisco, Mexico.

Introduction: FATCO syndrome also known as aplasia of the fibula, tibial campomelia and oligosyndactyly syndrome, has an autosomal dominant pattern of inheritance, although isolated cases have been reported. It is characterized by absence or hypoplasia of the fibula, shortening of the tibia and oligosyndactyly of feet and hands. Objective: To present a case report of a patient with FATCO syndrome without upper limb involvement. Case Report: 33 year old female product of the first pregnancy, apparently healthy nonconsanguinous parents. A maternal cousin has oligosyndactyly. The patient has been operated 56 times to lengthen both lower limbs. The physical examination revealed disproportioned short stature, normocephalous, no facial dysmorphies, normal ches, central obesity, lumbar hyperlodoris, normal genitals. Upper limbs with bilateral brachydactyly of 5th finger, normal palmar creases and cubitus valgus. Lower limbs with bilateral hypoplasia of tibiofibular segment. Right foot with absence of 4th and 5th toes and cutaneous syndactyly. Left foot with cutaneous syndactyly between all the toes and fusion of the 2nd and 3rd toes and brachydactyly of the 5th toe. Finger and toe nails are normal. Conclussions: The diagnosis of FATCO syndrome should be carefuly analyzed because it could be confused with other syndromes characterized by absence of the fibula, such as Fuhrman, Du Pan and Brachydactyly-ectrodactyly with fibular aplasia or hypoplasia syndromes. This patient shows the inferior limb characteristics of FATCO syndrome described by previous authors, however there is no upper limb affectation.

Geleophysic dysplasia is a clinically and genetically heterogeneous disease with aberrant autophagic function. *P. Piccolo[1], P. Campeau[2], R. Polishchuk[1], J. Hicks[3], J. Tolmie[4], G. Andria[5], G. Parenti[1,5], V. Sabatino[1], B. Lee[2,6], C. Bacino[2], N. Brunetti-Pierri[1,5].* 1) Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 3) Department of Pathology, Baylor College of Medicine, Houston, TX, USA; 4) Institute of Medical Genetics, Yorkhill Hospital, Glasgow, UK; 5) Department of Pediatrics, Federico II University, Naples, Italy; 6) Howard Hughes Medical Institute, Houston, TX, USA.

Geleophysic dysplasia (OMIM 231050) is an autosomal recessive disorder characterized by short-limb dwarfism, brachydactyly, and a 'happy-looking' facial appearance. It is frequently associated with cardiac valvular disease although the incidence and natural history of the heart complications remain unclear. Mutations in the *ADAMTSL2* gene resulting in dysregulation of TGF-β signaling have been recently recognized to be responsible for this condition. We screened for *ADAMTSL2* mutations seventeen cases of geleophysic dysplasia diagnosed on the basis of clinical and radiological findings. Pathogenic mutations were found in three of the seventeen cases, suggesting that additional and yet unknown gene(s) are involved in the pathogenesis of the disease. Ultrastructural analysis of skin fibroblasts of affected patients, either *ADAMTSL2* mutation positive or negative, showed the presence of cytoplasmatic lysosome-like inclusions. Biochemical analyses of fibroblasts failed to reveal the composition of such inclusions and therefore, the nature of the accumulated material remains unclear. Intriguingly, fibroblasts from affected patients showed a significative increase of autophagic functions as shown by Western blot and immunofluorescence analyses of LC3-II. TGF-β signaling pathway and autophagy and their potential relationship may play an important role in the pathogenesis of the disease.

855/F

Cornelia de Lange syndrome: report a new case. *S. Juarez Garcia[1], L. Hernandez Gomez[2], E. Hernandez Gomez[3], D. Gomez Torres[4].* 1) Dept Neuropsicologia Instituto Nacional de Rehabilitacion, Mexico; 2) Dept Audiologia Instituto Nacional de Rehabilitacion, Mexico; 3) Biologia, Facultad de Estudios Superiores Iztacala; 4) Instituto Nacional de Rehabilitacion, Mexico.

Cornelia de Lange syndrome can be caused by mutation in the NIPBL gene. A mild variant of Cornelia de Lange syndrome (CDLS3) has been related to mutation in the SMC3 gene, which encodes another component of the cohesin complex. The de Lange syndrome is recognized on the basis of characteristic facies (low anterior hairline, synophrys, anteverted nares, maxillary prognathism, long philtrum, 'carp' mouth) in association with prenatal and postnatal growth retardation, mental retardation and, in many cases, upper limb anomalies. Type I, or classic the patients have the characteristic facial and skeletal changes of the diagnostic, prenatal growth deficiency, moderate to profound psychomotor retardation, and major malformations which result in severe disability or death. Type II, or mild, the patients have similar facial and minor skeletal abnormalities to those seen in type I; however, these changes may develop with time or may be partially expressed. They have mild-to-borderline psychomotor retardation, less severe pre- and postnatal growth deficiency, and the absence of (or less severe) major malformations. Type III, or phenocopy, includes patients who have phenotypic manifestations that are causally related to chromosomal aneuploidies or teratogenic exposures. Small hands and feet, limb reduction anomalies, proximally placed thumbs, hirsutism, synophrys, low hairline, cutis marmorata, low birth weight, and growth retardation are more common in the de Lange syndrome Most cases are sporadic. We present a new case: female mexican child 10 years old is the three child of non consanguineous parents, pregnancy without adversities prenatal and postnatal. Delay in the psychomotor development and of the language. Low size and weight. She present hirsutismo, synophrys, nares anteverted, depressed nasal bridge, long philtrum, low implantation of hair, hipertelorism, epycanto, sunken brown eyes, long eyelashes, 4 metacarpiano its short, limb muscle hypotrophy . Language and learning disabilities. Mild mental retardation.

856/F

Mandibulofacial Dysostosis with Microcephaly, Cleft Palate, and Anomalous Ears. *M.A. Lines[1], S. Douglas[2], M. Guion-Almeida[3], Y. Alanay[4], G. Utine[4], D. Wieczorek[5], D. Bohm[6], A. Grix[7], C. Nava[8], L. Huang[2], J. Kohlhase[5], G. Baujat[8], D. Bulman[2], K. Boycott[1].* 1) Genetics, Children's Hospital of Eastern Ontario, Ottawa, Canada; 2) Ottawa Health Research Institute, Ottawa, Canada; 3) Clinical Genetics, Hospital for Rehabilitation of Craniofacial Anomalies, University of Sao Paulo, Sao Paulo, Brazil; 4) Clinical Genetics Unit, Hacettepe University, Ankara, Turkey; 5) Institute für Humangenetik, Universitätsklinikum Essen, Essen, Germany; 6) Center for Human Genetics Freiburg, Freiburg, Germany; 7) Genetics, Permanente Medical Group, Sacramento, CA, United States; 8) Medical Genetics, Université Paris Descartes, Necker-Enfants Malades Hospital, Paris, France.

Mandibulofacial dysostosis (MFD) is an inborn error of craniofacial development affecting structures derived from the first and second branchial arches. Treacher Collins syndrome is the prototypical form of MFD; however, MFD is also a feature of several other syndromes of unknown genetic etiology. Two previously published reports describe seven patients with a novel MFD phenotype characterized by microcephaly, cleft palate, and anomalous ears (Guion-Almeida et al, Clin Dysmorphol 15(3):171-4; Wieczorek et al, Am J Med Genet A 149A(5):837-43); we believe these reports describe the same phenotype, and have provisionally termed this conditon 'MFD with microcephaly' (MFDM). Building upon these earlier reports, and incorporating five additional cases, we present an updated clinical description of the MFDM phenotype. Cardinal features of this condition are microcephaly, metopic craniosynostosis, midface hypoplasia, micrognathia, cleft palate, short stature, and developmental delay. A highly specific ear phenotype is also observed, characterized by small, low-set ears, preauricular tags, auditory canal stenosis, and hypoplastic lobe/tragus. Other, inconsistently observed anomalies include cardiac septal defects, polydactyly, choanal atresia, and epilepsy. We are presently determining the molecular basis of this condition. *TCOF1* mutations have been excluded in several probands, confirming that MFDM is genetically distinct from Treacher Collins syndrome. In one affected individual, a complex de novo rearrangement was delineated on chromosomal microarray; this individual has a microdeletion of an agenic region of 4p12, in conjunction with a deletion/duplication of 17q21.31. The latter region contains a number of appealing positional candidates for the causative gene underlying this condition.

857/F

LRRK2 exons 31, 34, 35, 38 and 48 mutation analysis in a cohort of PD patients with a dominant pattern of inheritance from South Italy. *V. Scornaienchi[1], P. Tarantino[1], F.E. Rocca[1], E.V. De Marco[1], F. Annesi[1], D. Civitelli[1], V. Greco[1], G. Provenzano[1], A. Bacilieri[1], G. Nicoletti[1,2], A. Quattrone[2], G. Annesi[1].* 1) Institute of Neurological Sciences, National Research Council, Mangone, Cosenza, Italy; 2) Institute of Neurology, University of Magna Graecia, Catanzaro, Italy.

Mutations in the LRRK2 gene have been associated both in PD patients with a dominant pattern of inheritance and patients which appear to be sporadic because of reduced penetrance. Reported frequencies may be lower limits because only particular exons or mutations were screened in most studies. Mutations affecting residues p.G2019 (p.G2019S) in exon 41 and p.R1441 (p.R1441C, p.R1441G, p.R1441H) in the exon 31 are common confirmed disease-associated variations. The frequencies of these mutations are highly population dependent as well as the putative risk factor variations R1628P and G2385R. We hereby present the results of mutation screening of exons 31, 34, 35, 38, and 48 of LRRK2 in 69 autosomal dominat PD patients from South Italy. Diagnosis of PD was based on the UK Brain Bank criteria. All participants were recruited through the Institute of neurology at the "University of Magna Graecia" of Catanzaro and all of them gave informed consent. Mutation analysis of these five LRRK2 exons was carried out by PCR and sequencing. Our cohort was previously analyzed for alpha-synuclein gene mutations and LRRK2 exon 41 mutations (p.G2019S, p.I2012T and p.I2020T) and all patients resulted negative. Until now we screened all the 69 patients for LRRK2 exon 31, 35, 38 and 48. We identified the R1441C mutation (exon 31) in heterozygous state in a 56-year-old male with dominant PD. This patient descends from a PD family with a deceased affected mother and a deceased father with gait impairment. There was not other affected members in both maternal and paternal ascendants. In the other PD cases we found three described polymorphisms; IVS47-9 del(T) (58%) and A7155G (17%) in exon 48 and IVS35+23T®A in exon 35 (53%). We observed a R1441C mutation frequency of 1,5% (1/69) in our PD cohort from South Italy. This frequency is higher than other studies on italian sporadic PD patients have shown (0,01- 0,6%) thus confirming that the role of mutations in PD genes varies according to the origin of the studied population. Further, in order to well assess the R1441C mutation frequency in South Italian PD patients we will effect a mutation analysis of 500 PD sporadic cases.

858/F

OTO-PALATO-DIGITAL SYNDROME TYPE 2. CLINICAL AND MOLECULAR CORRELATION. *R. Baez-Reyes[1,2,3], A. Hidalgo-Bravo[4], S. Kofman-Alfaro[4].* 1) Dept Gen, Inst Natl de Perinatologia,; 2) Dept Gen, Clinic of Specialities of Women, SEDENA ,; 3) Escuela de Ciencias Quimico-Biologicas, IPN,; 4) Dept Gen, General Hospital of Mexico, Mexico City, MEXICO.

The otopalatodigital type 2 syndrome (OPD2), it's part of a spectrum of four entities with phenotype related and considered alellics variants (OPD1, OPD2, frontometaphyseal dysplasia and Melnick-Needles syndrome). It has a model of inheritance X-linked, associating to mutations that generate in the majority gain in the function of the gene of the Filamin A (FLNA), located in Xq28, composed by 48 exons and that codes for the Filamin protein with molecular weight of 280 kD uniting to actin filaments. The patient is product of first pregnancy, his mother and father with 18 and 25 years old, not consanguineous. The mother went to the consultation of Prenatal Dignosis to the 23.3 weeks with an ultrasound that showed multiple defects. It's was realized an amniocentesis with result 46,XY. To the 34.2 weeks was born a male for caesarean operation, with many features to the clinical examination: skull with wide fontanel and sutures, prominent forehead, ocular hypertelorism, antimongoloid slant to palpebral fissures, flat nasal bridge, small mouth with central cleft palate, micrognathia, dysmorfics ears, short neck, extremities upper with flexed fingers and syndactyly fingers in bilateral form, the extremities lower with limitation to the extension of both knees and feet with absence of great toes and left cryptorquidism. X-ray of skull base with undermineralizaion of cranial vault, humerus, femur and tibia were curved and small fibula, hypoplastic and irregular metacarpals and absent halluces; Echocardiogram with minimum interventricular communication subaortic; renal ultrasound normal; magnetic resonance with loss of volume left corticosubcortical, ventriculomegaly, callous body and fossa brain hypoplastic; visual potentials with decrease in the vision; auditory potentials with conductive hearing loss, realizing the diagnosis of OPD2. We took a blood sample of the baby's and mother for the extraction of the DNA and by means of PCR the exon was amplified 3 of the gene FLNA using the primers: 5'-TCC AGA ATC TGT TCC AGA GCG-3'(forward) and 5'-GCT GTG AAG GTT GCT GTT CCT-3'(reverse). In the patient and in her mother were discovered an insertion of a single nucleotide identified (Adenine) in the codon 209 of the exon 3 of the gene FLNA, same that generates a landslide of reading mark seemingly without codon of premature unemployment. This mutation yet not reported into the literature. The genetic counseling was given to his parents.

859/F

Interval Disease despite Routine Radiographic Screening in Vascular Ehlers-Danlos Syndrome. *M.A. Giovanni, M.F. Murray, J.P. Annes.* Division of Genetics, Brigham & Women's Hospital, Boston, MA.

Vascular Ehlers-Danlos syndrome (EDS) is an autosomal dominant connective tissue disorder characterized by vascular and visceral organ rupture with minor findings of thin translucent skin, easy bruising, acrogeria, and characteristic facial features. Vascular EDS is caused by a mutation in COL3A1 causing abnormalities in type III collagen. Here we present a 39 year old man who is monitored in an adult genetics clinic due to a familial mutation in COL3A1 (c.3473G>A, p.Gly1158Asp). The patient denied easy bruising, joint hypermobility, history of vascular, muscle, or tendon rupture; he denied any medication use. The patient reported a history of competitive athletics through his high school years with significant weight training into his 20's. Physical exam revealed a 5'7.7", normotensive, 187 pound Chinese-American man with pes planus and velvety skin; his Beighton score was 2. Notably absent was the presence of cigarette-paper scars, thin lips, narrow nose, high arched palate, or pectus deformity. The patient's family history included the death of his mother at age 53 secondary to intracranial hemorrhage. One maternal uncle died at age 36 of intracranial hemorrhage. A second maternal uncle brought the family to clinical attention with a celiac artery dissection at age 44, leading to COL3A1 testing. We instated our usual screening protocol including vascular imaging at an interval of every six months, alternating between CT angiography and MRA with annual clinical exams. Baseline imaging of the vascular tree was read as normal. Subsequent imaging studies showed normal vascular anatomy at each time point including November 2009. In February 2010, three months after his radiographic screening the patient presented to the emergency department at an outside institution with fever, cough, and left-sided abdominal pain. He was discharged with a diagnosis of community acquired pneumonia and possible renal infarct. The patient then followed up at our institution where CT angiography performed approximately one week later revealed left renal artery dissection with pseudoaneurysms and a left renal infarct. The patient was stented and successfully completed a three month period of anticoagulation. We present this case as a challenge in the medical management and screening of individuals with Vascular EDS. Due to the rapidly progressing nature of aneurysm and rupture, the utility of vascular imaging in preventing emergent events is questionable.

860/F

Generalized arterial calcification of infancy (GACI) is associated with biallelic mutations in *ABCC6*. *Y. Nitschke[1], U. Botschen[1], N. Chassaing[2], C. Deshpande[3], S. Garber[4], R. Chikarmane[5], B. Steinmann[6], T. Shahinyan[7], L. Martorell[8], L. Martin[9], R. Terkeltaub[10], F. Rutsch[1].* 1) Department of General Pediatrics, Münster University Children's Hospital, Münster, Germany; 2) Department of Genetics, Toulouse University Hospital, Toulouse, France; 3) Department of Clinical Genetics, Guy's Hospital, London, UK; 4) Division of Neonatology, Department of Pediatrics, Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA, USA; 5) Institute of Medical Genetics, St. Peter's University Hospital, New Brunswick, New Jersey, USA; 6) Division of Metabolism and Molecular Pediatrics, University Children's Hospital, Zurich, Switzerland; 7) Arabkir Joint Medical Centre, Yerevan, Armenia; 8) Department of Genetics, Hospital Sant Joan de Déu, Barcelona, Spain; 9) Department of Dermatology, Angers University Hospital, Angers, France; 10) VA Medical Center, Department of Medicine, University of California San Diego, San Diego, California.

Generalized arterial calcification of infancy (GACI, MIM 208000) is a rare autosomal recessive disorder characterized by calcification of the media and myointimal proliferation leading to arterial stenoses frequently associated with death in early infancy. In 80% of GACI patients, the disease is caused by mutations in *ENPP1*, which encodes ecto-nucleotide pyrophosphatase/ phosphodiesterase 1 (NPP1). NPP1 is a generator of extracellular inorganic pyrophosphate, a physiologic inhibitor of hydroxyapatite deposition. The genetic cause of 20% of analysed GACI patients remains obscure. Most recently, mutations in *ABCC6* (ATP-binding cassette subfamily C number 6), the gene associated with pseudoxanthoma elasticum (PXE, MIM 264800), have been found in a male patient with PXE, whose younger brother died of generalized arterial calcification of infancy at the age of 15 months (Am J Med Genet 152A:118-123; 2010). Unfortunately, no DNA of the deceased younger brother was available. No *ENPP1* mutation was found in the living family members. We therefore hypothesized that GACI could be independent of *ENPP1*, but related to *ABCC6* mutations. To prove our hypothesis, we sequenced all 31 exons and their flanking splice sites of *ABCC6* in 18 GACI patients without mutations in the coding region of *ENPP1*. Excluding SNPs, we detected in 5 patients 6 different biallelic mutations in *ABCC6* known to cause PXE and the novel mutation c.450insC (p.A151fsX45). Two patients were homozygous for mutation c.3662G>C (p.R1221H) and c.3940C>T (p.R1314W) respectively. The other three patients were compound heterozygous carriers of at least two of the following mutations: c.2787+1G>T and 3736-1G>A affecting splicing, c.1552C>T (p.R518X), c.3105-3107delCTT (p.F1036del), c.3940C>T (p.R1314W) and c.450insC (p.A151fsX45). Our study emphasizes that GACI is not only associated with mutations in *ENPP1*, but also with mutations in *ABCC6*, recently described in PXE. We conclude that deficiencies of NPP1 and ABCC6 lead to alterations in the same pathogenetic pathway.

861/F

Dysmorphic features, learning disability, immune abnormalities and predisposition to vasooclusive disease in two sisters: a new autosomal-recessive syndrome? *M. Velinov[1], N. Dolzhanskaya[1], P. Ramaswamy[2], L. Barinstein[2], R.M. Stuart[3], P. Kahn[4], N. Feldstein[3], R.E. Madrid[1].* 1) NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 2) Maimonides Infants & Children Hospital Brooklyn, NY; 3) Columbia University Medical Center, New York, NY; 4) New York University School of Medicine, New York, NY.

A 20 year-old female patient presented with mental retardation and a history of Moya moya disease with ischemic strokes at the age of 8. She had a learning disability prior to the stroke. After the stroke her cognitive impairment became more pronounced. This patient's parents were first cousins of Middle Eastern origin. The family history was significant for 6 close family relatives, all of whom suffered strokes in their 60s or 70s. The patient's 16 year-old sister had learning disability and chronic muscle pain in her legs. Her EKG showed evidence of mild intraventricular conduction delay with a QRS duration of 100 msecs with T wave changes suggestive of myocardial damage. By echocardiogram her ventricular systolic function was at the lower end of normal. The two sisters had a similar dysmorphic facial appearance including prominent philtrum, bulbous nose and severe acne. They both had increased subcutaneous tissue in their faces and slim bodies. Both sisters were found to have elevated levels of Rheumatoid factor, C-reactive protein, total IgM and erythrocyte sedimentation rate on repeat measurements. Comprehensive laboratory testing for rheumatoid/ autoimmune disorders was negative. Chromosome analysis and array CGH analysis were normal. Muscle biopsy was done on the younger sister and revealed normal morphology. Genome array expression analysis on peripheral native lymphocytes showed abnormal expression levels of a number of immune response-associated genes in both patients compared to healthy controls. Significant up-regulation was observed in the gene RNF125, a gene involved in T lymphocyte activation. Most significant down-regulation was observed in the gene IFIT1 that is involved in suppression of anti-viral responses. We propose that these two sisters suffer from a new autosomal-recessive syndrome. Carrier status for the reported condition may predispose to strokes as observed in family relatives.

862/F

A Spectrum of Mutations found in Noonan Syndrome. *K.M.B. Vinette[1], S.M. Kirwin[1], E. Hopkins[2], K. Gripp[2], C. Jornlin[1], N. Manolakos[1], V. Funanage[1]*. 1) Molec Diagnostics Lab, Nemours/A I duPont Hosp, Wilmington, DE; 2) Medical Genetics, Nemours/duPont Hosp for Children, Wilmington, DE.

Objective: As a Molecular Diagnostics Laboratory in a pediatric setting, we encounter a wide variety of Noonan and LEOPARD syndrome associated mutations. These clinically related disorders are caused by a family of genes encoding the RAS/MAPK cell signaling pathway. We describe here several novel changes found in patients with a clinical diagnosis of Noonan syndrome referred for molecular testing. Methods: A 5-tiered sequencing approach with sequential testing for the genes associated with Noonan syndrome is performed in our laboratory. The typical order is as follows: PTPN11, SOS1, RAF1, KRAS and SHOC2. Results: A total of 65 probands and 21 family members were tested for mutations consistent with Noonan syndrome. 1) PTPN11, [n=47], 14 (30%) samples positive, showing 10 different mutations. Two patient results were found of great interest, as one patient carries two different mutations within exon 3 in cis (1 novel and 1 previously described); another patient carries a previously described mutation within exon 4 and a second change (deletion of at least exon 4) in trans. 14 family members were tested with 2 positives. 2) SOS1, [n=28] with 4 confirmed mutations (14%), 3 previously described and one novel mutation. 3) RAF1, [n=33] 5 patients positive (15%), and interestingly, no parent [n=3] was found to carry their child's mutation. 4) KRAS, [n=24] 2 patients were found to carry a mutation (8%); one determined to be de novo and the other mutation was previously described. 5) SHOC2, no mutations were detected in 5 patients tested. Conclusion: Molecular testing confirmed a suspected diagnosis of Noonan syndrome in 25 of 65 patients (38%), with mutations in PTPN11 in 14 of 25 mutation positive individuals (56%), SOS1 in 4/25 (16%), RAF1 5/25 (20%), and KRAS 2/25 (8%). This mutation distribution is consistent with previous data suggesting that about half of all cases are due to PTPN11 mutations, and that changes in KRAS are less common than those in RAF1 and SOS1. This mutation spectrum supports the use of our sequential testing strategy, as the percentage of positive results for each gene sequenced is higher than it would be if all genes were studied in parallel.

863/F

Severe course of Alagille syndrome associated with a novel NOTCH2 mutation. *C. Zweier[1], G. Hammersen[2], R. Behrens[3], C. Gläser[4], C. Schmidt[4], A. Müller[5], H.E. Ulmer[5], A. Rauch[1,6]*. 1) Institute of Human Genetics, University Erlangen-Nuremberg, Erlangen, Germany; 2) Cnopf's Pediatric Hospital, Nuremberg, Germany; 3) Zentrum für Neugeborene, Kinder und Jugendliche, Südklinikum, Nuremberg, Germany; 4) Institute of Human Genetics and Medical Biology, Halle, Germany; 5) Department of Paediatric Cardiology, University Medical Centre, Heidelberg, Germany; 6) Institute of Medical Genetics, University of Zurich, Schwerzenbach-Zurich, Switzerland.

Alagille syndrome is a multisystemic disorder with hepatic bile duct paucity and cholestasis in association with other manifestations. In most of the cases haploinsufficiency of JAG1 can be identified as causative for the disease. Only recently also mutations in NOTCH2, the receptor of Jagged 1, have been shown to cause Alagille syndrome in two families. We report on the third mutation in NOTCH2 associated with an unusual severe course of Alagille syndrome with systemic arterial dysplasia. The male patient was born small for gestational age and the neonatal period was complicated by bilateral pneumothorax, renal insufficiency, persistent ductus arteriosus, arterial hypertension and cholestasis. No ophthalmologic or skeletal anomalies were found. At the age of 6 months the boy was dystrophic and showed jaundice and alopecia. In the further course he developed hyperparathyreoidism and recurrent crises with seizures, hypoxia and lactate acidosis. Extensive metabolic testing showed no abnormal results, liver biopsy showed moderate cholestasis and mild hypoplasia of bile ducts. At the age of 12 months the patient started to sit and spoke first words. Because of increasing hypertension of the pulmonic arteries intracardiac catheter examination was performed which revealed filiform endings of the peripheral vessels and furthermore hypoplasia and multiple stenosis of the aorta and large arteries. The patient deceased at the age of 15 months. Karyotyping with FISH-analysis at the JAG1-Locus, JAG1 sequencing and MLPA had revealed normal results. NOTCH2 sequencing showed the novel de novo splice site mutation c.6027G>A. This is the third mutation in NOTCH2, confirming its causative role in Alagille syndrome. If the severe vascular phenotype is an effect of the novel NOTCH2 mutation or an extreme manifestation within the Alagille spectrum regardless of the underlying gene remains unclear.

864/F

HEMATOLOGIC DIAGNOSIS OF MUCOPOLISACCHARIDOSIS (MPSs)IN PEDIATRIC PATIENTS FROM THE DEPARTMENT OF GENETICS. TWO CASES REPORT, HOSPITAL PARA EL NIÑO POBLANO, MEXICO. *P. Sanchez-Meza[1], J.M. Aparicio-Rodriguez[2,4], M.L. Hurtado-Hernandez[3], I. Marroquin-Garcia[3]*. 1) Hematology; 2) Genetics; 3) Cytogenetics, Hospital para el Nino Poblano, Puebla; 4) Estomatology, Benemerita Universidad Autonoma de Puebla, Mexio.

INTRODUCTION. The mucopolysaccharidosis (MPSs) are rare genetic disorders in children and adults. They involve an abnormal storage of mucopolysaccharides, caused by the absence of a specific enzyme. Without the enzyme, the breakdown process of mucopolysaccharidosis is not completed. Development and the function of various organs of the body. The MPS diseases are part of a larger group of disorders known as Lysosomal Storage Disorders (LSDs). A deficiency in the activity of a specific protein (enzyme) is observed in our body cells. MATERIAL AND METHODS. At hematology, the type of MPSs was diagnosed as MPS type VI or Maroteaux Lamy syndrome taking in consideration; some lymphocytes has multiple blue intra lysosomal granulations, big vacuoles and different granulations size. The monocytes had more and bigger blue intra lysosomal granulations than normal. All mature neutrophils had also a huge quantity of blue intra lysosomal granulations that can not be different from those toxic cell granulations. However, in both patients from this study, blue granulations were observed into the esosinophils, such granulations had different size, shape and color that varied from gray to black. CONCLUSION. The role of lysosomes is to degrade final material made by these cells into simpler products in order to be used again. This process requires the sequential action of different enzymes. If one of these enzymes is present in insufficient amounts, the recycling process cannot proceed and the undegraded material remains stored within the lysosome and, therefore, the cell. leading to the emergence of hematological and clinical symptoms. It is important to mention that lysosomal granulation storage in both hematological cells (eosinophils y neutrophils) are patgnomonic characteristics in order to confirm with the clinical symptoms MPSs. Therefore we considered that hematological morphology became a very powerful tool in this metabolic diseases. Some of the MPSs are inherited in a autosomic recessive trait, as MPS II or Hunter Syndrome, the MPS diseases are caused by a recessive gene. Where both parents are considered as healthy carriers. However only the Hunter syndrome has a different form of inheritance as sex-linked where females may be carriers of the disease. The early genetic diagnosis is important since some of the MPSs have already enzymatic treatment and not only the clinical manifestations are stopped but the quality of life is improved.

865/F

TRPV4 gene analysis in three Brazilian patients with skeletal dysplasias - A novel mutation in metatropic dysplasia. *G.L. Yamamoto[1], F.B. Piazzon[1], M.C. Moreira[1], L.A.N. Oliveira[2], C.A. Kim[1], A.C. Pereira[3], D.R. Bertola[1]*. 1) Unidade de Genética Médica, Instituto da Criança, Faculdade de Medicina da Universidade de São Paulo, São Paulo, São Paulo, Brazil; 2) Radiologia, Instituto da Criança, Faculdade de Medicina da Universidade de São Paulo, São Paulo, São Paulo, Brazil; 3) Laboratório de Biologia e Cardiologia Molecular, InCor, Faculdade de Medicina da Universidade de São Paulo, São Paulo, São Paulo, Brazil.

The TRPV4 gene, that codes a calcium-permeable ion channel, is associated with several previously considered distinct skeletal dysplasias - autosomal dominant brachyolmia, spondylometaphyseal dysplasia Kozlowski type, metatropic dysplasia, spondyloepiphyseal dysplasia Maroteaux type and parastremmatic dysplasia. Due to their rarity, few patients have been screened for mutations in this gene, but it seems that these disorders are allelic conditions. It is therefore important to evaluate additional patients, especially from different populations to confirm this specificity and to expand the mutational spectrum. We performed a bi-directional sequencing analysis of the TRPV4 gene in three patients, one presenting a clinical/radiological diagnosis of spondylometaphyseal dysplasia Kozlowski type and additionally a mild ventriculomegaly, and two with diagnosis of metatropic dysplasia, one with a mild form and the other severe with death due to respiratory compromise at 4 months of age. The results showed p.A594H, p.P799L and p.W733G mutations in the TRPV4 gene, respectively. The latter is a novel mutation which Polyphen analysis predicts damage to the protein. The other two mutations found in our patients were highly prevalent in the few cases described by different groups. None of the parents carried the specific mutation found in their child. These results corroborate the fact that spondylometaphyseal dysplasia Kozlowski type and metatropic dysplasia are caused by different mutations in the TRPV4 gene, all in heterozigosity. The presence of ventriculomegaly in a patient with spondylometaphyseal dysplasia Kozlowski type could be coincidental or this SNC abnormality could be part of this skeletal dysplasia. Further clinical description of other cases is necessary to confirm this association.

866/F

Survival of a Male Mosaic for PORCN Mutation with Mild Focal Dermal Hypoplasia Phenotype. *K. Kosaki[1], H. Yoshihashi[2], H. Ohki[2], A. Ishiko[3].* 1) Dept Pediatrics, Keio Univ, Tokyo, Japan; 2) Dept Clin Genet, Tokyo Metropolitan Childrn's Med Ctr; 3) Dept Dermatol, Keio Univ, Tokyo, Japan.

We report a 46,XY boy with a mild FDH phenotype who had both wild-type and mutated copies of the PORCN gene and was, therefore, mosaic for the mutation. He had cutaneous syndactyly, hydronephrosis, and nail dystrophy. Small whitish depigmented spots, which were slightly depressed from the skin surface, were distributed linearly on the trunk and arms. Aside from these findings, streaks of brown-pigmented macules were seen on the dorsal aspect of the legs. Both the linear arrangement of the whitish spots and the streaks of pigmented macules followed the lines of Blaschko. The phenotype of the patient, who did not exhibit cribriform atrophy, telangiectasia or fat herniation, seemed to be much milder than that of typical female patients with FDH. Analysis of the genomic DNA extracted from the peripheral lymphocytes revealed a transition 129 (G to A9 within exon 1 of PORCN, which leads to a non-sense mutation W43X. The percentage of peripheral lymphocytes carrying a mutation was estimated to be 50% by the subcloning and sequencing of individual clones of the PCR product amplified across the mutation. This patient's case history provides further molecular evidence supporting the concept that "male FDH" does exist and that typical features such as telangiectasia and fat herniation are sometimes abs.

867/F

A Case of Suspected Ankyloblepharon-ectodermal dysplasia-clefting syndrome(AEC) from Iran with possible autosomal recessive inheritance. *H. Pour-Jafari[1,2], R. Yadegarazari[1], B. Pourjafari[2], A. Yazdanfar[3], S. Irani[4], F. Talebzadeh[2], K. Hasrak[1].* 1) Molec Med & Gen, Sch Med, Hamadan Un, Hamadan, Iran; 2) Research Center for Molecular Medicine, Hamadan University of Medical Sciences, Hamadan, Iran; 3) Dermatology Dept., School of Medicine, Hamadan University of Medical Sciences, Hamadan, Iran; 4) Oral Pathology Dept., School of Dentistry, Hamadan University of Medical Sciences, Hamadan, Iran.

Ankyloblepharon-ectodermal dysplasia-clefting syndrome or Ankyloblepharon filiforme adenatum-ectodermal dysplasia-cleft palate syndrome (AEC) is one of at least 150 known types of ectodermal dysplasia. These disorders affect tissues that arise from the ectodermal germ layer, such as skin, hair, and nails. According to most references, it is an autosomal dominant disorder and caused by different mutations in TP73L (p63) gene. In the other hand some studies have showed an autosomal recessive mode of inheritance. We report a case with AEC syndrome and possible autosomal recessive inheritance from Iran. The patient was an 8-month-old girl, with ankyloblepharon filiforme adnatum, cleft palate and skin erosions at birth. She had parental consanguinity and presented many of major and minor criteria of the disease. Other disorders like CHAND syndrome, Rapp-Hodgkin syndrome, ectrodactyly-ectodermal dysplasia-clefting (EEC) syndrome and other congenital ectodermal dysplasia diseases can mimic AEC syndrome because of similar and overlapping clinical features. Those points were considered in our study, but her clinical features had no conformity and we rolled them out according to diagnostic criteria of the mentioned disease. However, more studies need to be done for revealing the type of molecular defect and definite pattern of inheritance.

868/F

***POMC* gene mutation analysis and genotype-phenotype correlations in two patients with early-onset obesity.** *Y. Yang[1], M.S. Mendiratta[2], A. Balazs[2], A. Willis[1], L. Potocki[1], V.C. Sheffield[3], L.P. Karaviti[2], C.M. Eng[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Department of Pediatrics, University of Iowa, Iowa City, IA.

Pro-opiomelanocortin (POMC) is the precursor protein for several peptide hormones including adrenocorticotropic hormone (ACTH), melanocyte-stimulating hormones (MSH) α, β, and γ, and β-endorphin. The *POMC* gene, as well as four other genes in the leptin signal pathway, *LEP*, *LEPR*, *PCSK1*, *MC4R*, is associated with rare, monogenic forms of obesity. Additional phenotypes caused by bi-allelic *POMC* mutations include adrenal insufficiency due to lack of ACTH and red hair pigmentation due to MSH deficiency. The latter may be less obvious in patients of ethnic groups other than Caucasian.

We have recently developed clinical test for *POMC* gene sequencing and identified *POMC* mutations in two patients with early-onset obesity. The first patient is an 18-month Hispanic girl with a history of adrenal deficiency, obesity and developmental delay. The patient was found to be homozygous for a novel c.231C>A (p.Y77X) nonsense mutation in the *POMC* gene. Parental studies showed that both parents were heterozygous for the mutation and therefore confirmed the homozygous state of the mutation in the patient. This deleterious mutation introduces a premature stop codon at amino acid position 77 of the POMC protein and is predicted to result in absence of hormones encoded downstream of the mutation, namely γ-MSH, ACTH, α-MSH, β-MSH, and β-endorphin. The second patient is a 20-month Caucasian boy with morbid obesity, tall statue, rapid excessive weight gain and developmental delay. A heterozygous c.706C>G (p.R236G) missense mutation was identified in the *POMC* gene of this patient. A second mutation was not detected. The c.706C>G (p.R236G) mutation in the heterozygous state was previously reported in patients with obesity but not affected by adrenal insufficiency or red hair pigmentation. In vitro and populations studies indicated that the mutation may confer an inherited susceptibility to obesity by producing an aberrant β-MSH/β-endorphin fusion protein that competes with the nature product for MC4R binding and interferes with central melanocortin signaling.

In summary, we have identified a novel nonsense mutation and a previously characterized missense mutation in the *POMC* gene of two obese children. In addition to confirmation of diagnosis, the clinical molecular testing of *POMC* mutations may provide better understanding of genotype-phenotype correlations and enable better disease management and genetic counseling.

869/F

A case of Congenital Hypomyelinating Neuropathy, a rare disorder and expanding the natural history. *A. Alfares[1], S. Melançon[1], N. Braverman[1], C. Hawkins[2].* 1) Department of Medical Genetics, McGill University Health Center, Montreal, QC, Canada; 2) Dept of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, ON, Canada.

Congenital hypomyelinating neuropathy (CHN) is characterized clinically by early onset of hypotonia, areflexia, distal muscle weakness, and very slow nerve conduction velocities (NCV). Only 8 cases have been previously reported. The neonatal forms of CHN feature severe decreased myelin sheath formation and are associated with defects in the Myelin Protein Zero (MPZ) or in the Early Growth Response 2 (EGR2) genes. Myelin protein-zero is the major structural protein of peripheral myelin, accounting for more than 50% of the protein present in the sheath of peripheral nerves. Expression of the MPZ gene is restricted to Schwann cells. Mutations in the MPZ gene cause distinct neurologic diseases, including CHN, Déjérine-Sottas syndrome (DSS), and CMT1B. The protein encoded by EGR2 is a transcription factor targeting genes critical for myelination in Schwann cells. Defects in EGR" are associated with Charcot-Marie-Tooth disease type 4E (CMT4E), CHN with early-onset slow NCV and a Déjérine-Sottas syndrome-like presentation. Respiratory dysfunction and cranial nerve abnormalities may also occur. We describe a new case of CHN in an infant with diffuse hypotonia and weakness, mild dysmorphic features and joints contractures. A nerve biopsy confirmed the diagnosis of CHN by showing diffusely thin myelin sheaths. Molecular analysis of MPZ, EGR2 and seven other genes associated with CHN or CMT failed to identify any pathological variants. This case provides additional insights into the natural history of this rare congenital disorder and suggests that (1) there are mutations in these genes not identifiable by routine gene sequencing, or that (2) since the sensitivity of mutation detection in these genes is low, perhaps defects in other genes involved in myelin synthesis pathways might cause this disorder. We will review these potential candidates.

870/F

IL1RAPL1 Gene Deletion as a Cause of X-linked Mental Retardation. *J.A. Hellings, E.L. Youngs, M.G. Butler.* Departments of Psychiatry & Behavioral Sciences and Pediatrics, University of Kansas Medical Center, Kansas City, KS 66160.

Mental retardation affects approximately 2% of the population with males outnumbering females due to involvement of over 300 genes on the X chromosome. The most common form of X-linked mental retardation (XLMR) is fragile X syndrome. We report a family with an apparent XLMR pattern with both the proband and his mother having an Xp21.3 deletion detected with chromosomal microarray analysis involving the IL1RAPL1 gene. He was born full term, walked at 16 months and had first words at 8 months. A normal chromosome study was reported at 4 years of age. Our proband has one full brother with learning problems and a maternal half brother with 47,XYY syndrome and mental retardation. Learning problems were reported in two maternal uncles, one maternal aunt and three cousins. The proband's mother attended special education classes and dropped out of school in the eleventh grade. On physical examination at 15 years, 9 months of age, our proband was cooperative and had a normal height, weight and head circumference. He had prominent supraorbital ridges, an anterior tilt to his head, deep set eyes, a sloping forehead with a broad face, synophrys and anterior hair whorls, and a short prominent nose with a long wide philtrum. He presented with atypical autism, ADHD, self-injury, impulsive aggression and an IQ of 55 with limited expressive language. A chromosomal microarray study showed a 950 kb deletion (located at 29.13 to 30.08 Mb from pter) involving bands Xp21.3-p21.2. The interleukin 1 receptor accessory protein-like 1 (IL1RAPL1) gene located in this region was partially deleted and confirmed by FISH. The proband's mother had the same deletion. IL1RAPL1 is highly expressed in the postnatal brain, specifically hippocampus suggesting a specialized role in memory and learning abilities. This gene is coined mental retardation, X-linked 21; MRX21 (OMIM 300143) and illustrates the importance of interleukin signaling pathways and the immune system in cognitive function. Hence, our family is the third reported with involvement of this gene in causing XLMR and the first identified with chromosomal microarray studies. Our proband showed similar dysmorphic features noted in previously reported males including a broad face with sloping forehead, ptosis, synophrys, prominent suprorbital ridges and nasal root, long and wide philtrum and a small mouth. Additional reports are needed to further characterize whether syndromic features are related to disturbances of this gene.

871/F

Ablepharon Macrostomia syndrome, a heterogeneous disorder: evidence for both autosomal dominant and recessive inheritance. *S. Kallish[1], SP. Bartlett[2,3], JA. Katowitz[4,5], DM. McDonald-McGinn[1,6], EH. Zackai[1,6].* 1) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Plastic Surgery, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Plastic Surgery, University of Pennsylvania School of Medicine, Philadelphia, PA; 4) Division of Ophthalmology, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Division of Ophthalmology, University of Pennsylvania School of Medicine, Philadelphia, PA; 6) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA.

Ablepharon Macrostomia syndrome (AMS) is a rare syndrome characterized by absent eyelids, fusion defects of the mouth, abnormal ears, ambiguous genitalia, skin findings, and speech delay. We present three patients with features of AMS.

Patient 1 was noted prenatally to have micrognathia, finger anomalies, and club feet. At birth she was found to have deficient skin of the eyelids and lips, macrostomia, absent nipples, and hypoplastic labia majora and minora. Examination of her extremities revealed 1st-2nd finger syndactyly. Her left hand had a small left thumb, which was syndactylous with the 2nd digit. Her feet had total syndactyly of digits 2 through 5 bilaterally, with partial syndactyly of the 1st digit. They were medially rotated bilaterally. Her development was normal at 7 months of age. Syndactyly of the toes has been reported once before in association with AMS, in two siblings. One had typical features of AMS and the other had overlapping features of AMS and Fraser syndrome (in which syndactyly is more common), suggesting autosomal recessive inheritance (Cavalcanti et al, Am J Med Genet 2007).

Patient 2 presented prenatally with an omphalocele. At birth she was also noted to have exophthalmos, absent eyelids, abnormal ears, and a large mouth with unfused labial commissures. On examination, she was found to have the hair abnormalities typical of AMS and hypoplastic labia of her genitals. Her development was normal at 2 months of age. Patient 3 is the father of patient 2. He also had an omphalocele. He had hypoplastic ears, minimal eyelid tissue with sparse eyebrows, and absent labial commissures of the mouth. His hands had single palmar creases with webbing of his fingers. The diagnosis of AMS in both father and daughter in this family suggests autosomal dominant inheritance. One other family with autosomal dominant inheritance of AMS has been reported (Ferraz et al, Am J Med Genet 2000).

Fewer than 20 patients with AMS have been described in the literature thus far. These patients represent further clarification of the features of AMS, including more severe foot anomalies than previously described. These cases also provide further evidence that AMS is a heterogeneous disorder, demonstrating both dominant and recessive inheritance.

872/F

Axenfeld-Rieger, microcephaly and congenital hypothyroidism: A New Syndrome? *E. McPherson[1], C. Zaleski[1], I. Zador[1], H. Murali[1], A. Grajewski[2].* 1) Marshfield Clinic, Marshfield, WI; 2) University of Minnesota, Minneapolis, MN.

We report a family in which 8 individuals in 3 generations have had anterior chamber abnormalities, primarily Axenfeld-Rieger anomaly along with varying combinations of congenital hypothyroidism, microcephaly, developmental delay and minor limb anomalies. Although they have minor facial anomalies similar to other patients with Rieger syndrome (flat midface, thin upper lip), these individuals do not fit any of the known syndromes with Axenfeld-Rieger anomaly such as Rieger syndrome type 1 (with hypodontia and periumbilical abnormalities due to mutations in PITX2), Rieger syndrome type 2 (dental, hearing, and cardiac anomalies, hydrocephalus), Rieger syndrome type 3 (cardiac and sensorineural hearing loss due to mutations in FOXC1), Axenfeld-Rieger with leukoencephalopathy (due to mutations in COL4A1), or other syndromes with anterior chamber anomalies such as SHORT syndrome or Peters Plus. Furthermore, one affected child with bilateral congenital glaucoma due to Rieger anomaly, congenital hypothyroidism, microcephaly with OFC -3SD, and developmental delay tested negative for mutations in PITX2 and FOXC1. He also had a normal karyotype (46,XY), CGH microarray and extensive biochemical testing including lactate, pyruvate, very long chain fatty acids, amino acids, organic acids, carnitine, acylcarnitine profile, and carbohydrate deficient transferrin all with normal results. An MRI of his head showed only minimal volume loss. Expression of the condition varied among family members. One obligate heterozygote was said to be normal but never had a detailed examination. Anterior chamber abnormalities including Axenfeld-Rieger anomaly, glaucoma and/or retinal detachment were found in all 8 affected. 4 had congenital hypothyroidism. 5/6 with known head measurements were microcephalic and the 6th had an OFC just above the 3rd percentile. 4 had hearing loss. 4 had developmental delays not attributable to vision or hearing impairment. All who were closely examined had minor limb anomalies (including one with hypoplastic toes and one with severe metatarsus adductus). We believe this family has a new autosomal dominant syndrome with Axenfeld-Rieger anomaly, congenital hypothyroidism, microcephaly, developmental delay, hearing loss and minor limb anomalies.

873/F

Mild Cornelia de Lange phenotype with single central incisor and insertional polydactyly. *J. Ranells, T. Ferlita, P. Newkirk.* Dept Pediatrics, Univ South Florida Col Med, Tampa, FL.

A 33 month old male was evaluated for unusual polydactyly with extra digit between the 4th and 5th fingers of the left hand, left choanal stenosis, left cryptorchidism and dysmorphic features. Physical exam showed height of 90 cm (25th centile), weight 12.1 kg (10th centile), OFC 47 cm (2nd centile), narrow forehead, epicanthal folds, long lashes, slight synophros, inner canthal distance 2.2 cm (10th centile), outer canthal distance 7.3 cm (30th centile), palpebral fissure length 2.3 cm (mean 2.5 cm), short broad nose with upturned tip, narrow philtrum with bowed upper lip, single upper central incisor, narrow palate with deep bilateral grooves, prominent ears, micrognathia, left mandibular spur, flattened umbilicus, left simian crease, hand and finger length <3rd centile, 5th finger clinodactyly with single flexion crease, minimal syndactyly of toes 2-3 and mild speech delay. Mild Cornelia de Lange syndrome (CdLS) was suspected. Brain MRI scan, echocardiogram, renal sonogram, 1.8 million SNP chromosome microarray and NIPBL analysis (research, courtesy of Dr. Krantz) were normal. Prenatally, reduced fetal activity and oligohydramnios were noted. Delivery was by cesarean section at 36 weeks for poor biophysical profile. Birth weight was 2520 gm, length 46 cm and OFC 34 cm. Radiographs showed distal left radius slightly smaller than right. He had severe GE reflux. Thickened bony cartilage was encountered during placement of a right lacrimal duct stent. At age 7 years, height is 103.6 cm (10th centile), weight 18.7 kg (50th centile), OFC 48.7 cm (2nd centile). He has lateral nasal prominences, mandibular spurs, short neck, glandular hypospadias, ulnar loops on all digits except left 2nd finger with radial loop, high pitched nasal voice and mild anxiety. He is sociable, has mild speech and fine motor difficulties. A brother was stillborn at term, birth weight 2.3 kg. He had single umbilical artery, bilateral bilobed lungs and heterotopic spleen within the tail of the pancreas. Karyotype was normal. CdLS is a complex developmental disorder with wide phenotypic variability. Mutations in NIPBL, SMC1A and SMC3, encoding proteins in the cohesin pathway, have been identified in 55-60% of affected individuals. Recognition of variant phenotypes may lead to identification of other genes involved in the pathogenesis of CdLS.

874/F

Craniosynostosis: Thinking Beyond *FGFR* and *TWIST*! *E.H. Zackai[1], S.P. Bartlett[2], L.A. Whitaker[2], T. Shaikh[1], N.B. Spinner[3], D.M. McDonald-McGinn[1].* 1) Division of Human Genetics; 2) Division of Plastic Surgery; 3) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA.

Craniosynostosis may occur alone or in association with well-described syndromes due to mutations in *FGFR1*, *FGFR2*, and *FGFR3* or as a result of mutations/deletions/duplications in *TWIST*. Here we report 4 patients with craniosynostosis whose presentations were not consistent with a classic syndrome. Of these, 2 were found to have chromosomal aneuploidy suggesting the possibility of new associated loci and 2 with metopic synostosis and polysyndactyly were found to have GLI3 mutations suggesting a novel association. Patient 1, a 4-year-old male presented with pancraniosynostosis, hypertelorism, hearing loss, laryngotracheomalacia and developmental delay. Using array studies he was found to have a 4q27-q31.22 microdeletion. Of note, Del Valle Torrado reported a similarly affected patient with a cytogenetically visible deletion in 1982 thus suggesting a potential locus for craniosynostosis in this region which we may now have narrowed by use of the array. Patient 2, a 3-month-old female presented with unicoronal craniosynostosis, IUGR, and an umbilical hernia. She was found to have trisomy 9 mosaicism in 50% of her lymphocytes. Interestingly, coronal synostosis with trisomy 9 mosaicism has been reported previously (Diaz-Mares 1990; Kaminker 1985; Mantagos 1981; Tarani 1994). Patients 3 & 4 with metopic craniosynostosis and polysyndactyly were found to have mutations within the last third (Exon 14) and first third (Exon 6) of the GLI3 gene, respectively. Although the association of metopic craniosynostosis with GLI3 mutations has not been reported previously, two patients were described with metopic synostosis and polysyndactyly prior to mutational analysis (Hootnick 1972, Guzzetta 1996). Thus, these latter 4 patients likely fall within the GLI3 morphopathy spectrum and the list of findings associated with GLI3 mutations should now be broadened to include metopic craniosynostosis. In summary, these cases emphasize the importance of thorough evaluation of the patient and in the presence of findings outside the usual craniosynostosis syndromes suggest further workup for appropriate counseling and management.

875/F

Holoprosencephaly, ectrodactylt, and bilateral cleft lip - palate syndrome and Xq microduplicationl A clue to understanding the genetic cause. *R. Kosaki[1], N. Okuno[2], C. Torii[2], K. Kosak[2].* 1) Dept Ped, Keio School of Med, Tokyo, Japan; 2) Dep Clin Genet & Mol Med, Natl Ctr Child Hlth & Dev, Tokyo, Japanc.

The unique combination of holoprosencephaly and ectrodactyly was first described by Hartsfield et al in 1984. Fifteen cases have been reported to date and the condition is likely to represent a single genetic entity (OMIM 300571, Hartsfield syndrome). The underlying genetic defect is yet to be unraveled. Mutation analyses of genes which cause holoprosencephaly including SHH, SIX3, ZIC2, an TGIF or genes which cause ectrodactyly including TP63 have been negative. Based on the observation that male patients have preferentially been affected, X-linked recessive mode of transmission has been suggested for this condition. Yet, no candidate genes have been suggested on the X chromosome. We report a patient with a full-brown Hartsfield syndrome phenotype who had a microduplication at Xq24 that involved at least 5 genes: A Japanese boy was born by a vaginal birth at 42 weeks gestation .He had bilateral ectrodactyly of the hands. He had midline cleft lip with aplasia of premaxillary segment, cleft palate, a low nasal bridge. Hypotelorism was minimal. He had micropenis with undescended testes. A CT scan of the brain revealed lobar-type holoproencephary. Cleft lip and palate was repaired a age 2 years and ectrodactyly was repaired at age 3. He had multiple episodes of hyper natremia with serum sodium level as high as 194 mEq/l. His development was mildly delayed: He could stand without support at age 1 year and walked alone at age 18 months. His G-banded karyotype was normal. Array comparative genomic hybridization using the Whole Human Genome CGH array (Agilent)revealed a de novo deletion of 0.3 Mb, on Xq24. The fact that the duplication has never been recognzied as benign copy number variation in various CNV databases does not prove but does suggest that the duplication could be pathogenic. From a clinical standpoint, it is important to note that the proband, who performed relatively well for a patient with holoprosencephaly, went through multiple episodes of potentially life-threatening hypernatremia.

876/F

A Newly Described Mutation of the CLCN7 Gene Causes Neuropathic Autosomal Recessive Osteopetrosis in an Arab family. *A.Y. Edrees[2], A.A Dabbagh[3], J.Y Alaama[1,2].* 1) Department of Genetic Medicine,Faculty of Medicine, jeddah, Saudi Arabia; 2) Princess Al Jawhara Center of Excellence in Resear, jeddah 21533, Saudi Arabia; 3) Department of Pediatrics,Faculty of Medicine,King Abdulaziz University,jeddah,Saudi Arabia.

Autosomal recessive osteopetrosis may be due to mutations in TCIRG1 (50%), CLCN7 (15%) or OSTM1 (2%) CLCN7 mutations can also lead to autosomal dominant or an intermediate form. Neurologic manifestations in osteopetrosis are usually secondary to sclerosis of the skull bones. A rare neuropathic subtype exists that resembles neuro-degenerative storage disorders. This form does not respond to hematopoietic stem cell transplantation. Preliminary reports suggest that this form is more likely caused by mutations in the CLCN7 gene in an autosomal recessive manner. This case report provides further evidence for this phenotype-genotype correlation in that we present a previously unreported mutation in the CLCN7 gene in a Yemeni patient with the neuropathic form. This is also the first report of any mutation in osteopetrosis patients of Arabic ethnicity. A literature review suggests that this type may be more common in Arabs. Thus cascade genetic screening of autosomal recessive-osteopetrosis in patients of early onset. Arabic ancestry may preferably start with CLCN7 rather than TCIRG gene as is routine identifying a mutation in the CLCN7 gene in a patient with early onset autosomal recessive-osteopetrosis may also guide therapeutic decisions, regarding further genetic studies on Arab individuals with osteopetrosis may provide evidence for an alternative pattern of mutations in this sub-group founder effects, and important phenotype-genotype correlation data. Molecular testing of further Arab patients may prove that this type of mutation is recurrent or that the range of mutations causing autosomal recessive-osteopetrosis is different from that reported from the Western and has unique pattern. To our knowledge this is the first report of osteopetrosis in a Yemeni family and the first report of a genetic mutation in an Arabic patient. It is also the first report of this specific mutation in the literature. Keywords: CLCN7; osteopetrosis; autosomal recessive; new mutation; DNA analysis; homozygous; Arab; neuropathic form.

877/F

Ophthalmic findings in the Greek isolate of Cohen syndrome. *S. Douzgou[1], J.R. Samples[2, 3], N. Georgoudi[4], M.B. Petersen[1].* 1) Department of Genetics, Institute of Child Health, "Aghia Sofia" Children's Hospital, Athens, Greece; 2) Rocky Vista University, Parker CO, USA; 3) Oregon Health & Sciences University, Department of Opthalmology, Portland, USA; 4) Department of Mental Health and Social Welfare, Institute of Child Health, Athens, Greece.

Cohen syndrome is a rare condition of mild to moderate developmental delay, characteristic craniofacial features, childhood hypotonia, joint hyperextensibility, neutropenia, and a variety of ophthalmic abnormalities. A high frequency of the syndrome has been observed in a Greek island with 2,000 inhabitants and a high degree of inbreeding. All patients were homozygous for a COH1, exon 6 to 16 deletion, suggesting a founder effect. We present the results of their first systematic ophthalmologic assessment. Myopia and chorioretinal atrophy were present in all patients of this cohort. Yet, in contrast to all groups previously reported, the majority presented corneal changes, independently from age, gender and family history. A pair of sisters, aged 11 and 15 years old, presented bilateral keratoconus. More frequently (86%) than in any other ethnic group, Greek patients presented cataracts that were bilateral and often graded as high as 3, even at a young age. As a whole, the ophthalmic phenotype of the Greek isolate of Cohen syndrome is characterized by the involvement of both the posterior and the anterior eye segment, bilaterally, in the majority of cases (93%). Greek Cohen subjects that share a founder mutation are at a higher risk of developing blindness in respect to those of other ethnicities and genotypes. This study added to the range of visual problems seen in children and adults with Cohen syndrome the finding of thin corneas and highlighted the need for pachymetry measurement as a means of surveillance and prediction of the visual impairment frequently observed.

878/F

Involvement of LTBP4 and FBLN5 mutations in patients with autosomal recessive cutis laxa : clinical and molecular considerations. *F. Malfait, P. Vlummens, T. Van Damme, L. Van Laer, A. De Paepe.* Ctr Med Gen, Ghent Univ Hosp, Gent, Belgium.

Hereditary cutis laxa delineates a heterogeneous group of conditions characterized by abnormalities of the elastic fibers and presenting with loose, sagging and inelastic skin and variable systemic manifestations. Mutations in the fibulin-5 gene (FBLN5) cause an autosomal recessive form of cutis laxa (ARCL) characterized by severe skin laxity, pulmonary emphysema and peripheral pulmonary artery stenosis. Very few FBLN5 mutations however, have been identified so far and the genetic defect remains unknown in a significant proportion of patients. Recently the gene encoding the latent transforming growth factor-beta binding protein 4 (LTBP4) was shown to be implicated in families with an ARCL phenotype. In the current study, we examined a cohort of 16 patients with ARCL. Direct sequencing of FBLN5 in all patients identified 1 known and 1 novel mutation (p.C217R and p.E391X) in 2 probands, whereas molecular analysis of LTBP4 in the 14 remaining probands identified 9 novel loss-of-function mutations (p.R448X, p.C617X, p.S803X, p.Q1221X, p.Q1296X, p.R1377X, c.1263delC, c.4114dupC and c.780+2T>G) and 1 known mutation (c.4127insC) in a total of 8 patients. These results show that LTBP4 mutations are more prevalent than FBLN5 mutations in ARCL. Phenotypic comparison between LTBP4 and FBLN5 mutation positive patients shows overlapping but also distinguishing clinical features, i.e. LTBP4 mutation positive patients have more severe gastro-intestinal and urinary tract involvement. Our results also suggest LTBP4 as the first gene to test in the molecular work up of patients with ARCL.

879/F

***Frem1* as a model for congenital diaphragmatic hernia (CDH) and bifid nose, renal agenesis, and anorectal malformations syndrome.** *T. Beck, M. Wat, B.J. Kim, H. Zaveri, M. Justice, B. Lee, D.A. Scott.* Molec & Human Gen, Baylor College Med, Houston, TX.

Congenital diaphragmatic hernia (CDH) is a sporadic birth defect that affects approximately 1:4000 newborns. In a recessive ENU mutagenesis screen we identified a mouse strain, *eye2*, with several congenital anomalies including retrosternal CDH, lung segmentation defects, kidney agenesis and a propensity to develop rectal prolapse. In addition, test crosses showed that approximately 50% of homozygotes die in utero. Traditional linkage mapping, followed by sequencing of positional candidate genes, revealed the *eye2* mutation to be a homozygous L826X change in the extracellular matrix protein Frem1. Recently, mutations in FREM1 were found in three consanguineous families with bifid nose, renal agenesis, and anorectal malformations (BNAR) syndrome. The clinical features associated with this syndrome have obvious overlaps with the defects seen in our *Frem1* mouse models. Mice deficient in *Slit3*—which encodes a large secreted molecule—also have retrosternal CDH and kidney agenesis. We have shown that an in vivo genetic interaction exists between *Frem1* and *Slit3* with regards to renal agenesis. We hypothesize that FREM1 and SLIT3 work together to promote invasion of the metanephric mesenchyme by the ureteric bud in the developing embryo and that failure of this process leads to the kidney agenesis seen in children with BNAR syndrome.

880/F

Hearing Loss, Inner Ear and Sinuses in Cornelia de Lange Syndrome. *A.D. Kline[1], A. Munitz[2], A. Kimball[1], J. Nogee[4], S. Ishman[3,4].* 1) Harvey Inst Human Gen, Greater Baltimore Med Ctr, Baltimore, MD; 2) Dept of Radiology, Greater Baltimore Medical Center, Baltimore, MD; 3) Division of Pediatric Otolaryngology, Department of Head and Neck Surgery; 4) Johns Hopkins University School of Medicine, Baltimore, MD.

In children with an underlying syndrome and sensorineural hearing loss, there is known to be a higher incidence of a cochlear or vestibular abnormality. Otolaryngologic involvement is common in Cornelia de Lange syndrome (CdLS), particularly hearing loss, both conductive and sensorineural. A prior limited study of temporal bone CT scans in CdLS reported abnormalities including ossicular dysmorphism, hypoplastic cochlea, and dysplastic vestibule, with correlation found between the number of structural findings, hearing loss severity and overall severity of CdLS. In addition, sinusitis and nasal polyposis is more common in CdLS than in the general population, with estimates of 39% and 12% in adults with CdLS. Identification of chronic versus acute sinus disease and the causes and implications of this association in CdLS have not been investigated. Gastroesophageal reflux disease (GERD) has been thought to contribute to chronic sinusitis in the general population, and correlations have been noted, including detection of H. pylori in nasal polyps, although overall the link has been controversial. This is significant, since reflux occurs in over 90% of individuals with CdLS, with complications at a young age. While a direct link has not been shown, patients often manifest a broad spectrum of behavioral difficulties ranging from self-injury, aggression, and anxiety to sleep disturbance, which may indicate a hidden source of pain, such as sinusitis. We have obtained temporal bone CT scans on 8 individuals with CdLS and a history of hearing loss, non-sedated in most. Two (25%) demonstrated ossicular abnormalities and 2 had a hypoplastic cochlea; 1 has had significant benefits from a cochlear implant. Three (38%) were found to have mucous retention cysts versus nasal polyposis; 2 of these had associated sinusitis. Five (63%) had sinus abnormalities despite having no acute symptoms at the time of the CT scan, and 1 of these had mastoid opacification as well as sinusitis. Of these patients, 4 (80%) have GERD and significant behavioral issues. These findings have significance in terms of management and treatment. Cohesin, the protein complex affected in CdLS, is known to bind preferentially to many actively transcribing genes and control gene regulatory sequences; it is likely that there is abnormal regulation of the otic placode, when mutations in genes for cohesin are present.

881/F

Mutations in *ZIC3*, *LEFTYA* and *ACVR2B* are a common cause of heterotaxy and associated cardiovascular anomalies. *L. Ma[1], S. Tierney[2], P. Lanzano[1], W.K. Chung[1].* 1) Division of Molecular Genetics, Department of Pediatrics, Columbia University, New York, NY 10032; 2) Department of Cardiology, Children's Hospital Boston, 300 Longwood Avenue, Boston, MA 02115.

Background- A spectrum of congenital heart disease is caused by left-right asymmetry disturbances and may present as an isolated cardiac anomaly or in association with abdominal situs anomalies referred to as situs ambiguous or heterotaxy. Methods and Results- To study the frequency of mutations in the Zinc Finger Protein of the Cerebellum 3 (ZIC3), Left Right Determine Factor 2 (LEFTYA), Activin A Receptor Type IIB (ACVR2B), and Cryptic Protein (CFC1) in heterotaxy, we screened 50 unrelated patients with heterotaxy associated congenital heart disease by dideoxy sequencing of all the coding exons and splice sites. The study cohort included 48% of subjects with atrial ventricular cushion defects and 70% with mal-position, interruption or absence of the superior or inferior vena cava. 17% had isolated congenital cardiovascular diseases without extra cardiac manifestations. Two novel genetic changes in *ZIC3* and one novel variant in *LEFTYA* were identified. None of these variants was observed in 100 ethnically matched control samples. One previously reported missense mutation in *ACVR2B* was identified in 2 unrelated subjects. The genetic changes identified in ZIC3, LEFTYA and ACVR2B are all located in highly conserved regions and probably affect protein function in left right axis formation and cardiovascular development. Conclusions: Mutations in ZIC3, LEFTYA and ACVR2B were identified in 5/50 subjects with heterotaxy for a yield of approximately 10%. Our results expand the mutation spectrum of monogenic heterotaxy and associated cardiovascular diseases and suggest that there are other causes of heterotaxy yet to be identified. Key words: heterotaxy, left-right asymmetry, congenital cardiac diseases, ZIC3, LEFTYA, ACVR2B, CFC1.

Dyschromatosis symmetrica hereditaria: consideration of the pathogenesis with dermoscopic features. *N. Oiso[1], I. Murata[2], M. Hayashi[2], T. Suzuki[2], A. Kawada[1].* 1) Dept Dermatology, Kinki Univ Fac Med, Osaka-Sayama, Japan; 2) Dept Dermatology, Yamagata Univ Sch Med, Yamagata, Japan.

Dyschromatosis symmetrica hereditaria (DSH) is characterized by hyperpigmented and hypopigmented macules on the dorsal hands and feet. It is a genodermatosis caused by a mutation in ADAR1 as an autosomal dominant inheritance. We show a 24-year-old Japanese man having a mixture of oval or round, hyperpigmented and pigmented spots 1-7 mm in diameter and irregularly shaped hypopigmented macules on the dorsal hands and feet. The consanguinities had no such pigmentation. To verify the diagnosis precisely, a genetic study was performed. A novel two-nucleotide deletion mutation (c.1096-1097delAA,p.K366fs) was identified. The precise pathogenesis is uncertain. We found extraordinary dermoscopic features, which had not been described previously. In the hyperpigmented macules, round and variously pigmented spots 0.5 to 1.5 mm in diameter were connected to each other, producing oval hyperpigmented macules. Within each hypopigmented lesion, independent spots were sparsely distributed. Dermoscopy showed the different characteristic of each pigmented spot, such as the degree of pigmentation and the epidermal-dermal structure, and suggested that the spots have varied melanocyte dysfunction, aberrant melanocyte and keratinocyte interaction, and impaired construction of rete ridges. The ADAR1 gene encodes adenosine deaminases acting on RNA 1 (ADAR1) which catalyze the conversion of adenosine into inosine in RNA molecules. It is an important post-transcriptional mechanism for generating transcript diversity. We suppose that dysfunction of ADAR1 induces such various pigment appearances due to the dysregulated post-transcriptional system.

Expression of Mutant RAB23 Proteins of Carpenter Syndrome Ablate Membrane Trafficking with Consequent Cytosolic Accumulation. *W.A. Paznekas[1], J. Dutta[1], V.R. Thrane[1], A. Iacovelli[1], H. Vega[1], N. Elcioglu[2], Y. Kasai[1], E.W. Jabs[1].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Department of Pediatric Genetics, Marmara University, Istanbul, Turkey.

Carpenter syndrome (Acrocephalopolysyndactyly Type II [MIM #201000]) presents with acrocephaly, diamond-shaped facies, brachysyndactyly of the fingers, preaxial polydactyly and syndactyly of the toes, hypogenitalism, obesity, and mental retardation. Jenkins et al. (2007) and Alessandri et al. (2010) have reported recessive RAB23 mutations in this condition. Mutations identified in 16 families were 5 different premature stop codons and the missense C85R. We have identified RAB23 mutations in 6 additional Carpenter patients, one homozygous for the novel Y79del mutation and 5 homozygous for L145X previously seen in 13 families. Of note, we found L145X alleles for the case presented in Temtamy's (1966) publication defining Carpenter syndrome. RAB23 is a member of the Rab GTPase protein family that cycles between active GTP-bound and inactive GDP-bound states to facilitate membrane trafficking and intracellular signaling of specific effectors. Essentially soluble proteins, they are modified at the C-terminus by prenylation a mechanism for membrane association of cytoplasmic proteins through covalent attachment of hydrophobic molecules to terminal cysteine(s). These cysteine(s) are modified by Rab geranylgeranyl transferase when the Rab protein is in complex with Rab escort protein (REP). We hypothesize that RAB23 mutations lead to proteins with loss of prenylation resulting in intracellular mislocalization. The L145X mutation removes the prenylation domain; Y79del may ablate REP association and prenylation; and C85R is predicted to disrupt protein structure. Each mutation is presumed to affect prenylation and thereby protein localization. To determine the possible effect of mutations identified in Carpenter syndrome we cloned wild-type and mutant (Y79del, C85R, and L145X) RAB23 cDNA-GFP constructs and performed transient transfections in HeLa cells. Results show that while cell membrane distribution is observed for over-expression of wild-type RAB23, distribution of each of the three mutant proteins is confined to the cytosol. Our results suggest that loss of prenylation is the underlying mechanism for the pathogenesis of Carpenter syndrome.

Craniosynostosis Syndromes in Thailand -Twenty years Experience. *P. Wasant.* Dept Ped/Div Med Gen, Siriraj Hosp/Mahidol Univ, Bangkok, Thailand.

The craniosynostoses are etiologically and pathogenetically heterogeneous. Premature closure of cranial sutures may occur as isolated condition or associated with other anomalies. Almost 100 syndromes are known (Gorlin et al, 1990 ; Cohen and McLean, 2000). The most exhaustive review is that of Cohen and McLean (2000). Sagittal synostosis is the most common type. Coronal synostosis occurs less frequently. Most cases of isolated craniosynostosis are sporadic. Metopic and lambdoid synostoses are uncommon. Associated anomalies are more frequent in coronal than sagittal synostosis. Most common anomalies are limb defects, ear anomalies and cardiovascular malformations. Paternal origin of sporadic FGFR mutations is suggested. (Jones et al, 1975 ; Moloney et al, 1996 ; Glaser et al, 2000). Twenty years clinical experience of craniosynostosis at Genetics Clinic, Siriraj Hospital Faculty of Medicine, Mahidol University, Bangkok, Thailand, the largest teaching hospital in Thailand; will be presented. Accurate diagnosis , genetic counseling and early intervention are extremely important in prognosis and subsequent outcome. Clinical/genetic evaluation and a gallery of craniosynostosis syndromes: Crouzon, Apert, Pfeiffer, Saethre-Chotzen, Cole-Carpenter, Antley-Bixler syndrome and nonsyndromic craniosynostoses: Kleeblattschadel, oxycephaly, scaphocephaly, metopic synostosis, will be presented. There is limitation of molecular analysis of craniosynostosis in Thailand.

885/F

Familial congenital diaphragmatic hernia, cystic kidneys and cardiac anomalies: A new X-linked syndrome? *A. Yeung[1], S. Keating[2], R. Silver[3], D. Chitayat[1,3].* 1) Division of Metabolic and Clinical Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital , Toronto, Ontario, Canada; 3) The Prenatal Diagnosis and Medical Genetics Program, Department of Obstetrics and Gynaecology, Mount Sinai Hospital, Toronto, Ontario, Canada.

Congenital diaphragmatic hernia (CDH) occurs in approximately 1 in 3000 live births and is associated with significant morbidity and mortality. Etiologically, CDH is heterogeneous with most isolated cases being multifactorial. About 50% of cases are 'non-isolated', with associated extra-pulmonary anomalies. Some of these cases are single gene disorders and 5-10% have a chromosomal etiology.

We describe two male siblings of non-consanguineous Caucasian parents with CDH, distinctive facial dysmorphism, dilatation of the ascending aorta, valvular dysplasia and enlarged cystic kidneys - a constellation of features not consistent with other previously described CDH syndromes. The cardiac findings point to an associated connective tissue disorder.

Karyotype in both siblings was 46, XY and microarray analysis was normal suggesting that a single gene defect is the underlying cause of this syndrome. A maternal uncle had died in infancy as the result of CDH. Thus, the pedigree is strongly suggestive of X-linked inheritance.

We review the features of other known X-linked CDH syndromes which include Simpson-Golabi-Behmel syndrome, Craniofrontonasal syndrome, Thoracoabdominal syndrome and X-linked Cornelia De Lange syndrome. None of these are reconciled by the phenotype in our two cases and indeed, genetic testing for *GPC3* to rule out Simpson-Golabi-Behmel syndrome was negative. We conclude that this family exhibits a new X-linked genetic syndrome of which congenital diaphragmatic hernia is a principal feature.

886/F

Prevalence and clinical features of Costello syndrome and cardio-facio-cutaneous syndrome in Japan. *Y. Abe[1], Y. Aoki[1], T. Niihori[1], H. Ohashi[2], K. Kurosawa[3], N. Okamoto[4], H. Kawame[5], S. Mizuno[6], T. Ogata[7], S. Kuriyama[8], S. Kure[1,9], Y. Matsubara[1].* 1) Dept Med Genet, Tohoku Univ Sch Med, Sendai, Japan; 2) Saitama Children's Med Ctr, Saitama, Japan; 3) Kanagawa Children's Med Ctr, Yokohama, Japan; 4) Osaka Med Ctr & Res Inst for Maternal & Child Health, Osaka, Japan; 5) Ochanomizu Univ, Tokyo, Japan; 6) Aichi Prefectural Colony Central Hosp, Nagoya, Japan; 7) National Res Inst for Child Health & Development, Tokyo, Japan; 8) Dept Epidemiology, Tohoku Univ Sch Med, Sendai, Japan; 9) Dept Pediatr, Tohoku Univ Sch Med, Sendai, Japan.

The RAS/MAPK signaling pathway is critical for human development and plays an important role in the formation and progression of cancers. Recent studies have shown that a group of genetic disorders results from dysregulation of the RAS/MAPK cascade. Costello syndrome and cardio-facio-cutaneous (CFC) syndrome are autosomal dominant congenital anomaly syndromes characterized by a distinctive facial appearance, heart defects, mental retardation and tumor predisposition. Germline mutations in HRAS have been identified in patients with Costello syndrome and those in KRAS, BRAF and MAP2K1/2 (MEK1/2) have been identified in patients with CFC syndrome. In order to assess the prevalence, natural history, prognosis and the rate of tumor development among Japanese patients, we designed a prevalence study of patients with Costello and CFC syndromes. The study consisted of two-tier questionnaire surveys, which were distributed to a total of 1244 hospitals, including randomly selected pediatric clinics at hospitals and institutions for severely-retarded children throughout Japan. The response rate of the first survey was 69% (856/1244). Fifty-six HRAS mutation-positive patients with Costello patients and 61 patients with CFC syndrome, who had mutations with KRAS, BRAF or MAP2K1/2, were reported in the first survey. The comprehensive molecular analysis of additional 35 suspected patients are currently under way. The second survey has been sent out, requesting additional detailed clinical information on each patient identified in the first survey. Of these, four of 27 HRAS-positive patients developed malignant tumors, including rhabdomyosarcoma, ganglioneuroblastoma and bladder carcinoma. Four of 44 patients with CFC syndrome developed hematologic abnormalities, including acute lymphoblastic leukemia, non-Hodgkin lymphoma and juvenile myelomonocytic leukemia. These results suggest the importance of molecular diagnosis and careful observation in patients with Costello syndrome and CFC syndrome. In our study, patients older than 30 years of age have not been identified. A long-term follow-up protocol of patients with Costello syndrome and CFC syndrome would be useful to understand the precise natural history, prognosis and the rate of tumor development.

Townes-Brocks Syndrome with Congenital Adrenal Hyperplasia. *B. Bozorgmehr, F. Afroozan, v. Hadavi, A. Kariminejad.* Dept Clinical Genetics, K-N Pathology & Genetics Ctr, Tehran, Iran.

Abstract: Townes-Brocks syndrome (TBS) characterized by imperforated anus , dysplastic ears , (over folded superior helices and preauricular tags) frequently associated with sensorineural and/or conductive hearing impairment , and thumb malformations triphalangeal thumbs, duplication of the thumb, preaxial polydactyly and rarely hypoplasia of the thumb. Renal impairment, including end-stage renal disease (ESRD), may occur with or without structural abnormalities (mild malrotation, ectopia, horseshoe kidney, renal hypoplasia, polycystic kidneys, vesicoutereral reflux). Congenital heart disease , genitourinary malformations and Mental retardation occurs in these patients. It is autosomal dominant disease with variability in the severity of expression. We are reporting a 8 year girl with dysplastic ears, deafness, dysplastic thumbs, small kidneys, history of repaired imperforated anus, and rectovaginal fistula. She is also diagnosed with congenital adrenal hyperplasia with congenital hyperplasia. We believe our patient is the first case of Townes-Brocks syndrome with congenital adrenal hyperplasia.

WIDE CLINICAL SPECTRUM IN ZIMMERMANN-LABAND SYNDROME. *M.G. González-Mercado[1,2], D. García-Cruz[1], A.J.L. Brambila-Tapia[1,2], J. Durán-González[1,2], N.O. Dávalos[1], J.A. Cruz-Ramos[1,2], M.O. García-Cruz[3], R. E'Vega[1], B.E. Ríos-González[1,2], M.G. Zavala-Cerna[4], I.P. Dávalos[1,2].* 1) Genética, CUCS, Universidad de Guadalajara, Guadalajara, Mexico; 2) División de Genética, CIBO, Instituto Mexicano del Seguro Social (IMSS). Guadalajara, Jalisco, México; 3) Clínica de Labio y Paladar Hendido, HGR 46, IMSS, Guadalajara, Jalisco, México; 4) División de Investigación, UMAE, Hospital de Especialidades, CMNO, IMSS, Guadalajara, Jalisco, México.

INTRODUCTION Gingival fibromatosis can be present as an isolated form or be part of a genetic disease. The Zimmermann-Laband syndrome (ZLS) is a rare disorder inherited as an autosomal dominant fashion; clinically characterized by gingival fibromatosis, bulbous soft nose, thick floppy ears, nail dysplasia, joint hyperextensibility, hepatosplenomegaly, skeletal anomalies and occasional mental retardation. CASE REPORT The proposita aged 9 years old, was the product of the 2nd pregnancy from non-consanguineous parents. At 7th months of pregnancy the mother presented polyhydramnios; and birth weight of 4,100 g. Generalized hypertrichosis mainly on limbs was detected at birth, at 5 months hepatomegaly, and at 11 months gingival fibromatosis. When she was 2 years 7 months joint hyperlaxity was evident and also nail hypoplasia particularly on 5th toes. The proposita presented delayed psychomotor development:, mainly in speech. At 3 yr. 6 mo. hypoacusia was diagnosed, the auditive evoked potentials revealed severe left hypoacusia and bilateral cortipathy. Clinically she presented wide forehead, telecanthus, high nasal bridge, bulbous nose, thick anthehelices and auricles, large mouth, thick lower lip, hypertrichosis on arms and legs, nail hypoplasia on 5th toes and hepatomegaly (2cm). Oral examination revealed generalized gingival hyperplasia covering the decidual teeth and leading to delay of dental eruption. The karyotype was normal. Family Data. The parents were clinically examined, and the father presented bulbous nose and thick auricles and lips. CONCLUSIONS We studied a 9 year-old girl with the ZLS and hypoacusia. The father presented minimal facial characteristics of ZLS, supporting a wide clinical spectrum in ZLS. Therefore we are considering ZLS as a contiguous gene syndrome or a consequence of a gene mutation with clinical variable expressivity.

889/F

Genital Abnormalities in Pallister-Hall syndrome: Two Case Report. *Y. Narumi[1], T. Kosho[1], G. Tsuruta[2], M. Shiohara[2], E. Shimazaki[3], T. Mori[3], A. Shimizu[2], Y. Igawa[4], S. Nishizawa[5], K. Takagi[6], R. Kawamura[1], K. Wakui[1], Y. Fukushima[1].* 1) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 2) Department of Pediatrics, Shinshu University School of Medicine, Matsumoto, Japan; 3) Department of Pediatrics, Nagano National Hospital, Ueda, Japan; 4) Department of Urology, Shinshu University School of Medicine, Matsumoto, Japan; 5) Department of Urology, Nagano Children's Hospital, Azumino, Japan; 6) Department of Obstetrics, Nagano Children's Hospital, Azumino, Japan.

Pallister-Hall syndrome (PHS) is a rare autosomal dominant disorder, characterized by hypothalamic hamartoma, central or postaxial polydactyly, bifid epiglottis, and various visceral anomalies. The disorder is caused by mutations in GLI3, a gene encoding a zinc finger transcription factor that regulates downstream target genes in the sonic hedgehog (SHH) signaling pathway. We describe two PHS patients with genital abnormalities: a female with hydrometrocolpos secondary to vaginal atresia and a male with micropenis, hypoplastic scrotum, and bilateral cryptorchidism. Nonsense mutations in GLI3 were identified in both patients. Clinical and molecular findings of 12 previously-reported patients who had GLI3 mutations and genital abnormalities were reviewed. Genital features in the male patients included hypospadias, micropenis, and bifid or hypoplastic scrotum, whereas all the females had hydrometrocolpos and/or vaginal atresia. No hotspot for GLI3 mutations has been found and genital features in PHS might present with a wide range of severities among patients with the same nucleotide change. Micropenis and cryptorchism in male PHS patients were speculated to be caused by absent or diminished gonadotrophins during fetal development. In our review of the literature, only 2 of 5 male patients had panhypopituitarism. No female patients in our review of the literature had panhypopituitarism. Urogenital and anorectal abnormalities in PHS might be related to dysregulation of SHH signaling caused by GLI3 mutations rather than hormonal aberrations.

890/F

Hematologic abnormalities associated with patients with cardio-facio-cutaneous syndrome. *Y. Saito[1], Y. Aoki[1], T. Niihori[1], A. Ohtake[2], A. Shibuya[2], K. Sekiguchi[3], S. Suenobu[3], T. Izumi[3], H. Muramatsu[4], S. Kojima[4], S. Kure[1,5], S. Tsuchiya[5], Y. Matsubara[1].* 1) Dept Med Genet, Tohoku Univ Sch Med, Sendai, Japan; 2) Dept Pediatr, Saitama Med Univ, Moroyama, Saitama, Japan; 3) Dept Pediatr and Child Neurol, Oita Univ Facul Med, Oita, Japan; 4) Dept. Pediatr, Nagoya Univ Graduate Sch Med, Nagoya, Japan; 5) Dept. Pediatr. Tohoku Univ Sch Med, Sendai, Japan.

Cardio-facio-cutaneous (CFC) syndrome is a multiple congenital anomaly/mental retardation syndrome characterized by a distinctive facial appearance, ectodermal abnormalities and heart defects. Clinically, it overlaps with both Noonan syndrome and Costello syndrome. Mutations in KRAS, BRAF and MAP2K1/2 (MEK1/2) have been identified in patients with CFC syndrome. We have previously reported that two CFC patients with BRAF mutations developed acute lymphoblastic leukemia. A patient with a MAP2K1 mutation, who developed hepatoblastoma, has also been reported. Here we report additional two patients with CFC syndrome who developed non-Hodgkin lymphoma and juvenile myelomonocytic leukemia (JMML) -like myeloproliferative disorder. The first patient developed pneumonia with pleurisy at two months of age and was diagnosed as having non-Hodgkin lymphoma (precursor T-cell lymphoblastic lymphoma) by cytopathologic examination of pleural fluid. He was suspected of having Noonan syndrome because of his facial appearance, webbed neck and cubitus valgus. Precursor T-cell lymphoblastic lymphoma was treated by TCCSG NHL 94-04 protocol. At 9 years of age, he was clinically re-evaluated and diagnosed as having CFC syndrome because of his distinctive facial appearance, multiple nevi and moderate mental retardation. Sequencing analysis revealed a germline p.A246P (c.736G>C) mutation in BRAF previously reported in CFC syndrome. The second patient was delivered by caesarian section at 32 weeks' gestation due to non-immune hydrops fetalis. He had curly hair, low-set ears, atrial septal defect, hepatosplenomegaly, pulmonary arteriovenous fistula and portosystemic shunt. At one month age, the patient showed marked monocytosis and decrease in platelet count. The diagnosis of JMML was made on bone marrow cell culture studies. Hematological abnormalities resolved spontaneously at three month of age. Sequencing of genomic DNA from the patient showed a heterozygous p. T241P (c.721A>C) mutation. This is the first report that a patient with CFC syndrome developed JMML-like myeloproliferative disorder. These results suggest the importance of molecular diagnosis and careful observation in children with CFC syndrome.

891/F

Renpenning Syndrome in Infancy. *S.A. Schrier, H. Feret, E.H. Zackai.* Division of Human Genetics, Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA.

Renpenning syndrome is a rare X-linked disorder characterized by the presence of mental retardation, short stature, small testicular volumes, as well as microcephaly, long, narrow facies, and prognathism. Mutations in the Polyglutamine binding protein 1 gene (PQBP1) have been found to be causative. Here, we report the first case in the literature of the youngest individual to be diagnosed with Renpenning. The proband, a 4 week-old male, was brought for evaluation due to concerns that he looked strikingly similar to an older brother with mental retardation, short stature, a "small head," small testes, and a maternal uncle with the same features. Physical examination of the infant at four weeks revealed a height of 50.3 cm (50th %), weight of 3.25 kg (25th %), and head circumference of 34.5 (10th %). The infant showed slight midfacial flattening, an inverted triangular face, and a small chin. Examination of the older brother was suggestive of Renpenning syndrome and therefore, the PQBP1 gene was sequenced in both individuals and the mother. They were found to have a hemizygous four pair deletion in the PQBP1 gene beginning at nucleotide 459 (c459_462del4). Review of the literature of Renpenning syndrome shows the youngest reported patient with the disorder to be 18 months of age. This patient had a rounded face at the time of diagnosis similar to childhood pictures of affected adults. However, in our case, the mother of the patient was able to recognize the facies as comparable to her affected brother and son early on. There is a paucity of data on birth parameters. Of 9 patients' data reported in the literature, 7 had normal birth weight, 2 were <2 %. Our patient's birth weight was normal. Birth length was available on only one and was normal as was our patient's. Birth head circumference on three patients were between 10-25%. Our patient's head circumference at 4 weeks was at the 10th %. Our patient's length at 4 weeks was at the 50th%. Thus, although his head circumference is disproportionate to length, microcephaly seems to be a developing problem with 86% of adults having head size < 3rd percentile. Short stature is not evident early on either and seems to be a progressive problem with 60% of adults being less than <3rd percentile in height. The patient will be followed prospectively to gain further insight into the natural history of this condition.

892/F

Heterogeneity of Mabry syndrome: hyperphosphatasia with seizures, neurologic deficit and characteristic facial features. *M.D. Thompson[1], T. Roscioli[2], M.N. Nezarati[3], E. Sweeney[4], P. Meinecke[5], P.M. Krawitz[6,7], C.C. Mabry[8], D. Horn[7], R. Mendoza[10], H. van Bokhoven[2], F. Stephani[2], C. Marcelis[2], A. Munnich[9], H.B. Brunner[2], D.E. Cole[1].* 1) Lab Medicine, Banting Inst, Univ Toronto, Toronto, ON, Canada; 2) Department of Human Genetics, University Medical Centre St. Radboud, 6525 GA Nijmegen, The Netherlands; 3) Department of Genetics, North York General Hospital, Toronto ON, Canada; 4) Royal Liverpool Children's Hospital, Liverpool, United Kindom; 5) Medizinische Genetik, Altonaer Kinderkrankenhaus, 22763 Hamburg, Germany; 6) Institut für Medizinische Genetik, Charité Universitätsmedizin Berlin, 13353 Berlin, German; 7) Berlin-Brandenburg Center for Regenerative Therapies (BCRT), 13353 Berlin, Germany; 8) University of Kentucky College of Medicine, Lexington, Kentucky, USA; 9) INSERM U781-Université Paris Descartes-Hôpital Necker-Enfants Malades; 10) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto ON, Canada.

Persistent hyperphosphatasia associated with developmental delay and seizures was originally described in a single family (OMIM#239300) in 1970. However, the condition is rare and the nosology has remained uncertain. Patient recruitment has been conducted globally in order to delineate this distinctive disorder and provides evidence in favor of autosomal recessive inheritance. Common to all patients is facial dysmorphism, particularly hypertelorism, a broad nasal bridge and a tented mouth. All patients have some degree of middle and distal phalangeal shortening that varies in position and degree. The persistent elevation of alkaline phosphatase (ALP) activity without any evidence for active bone or liver disease also varies considerably among patients (from ~1.3 to ~20 times the upper age-adjusted reference limit), but remains constant in any one individual. Identification of mutations in the type V phosphatidylinositol glycan (PIG) anchor biosynthesis (PIGV) gene in some but not all probands, also points toward genetic heterogeneity. The possibility that other genes in the PIG anchor biosynthesis pathway might be involved is an attractive one, since the PIG anchor is a major modulator of ALP expression on the cell surface. The substantial phenotypic variation, including variable degrees and extent of lysosomal storage in different probands, also argues for genetic heterogeneity in Mabry syndrome.

893/F

Hypermobility Syndrome in Japan. *A. WATANABE[1, 2], M. HATAKEYAMA[2, 3], R. TSUNODA[4], K. MATSUMOTO[5], H. KAWAME[3], T. SHIMADA[1, 2].* 1) Deptartment of Medical Genetics, Nippon Medical School, Tokyo, Japan; 2) Division of Clinical Genetics, Nippon Medical School Hospital, Japan; 3) Genetic Counseling Program, Graduate School of Humanities and Scieces, Ochanomizu University, Japan; 4) Department of Orthopedics, Nippon Medical School, Japan; 5) Department of Biosignaling and Radioisotope Experiment, Center for Integrated Research in Science, Shimane University, Japan.

Background: Hypermobility Syndrome (ICD-10 M357) is a connective tissue disorder characterized by generalized joint hypermobility and arthralgia (joint pain) in multiple joints (major criteria in Brighton criteria (2000)), while Ehlers-Danlos syndrome hypermobility type (EDS-HM) is also a connective tissue disorder characterized by generalized joint hypermobility, subluxations, dislocations and chronic pain. As both the conditions are rarely known in Japanese society, patients with the either condition are having much difficulty in getting enough support from those who are around and even from those who are healthcare professionals. The two conditions are treated as the same one here. Our research purpose is to focus on symptomatic status of patients with generalized hypermobility in Japan. Methods: 1. A retrospective chart review of patients seen and diagnosed from 2007 to present. 2. A short form of questionnaire was handed out and following 10 minutes interview per person during the 2010 EDS patients annual meeting. Data sets of general, mucocutaneous, musculoskeletal, cardiovascular, gastrointestinal, urogynecological, and ear-nose-throat symptoms were collected. Results: We have collected data sets from 20 patients. The most dislocated joints were; shoulders and knees. Wheel chairs were used by a number of patients because of the instable knees. Chronic pain even in joints without subluxations or dislocations was significant in most patients. Orthostatic disturbance was reported by more than half of the patients. More than one-third of patients had either cardiovascular or abdominal symptoms. Management of chronic pain was the most urgent issue while the number and the variation of approved indication drug is overly limited compared to the U.S.. Cutaneous findings were not at all common in this population. Conclusions: Here the broad phenotype of Hypermobility syndrome in Japan is described based on data from 20 patients. As many are suffering from symptoms not limited within that of joints, our goal will be to fully cooperate with department involved to maximize the QOL of patients with the chronic, disabling condition, let alone raising awareness in medical healthcare professionals.

894/F

Clinical and Molecular characterization of Children with Rubinstein -Taybi Syndrome from Western Canada. *O. Caluseriu[1], C. Beaulieu[1], C.R. Greenberg[2], F. Bernier[1], D.R. McLeod[1], M.A. Innes[1].* 1) Dept Med Gen, Alberta Children's Hosp, University of Calgary, AB Canada; 2) Departments of Biochemistry & Medical Genetics and Pediatrics & Child Health, University of Manitoba, Winnipeg MB Canada.

Rubinstein-Taybi Syndrome (RTS) is a rare multiple congenital anomaly syndrome, characterized by a distinctive facial gestalt with broad thumbs and great toes. Other features include growth and mental retardation and increased risk of malignancy. RTS is genetically heterogeneous, with approximately 50% of patients having mutations in the CREB binding protein (CREBBP) gene and 3% in its homolog EP300. Both code for transcriptional coactivators that interact with a large number of proteins and act as a potent histone acetyltransferase (HAT). The etiology of RTS in over 40% of patients is currently unexplained. While there are a few cases of children with consanguineous parents or affected siblings born to unaffected parents, RTS is typically autosomal dominant; most patients have confirmed or presumed de novo mutations. We present a group of Canadian children from the Prairie Provinces clinically diagnosed with RTS. Our cohort includes several typically affected patients including a concordant monozygotic twin pair and atypical cases including one with severe short stature and a single central incisor. Investigations planned on this cohort include full CREBBP sequencing and array CGH to exclude microdeletions. To date, one new missense substitution was found in CREBBP c.1982T>A, in a highly conserved region with CBP coactivator properties in one atypical RTS individual with normal stature. Of particular interest to our group is the identification of a number of Hutterite patients with possible RTS. All current Hutterites, an endogamous population, descend from fewer than 100 common founders and we have described over 30 autosomal recessive conditions (many novel) in this population. The first two related RTS Hutterite patients were born to unaffected consanguineous parents. Two further Hutterite patients with some features of RTS not directly related to the previous have also been identified. No mutation in CREBBP gene was found in one of the Hutterite patients and we suspect a possible autosomal recessive 'variant' with significant clinical overlap with RTS. Homozygosity mapping applied to this first patient identified several homozygous regions of interest. Further studies on other family members are needed to refine the candidate region that could reveal a recessive gene responsible for RTS in the Hutterite population. If a shared region of interest is identified, genes with histone acetyltransferase activity would be compelling candidates.

Negative cystic fibrosis meconium ileus in two Asian newborns: implications for diagnosis and counseling of a pathognomonic condition. *A. Iglesias.* Department of Pediatrics, Divison of Medical Genetics, Beth Israel Medical Center, New York, NY 10003.

Traditionally the presence of meconium ileus (MI) in a newborn is considered pathognomonic of cystic fibrosis (CF). Since screening immunoreactive trypsinogen activity is usually negative, molecular testing is currently use until a sweat test can be performed. Since therapeutic decisions, especially enzyme replacement, are usually done in the first weeks of life, having an early diagnosis is important. The advent of CF sequencing and deletion/duplication studies brings possibility of confirming the diagnosis early on a reality. We are presenting two newborn cases of MI. Both patients were from Asian descent. Patient one was born via c-section at 29 =BD weeks after a pregnancy complicated for maternal hypertension and echogenic bowel. Amniocentesis showed normal chromosomes, 46, XY. Surgical repair of MI was done and the diagnosis was confirmed upon pathology examination. Patient two was born full term after an uncomplicated pregnancy. Prenatal CF maternal screening was negative. MI and perforation were diagnosed at birth and repaired. Molecular testing for CF including sequencing and deletion/duplication studies were negative in both cases. Therefore the chances of these patients to be affected with CF were considered extremely reduced. However, no other etiologies for MI were found in either patient. Interestingly, further sweat testing results were either inconclusive or negative in both cases reinforcing the diagnostic dilemma. Both patients are currently being followed at a pulmonology clinic without special interventions and both are doing fairly well. Two main lessons can be drawn from these cases. First, MI although considered pathognomonic for CF, might be present as a non-CF etiology. Second, negative CF prenatal screening in Asian couples is a practice with very low yield. Accordingly, its use as a decision making tool should be questioned in this context, especially in the first case were echogenic bowel was present. Finally, the search for other etiologies for MI, although unsuccessful in these cases, seems to be prudent while waiting for the results of the molecular testing. Nevertheless, further follow-up with repeat sweat tests and clinical assessments seems to be a prudent practice until the diagnosis of CF can be completely excluded.

896/F

THE THREE FACES OF KABUKI SYNDROME. *A. Tsai.* Sect Clinical Gen & Metabolism, Childrens Hosp, Denver, B300, Denver, CO.

Introdcution: Kabuki syndrome (KS) is first described simultaneously by two groups in Japan. Because the facial features resembled the make-up of actors in traditional Japanese play, Kabuki, the syndrome was thus named. The inheritance was thought to be X-linked or Autosomal Dominant. Milunsky et al., 2003 reported a 3.5Mb duplication of 8p22-8p23 in six unrelated patients by microarray but this finding was not supported by later study. Various chromosomal anomalies were reported to have KS or KS-like phenotype. No single unifying etiology has been found. Material and Method: From 1999-2010, 50 patients age from 1 day to 15 years were ascertained in a tertiary care pediatric hospital/genetic clinic with a "suggestive diagnosis" of Kabuki syndrome. Patient with MCA who later on determined to be Kabuki syndrome was not included in this study. All patients received complete dysmorphology examination and laboratory work up whenever indicated by a single geneticist. 4 categorical diagnoses were delineated. Result: 4 patients with X chromosome anomalies: 45,XO, one large ring mosaicism with XIST present, one small ring chromosome without XIST and one with incontinentia pigmenti (IP) due to exons 4-10 deletion. 2. 4 patient with del/dup involving 8p22-8p23: 3. 8 patients on whom the diagnosis was concurred of unknown etiology. 4. 34 patients on whom the diagnosis were disagreed. Discussion: X chromosome anomalies represent one face of Kabuki syndrome. The long palpebral fissure with the lower lid shadow (eversion of eye lashes) w/ s heart defects tend to prompt this diagnosis. Matsumoto et al. pointed out that those patients with KS-like features and ring X tend to have more severe manifestations which are seen in this study in the patient with a smaller ring. The patient with IP and kabuki features may further narrow down the critical region. While 8p22-8p23 is a highly polymorphic region with CNVs, Shieh et al., 2006 also reported triplication of 8p22-8p23 in a patient with features similar to Kabuki Syndrome; so were the 4 patients ascertained here with duplication; mostly from the heart defects, arched eyebrow and ear anomalies. This represents the second face. Lastly, there is a clear (third) face with clinical constellations consistent with Kabuki syndrome yet etiology to be determined. While exome/large-scale sequencing is a powerful tool in identifying the cause of a mendelian disorder, careful classification of phenotype remain cruicial.

897/F

Quantitative measurement of FMRP as a screening and prognosis approach for the Fragile X Syndrome. *F. Corbin[1], M. Lessard[1], A. Chouiali[1], R. Drouin[2].* 1) Dept Biochemistry; 2) Dept Pediatrics, Facult Med & Hlth Sci, Universite de Sherbooke, Sherbrooke, PQ, Canada.

The fragile X syndrome is the leading cause of inherited mental retardation. In most cases, the syndrome results from a large expansion of CGG repeats in the 5' UTR of the FMR1 (Fragile X Mental Retardation 1) gene along with the methylation of its CpG Island. Classically, Southern blot and PCR analyses are the screening/diagnostic tools used to confirm this sole mutation (expansion and methylation) among affected boys and girls. Methylation of the FMR1 gene leads to transcriptional silencing of the FMR1 gene and the absence of its encoded protein FMRP (Fragile X Mental Retardation Protein) in affected cells. Cognitive functions among fragile X individuals are variable and tends to be higher in female and mosaic patients where FMRP is produced in a certain proportion of their neurons. A screening test based on quantitative FMRP measurement would therefore not only detect the fragile X syndrome but might also predict the cognitive functions of affected individuals. Therefore, a new quantitative approach based on the measurement of FMRP within blood sample components was developed to screen for fragile X syndrome. Levels of FMRP in a control population were first determined following the recruitment of participants of different ages and gender without any intellectual disabilities. The measured levels of FMRP in this population were then compared with those of fragile X syndrome subjects, recruited in our clinic. Cognitive functions were also assessed in these individuals using age-specific Wechsler intelligence scale and the Vineland adaptive behavior scale. Our results show that levels of FMRP in our control population follow a normal distribution and don't seem to be affected by age or gender. In fragile X individuals, levels of FMRP were significantly and sufficiently lower than controls to determine a cut-off value. Therefore a FMRP dosage below this value suggests the possibility of a fragile X syndrome diagnosis. Moreover, a direct proportional relationship was established between global IQ and FMRP level. In fact, as expected, levels of FMRP were higher in females as well as their global IQ scale. Finally, the proposed screening approach would not only discriminate fragile X from normal individuals but also predicts cognitive functions in confirmed fragile X cases. These clinical data would help to provide appropriate support for these patients.

898/F

EXPANDING THE PHENOTYPE OF AAA SYNDROME. *D. Kostiner, P. Himes.* Department of Medical Genetics, Kaiser Permanente, Portland, OR.

Achalasia-Addisonianism-Alacrima syndrome, also known as Triple-A syndrome or Allgrove syndrome, is a rare autosomal recessive condition with a prevalence of less than 1/1,000,000. It causes a triad of achalasia (hypertrophy of the gastroesophageal cardia, preventing food from entering the stomach); ACTH-resistant adrenal insufficiency; and alacrima (lack of tears). Other common features include autonomic dysfunction, anisocoria, decreased saliva, muscle weakness/wasting, and hyperkeratosis of the palms and soles. It often presents in childhood with adrenal crises, and can be lethal if not treated promptly. It is caused by mutations in the AAAS gene, which encodes a WD-repeat protein termed ALADIN. This protein is thought to be involved in cytoplasmic trafficking and/or normal peroxisomal function. The locus is on band 12q13 near the type II keratin gene cluster, which likely explains the hyperkeratosis seen in some patients. Our patient is a 38-year-old woman who presented for preconception counseling regarding her ACTH-resistant adrenal insufficiency. She was healthy at birth, but was diagnosed with non-CAH adrenal insufficiency at 2 years of age. Complications included febrile seizures (likely adrenal crisis), hypoglycemia, and orthostatic hypotension. She developed osteoporosis and poor dentition due to long-term steroid use. At 18, she was diagnosed with achalasia, for which she is treated annually with esophageal dilations and Botox via EGD. Exam findings include petite size (Ht 5'0", Wt 83 lbs, BMI 16), metopic prominence, deep-set eyes, alacrima, anisocoria, thin nose, poor dentition, cleft soft palate (s/p repair), geographic tongue, Buffalo hump (due to overtreatment with steroids), thin limbs, tiny hands, and mild hyperkeratosis of the palms. Intelligence is normal. Molecular testing of the AAAS gene revealed two mutations: Q145X, C->T in exon 5 and R230X, C->T in exon 7. Both are previously-reported nonsense mutations that cause premature truncation of the protein and/or nonsense-mediated mRNA decay. Identifying the correct diagnosis in this patient allowed for accurate preconception counseling, improved treatment regiment by her new endocrinologist, and information about what other complications might arise. This is also the first reported case of cleft soft palate in a patient with AAA syndrome, so oral clefting might be a new feature of the AAA phenotype.

899/F

Compound Heterozygosity of β°/β+-thalassemia (CD41/42-PolyA) with Non-deletional HbH Disease (--^{SEA}/α^{CS}α) - A rare combination in Malaysian Malays. *J.A.M.A. Tan[1], J.L. Kok[2], K.L. Tan[1], Y.C. Wee[1], E. George[3].* 1) Department of Molecular Medicine, Faculty of Medicine, University of Malaya, Kuala Lumpur, Malaysia; 2) Pediatrics Department, Hospital Kuching, Sarawak, Malaysia; 3) Hematology Unit, Department of Pathology, Faculty of Medicine and Health Sciences, University Putra Malaysia, Serdang, Selangor, Malaysia.

Preliminary diagnosis of hemoglobin disorders are carried out using hemoglobin analysis and electrophoresis. The co-inheritance of heterozygous β-thalassemia with homozygous α+-thalassemia (-α/-α) or heterozygous α°-thalassemia (--/αα) can present a near-normal hematological picture. Heterozygous β°-thalassemia with co-inheritance of heterozygous α°-thalassemia (--/αα) show normal MCV and MCH values. In contrast, patients with co-inheritance of deletional HbH disease (--/-α) and heterozygous β-thalassemia show anemia with marked hypochromic and microcytic red cells and very low MCV and MCH indices. Co-inheritance of β-thalassemia with non-deletional HbH disease is rare compared with the more common co-inheritance of β-thalassemia with deletional HbH disease. This study presents a unique Malay patient with HbH-CS disorder and β°/β+-thalassemia (CD41/42/PolyA). Molecular analysis was performed using Duplex-PCR and the Amplification Refractory Mutation System. The patient presented with hemolytic anemia and hepatosplenomegaly. Her hemoglobin at 2 months was 7g/dl and she received her first transfusion at sixteen months. She had increased Hb A_2 of 9.7% and absence of HbH inclusion bodies. A preliminary diagnosis of thalassemia intermedia was made in view of the Hb anlaysis and normal ferritin. Molecular studies were recommended to check for a more severe hemoglobinopathy, and compound heterozygous β-thalassemia/HbH-CS disorder was confirmed. The SEA α-gene deletion in *cis* (--^{SEA}/αα) is generally not present in the Malays, who more commonly posses the two α-gene deletion in *trans* (-α/-α). In addition, the β- gene mutation at CD41/42 is common in Malaysian Chinese and not in the Malays. The presence of both the SEA deletion and CD41/42 in the patient suggests an introduction of these two defects into this Malay family by a previous marriage with a Chinese. In conclusion, reliance on Hb analysis alone is not accurate especially in countries with a multi-racial population. The high frequency of different globin gene mutations together with interactions between α- and β-thalassemias can produce asymptomatic to moderate and severe phenotypes depending on the molecular defects involved. Although co-inheritance of β-thalassemia with HbH disease may result in at most, an intermedia thalassemia phenotype, confirmation of the defects by molecular analysis will provide valuable information that will greatly assist in genetic counseling and prenatal diagnosis.

900/F

Studying the Molecular Mechanism of Cornelia de Lange Syndrome (CdLS) by Using Patient-Derived iPS Cells. *D. Xu[1], J. Mills[2], M. Kaur[1], P. Gadue[2,3], D. French[2], I. Krantz[1].* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) hESC core facility, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pathology Center for Cellular and Molecular Therapeutics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Patients with Cornelia de Lange Syndrome (CdLS) display various congenital defects such as cognitive and behavioral impairment, growth delays and multiple structural defects. Approximately 65% of CdLS probands have an identifiable mutation in cohesin or cohesin-related genes such as *SMC1A*, *SMC3*, and *NIPBL*. The mutations in these genes seen in CdLS, results in disruption of the cohesin complexes' ability to regulate dynamic gene expression rather than its canonical role in regulating chromosome segregation. The disruption of cohesin's gene regulatory role is likely the underlying cause of the specific clinical features seen in CdLS. Our group and others have demonstrated a highly-regulated developmental and tissue specific pattern of gene dysregulation in CdLS individuals. The limitations in studying gene regulation during development in human samples in a temporal and tissue-specific manner have prohibited exploring the mechanism of disease during critical stages when these genes are most relevantly active. To overcome this problem, we have generated a series of induced pluripotent stem cell (iPSC) lines from a fibroblast cell line derived from a severely affected CdLS proband with a frame-shift mutation in NIPBL. A set of control iPSC lines were generated in parallel from a fibroblast cell line derived from a healthy person with matched age, race, and gender. In addition to morphology and growth features characteristic of stem-cells, these iPS cells highly express pluripotent genes such as *REX1*, *ABCG2*, and *DNMT3B*, indicating the fully reprogrammed state of these iPSC lines. These reprogrammed iPS cells have been induced into neuronal and cardiac lineages, further suggesting their de-differentiated state. The ongoing differentiation assays for inducing the iPS cells into different types of cells will provide invaluable specimens for studying the basic molecular mechanism of CdLS in distinct organs and systems. These studies are anticipated to lead to the identification of downstream "effector" target genes of cohesin action that may be critical to the development of specific tissues and will themselves be candidates for isolated structural and cognitive differences seen in constellation in CdLS.

901/F

Colon Cancer In RAPADILINO Syndrome. *K. Anyane-Yeboa, A. Burke, E. Guzman.* Dept Pediatrics, Columbia University Medical Center, New York, NY.

RecQ family of genes is named after RecQ protein of E. coli. Where studied, RecQ family members have been shown to be helicases involved in DNA repair after cell damage, except recQL4. Mutations in helicases have been shown to cause genomic instability disorders in man. Germline mutations of three of them five known human recQ helicases are cause autosomal recessive genomic instability disorders with cancer predisposition and/or aging. RecQ DNA has a helicase domain that is conserved across species. Bloom syndrome and Werner syndrome are autosomal disorders with mutations in RecQ helicases. Individuals with Bloom syndrome are growth delayed microcephalic and have increased susceptibility to various cancers including lymphomas and osteogenic sarcoma. Werner syndrome is associated with premature aging and susceptibility to sarcoma. RecQL4 mutations have been documented in three autosomal recessive disorders: Rothmund-Thomson, Baller-Gerold, and RAPADILINO syndromes. All three disorders are associated with radial and thumb hypoplasia, as well as susceptibility to Cancer. RAPADILINO syndrome, the rarest of these syndromes has been reported in 15 Finnish patients and a few other non-Finnish patients. Among the Finnish patients,there have been 2 osteosarcomas and 4 lymphomas, an overall cancer incidence of 40%. We report the first case of colon cancer in RAPADILINO syndrome in a 42-year-old man with history of low birth weight, cleft palate, and neonatal diarrhea, absent patellae, radial hypoplasia, absent thumbs, short stature, club feet, café-au-lait spots, and borderline intelligence, all features of RAPADILINO syndrome. Chromosome breakage studies revealed levels that are higher than for controls but less than for Fanconi Anemia.His cell are not sensitive to mytomycin C or diepoxybutane. He developed adenocarcinoma of the colon at 29 years of age and had right hemicolectomy but subsequently required total colectomy because of recurrence. Parents are Ecuadorian and there is no consanguinity. Sequencing of RecQL4 reveled 2 novel mutations: c.198delC and c.1465G>T (p.V489F) variant. To our knowledge this is the first reported case of colon cancer in this syndrome. We recommend careful follow-up patients with this syndrome, not only for lymphoma and osteosarcoma but also for colon cancer.

902/F

Genetic background of cochlear implant patients, GJB2 (Connexin 26) and GJB6 (Connexin 30) mutation spectrum. *R. Birkenhager, A. Aschendorff, S. Arndt, W. Maier, E. Lohle, R. Laszig.* Otorhinolaryngology H&N Surg, Univ Freiburg, Freiburg, GermanyDepartment of Otorhinolaryngology and Head and Neck Surgery, University Medical Center Freiburg, Killianstrasse 5, D-79106 Freiburg, Germany.

Congenital sensorineural hearing impairment affects approximately 1-3/1000 newborn. Especially mutations in the GJB2 gene connexin-26 are the reason for non-syndromic hearing impairment. In the present study 451 patients, from the cochlear program of the Department of Otorhinolaryngology, University Medical Center Freiburg (06/2003 - 12/2009), with severe to profound hearing impairment and no evidence of any additional syndrome and malformation of the temporal bones and inner ear in high resolution CT, were analyzed for genetic alterations in the GJB2 and GJB6 genes. Individual exon and intron transitions of the coding exons of the GJB2 gene were PCR amplified using standard conditions. Direct automatic sequencing of fragments was performed bidirectional. Additionally analyse of the GJB6 gene deletions was performed. Mutations in the GJB2 gene were found in 194/451 (43,0%) patients. 42/451 patients were heterozygous for GJB2 alterations, no other mutations were detectable (9,3 %). In five cases the mutation delGJB6-D13S1830 was found in combination with the c.35delG mutation in the GJB2 gene. The frequently-causing mutation c.35delG was detected homozygous in 104 patients (23,1 %). Forty different mutations were identified; fifteen of these gene alterations are novel (Met1Ile, Trp24Leu, Asp46Asn, c.146delC, del307-323 17nt, Trp134Arg, Trp134ter, Glu147Arg, Cys169Tyr, Ala171Gly, Ser183Phe, Gly200ter, Tyr220His, Lys221Asn, ter227Tyr). These mutations were detected in most cases in combination with the mutation c.35delG. These results demonstrate that individuals with severe to profound hearing impairment or deafness should be investigated for GJB2 (connexin-26) mutations. In the case of identification of GJB2 mutations genetic consulting can be offered. Additional screening of newborns with suspected hearing impairment can help to find out early patients who require intensive speech therapy, needs hearing aid and might be candidates for cochlear implantation.

903/F

Schnyder's Corneal Dystrophy: A genetic analysis in humans and canines. *B.N. Kostiha[1,2], M.L. Nickerson[1,3,4], M. Dean[1], J.S. Weiss[5].* 1) Cancer and Inflammation Dept., National Cancer Institute, NIH, Frederick, MD; 2) Biomedical Science Graduate Program, Hood College, Frederick, MD; 3) Graduate Partnership Program, NIH, Bethesda MD; 4) Molecular Medicine Program, Institute for Biomedical Science, George Washington University, Washington, DC; 5) Kresge Eye Institute, Departments of Ophthalmology and Pathology, Wayne State University School of Medicine, Detroit, MI.

Schnyder corneal dystrophy (SCD, MIM: 121800) is a rare autosomal dominant disease with abnormal deposits of cholesterol and phospholipids in the cornea. The diagnostic phenotype is a progressive bilateral corneal opacification resulting in a gradual decrease in visual clarity. A novel gene mutated in SCD, *UBIAD1*, was previously identified independently by two groups. *UBIAD1* is predicted to contain a prenyl-transferase domain and eight transmembrane spanning regions. Treatment is limited for the disease with only two types of treatment available, a phototherapeutic keractectomy and penetrating keratoplasty surgery. As a result, an animal model is of interest. Within this study both the analysis of humans and canines is presented to further understand genotypic to phenotypic correlation of the disease. Furthermore, the study is an important step toward determining if a canine would be a suitable animal model to investigate other treatment options. Patient recruitment occurred through referrals from physicians, family members, self, and publication searches. Genomic DNA isolation occurred from blood samples and the DNA was amplified using a touchdown PCR method. When needed TOPO® PCR cloning and colony PCR occurred to isolate region of interest. DNA sequencing was done using the 3730 DNA Analyzer. Analysis for alterations was completed using a sequence viewer. Sequence alignment, homology, and phylogeny were also done using ClustalX and MEGA. This study presents analysis of ten new SCD families. Of these ten, five have novel genetic alterations A97T, D112N, V122E, V122G, and L188H. One family is of Native American ethnicity, this is the first report of SCD in this ethnic group. The other five families all have the putative hotspot mutation of N102S. The mutated amino acids are observed (15/17) to be highly conserved across species, including canines. Four canines underwent analysis which resulted in finding a single nucleotide polymorphism and an intronic variant, neither thought to cause SCD in the canine. Previous SCD analysis demonstrates families who are known to have the disease but have no alterations within the protein coding regions of the *UBIAD1* gene; it is thought that the canine may follow the same suit as these families.

904/F

A SATB2 nonsense mutation causes Cleft Palate and Cognitive Defects through a dominant negative effect. *P. Leoyklang[1], K. Suphapeetiporn[2], M. Huizing[3], WA. Gahl[3], V. Shotelersuk[2].* 1) Biomedical Science Program, Faculty of Graduate School, Chulalongkorn University, Thailand; 2) Department of Pediatrics, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand; 3) Medical Genetics Branch, NHGRI (NIH), Bethesda, MD.

SATB2 (special AT-rich sequence-binding protein2) (*608148) encodes a DNA binding protein, forming a homodimer that specifically binds nuclear matrix attachment regions and is involveds in transcription regulation and chromatin remodeling. In 2007, we found a 36-year-old man with cleft palate, generalized osteoporosis, and profound mental retardation. He had a de novo germ-line nonsense mutation (c.7154C>T; p.R239X) of SATB2 (Human Mutation. 2007; 28: 732-738). Whether the mutation causes disease through haploinsufficiency, a dominant-negative or a gain-of-function effect was not determined. Here, we first show that the mutant protein is stable. Then, using immunofluorescence and subcellular fractionation, we demonstrate that both the wild-type and mutant SATB2 localize to the nucleus. In addition, protein-protein interaction studies show that the mutant truncated SATB2, which retains the dimerization domain, can form a dimer with the wild type SATB2. These findings strongly suggest that the severe clinical features of our patient are caused by a dominant negative effect of the SATB2 nonsense mutation, rather than to a haploinsufficiency, which associated with a milder phenotype.

905/F

A Japanese family of nemaline myopathy which is caused by *TPM2* mutation. *J. Goto, H. Ishiura, Y. Fukuda, Y. Nagashima, J. Shimizu, Y. Takahashi, Y. Ichikawa, S. Tsuji.* Dept Neurology, Grad Sch Med, Univ Tokyo, Tokyo, Japan.

Background: Nemaline myopathy is a heterogeneous group of congenital myopathy which is characterized by presence of nemaline rods in skeletal muscle fibers. To date, six causative genes have been identified; *ACTA1* (NEM3), *TPM2* (NEM4), and *TPM3* (NEM1) for autosomal dominant types, and *TNNT1* (NEM5), *NEB* (NEM2), and *CFL2* (NEM7) for autosomal recessive types. We experienced an autosomal dominant nemaline myopathy family, of which the proband was a male at the age of 64 years old and showed slowly progressive proximal muscle atrophy and weakness, dysphagia, rigid spine, dilated cardiomyopathy and type 2 repiratory failure. **Object:** To identify the genetic cause, the linkage analysis of the family and sequencing of causative genes were performed. **Subjects and Methods:** This study was approved by the University of Tokyo Institutional Review Board. Informed, written consent was obtained from all participants. The family consisted of three generations and 12 individuals. Seven members were affected. The affected father of the proband was deceased. Genomic DNA was extracted from four affected members and two married-in individuals. Genotyping was carried out using Affymetrix SNP Array 6.0 and linkage analysis was performed using Allegro 2.0 through the processing of the SNP data by SNP HiTLink (BMC Bioinformatics 2009,10:121; URL: www.dynacom.co.jp/u-tokyo/snphitlink). Candidate genes were sequenced by Sanger method. **Result:** Estimated maximum LOD score of the family was approximately 0.9. The linkage analysis revealed that zero to two regions every chromosome remained to be candidate regions. *TPM3* was excluded among the three causative genes for autosomal dominant nemaline myopathies. All exons and their flanking regions of *ACTA1* and *TPM2* were sequenced. A single nucleotide substitution, *TPM2* c.349G>A(p.Glu117Lys), was identified as the causative mutation. **Discussion:** The linkage analysis system using a SNP array and SNP HiTLink is a useful and high-throughput system in both research and clinical practice. Myopathies which are caused by mutations of *TPM2* have been reported as different names; nemaline myopathy-4 (NEM4), congenital cap myopathy and distal arthrogryposis (DA2B). They show different clinical features and also some features are overlapping. It is important to elucidate clinical/phenotypical spectrum or genotype-phenotype co-relation of myopathy caused by *TPM2* mutation.

906/F

Germline *DICER1* Mutations and Familial Cystic Nephroma. *A. Bahubeshi[1,2], N. Bal[3], T. Rio Frio[1,4], N. Hamel[1,4], C. Pouchet[1,2], A. Yilmaz[1,2,4], d. Bouron-Dal Soglio[5], M. Tischkowitz[1,2], J.R. Priest[6], W.D. Foulkes[1,2,4].* 1) Program in Cancer Genetics, Departments of Oncology and Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Lady Davis Institute, Segal Cancer Centre, Jewish General Hospital, Montreal, Quebec, Canada; 3) Department of Pathology, Baskent University Faculty of Medicine, Ankara, Turkey; 4) The Research Institute, McGill University Health Centre, Montreal, Quebec, Canada; 5) Department of Pathology, CHU Sainte Justine, 3175 Chemin de la Côte-Ste-Catherine, Montréal, Québec, Canada; 6) The International Pleuropulmonary Blastoma Registry, St. Paul, Minnesota, USA.

BACKGROUND-Multilocular cystic nephroma (CN) is a benign kidney tumor and is part of a family of kidney neoplasms including cystic partially differentiated nephroblastoma and Wilms Tumor (WT). CN is rarely familial or bilateral, but it occurs in approximately 10% of families where pleuropulmonary blastoma (PPB) is present. Recently, germline mutations in *DICER1* were found in familial PPB. We searched for *DICER1* mutations in two families with familial CN; PPB was present in one family. Additionally, we tested germline DNA from 50 children with sporadic WT for *DICER1* mutations.

METHODS-We screened two families for mutations in the DICER1 gene. Also, we investigated cystic nephromas for loss of heterozygosity and DICER1 expression.

RESULTS-Both families with multiple CN were found to have mutations in *DICER1* leading to premature stop codons, predicted to result in loss of the ribonuclease and dsRNA binding domains. These domains are essential to the function of DICER1. No germline mutations were found in any of the 50 children who had developed WT.

CONCLUSION-We have established that *DICER1* mutations cause familial CN and may be implicated in bilateral CN. No germline mutations were found in the WT cases, suggesting that *DICER1* mutations are unlikely to play a major role in the etiology of sporadic WT. Our results provide further evidence implicating miRNA dysregulation in tumorigenesis.

907/F

A case of likely digenic inheritance of oculocutaneous albinism. *C. Dinsmore[1], A. Hamosh[1], P.W. Chiang[2].* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) UCHSC DNA Diagnostic Laboratory, University of Colorado Denver School of Medicine, Aurora, CO.

Oculocutaneous albinism (OCA) is a well-known autosomal recessive disease caused by mutations in one of four genes in the melanin synthesis pathway. Digenic inheritance has been recognized in a few other recessive diseases, such as retinitis pigmentosa and non-syndromic hearing loss. Here we report a case of likely digenic inheritance of oculocutaneous albinism. The proband, a 27 year-old female, presented to our clinic for genetic counseling regarding ocular albinism. Her ophthalmologic history was significant for nystagmus, decreased visual acuity, retinal hypopigmentation, foveal depressions, and iris transillumination. Although fair, her skin and hair color were consistent with the complexion of her first-degree relatives and her Irish-English-Scottish ancestry. Bidirectional sequence analysis identified one mutation in the *TYR* (OCA1) gene, p.T373K:c.1118C>A, and one mutation in the *OCA2* (P) gene, p.N489D:c.1465A>G. Sequence analysis of *TYRP1* (OCA3), *SCL45A2* (OCA4), and *GPR143* (OA1) was negative. Parental testing revealed her father carries the *TYR* gene mutation, and her mother carries the *OCA2* gene mutation. Both of these mutations have been reported as disease-causing mutations in the literature. There is debate in the literature regarding whether the types of OCA represent a spectrum or distinct genotypic, phenotypic, and biochemical entities. This observation of likely digenic inheritance supports the view of OCA as a spectrum. We cannot rule out the possibility that a second unidentified mutation is present in either the *TYR* or *OCA2* gene. However, this result is consistent with several other published cases of autosomal recessive ocular albinism (AROA) in which only one mutation is identified. Recently, we proposed a new disease mechanism for OCA and suggested that multiple genetic factors, including modifiers from other genes, are necessary to cause the condition, especially in cases of AROA. We have also shown a haploinsufficiency effect of OCA2 in a Hispanic family we studied. Therefore, the presence of one mutation in *TYR* and one mutation in *OCA2*, together with the lighter pigmentation profile of the patient, crossed the threshold and caused AROA in this patient. The knowledge of likely digenic inheritance in OCA is clinically important since the recurrence risk in this case is 25% rather than the <1% risk to individuals with autosomal recessive conditions.

Association of Rubinstein-Taybi Syndrome with a novel point mutation in the EP300 acetyltransferase domain. *D. EL IMAM[1], M.E. Ahearn[2], R. Faugue[3], N. Bishopric[1,3].* 1) Department of Molecular and Cellular Pharmacology, University of Miami, Miami, FL; 2) Department of Genetics, University of Miami, Miami, FL; 3) Department of Medicine, University of Miami, Miami, FL.

Introduction: Rubinstein Taybi Syndrome (RTS) is a rare syndrome characterized by mental retardation, dysmorphic features and skeletal abnormalities. Classical and non-classical forms of RTS have been described. 52 mutations within the CREBBP gene have been linked to RTS, as well as 6 mutations in EP300. CREBBP and EP300 encode paralogous nuclear histone/factor acetyltransferases (HATs) that activate signal-dependent transcription through acetylation of histones and DNA-binding transcription factors. The majority of CREBBP mutations span or lie in the HAT domain and result in CREBBP haploinsufficiency. EP300 has only recently been linked to RTS and studied in a smaller subset of RTS patients; all mutations to date involve deletions or nonsense mutations. It remains unknown whether EP300 mutations are responsible for milder or non- classical forms of RTS, or whether EP300 haploinsufficiency results in unique clinical manifestations. Aims: (1) to develop an RNA-based method for genetic screening in RTS; (2) to study the functional significance of EP300 mutations. Methods: A mother and daughter with clinically diagnosed classical RTS were studied. Immortalized lymphocytes were cultured and used to isolate RNA and DNA. New PCR primers sets were designed to amplify overlapping fragments of the CREBBP and EP300 coding sequence. Transcripts were amplified and sequenced from lymphocyte RNA. Genomic DNA of the probands was amplified using published primers for CREBBP and EP300. Exomic DNA sequencing was used to confirm RNA-derived cDNA sequence analysis. Results: A novel point mutation was found in mother and daughter at position 3386 A>G in exon 15, changing isoleucine to valine. The amino acid substitution lies within the HAT domain, potentially affecting p300 acetyltransferase activity. Genotypes determined from RNA and DNA sequencing were concordant. The mutation was not found in 96 individuals with no evidence of genetic disorders. Conclusions: (1) We have identified a novel point mutation in two patients with RTS in the HAT domain of EP300, the first reported missense mutation in this gene. Our finding confirms the genetic heterogeneity of RTS and the contributing role of EP300 in the phenotypic heterogeneity of this syndrome. The mutation is expected to affect HAT activity and/or p300 protein stability. (2) RNA-based sequencing can be an efficient alternative to exomic DNA sequencing for mutation screening and genotype-phenotype discovery in RTS.

909/F

Comprehensive search for exonic deletions within the CREBBP gene in Rubinstein-Taybi syndrome patients using MLPA. *M.J. van Belzen[1], C.A.C. van der Lans[1], J.G. Dauwerse[1,2], D.J.M. Peters[2].* 1) Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Human Genetics, Leiden University Medical Center, Leiden, Netherlands.

Rubinstein-Taybi syndrome (RSTS) is a rare disorder affecting approximately 1/100,000 newborns. The syndrome is characterized by mental and growth retardation, and a particular dysmorphology mainly concerning the face, hands and feet. The most frequent cause of RSTS are mutations in the CREBBP gene, which are found in 30-50% of patients. Mutations in the EP300 gene are less common, with a frequency of <10%. Mutations in CREBBP are primarily nonsense, frameshift and splice site mutations that occur over the entire coding region, although also several pathogenic missense mutations have been identified. In addition, large deletions, mostly of the entire gene, have been detected by FISH. Recently, smaller deletions were detected by quantitative multiplex fluorescent PCR and multiplex PCR/liquid chromatography. We used the multiplex ligation-dependent probe amplification (MLPA) technique, with probes for every exon of CREBBP, to test for the presence of deletions and duplications in a group of 121 patients suspected of having RSTS. For all patients the coding region of CREBBP, including intron/exon boundaries, was completely sequenced and in 39 patients a pathogenic mutation was detected. In 10 of the remaining 82 mutation-negative patients, eight different deletions were detected. Only one deletion comprised the entire gene. The other deletions were much smaller, between 1 and 8 exons, and two deletions had occurred twice. One deletion occurred in mosaic form in both blood and buccal cells of the patient. No exonic duplications were found. In total, deletions were found in 8% of this group of RSTS patients, and they represented 20% of all detected pathogenic CREBBP mutations. Therefore, screening for exonic CREBBP deletions is an important part of mutation scanning in RSTS patients.

Molecular and Clinical Findings in Type VI Ehlers Danlos with Lysyl Hydroxylase Deficiency. *Z. Xu[1], D. Vats[2], E.M. Blevins[3], J. Yang[1], L.J. Sloper[1,4], M.J. Willis[3], A.M. Slavotinek[2], J.H. Black[5], N.B. McDonnell[1].* 1) National Institute on Aging, Baltimore, MD; 2) Department of Pediatrics, University of California, San Francisco, CA; 3) Navy Medical Center San Diego, San Diego, CA; 4) MedStar Research Institute, Baltimore, MD; 5) Department of Surgery, Johns Hopkins University School of Medicine, Baltimore, MD.

The type VI variant of the Ehlers-Danlos Syndrome (EDS) is a rare, autosomal recessive connective tissue disorder characterized by scoliosis, hypotonia, easy bruising, scleral fragility, and friable, hyperextensible skin. The implicated gene is mutations in *PLOD1*, resulting in deficient activity of lysyl hydroxylase, an intracellular enzyme involved in the formation of mature collagen. Here, we present clinical and molecular findings in four probands with EDS VI who were diagnosed by reduced pyridinum cross-links in the urine. Patient 1, a girl, was born with hypotonia and intracranial bleed. Bruising and scoliosis at 8 months of age led to diagnosis of EDS VI. Patient 2, a boy, was diagnosed at age 5 due to hypotonia, scoliosis and skin fragility. At age 6, he developed two aneurysms in his legs, one of which progressed to rupture. The aneurysms were successfully treated surgically. Patient 3 is a child of consanguineous parents (uncle-niece), who presented with hypotonia, skin fragility and scoliosis in early childhood. Progressive scoliosis was surgically corrected at age 15, followed by development of aortic and subclavian dissections and aneurysms within two weeks of the procedure. Patient 4 is a 6-year-old child of consanguineous parents (half-first cousins), with neonatal hypotonia, multiple intracranial hemorrhages, hyperextensible joints, lax skin, kyphosis and gross motor delay. By bidirectional sequencing of 19 exons of *PLOD1*, we identified six mutations in the forms of compound heterozygotes or homozygotes in these four unrelated patients with EDS VI. Out of the six mutations, four were novel and five were premature termination mutations. This is the first report of an initiation codon mutation of human *PLOD1*. Using quantitative real-time PCR, we analyzed the relative amount of *PLOD1* mRNA transcripts in the fibroblast cells from two patients, providing evidence for the reduced *PLOD1* expression in these patients. The findings suggest that in children with hypotonia, type VI Ehlers Danlos should be suspected especially in the setting of consanguinity. All our patients had undergone evaluations for suspected neuromuscular disorders prior to the correct diagnosis. Also notable are clinical features of intracranial bleed and relatively good outcomes with vascular surgeries. Scleral rupture was not found in any of the probands to date. Molecular testing has a high yield and allows for prenatal diagnosis.

911/F

Atypical Autism Profile in Children with Cornelia de Lange Syndrome. *S. Srivastava[1], A.D. Kline[2], M. Grados[3].* 1) Johns Hopkins University, Baltimore, MD; 2) Harvey Institute for Human Genetics, Greater Baltimore Medical Center, Baltimore, MD; 3) Johns Hopkins University, Baltimore, MD.

Purpose: Cornelia de Lange Syndrome (CdLS) is a monogenic disorder characterized by growth retardation, craniofacial abnormalities, deficits in limb development, and intellectual disability. Also commonly noted are autistic features, including avoidance of social interaction and physical contact, self-stimulatory movements, and deficits in expressive language. However, the specific delineation of autistic features in CdLS are not well understood. Given the description of autism traits in other monogenic disorders, we seek to define the autism profile for children with CdLS and examine its association with a range of maladaptive behaviors and adaptive functioning measures. Methods: Children with CdLS 5-17 years of age were recruited from specialized clinics and family support group (CdLS Foundation). The clinical diagnosis of CdLS was ascertained using the CdLS Diagnostic Checklist (Kline). A cross-sectional sample of 41 ascertained children with CdLS ages 5-17 years were then evaluated using the interview-based Childhood Autism Rating Scale (CARS; Schopler), interview-based Vineland Adaptive Behaviors Scales (VABS; Sparrow), and the parent-report Aberrant Behavior Checklist (ABC; Aman) in order to assess autistic features, adaptive functioning, and maladaptive behaviors, respectively. Results: For the 41 children with CdLS, 3 autism severity groups were formed based on CARS scores: no significant autism features (n=7; 18%); moderate-mild autism features (n=17; 41%); severe autism features (n=17; 41%). Frequently endorsed CARS items included abnormal emotional response, abnormal body use (self-injury, stereotypies), poor object use, lack of adaptation to change (rigidity), and lack of verbal communication. Relatively spared domains included forming relationships and nonverbal communication skills. Autism severity was associated with temper outbursts and mood swings (Irritablity scale ABC), repetitive behaviors (Stereotypy subscale ABC) and low mood/social avoidance (Apathy subscale ABC). Adaptive skills were also impacted negatively by autism severity scores. Conclusions: Autism features in CdLS children are characterized by deficits in verbal skills and repetitive behaviors with relatively spared social cognition. Further, autism traits are associated with maladaptive behaviors and lower adaptive skills. As in other autism-related monogenic disorders, an atypical autism profile is present in children with CdLS.

VMD2-related autosomal dominant vitreoretinochoroidopathy: Range of developmental ocular anomalies. *A. Vincent, C. Mcalister, E. Heon.* Department of Ophthalmology, Hospital for Sick Children, Toronto, Ontario, Canada.

Purpose: To explore the spectrum of phenotypic characteristics of autosomal dominant vitreoretinochoroidopathy (ADVIRC) in a family with p.V86M mutation in *VMD2*. Methods: Six affected subjects across three generations underwent ophthalmological evaluation and electrophysiological testing. Goldmann visual field analysis was performed on four. Five family members including three affected were directly sequenced for mutations in the *VMD2* gene. Results: A heterozygous change, p.V86M (c.256G>A), was identified in *VMD2* gene in three affected subjects and was shown to co-segregate with the disease. The best corrected visual acuity ranged from ≥ 20/25 (4 cases; age range 27 - 61 years) to absent perception of light (case 3; 63 years). Color vision was normal in all four tested. Angle closure glaucoma was observed in two subjects whereas shallow anterior chambers and microcornea was noted in one. Iris dysgenesis with abnormal sphincter pupillae was observed in two subjects. Cataracts were observed in three (cases 3, 5 & 6; ages 61, 32 and 28 years respectively) and a history of prior cataract surgery was noted in one (case 1). The classical peripheral concentric band of retinal hyperpigmentation was noted in five. One subject (Case 3 - mother of proband) was blind with dense cataracts at diagnosis precluding retinal evaluation but had anterior segment anomalies, angle closure glaucoma, abnormal electroretinogram (ERG) and the V86M mutation. Bilateral optic nerve hypoplasia was noted in at least one (case 2). Goldmann fields were normal in three (cases 2, 4 & 5; age range 27 -61 years) but showed only central 10^0 preservation in one (case 1; 42 years). Full-field ERG responses were near normal in two subjects (cases 2 & 5; ages 27 & 32 years respectively), moderately reduced in two (cases 4 & 6; ages 61 & 28 years respectively) and non-detectable in two others (cases 1 &3; ages 42 & 63 years respectively). Electro-oculography showed borderline Arden's ratio in case 2 but was not performed in others. Optical coherence tomography showed normal macular thickness in one (case 2; 27 years) and severe thinning in one (case 1; 42 years). Conclusion: Marked intra-familial phenotypic variability is demonstrated in ADVIRC. Developmental ocular anomalies being potential risk factors for development of glaucoma, should be recognized in ADVIRC. Optic nerve hypoplasia and iris dysgenesis are novel observations that extend the ocular phenotype in ADVIRC.

913/F

Chronic lung disease in patients with cutis laxa. *R. Westman[1], S. Henger[1], A. Shifren[2], R.D. Yusen[2], R.P. Mecham[2,3], F. Sciurba[4], Z. Urban[1].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Medicine, Washington University of School of Medicine, St. Louis, MO; 3) Department of Cell Biology and Physiology, Washington University of School of Medicine, St. Louis, Mo; 4) Department of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Cutis laxa (CL) is a genetically and phenotypically heterogeneous group of disorders characterized by loose, inelastic, and redundant skin. The different types of CL are classified by inheritance, clinical, and molecular findings. Genes found to cause CL include ELN, FBLN4, FBLN5, ATP6V0A2, LTBP4, PYCR1, RIN2, and ATP7A. Patients with CL often develop pulmonary involvement that may consist of emphysema or respiratory distress. This study aimed to characterize the pulmonary phenotype of the different types of CL based on mutational status. METHODS: The study collected clinical and genetic data of patients with CL. RESULTS: Of the 26 participants, 10 were heterozygous for an ELN mutation, 4 were heterozygous for a LTBP4, 6 were homozygous or compound heterozygous for LTBP4 mutations, 4 were homozygous or compound heterozygous for ATP6V0A2 mutations, and 2 were homozygous for FBLN4 mutations. Of the ELN patients, 5/10 had no significant pulmonary involvement and 3/10 had obstructive lung disease. For LTBP4, 2/4 heterozygotes had no pulmonary involvement, 1/4 had a history of asthma and wheezing, and 1/4 had COPD with bronchiectasis and tracheal diverticulum, and 6/6 LTBP4 homozygotes and compound heterozygotes had significant pulmonary involvement including neontatal respiratory distress, emphysema, tachypnea, pneumonia, herniated lungs, and/or diaphragmatic hernia. In ATP6V0A2 patients, 4/4 had mild to moderate pulmonary involvement with bronchiectasis, diaphragmatic hernia, history of pneumonia, or moderate obstructive disease. In FBLN4 patients, 1/2 had emphysema and diaphragmatic hernia and 1/2 died from respiratory failure. CONCLUSION: Patients with CL have a heterogeneous type and severity of pulmonary complications that do not clearly correlate with genotype. Future studies of patients with CL will require a larger sample size and additional data collection to establish genotype-phenotype correlations.

914/F

Ulnar-Mammary syndrome: Expending the phenotype to include ankyloglossia and cleft lip and palate. *J. Jessen[1], B.H.Y. Chung[1,2], B. Fernandez[3], C. Li[4], D. Chitayat[1,2].* 1) Dept Prenatal Diagnosis, Mount Sinai Hosp, Toronto, ON, Canada; 2) Clinical and Metabolic Genetics, Department of Paediatrics, Hospital for Sick Children, Toronto ON, Canada; 3) Disciplines of Genetics and Medicine, Memorial University of Newfoundland, St. John's, Newfoundland, Canada; 4) Clinical Genetics Program, McMaster Children's Hospital, McMaster University, Ontario, Canada.

The ulnar-Mammary syndrome is an autosomal dominant condition with intrafamilial variability extending from non-penetrant to the known clinical manifestaions, seen within the same family. The main features are ulnar ray defects with missing digits or post-axial polydactyly, ano-genito-urinary abnormalities and hypoplasia of the apocrine glands and breasts. New clinical manifestations are being added in almost every publication making the diagnosis very difficult. We noted two additional findings: ankyloglossia and cleft lip and palate. CASE REPORT: The proband parents were first seen for abnormal fetal ultrasound at 15 weeks gestation, showing bowed and shortened humeri, single forearm bones, bilateral elbow and wrist contractures and bilateral oligodactyly. He also had fenestrated ASD, ankyloglossia, cleft lip and palate, short clavicles with slopped shoulders and unpalpable pectoralis major, laterally displaced inverted nipples and undescended left testis with hypoplastic left hemiscrotum. Karyotype and BAC microarray analysis were normal and DNA analysis for TBX5, EDA1, and TP63 genes showed no detectable mutation. .Detailed family history suggested that his paternal aunt had right upper limb findings similar to the proband and was previously diagnosed as having Holt-Oram syndrome (HOS). Further investigation showed ankyloglossia, and in her recent experience as a mother she had difficulty in lactation from her right breast. TBX3 testing was first done in her and subsequently in our proband and his asymptomatic father detected a familial heterozygous p.R131X mutation in the TBX3 gene. CONCLUSION: UMS is a rare autosomal dominant disorder caused by TBX3 mutations. The diagnostic challenge is related to the poor genotype-phenotype correlation and intrafamilial and interfamilial variability in clinical manifestations. We report two additional clinical observations: ankyloglossia and cleft lip and palate not previously reported in UMS. Different members of the family are dispersed geographically and assessed by different geneticists, making it difficult for any individual geneticist to make the diagnosis. In fact this family was reported as a new syndrome by Li et al., 2009. This illustrates the importance of detailed history and examination, inter-professional communication and sharing of investigation findings in clinical genetics.

915/F

Arylsulfatase E deficiency: functional analysis of novel mutations in patients with CDPX1 and examination of phenocopies. *C. Matos-Miranda[1], G. Nimmo[1], B. Williams[2], S. Bale[2], N. Braverman[1].* 1) Montreal Children's Hospital Research Institute, Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) GeneDx, Gaithersburg, Maryland, USA.

X-linked recessive brachytelephalangic chondrodysplasia punctata (CDPX1) is a disorder of bone development characterized clinically by chondrodysplasia punctata (CDP), nasomaxillary hypoplasia and brachytelephalangy. There is a wide range of clinical severity in affected males. CDPX1 is caused by inherited deficiency of Arylsulfatase E (ARSE), a Golgi enzyme whose natural substrate is unknown and, is inhibited by warfarin, a drug that reduces vitamin K levels. Nevertheless, almost half of the patients with CDPX1 phenotypes do not have identifiable ARSE mutations. Although this could be due to undetected ARSE mutations or genetic heterogeneity, some could be phenocopies due to fetal deficiency of vitamin K in the first trimester of pregnancy. This has been observed with maternal warfarin use and maternal small bowel disease, pancreatitis and severe hyperemesis gravidarum. We propose that fetal vitamin K deficiency could inhibit a normal ARSE enzyme, thus generating CDPX1 phenocopies. Through the NIH-CETT program, we identified 20 novel missense variations in ARSE and 17 potential phenocopies. In order to determine the effect of the variations on protein function, we engineered all ARSE mutant constructs and transiently expressed them in COS1 cells, which do not have high interfering sulfatase activities. ARSE activity was measured using the fluorogenic artificial substrate, 4-MU. Our results showed that most mutant alleles had negligible ARSE activity, suggesting that they were pathological. However, alleles located in the C-terminal region showed potential residual activity, indicating an association between mutation position in the protein domains and loss of activity. As part of the CETT program, we also collected clinical data on all patients and we are currently evaluating it to determine genotype-phenotype correlations amongst patients with ARSE mutations, and to identify maternal effects in mutation negative patients.

916/F

P2RX7 rs1718119 and External Apical Root Resorption during Orthodontia. *J.K. Hartsfield[1,2,3,4], T. Moremi[1,2], G. Falcão-Alencar[1,2,5], L.A. Morford[1,2], D.W. Fardo[2,6], J.V. Macri[3], G.T. Kluemper[1].* 1) College of Dentistry, Univ Kentucky, Lexington, KY; 2) Hereditary Genomics lab, Univ Kentucky, Lexington, KY; 3) School of Dentistry, Indiana Univ, Indianapolis, IN; 4) School of Medicine, Indiana Univ, Indianapolis, IN; 5) Universidade De Brasilia, Laboratorio ge Genetica, Departamento de Genetica e Morfoligia, Brasilia, Brazil; 6) College of Public Health, Univ Kentucky, Lexington, KY.

Objective: External Apical Root Resorption (EARR) concurrent with orthodontic treatment is a complex trait. Previous studies have demonstrated that variation in the human *IL-1*β gene is associated with increased EARR in orthodontic patients. The purinergic receptor P2X, ligand-gated ion-channel-7 (*P2RX7*), is an upstream mediator of IL-1β production in both monocytic and osteoclastic cells. This study investigates the association of a non-synonymous (Ala348Thr) gain-of-function SNP in the human *P2RX7* gene, rs1718119, with moderate to severe EARR of the maxillary incisors in orthodontic patients. The null-hypothesis states that variation in *P2RX7* is not associated with EARR. The alternative-hypothesis states that variation in *P2RX7* is associated with EARR. Methods: DNA was isolated from the buccal swabs of 279 Caucasian orthodontic patients (55 EARR cases, 224 controls). Taqman®-based genotyping was utilized for the allelic discrimination of rs1718119 on the Roche LightCycler480. Pre/post-treatment radiographs were analyzed qualitatively by three investigators for EARR of the maxillary-incisors. Subjects were considered to be "affected" when at least two-of-three investigators agreed that EARR was moderate to severe based on graphic standards on at least one of the maxillary incisors. The Cochrane-Armitage trend test assuming an additive mode of inheritance was used to evaluate the association of the SNP and susceptibility to EARR. Results: All rs1718119 genotypes were in Hardy-Weinberg equilibrium. The Cochrane-Armitage Trend Test revealed a p-value of 0.076. Conclusion: While the null-hypothesis could not be rejected for rs1718119 (*P2RX7*) and EARR during orthodontia, the data are suggestive that analysis of additional subjects could reveal a small effect of *P2RX7* on EARR. If demonstrated, this would indicate that *P2RX7* (or a locus in linkage disequilibrium with it) plays a role in EARR of maxillary-incisors during orthodontic treatment. Currently, additional subjects are being analyzed along with analysis of rs208294 *P2RX7* genotypes. This research was supported in part by the Indiana U. Bixler Fund for Genetics Research and Education, the U. of Kentucky E. Preston Hicks Endowed Chair, and the Southern Association of Orthodontics.

917/F

Bardet-Biedl syndrome: A milder phenotype in a female with a proven BBS1 mutation. *K. Bermudez Wagner[1], E. Heon[2], J. Duncan[3], A. Slavotinek[1].* 1) Department of Pediatrics, Division of Genetics, University of California, San Francisco , CA; 2) Department of Ophthalmology and Vision Science. The Hospital for Sick Children Research Institute, Ontario, Canada; 3) Retinal Degenerations Clinic. Department of Opthalmology. University of California, San Francisco, CA.

Bardet-Biedl syndrome (BBS) is usually diagnosed clinically; however, less severe phenotypes may be under-diagnosed and mutation analysis is useful in such situations. We describe a mildly affected 14 year old female who was homozygous for the p.Met390Arg mutation in the BBS1 gene. At birth, she had postaxial polydactyly on both feet and postaxial skin tags on both hands which were removed at 3 months. At age 7, she presented with a refractive eye disorder and was diagnosed with retinitis pigmentosa at 12 years and Bardet-Biedl syndrome at 14 years of age when she had marked visual deterioration (corrected visual acuity 20/200 bilaterally) and night blindness. On examination at 14 years, height was 156.2 cm (10-25%), weight was 64.1 kg (75-90%) and BMI was 26 mg/m2 (overweight defined as > 25 mg/m2; her BMI is much reduced from the mean BMI in BBS females of 31.5 mg/m2). She had slight truncal adiposity, bitemporal narrowing, short and upslanting palpebral fissures, mild retrognathia with a high and narrow palate, brachydactyly with single palmar creases, a sandal gap between the 1st and 2nd toe and pes planus. A renal ultrasound showed mild pelviectasis of the left kidney with persistent microhematuria but normal renal function tests, and she had had normal menarche at 12 years. She had met all of her developmental milestones appropriately and was in regular school, although she had recently been noted to have mild learning disabilities. Genetic testing showed homozygosity for p.Met390Arg in BBS1; both parents were heterozygous for the same mutation. Ethnicity was Nicaraguan and there was no known consanguinity or other relatives who were similarly affected. Although mutations in BBS1 are commonly associated with a 'classical' BBS phenotype, this child was diagnosed at a relatively late age compared to the average age at diagnosis of 9 years (Beales et al., 1999) and she had relatively minor manifestations, having achieved good grades in school until the time of visual deterioration. A milder BBS phenotype in association with p.Met390Arg was also observed in two males with rod-cone dystrophy and polydactyly but without significant obesity or learning difficulties, similar to this child (Cannon et al., 2008). The mild presentation in this girl is consistent with the wide range of phenotypic variability in BBS, and emphasizes the importance of molecular testing.

918/F

Treacher Collins-like mandibulofacial dysostosis with X-linked recessive inheritance. *A. Bytyci Telegrafi, N.L. Sobreira, A. Hamosh, M. Gunay-Aygun.* Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Treacher Collins syndrome (TCS) (MIM #154500) is a form of mandibulofacial dysostosis characterized by symmetrical hypoplasia of the zygomatic bones, downslanting palpebral fissures, lower eyelid colobomas, absent eye lashes, micrognathia, external ear abnormalities and conductive hearing loss. Inheritance pattern is typically autosomal dominant; although autosomal recessive inheritance was also suggested. TCOF1, is the only gene currently known to cause TCS; presence of several TCS patients without TCOF1 mutations suggests locus heterogeneity. TCOF1 encodes Treacle, a nucleolar protein probably involved in nucleolar-cytoplasmic transport. We present a family with a TCS -like phenotype with apparent X-linked recessive inheritance. The proband's prenatal ultrasound at 36 weeks showed micrognathia and polyhydramnios. Amniocentesis showed a normal 46 XY fetal karyotype. Postnatal examination revealed a full term male infant with normal growth parameters. He had symmetrical facial dysmorphism characterized by downslanting palpabral fissures, bilateral zygomatic hypoplasia, midline U-shaped cleft palate and severe micrognathia. There was no coloboma of the eyelids; lower eye lashes were partially absent. External ears were normally formed and placed; ear canals were patent. There was one small ear pit on the right. He had bilateral preauricular hair displacement. There were no limb abnormalities; digits were well formed. Remainder of the exam was unremarkable. Hearing was normal on the right and indeterminate on left ear. Echocardiogram revealed a structurally normal heart. Family history revealed 4 other males with micrognathia, zygomatic hypoplasia, and cleft palate. These included a maternal uncle, and 3 male cousins on the maternal side. All but one of these other affected males died within the first months of life secondary to respiratory distress; a 2-month-old cousin, who is alive, had coloboma of the lower eyelids and bilateral atresia of the external ear canals in addition to the above phenotype. Mother and maternal grandmother had normal facial features. The X-linked recessive TCS-like phenotype in this family may be caused by mutations in a gene on the X chromosome, probably encoding a protein involved in the same functional pathway as Treacle. Alternatively, this might be a sex-limited expression of a gene located elsewhere in the genome. Molecular and clinical studies of the affected and unaffected members of this family are underway.

919/F

A paradoxical genotype-phenotype correlation for *EFNB1* mutations: worse outcome in mosaic than constitutionally-deficient males. *S.R.F. Twigg[1], C. Babbs[1], A. Goriely[1], H.G. Brunner[2], H.V. Toriello[3], I.M.J. Mathijssen[4], A.J.M. Hoogeboom[5], B.R. Pober[6], M.R. Passos-Bueno[7], S.A. Wall[8], A.O.M. Wilkie[1,8,9].* 1) Clinical Genetics, Weatherall Institute of Molecular Medicine, University of Oxford, UK; 2) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3) Michigan State University's College of Human Medicine, MI, USA; 4) Department of Plastic and Reconstructive Surgery, Erasmus Medical Center, Rotterdam, The Netherlands; 5) Department of Clinical Genetics, Erasmus Medical Center, Rotterdam, The Netherlands; 6) Center for Human Genetics, Massachusetts General Hospital, Simches Research Building, Boston, MA, USA; 7) Centro de Estudos do Genoma Humano, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brazil; 8) Department of Plastic and Reconstructive Surgery, Oxford Radcliffe Hospitals NHS Trust, Oxford, UK; 9) Department of Clinical Genetics, Oxford Radcliffe Hospitals NHS Trust, Oxford, UK.

Craniofrontonasal syndrome (CFNS) is an X-linked disorder caused by loss-of-function mutations of *EFNB1*, which exhibits an unusual sex reversal in phenotypic severity: females characteristically have frontonasal dysplasia, craniosynostosis and additional minor malformations, but males are usually mildly affected with hypertelorism only. The proposed mechanism to explain the paradoxically worse CFNS female outcome is termed cellular interference. *EFNB1* is randomly X-inactivated in females, generating two cell populations that express on their cell surfaces either the mutant or wild type protein, ephrin-B1; as ephrin-B1 is normally involved in cell-cell attraction/repulsion, the interaction of these two cell types is thought to lead to the formation of abnormal tissue boundaries, a process that does not occur in hemizygous males. A subset of males, however, has more severe features overlapping those of females. To investigate these unexplained observations, we studied five sporadically affected males diagnosed with the full-blown CFNS phenotype.

Hypothesizing that the more severe male phenotype might also be due to cellular interference, we examined different tissue samples from each male through a combination of Wave DHPLC, sequencing (both dideoxy and massively parallel) and multiplex ligation-dependent probe amplification (MLPA) analysis. We identified mosaic mutations of *EFNB1* in each male, comprising 3 missense changes, 1 gene deletion, and a novel point mutation within the 5' untranslated region. The latter variant (-95T>G), mutates the STOP codon of a small 5' upstream open reading frame (uORF). A nucleotide change at the same position was also found in a classically affected CFNS female (-95T>C). We demonstrate, by luciferase assay, that mutation of -95T is likely to interfere with translation of the wild type protein, probably because the mutant uORF now overlaps the downstream *EFNB1* ORF.

This study, in demonstrating that mosaic *EFNB1* mutations in males are paradoxically associated with a more severe phenotype than fully hemizygous mutations, has provided support for the proposed pathogenic mechanism of CFNS. Furthermore, this work has led to the discovery of a mutation hotspot within the 5' untranslated region of *EFNB1*, likely to interfere with translation of the wild type protein.

Novel compound mutations in the CLNC7 gene causing Osteopetrosis. *E. GUZMAN, H.H. SHUHAIBER, A. BURKE, K. ANYANE-YEBOA.* COLUMBIA UNIVERSITY MEDICAL CENTRE, NEW YORK, N.Y.

Osteopetrosis ("marble bone disease") is a descriptive term that refers to a group of rare, heritable disorders of the skeleton characterized by increased bone density on radiographs. The overall incidence of these conditions is difficult to estimate but autosomal recessive osteopetrosis (ARO) has an incidence of 1 in 250,000 births, and autosomal dominant osteopetrosis (ADO) has an incidence of 1 in 20,000 births. Osteopetrotic conditions vary greatly in their presentation and severity, ranging from neonatal onset with life-threatening complications such as bone marrow failure (e.g. classic or "malignant" ARO), to the incidental finding of osteopetrosis on radiographs (e.g. osteopoikilosis). We describe one neonate with DNA molecular testing showed two compound mutations in the CLNC7 gene(c.1504T>C; Cys502Arg) and (c.2011C>T; Gln617Term). Testing reveals two dIscrete changes in the CLCN7 gene. Neonate suffered from mutiple bone fractures, pale fundus eye exam. Further testing of parents showed both parents are carriers of the mutation. The child eventually expired. The severe infantile forms of osteopetrosis are associated with diminished life expectancy, with most untreated children dying in the first decade as a complication of bone marrow suppression. Life expectancy in the adult onset forms is normal. It is anticipated that further understanding of the molecular pathogenesis of these conditions will reveal new targets for pharmacotherapy.

NIIKAWA-KUROKI SYNDROME, A NEW CASE MEXICAN. *L. Hernandez-Gomez[1], S. Juárez-García[2], E. Hernández Gómez[3], D. Gómez Torres[4].* 1) Dept Audiologia, Instituto Nacional de Rehabilitacion, México; 2) Dept Neuropsicología, Instituto Nacional de Rehabilitacion, México; 3) Biología, Facultad de Estudios Superiores Iztacala; 4) Instituto Nacional de Rehabilitacion, México.

Kabuki syndrome is a congenital mental retardation syndrome with additional features, including postnatal dwarfism, a peculiar facies, skeletal anomalies in 92%, dermatoglyphic abnormalities in 93%, mild to moderate mental retardation in 92%; postnatal growth deficiency in 83% and congenital heart defects. Ophthalmologic and otologic problems were common, particularly recurrent otitis media. The incidence of the disorder in Japanese newborns was estimated at 1 in 32,000. All cases were sporadic. The sex ratio was even, and there was no correlation with birth order. Consanguinity was not increased among the parents, and no exogenous agent could be incriminated. Three of the 62 patients had a Y chromosome abnormality involving Yp11.2. In general, the findings of Niikawa et al. (1988) were considered compatible with an autosomal dominant disorder in which each patient represents a fresh mutation We present a new case: female mexican child 10 years old of non consanguineous parents, pregnancy without adversities prenatal and postnatal ,with recurrent otitis media Physical exploration: female with auditory conduct normal, voice and language without alterations. facies characterized by long palpebral fissures with eversion of the lateral third of the lower eyelids arched eyebrows with sparse or dispersed lateral one-third, prominent ears, depressed nasal tip, severe maxillary recession, malocclusion, microdontia, high-arched palate, small dental arch, midfacial hypoplasia. Spine with scoliosis. Audiometric test showed normal audition right, left without answer. Speech audiometric test showed normal right, left without answer. Timpanogram curves As of Jerger bilateral. Stapedial reflex present in right, absent left. Psychology test mild mental retardation Computed Tomografhy of the petrous bones. No middle ear abnormalities were identified, left dysplasia of the inner ear (hypodysplasia of the cochlea, vestibule, and semicircular canals).

Genetic variants associated with acute toxic hepatitis. *A. Krumina[1], L. Piekuse[1], M. Kreile[1], J. Keiss[1, 2], V. Sondore[2], A. Chernushenko[2].* 1) Dept Biol & Microbiol, Riga Stradins Univ, Riga, Latvia; 2) Infectology Center of Latvia, Riga, Latvia.

Acute toxic hepatitis (ATH) is an inflammation of the liver caused by various toxic chemicals. The role of genetic factors in different outcome of the disease has not yet been clearly defined. The aim of the research was to investigate whether particular mutations in the genes *GSTT1, GSTM1, GSTP1, GSTA1, MTHFR, and UGT1A1* coding for six liver detoxification enzymes are associated with clinical outcome in patients with ATH. Objects of the study were 58 patients with ATH (18 lethal cases, 40 - non-lethal cases) caused by drinking of illegally produced alcohol, and 224 healthy individuals. Genomic DNA was isolated from peripheral blood samples. Mutations were analysed using multiplex polymerase chain reaction (PCR), PCR - RFLP, and direct DNA sequencing. Differences between patients (lethal and non-lethal cases) and control subjects were analysed with SPSS statistical package. Frequencies of mutation C677T in the gene *MTHFR, GSTT1* null genotype, and *GSTT1/GSTM1* double null genotype were significantly higher in ATH patient group compared to control subjects. These frequencies were also higher in ATH lethal cases compared to non-lethal cases. Conclusion: there are genetic variants of liver detoxification enzymes predisposing to more severe clinical manifestation of acute toxic hepatitis.

923/F

Amyoplasia revisited. *J.G. Hall.* Dept Pediatrics and Medical Genetics, University of British Columbia, Vancouver, BC, Canada.

In the early 1980s, we identified Amyoplasia as a specific entity from within the heterogeneous group of disorders described at that time as Arthrogryposis Multiplex Congenita (multiple congenital contractures). It represented one third of cases within a large study (e.g., 135 of 350 patients) of individuals with multiple congenital contractures who survived the newborn period. In the subsequent 30 years, we have accumulated almost 600 cases of confirmed Amyoplasia which greatly expands the variability of phenotype and natural history. About 60% of cases have “classical” four limb involvement with symmetric characteristic positioning of limbs at birth. The affected individuals are sporadic and of normal to high normal intelligence. Prognosis is dependent on the amount of functional muscle and early physical therapy to loosen contractures. Additional subtypes of Amyoplasia which have been identified include: 1) only upper limb involvement, 2) only lower limb involvement, 3) three limb involvement in a predictable pattern, 4) severe involvement with flexed elbows and markedly decreased muscle mass, 5) severe hyperextension of the spine such that the feet touch the head at birth, 6) trismus of the jaw with variable types of contractures at birth. 15% of affected individuals have additional major anomalies related to vascular compromise. 6% of cases of Amyoplasia represent only one of a MZ twin pair (20 times increased above expected). Affected limbs lack normal growth ending up 10%-20% shorter than normal. We continue to postulate vascular compromise between 6 and 11 weeks of embryonic development plays a role in producing the Amyoplasia phenotype. It is important to distinguish Amyoplasia from genetic forms of arthrogryposis.

924/F

The middle interhemispheric variant of holoprosencephaly in a series of 23 patients. *K.E. D'Aco[1], B.D. Solomon[2], N.J. Clegg[3], M.R. Delgado[3], J.S. Hahn[4], L.K. Conlin[5], E.H. Zackai[1], M. Muenke[2].* 1) Division of Human Genetics, Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Medical Genetics Branch, National Human Genome Research Institute, National Insitututes of Health, Bethesda, MD; 3) Department of Neurology, Texas Scottish Rite Hospital for Children, Dallas, TX; 4) Departments of Neurology and Diagnostic Radiology, Stanford University School of Medicine, Palo Alto, CA; 5) Depatment of Pathology and Laboratory Medicine, Children's Hospital of Philadelphia, Philadelphia, PA.

Syntelencephaly, or middle interhemispheric variant (MIHV), is a rare subtype of holoprosencephaly (HPE) manifesting with incomplete formation of the interhemispheric cerebral fissure, affecting separation of the posterior frontal and/or parietal lobes. MIHV clinically overlaps classic HPE subtypes (alobar, semilobar, lobar) with comparable incidence of seizures and dystonia, but has milder neurocognitive deficits and lower prevalence of endocrinopathies. The etiology of classic HPE is extremely heterogeneous, including multiple genetic and teratogenic causes. Here we report 23 new cases of MIHV with their associated genetic workup, focusing on one patient whose HPE etiology supports the involvement of a key HPE candidate gene. From a separate, unselected cohort of approximately 1,000 probands with HPE we identified the MIHV subtype in 22 probands (0.2%). All 22 probands were tested for mutations in SHH, ZIC2, TGIF and SIX3. One patient had a maternally inherited mutation in SIX3, one had a de novo whole-gene deletion of ZIC2, and three had intragenic mutations in ZIC2 (one de novo, one paternally inherited, and one unknown). There is strong functional evidence for the pathogenicity of all implicated variants. No other patients had identified causes for their phenotypes. Compared to the larger classic HPE cohort diagnosis was slightly later; only one patient was a deceased infant. All patients had developmental delay, though with less cognitive impairment than in classic HPE, and facial malformations were typically less severe in the MIHV group. There was a non-statistically significant over-representation of females, making up 64% of the MIHV cohort (p=0.201). Other findings traditionally associated with HPE, such as cleft lip/palate and hydrocephalus, were common manifestations. Case 23 was diagnosed with MIHV as a neonate secondary to IUGR, microcephaly and hypertonia. He did not have hypotelorism or midline facial defects. No mutations were found in SHH, ZIC2, TGIF or SIX3. His karyotype revealed ring chromosome 21 in 85% of cells with a 10.21Mb deletion within 21q22.13q22.3 that includes the well-established critical region 21q22.3 associated with HPE1. Case 23 demonstrates a third identified genetic etiology for MIHV-type HPE and highlights the importance of continued work to identify the gene corresponding to HPE1. Our cohort as a whole demonstrates that the MIHV subtype represents a small but important fraction of HPE patients.

925/F

Follow up: hydranencephaly with renal agenesis in a girl with normal intelligence. *T. Wegman-Ostrosky, D. Garcia-Cruz, J. Sanchez-Corona, JE. Garcia-Ortiz.* CIBO, IMSS, Guadalajara, Jalisco, México.

Hydranencephaly is a rare CNS abnormality occurring in less than 1 per 10,000 births worldwide. It is defined as a complete or incomplete brain destruction with a bilateral internal carotid artery distribution, resulting in a fluid replacement of the cerebral hemispheres covered with leptomeninges and dura The brain damage generally occurs in the second trimester of gestation, after formation of brain and ventricles. The pathogenesis of hydranencephaly is vascular, but also has been associated to intrauterine infections, particularly toxoplasmosis and viral infections, or in utero drugs exposure. Hydranencephaly has a poor prognosis; most affected patients die after birth and rarely, may survive the teen age. Renal agenesis has been frequently associated to hydranencephaly even the etiology is unknown. Here, we present a 11 years old female patient with hydranencephaly, renal agenesis and normal neurological development. She was the first product of healthy non consanguineous parents. Her family background was unremarkable. She was delivered via Caesarean section, her birth weight was 3550 grams, her Apgar score was 9/9 .No MCA were observed at neonatal period. Her development milestones were normal. At age of 4 years she was hospitalized for urinary tract infection, incidentally left renal agenesis was observed with USG. Due to observed macrocephaly a cranial CT scan was ordered and hydranencephaly was diagnosed. She did or did not presented seizures, frequent migraine episodes have been presented since this diagnosis. Currently she is years-old and her school achievement is completely normal. To our knowledge, there are 5 published cases in the literature with the association of hydranencephaly with renal agenesis, all of them showing from severe to moderate developmental delay. Our patient would be the only one showing a normal intelligence to date.

Advanced maternal age increases the proportion of UPD in Prader-Willi syndrome. *T. Nagai[1], K. Matsubara[1,2], T. Ogata[2], K. Obata[1], S. Sakazume[1], Y. Kido[1], N. Murakami[1].* 1) Dept Ped, Koshigaya Hosp, Dokkyo Univ Sch Medicine, Koshigaya Saitama, Japan; 2) National Research Institute for Child Health and Development, Department of Molecular Endocrinology, Tokyo, Japan.

INTRODUCTION: Generally genetic causes of Prader-Willi syndrome (PWS) are known that microdeletion of the paternally inherited 15q11-13 and upd(15)mat occur around 70% and 25% of patients, respectively. However, Whittington et al. (2007) have reported an increase in the frequency of upd(15)mat among the children aged under 5 years in the UK. This phenomenon may be due to advanced maternal age that is widely observed in developed countries, because upd(15)mat usually result from trisomy rescue, and advanced maternal age is a risk factor for the development of trisomies such as Down syndrome. To examine this possibility, we studied Japanese patients with PWS. METHODS: We performed methylation test, FISH, MLPA, and microsatellite analysis for 153 patients with PWS with normal karyotype (F:M 96:57, ages; 0-53 years), and classified them into four types: (1) deletion type, (2) trisomy rescue type disomy, (3) monosomy rescue type disomy, and (4) other imprinting defects. Then, we compared the data from 103 patients born at or before 2002- (GrI) and 50 patients born in the period 2003-2009 (GrII). RESULTS: In GrI, 85 (83%) had microdeletions, 14 (13%) had trisomy rescue type disomy, and 3 (3%) had monosomy rescue type disomy. In GrII, 30 (60%) had microdeletion, 14 (28%) had trisomy rescue type disomy, and 3 (6%) had monosomy rescue type disomy. The frequencies of microdeletion and trisomy rescue type disomy were significantly different between the two groups (P=0.001). There was significant difference in the maternal age at birth between the two groups (median 30, range 19-48 vs. median 35, range 23-45, P=0.0004). Between microdeletions and trisomy rescue type disomy, maternal age at birth was similar (P= 0.063) in GrI but was significantly different in GrII (P=2.5E-06). DISCUSSION: These results suggest that advanced maternal age is a risk factor for the development of trisomy rescue type upd(15)mat in GrII. Although the difference in the maternal age at birth was significantly different between the two different time periods, further investigations will be required to assess the maternal age effect on the development of trisomy rescue type upd(15)mat.

Recurrent erythema nodosum in a patient carrying a mutation in the Mediterranean fever gene (MEFV). *M. Michelson-Kerman[1,2], C. Vinkler[1,2], M. Yanoov-Sharav[1,2], I. Nezer[1], D. Lev[1,2].* 1) Inst Med Genetics, Wolfson Medical Ctr, Holon, Israel; 2) Maccabi Health Sevice, Wolfson Medical Center, Holon. Israel.

Erythema nodosum (EN)is a painful disorder of the subcutaneous fat, the common type of panniculitis. The disorder is characterized by tender, nodular lesions on the anterior aspects of the lower extremities. The process is considered to be an immunologic response and may serve as a marker for systemic diseases such as inflammatory bowel disease, tuberculosis, sarcoidosis, bacterial or deep fungal infection and cancer. Certain antibiotics, oral contraceptives and pregnancy may also be associated. The condition is usually self-limiting and specific treatment is seldom needed in uncomplicated cases. We present an unusual recurrent course of erythema nodosum in a 35 year old woman who is a carrierof a mutation in the MEFV gene. A 35 year old, generally healthy, non-pregnant, woman from Sephardic Jewish ancestry, had suddenly developed painful palpable nodules on the anterior aspects of the lower extremities. Diagnostic evaluation included normal blood count, erythrocyte sedimentation rate and normal liver functions. C-reactive protein, antistreptolysin O-titer, blood cultures and tuberculosis test were negative. Chest radiography was normal. The symptoms exacerbated despite treatment with nonsteroidal anti-inflammatory drugs. Clinical improvement appeared after two courses of corticosteroid therapy, which is unusual for common erythema nodosum course. Mutational analysis of the MEFV gene revealed a heterozygous E148Q mutation. Familial Mediterranean fever (FMF) is an autosomal recessive disease characterized by recurrent attacks of fever with serosal inflammation. The FMF gene (MEFV) encodes the protein pyrin that plays an important role in modulating the innate immune response. MEFV mutations have been identified primarily in patients from Mediterranean populations and in Israel the carrier state is as high as 1 in 5. Although the clinical spectrum and genetic alteration in FMF is variable, erythema nodosum has never been described as a presenting sign of FMF especially in patients with a heterozygous mutation. Various heterozygous mutations in the MEFV gene have been described in association with certain diseases such as Henoch-Schonlein purpura, rheumatoid arthritis and other auto inflammatory disorders and are are considered to be modifying factors. We suggest that MEFV, and particularly the E148Q mutation, is an important susceptibility factor and an independent modifier for the clinical manifestations of erythema nodosum in our case.

928/F

CAUDAL DUPLICATION. A CASE REPORT. *I.P. Davalos[1,2], T. Wegman-Ostrosky[1,2], R. Alferez-Morfin[3], M.G. González-Mercado[1,2], M.L. Ramírez-Dueñas[1], J.A. Cruz-Ramos[1,2], N.A. Vázquez-Cárdenas[1,2], A.J.L. Brambila-Tapia[1,2], B.E. González-Ulloa[3].* 1) División de Genética, CIBO, Instituto Mexicano del Seguro Social (IMSS). Guadalajara, México; 2) Doctorado en Genética, IGH, CUCS, Universidad de Guadalajara. Guadalajara, México; 3) Servicio de Radiología e Imagen , UMAE, Hospital de Especialidades, CMNO, IMSS. Guadalajara, México.

INTRODUCTION We present a case of caudal duplication syndrome, this disorder is associated with partial or complete duplication of different organs in the caudal region spe=ACcially gastrointestinal and urogenital tracts. CASE REPORT We describe a 21 year old female patient. She was born at full-term by normal delivery, weight of 2500. There was no history of neonatal distress. Physical examination at birth revealed imperforate anus sigmoid corrected surgically by colostomy at 10 days and was detected the presence of 3 labia mayora. At birth was diagnosed Caudal Duplication (bladder, uterus and vagina). She has normal psychomotor development. She had no family history of other similar case or congenital anomaly. She suffers from chronic constipation and recurrent infection urinary track. Recently, she presented a severe massive fecal impaction (fecaloma). The RNM revealed double bladder cavity, with well defined borders, normal bladder filling, two uterus, each one with an ovary, with cystic imagens and a calcified fecaloma. DISCUSION/CONCLUSIONS .The pathogenesis of the caudal duplication anomaly is still unclear. It has been proposed that this malformation resulted from an insult to the caudal cell mass and hindgut at approximately the 23rd through the 25th day of gestation. Hypermethylation of the AXN1 gene has been implicated in caudal duplication anomalies. We present a mexican female case of caudal duplication and calcified fecaloma.

929/F

Amelogenesis imperfecta, severe mental retardation, epilepsy (Kohlschutter-Tonz syndrome): questioning the autosomal recessive inheritance, about a new family. *S. Mercier[1], M. Blayau[2], L. Pasquier[1], C. Dubourg[2], C. Henry[3], C. Allaire[4], D. Bonneau[5], M. Tardieu[6], J.L. Sixou[7], S. Odent[1].* 1) Genetique clinique, CHU Rennes, RENNES, France; 2) Laboratoire de Genetique Moleculaire, CHU Hopital Pontchaillou, Rennes, France; 3) laboratoire de Cytogenetique, CHU Hopital Pontchaillou, Rennes, France; 4) Service de Pediatrie, CHU Hopital Sud, Rennes, France; 5) Service de Genetique, CHU Angers, Angers, France; 6) Service de neurologie pediatrique, CHU Bicetre, Le Kremlin-Bicetre, France; 7) Faculte Odontologie, Rennes 1, CHU Rennes, Rennes, France.

Amelogenesis imperfecta ("yellow teeth") is a rare condition. Its association with severe and progressive developmental delay and epilepsy was described for the first time in 1974 as Kohlschutter-Tonz syndrome (OMIM 226750). The 26 published cases from nine different families strongly suggested an autosomal recessive mode of transmission because of the context of consanguinity and / or several cases of recurrence in siblings with normal parents. We report the case of a family with two sons and a daughter born to two different unions of the mother. Both fathers had no known relationship and a panel of nine microsatellites confirmed that the first affected boy and the girl had different fathers. The brothers, from the first marriage, died respectively at 15 years and 14 years. They both presented a severe progressive encephalopathy, seizures, dental anomalies with oligodontia, enamel dysplasia, dental malpositions, and progressive microcephaly. A nonspecific cerebral atrophy was described on MRI. The karyotype, the FISH analysis of telomeres, and metabolic evaluation were normal. During the second marriage, genetic counseling was first reassuring, with a strong probability of autosomal recessive or X-linked disease, especially as the fetus was a female during a new pregnancy. Unfortunately, this patient also had a developmental delay in the first months, seizures at six months, and dental anomalies similar to those of her half-brothers. The first eruption of teeth was delayed, occurring at the age of 5 years. The head circumference curve bent at 3 months. At 8 years, she did not sit, had no language, and was dysmorphic (round face, large mouth, short philtrum). The mitochondrial respiratory chain activity and mitochondrial DNA were normal in lymphocytes and fibroblasts. CGH array study (Agilent chip 4x44K) was normal. There was no skewed X-inactivation in the mother. In conclusion, the etiology of Kohlschutter-Tonz syndrome remains unknown, and this pedigree is consistent with an autosomal dominant pattern of inheritance with a recurrence due to germline mosaicism in the mother. This report emphasizes the importance of detailed dental examination in the assessment of children with severe epilepsy and developmental delay.

930/F

Overgrowth with increased proliferation of fibroblast and matrix metalloproteinase activity related to reduced TIMP1: A new syndrome? *V. Shah[1], B.H.Y. Chung[2,3], A. Hinek[4], D. Chitayat[2,3].* 1) Pediatrics, Mount Sinai Hospital, Toronto, ontario, Canada; 2) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 3) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 4) The Heart Centre - Cardiovascular Research, Hospital for Sick Children, Toronto, Ontario, Canada.

We report on a child with prenatal onset overgrowth associated with facial dysmorphism, thick, excessive wrinkled skin, cleft palate, Chiari malformation and polymicrogyria. His clinical features do not resemble any reported overgrowth syndromes. Genetic investigations tests including testing the possibility of epigenetic alterations of 11p15 region and mutations of the CDKN1C gene (Beckwith-Wiedemann syndrome), mutations and dosage changes of GPC3 gene (Simpson-Golabi-Behmel syndrome), mutations of HRAS gene (Costello syndrome) and chromosomal rearrangement by karyotype and oligo-array. Using immunohistochemistry, we found that cultured skin fibroblasts obtained from this patient demonstrated normally assembled elastic fibers and normal pattern of chondroitin sulfate-deposition with defective deposition of Collagen I fibers. In addition, the fibroblasts revealed high levels of immuno-detectable metalloproteinase (MMP) and undetectable tissue-inhibitors of metalloproteinase (TIMPs). The defective collagen deposition in the fibroblast culture can be reversed by broad spectrum MMP inhibitor - doxycycline. The fibroblasts of this patient also had an increased rate of cellular proliferation. We propose that this is a previously unreported syndrome with overgrowth associated with increased cellular proliferation and defective collagen I deposition due to an imbalance between MMP and TIMP in fibroblasts.

931/F

A Genome-Wide TDT analysis in children with idiopathic intellectual disability. *M. Yazdanpanah[1,2], S. Adam[1,2], F.R. Zahir[2,3], T. Tucker[2,3], M.A. Marra[3,4], J.M. Friedman[1,2,3].* 1) Department of Medical Genetics, University of British Columbia, British Columbia Clinical Genomics Network, Vancouver, Canada; 2) Child & Family Research Institute, Vancouver, Canada; 3) Department of Medical Genetics, University of British Columbia, Vancouver, Canada; 4) Genome Sciences Centre, British Columbia Cancer Agency, Vancouver, Canada.

BACKGROUND Intellectual disability (ID) is etiologically heterogeneous. Genomic imbalance, mendelian conditions and teratogenic exposures are responsible in some cases, but the cause remains unknown in most instances. Multifactorial inheritance has been suggested as an important cause of ID, but the genetic factors involved are unknown. OBJECTIVE: To identify susceptibility genes for idiopathic ID in affected trios in a genome-wide association study. METHODS We used a multistage design to perform a genome-wide transmission disequilibrium test (TDT) analysis in children with idiopathic ID and both of their unaffected parents. The children had moderate-to-severe mental retardation or developmental delay of unknown cause after complete clinical evaluation. In our first stage (discovery phase), we performed genome-wide SNP genotyping with 500 K Affymetrix Gene Chip® arrays on 154 ID trios. We included the SNPs that passed the quality control filter including 90% genotype call rate, MAF ≥1%, and HWE p<10-4 for both the affected children and their parents. Association analysis was performed using PLINK software. RESULTS In our preliminary analysis, the overall genotyping rate was 0.95%. We identified a set of top-ranking SNPs based on a significance threshold criteria of p<10-4. We observed an excess of independent regions associated at p<10-4, suggesting that common susceptibility variants for idiopathic ID exist,but our initial study did not have sufficient statistical power to identify them definitively. Next we will replicate the top-ranking SNPs found in the discovery phase in an independent cohort of 55 ID trios.

932/F

LEUKOCYTE HYPERADHESIVENESS: A NOVEL SYNDROME CHARACTERIZED BY DELAYED SEPARATION OF THE CORD AND RECURRENT SKIN INFECTIONS. *O. Abdul-Rahman[1], L. Svensson[2], A. McDowell[2], K. Yarbrough[1], N. Hogg[2].* 1) Division of Medical Genetics Department of Pediatrics, Univ Mississippi, Jackson, MS; 2) Leukocyte Adhesion Laboratory, Cancer Research UK London Research Institute, London, UK.

Leukocyte adhesion deficiency-1 (LAD-1) is an autosomal recessive disorder characterized by recurrent bacterial infections, defective neutrophil mobility, and delayed separation of the cord caused by mutations in the beta-2 (CD18) subunit common to three integrins. We report a patient with features of LAD-1 in whom a newly identified defect in leukocyte adhesion was detected representing a potentially novel condition. The patient's umbilical cord did not separate until 6 weeks of age, followed by omphalitis. Over the first two years of life, the patient developed multiple episodes of skin infections. Leukocyte adhesion deficiency was initially suspected. However, sequencing of the β2 (CD18) subunit was normal. Adhesion assays on ICAM-1 and fibronectin substrates revealed that the patient's T cells were highly activated with a background adhesion level that was as high as stimulated control cells. Migration assays evaluated the patient's T cells migrating on ICAM-1 using time-lapse microscopy. The cells were extremely adherent and polarized when compared with control T cells, migrating at a rate of 4.05 μm/min compared to 16.07 μm/min for the controls. Our patient demonstrated normal integrin expression, but significantly high adhesion to integrin substrates resulting in abnormally slow migration rates. Since sequencing of the beta-2 subunit was normal (LAD-1), it suggests there may be a problem in the cytoskeletal machinery that regulates integrin turnover. However, this pathway has not been well-characterized. Further studies of other cell lines such as platelets and neutrophils are currently underway to establish the extent of abnormal cellular adhesion.

Molecular analysis suggests loss of IgA-plasma barrier in intestinal transplant rejection. *C. Ashokkumar[1], M. Ningappa[1], S. Ranganathan[1], L. Schmitt[1], B.W. Higgs[1], Q. Sun[1], C. Kim[2], H. Hakonarson[2], R. Sindhi[1]*. 1) Surgery, Children's Hospital of Pittsburgh , Pittsburgh, PA; 2) Center for Applied Genomics, Children's Hospital of Philadelphia, PA.

Background: Acute cellular rejection (ACR) limits graft survival after intestinal transplantation (ITx). Purpose/Methods: To identify potential mechanisms, differentially expressed genes in allograft tissue with ACR (n=9, rejectors) were characterized with Affymetrix 1.0 ST gene arrays using case-controlled comparison with rejection-free biopsies (n=8 non-rejectors). Replication testing included qRT-PCR and immunohistochemistry (IHC) of biopsy tissue from 8 rejectors and 4 non-rejectors for protein products of candidate genes. Results: Among differentially expressed genes, down regulated CCR10 (negative fold-change 1.275, p=4.95E-04) confirmed by qRT-PCR replication (p=0.012) in rejecting intestine allografts was of interest because in the intestine CCR10 is only co-expressed with IgA, which is present on >70% of normal intestinal plasma cells. Serial biopsy tissue further showed downregulation of the CCR10 gene in rejectors within 4 hours of graft reperfusion (p=NS). CCR10 expression normalized to levels seen in non-rejectors by months 4-12. These changes mirrored serial changes in counts/hpf for mature CD138+plasma cells in IHC studies. Average CD138+plasma cell counts/high power field were lower in biopsies showing ACR compared with rejection free biopsies early after ITx (2.8 vs 27 median cells/hpf, p=0.042). By months 4-12, CD138+plasma cell counts were similar in both outcome groups. Donor-specific alloreactivity measured by allo-antigen-specific CD154+T-cytotoxic memory cells is enhanced during ACR, and was negatively correlated with CD138+plasma cells (Spearman's r= -0.689, p=0.040) corroborating downregulation of the CCR10 gene during ACR. Colocalization studies with confocal microscopy of sequential biopsies from 2 rejectors and 2 non-rejectors showed fewer IgA+cells and more numerous IgG+cells within 4 hours of allograft reperfusion and during ACR among rejectors, compared with non-rejectors. Conclusions: During intestine allograft rejection, downregulation of the CCR10 gene indicates a replacement of the mature CD138+plasma cell population of intestinal allografts with inflammatory IgG+plasma cells. These changes may contribute to antibody-mediated intestine allograft injury.

Investigating the Role of Fragile X Related Proteins in Mammalian Circadian Behaviors. *J. Lumaban, D. Nelson.* Molec & Human Gen, Baylor College Med, Houston, TX.

Fragile X syndrome, the most common form of inherited mental retardation, results from the absence of the *fragile X mental retardation 1 (FMR1)* gene product FMRP. *FMR1* has two paralogs in vertebrates: *fragile X related gene 1* and *2* (*FXR1* and *FXR2*). One of the behavioral symptoms observed in fragile X patients is the increased occurrence of sleep disorders. Mice that are lacking in both *Fmr1* and *Fxr2* (double knockout) exhibit complete loss of rhythmic activity in both the light:dark cycle and total darkness, and display significant alterations in the cyclical patterns of abundance of core clock component messenger RNAs in the liver, but not the suprachiasmatic nucleus. These findings suggest that Fmrp and Fxr2p are acting downstream of the central clock to control rhythm in mice, but it is unclear how the FXRs affect the peripheral outputs such as in the liver. Locomotor assays with restricted feeding demonstrate that the *Fmr1/Fxr2* double KO mice were able to adjust their rhythm to food availability, and developed food anticipatory activity (FAA), which is an increase in wheel-running activity 3-4 hours prior to a scheduled food presentation. The entrainment response, however, is not as strong as that of the other mice tested: WT, *Fmr1* KO, *Fxr2* KO and even the *Fmr1* KO/*Fxr2* heterozygous (KOH) mice. Current efforts are underway to test whether this entrainment is also observable in the cycling of mRNA expression of clock genes in the liver. Since the *Fmr1/Fxr2* double KO mice are able to entrain to food as a circadian input, and thus have a functional clock, we are also testing whether the arrhythmic behavior previously observed is due to circadian defect or sleep disorders, using both home cage behavior analysis and electroencephalography. The *Fmr1/Fxr2* double KO mice also had a significantly higher mortality rate in the first three days of restricted feeding, and could indicate a difference in their physiological response to food restriction. The liver clock is known to contribute to glucose homeostasis, and efforts are underway to test for the specific involvement of FXRs in this system. The close association of food input to the circadian system and the timing of sleep and wakefulness, together with the typical disturbances of circadian behavior and sleep in Fragile X syndrome, opens up a new perspective for the investigation and treatment of patients suffering from this disorder.

Association mapping for age related hearing impairment using a mouse model. *J. Ohmen[1], X. Li[1], C. White[1], A. Lusis[2], R. Friedman[1].* 1) Molecular Biology and Genetics, House Ear Institute, Los Angeles, CA; 2) Department of Medicine Dept of Microbiology and Immunology and Molecular Genetics UCLA, Los Angeles, CA 90095.

Age-Related Hearing Loss or AHL (sometimes referred to as presbycusis), is the most prevalent sensory impairment in the elderly. ARHI is a complex disease caused by an interaction between environmental and genetic factors. While the environmental factors conferring altered risk for ARHI have been extensively studied, investigations into the genetic risk factors have only recently been initiated. We have recently initiated a genetic study of AHRI in the mouse. The study design uses a recently developed association mapping technique that has been termed the Hybrid Mouse Diversity Panel, or HMDP. The HMDP consists of over 100 inbred and recombinant inbred strains of mice for which genome-wide SNP data is available. Phenotypic measurements are made in all 100 strains and when combined with the genotype data, uses association mapping to map genes at single gene resolution. The program used to measure the association is called EMMA, and includes features that compensates for population stratification within the different strains of mice used. We have initiated our study of ARL in this collection of mice and present data that confirms it's utility by the confirmation of previously identified AHL loci. Novel loci identified and the positional candidate genes are discussed.

A Mouse Model for Testing the Influence of Maternal Obesity on the Offspring Health. *H. Miller[1], D. Buchner[2], J. Nadeau[2], D. Serre[1].* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH; 2) Department of Genetics, Case Western Reserve University, Cleveland, OH.

Several studies have shown the maternal obesity during pregnancy increases the risk for the offspring to develop metabolic diseases in adulthood. However, the molecular basis underlying these life-long consequences remain poorly understood. Here we present a mouse model for testing the influence of maternal obesity during pregnancy on the health of the offspring in adulthood. We fed C57BL/6J female mice on either a low-fat (LF) diet or a high-fat (HF) diet for 5 weeks prior to mating and maintained them on these diets throughout pregnancy and lactation. Offspring from LF and HF mice were separated after weaning and assigned on either the HF or LF diet for 6 weeks. We showed that maternal diet during pregnancy significantly affects birth weight and several metabolic traits in male and female adult offspring. In addition, for some of these traits the influence of maternal diet was exacerbated by feeding the mice a high fat diet postnatal. We are now extending this model to include analysis of older animals (26 weeks of age) as well as embryos and pups in order to better understand the etiology and consequences of maternal obesity during pregnancy.

Association of peroxisome proliferator-activated receptor (PPAR)-gamma2 gene Pro12Ala missense mutation in Kuwaiti patients with primary knee osteoarthritis. *M. Haider[1], K. Al-Jarallah[2], D. Shehab[2].* 1) Dept Pediatrics, Fac Med, Kuwait Univ, Safat, Kuwait; 2) Dept of Medicine, Fac Med, Kuwait Univ, Safat, Kuwait.

Peroxisome proliferator-activated receptors (PPARs) play an important role in a number of cellular and metabolic functions. This study was undertaken to determine the prevalence of a missense mutation (Pro12Ala) in the PPAR-gamma2 gene in Kuwaiti Arab patients with primary knee osteoarthritis (OA) and healthy controls with the aim of identifying a possible association. The prevalence of PPAR-gamma2 gene Pro12Ala missense mutation was determined in 104 Kuwaiti Arab patients with primary Knee OA and 111 ethnically matched healthy controls by PCR-RFLP of the genomic DNA. The prevalence of this Pro12Ala missense mutation was also determined in clinical subgroups of OA patients divided on the basis of age of onset, function and radiologic grading. Significant difference was detected in the prevalence of PPAR-gamma2 gene Pro12Ala genotypes in the subgroups of patients classified on the basis of age of onset and on functional assessment using Lequesne's functional index and radiological grading using Kellgren-Lawrence (K-L) grading. Our data from Kuwaiti Arabs show that the possession of Pro-Pro genotype of the PPAR-gamma2 gene mutation constitute a risk factor for development of primary knee osteoarthritis.

938/W

Familial Idiopathic Scoliosis in Males: Localization to Chromosome. *C.M. Justice[1], K. Swindle[2], S. Cook[2], J. Dunn[2], N.H. Miller[2].* 1) Genometrics Section, IDRB, NHGRI, NIH, Baltimore, MD; 2) University of Colorado, The Children's Hospital, Denver, Colorado.

Idiopathic scoliosis is present in 2 to 3% of children or adolescents and is defined by a lateral curvature of the spine ≥ 10° for which the cause is unknown. For curvatures of 10 degrees, the proportion of affected females to affected males is approximately 1:1, but the proportion of affected females to affected males increases dramatically as the magnitude of the scoliotic curve increases [Roach 1999]. In our initial population of 202 families, there were approximately 7 affected females for every affected male at curvatures ≥ 30°. Lateral curvatures of 30 degrees are less prevalent in the pediatric population, with a prevalence of approximately 0.2 percent [Miller 1999]. The goal of this study was the identification of genetic determinants in families that include males with severe lateral curvatures. The males with severe curve subset was comprised of 25 families (207 individuals) in which at least one male was diagnosed in adolescence with a ≥30° lateral curvature. There were 123 scoliotic individuals (48 male; 75 female), and 85 unaffected individuals (45 male; 40 female) in this subset. A genomic screen was performed with a modified CHLC v.9 marker set. Fine mapping was done with a custom SNP panel and ABI Taqman methodology on an ABI 377 platform. The initial genome-wide screen and subsequent analyses were analyzed by model-independent linkage analysis using SIBPAL (S.A.G.E. v5.1). The genome-wide linkage analysis for the qualitative and quantitative traits resulted in significant p-values (2 adjacent markers with p-values < 0.01) on chromosomes 2, 16 and 22. The most significant p-value was obtained for the qualitative analysis (threshold set at ≥ 10°) for d22s689 (p-value= 4.2 x10-8), for which an adjacent marker, d22s685 (p-value = 3.8 x x10-4) was also significant. Fine mapping with SNPs confirmed this region as being linked to FIS in our subset of families with adolescent males with curvatures ≥30°. Significant SNPs lie primarily in the introns of the LARGE gene, integral to the development and maintenance of skeletal muscle, and SFI1, responsible for the integrity of the chromosomal centromere complex. Future goals include association and sequencing analyses of this region. FIS is a complex genetic disorder, and utilizing clinical criteria may aid in decreasing the heterogeneity of our large familial idiopathic study population, and enhance the successful identification of specific genes responsible for this disorder.

Association study on HAPLN1 and MMP genes and osteoarthritis. *A. Nakki[1,2], A. Harilainen[3], K. Tallroth[3], P. Leino-Arjas[4], M. Heliövaara[2], J. Kaprio[1,5], L. Peltonen[1], J. Saarela[1], U. Kujala[6].* 1) Institute for Molecular Medicine Finland FIMM, University of Helsinki, Helsinki, Finland; 2) National Institute for Health and Welfare, Helsinki, Finland; 3) ORTON Orthopedic Hospital, Invalid Foundation, Helsinki, Finland; 4) Finnish Institute of Occupational Health, Helsinki, Finland; 5) Department of Public Health, University of Helsinki, Helsinki, Finland; 6) University of Jyväskylä, Jyväskylä, Finland.

Background. Osteoarthritis (OA) is a degenerative joint disease common in the elderly and the heritability ranges between 40-60 %. The disease progresses by the breakage of the extracellular matrix of the cartilage formed by collagens, aggregans and hyaluronic acid. Matrix metalloproteinases (MMP) are a group of enzymes breaking down the collagen network and aggrecans. Our aim was to study the putative role of four MMP genes and hyaluronan and proteoglycan link protein 1 gene (HAPLN1) in OA, all potentially playing a role in the stability of the cartilage. Methods. We genotyped a total of 37 tagging SNPs covering the MMP3, MMP8, MMP9, MMP13 and HAPLN1 genes in 134 severe radiological familial hand OA cases, 113 unrelated radiological bilateral primary knee OA cases and 2436 population based control samples. The Pseudomarker program was used to monitor for association. For evaluating the strongest association findings, two of the studied SNPs were genotyped in 398 clinician diagnosed knee OA cases and 2708 healthy controls. Results. Eight variants in MMP8, MMP9 and HAPLN1 genes provided nominal evidence for association with OA (p<0.05). The strongest association signals were observed for rs1940475 in MMP8 with combined radiological hand and knee OA (p=0.008) and for rs17577 in MMP9 in radiological hand OA (p=0.004). The SNPs did not associate with the clinician diagnosed knee OA (p=0.10, p=0.72 respectively). Discussion. Initial evidence for association was observed between the MMP8, MMP9 and HAPLN1 genes and severe radiological hand OA and combined hand and knee OA. The SNPs showing the strongest evidence for association with hand OA and combined hand and knee OA did not associate with clinician diagnosed knee OA. The role of the genes might be stronger in hand OA than in knee OA but further conclusions cannot be made without a replication of the results. Analyses between all the studied SNPs in 75 clinician diagnosed knee OA cases are ongoing.

Association of CYP19A1-CYP17A1 gene polymorphisms with serum steroid hormone levels of Turkish osteoporotic postmenopausal women. *M.B. Yilmaz[1], A. Pazarbasi[1], A.I. Guzel[1,3], S. Kocaturk-Sel[1], I.F. Urunsak[2], S. Basaran[4], M. Kasap[1], H. Kasap[1], O. Demirhan[1], D. Alptekin[1].* 1) Cukurova University, School of Medicine, Dept of Medical Biology and Genetics, Adana, Turkey; 2) Cukurova University, School of Medicine, Dept. of Obstetrics and Gynecology, Adana, Turkey; 3) Rize University, School of Medicine, Dept of Medical Biology, Rize, Turkey; 4) Cukurova University, School of Medicine, Dept. of Physical Therapy and Rehabilitation, Adana, Turkey.

Osteoporosis, a common disease characterized by a generalized reduction in bone mineral density (BMD) and disruption of bone architecture, is a very important public health problem. Sex steroids are the most intensively focused physiologic regulators of the bone mass. Therefore, genes regulating sex steroid production and metabolism are possible candidates for osteoporosis and genetic polymorphisms seen in these genes most likely affect osteoporosis susceptibility in an individual. Of these genes CYP17A1 and CYP19A1 encodes the enzymes catalyzing the rate limiting steps of estrogen biosynthesis. CYP19A1 catalyze the conversion of testosterone to biologically active estradiol. Previously, it has been shown that a silent polymorphism (G®A) in exon 3 of CYP19A1 gene was associated with osteoporosis. The other rate limiting enzyme CYP17A1 catalyzes the conversion of progesterone and pregnenolone into precursors of potent androgens. In the 5 promoter region of the CYP17A1 gene, a T®C substitution has been described to alter CYP17A1 gene expression. In the present study, we tested the association of CYP17A1 and CYP19A1 polymorphisms with BMD in postmenopausal women with osteoporosis in Turkey. We found that GG genotype frequency of CYP19A1 is higher than that of AA and GG and the estradiol concentrations were found to be higher in AA compared to GG and GA genotypes. As for CYP17A1 gene, we did not find any significant association between T®G polymorphism and serum steroid concentrations. In conclusion, our results may suggest that postmenopausal women having CYP19A1 gene GG and GA genotypes comprise a higher risk for osteoporosis.

Whole genome expression analysis of amniocytes from anencephalic and control fetuses. *C.A. Markunas, K. Soldano, A. Byrd, H. Cope, P. Xu, A.E. Ashley-Koch, S.G. Gregory.* Center for Human Genetics, Duke University Medical Center, Durham, NC, USA.

Anencephaly is a devastating neural tube defect (NTD) affecting roughly 1/4000 babies in the US. Anencephaly occurs when the neural tube fails to close in the cranial region, which results in an absence of the brain and skull. NTDs, such as anencephaly, are thought to have a complex etiology, resulting from both genetic and environmental factors. One approach to identifying novel candidate genes is to examine gene expression during early stages of development in Anencephalic and normal fetuses. Using Illumina HT-12 expression beadchips (48793 probes), we performed whole genome expression analysis using amniocytes from Anencephalic (N=4) and control (N=4) fetuses. Whole genome expression data were pre-processed as follows: 1) quality control assessment and background subtraction using Illumina's GenomeStudio, 2) variance stabilizing transformation and quantile normalization using the R package, Lumi, 3) adjustment for batch effects using ComBat, and 4) non-specific filtering in order to remove the least variable probes. Out of the remaining 4840 probes, we identified 512 probes that were significantly differentially expressed (Welch's t-test p<0.01, FDR q<0.10). Sixty three percent of these were down-regulated in cases compared to controls. Further analyses were performed using DAVID in order to identify biological pathways and gene ontology (GO) terms that were enriched for in our results. We identified two significant KEGG pathways (FDR q<0.05), the ECM-receptor interaction and Pathways in cancer, as well as several significant GO terms, including developmental process, cell differentiation, regulation of cell death, regulation of cell proliferation, protein binding, and others. To further validate our findings and identify novel candidate genes for follow-up, we compared our results to previous findings from an Anencephaly family-based genetic association study (N=45 families), as well as an expression study which identified genes which were differentially expressed in rostral neural tube tissue during Carnegie stages 12 (time of neural tube closure (NTC)) and 13 (NTC complete). One gene, Spectrin, beta, non-erythrocytic 1 (SPTBN1), was nominally significant (p<0.01) in all three studies and an additional forty five genes were significant in at least two of the studies. Interestingly, SPTBN1 was down-regulated in amniocytes of Anencephalic cases and up-regulated during early Carnegie stage 12 compared to 13, suggesting SPTBN1 may play a role in NTC.

The Apolipoprotein E (APOE) polymorphisms influence on sleep parameters in Obstructive Sleep Apnoea Syndrome. *R. Pellegrino, DR. Manzzotti, CS. Guindalini, R. Santos-Silva, LR. Bittencourt, S. Tufik.* Psicobiologia, Univ Fed Sao Paulo - UNIFESP, Sao Paulo, Brazil.

The majority of sleep disorders are known to be a result of a complex interaction between environmental factors and individual genetic susceptibility. OSAS (Obstructive Sleep Apnoea Syndrome) is characterized by repeated episodes of declines in breathing (hypopneas) or interruption of breathing (apneas).The APOE is a lipoprotein commonly known to directly act in cholesterol transport and plasma lipoprotein metabolism. It has been suggested that APOE isoforms may be involved in OSAS physiopathology through mechanisms related not only to alteration in lipid metabolism, but also to the binding to beta-amyloid proteins, which can eventually lead to neurofibrillary plaques and tangles in the brain respiratory control center. The aim of this study was to evaluate the association between APOE genotypes and sleep parameters in a population based sample from São Paulo, Brazil. APOE genotypes were evaluated in 885 individuals participating in the Epidemiologic Sleep Study of Sao Paulo city, a population-based survey adopting a three-stage randomized cluster sampling. The volunteers were subjected to a full-night polysomnography. Diagnosis of OSAS was performed according to the International Classification of Sleep Disorders (ICSD-2). No significant association was found between APOE genotypes/alleles and OSAS diagnosis. Nevertheless, individuals with OSAS and carrying the APOE E2 allele showed longer sleep latency, lower sleep efficiency, higher number of brief arousals and arousals/hour, when compared to APOE E3 allele homozygous and individuals carrying the APOE 4 allele (p£0.02). APOE E2 allele carriers also spent significantly more time awake (p=0.01), showed higher percent of stage 1 (p= 0.03) and low percent of stage 3 and 4 (p=0.02) compared to APOE E3 homozygous. No significant differences were found between APOE E3 homozygous and APOE E4 allele carriers. In individuals without OSAS, sleep parameters did not differ among the APOE genotypes. Our data showed that the presence of APOE E2 allele is significantly associated with a decrease of sleep quality only in patients with OSAS, suggesting the APOE gene polymorphisms and its regulatory region may contribute in the molecular basis of OSAS physiopathology. Further studies are necessary to fully characterize the role of APOE cluster in sleep architecture and associated phenotypes.

943/W

Association of methylenetetrahydrofolate reductase gene polymorphisms with sporadic amyotrophic lateral sclerosis. *A. Sazci[1], E. Ergul[1], M.D. Sozuguzel Ozel[1], H.A. Idrisoglu[2].* 1) Dept Medical Biology and Genetics,Faculty of Medicine, Kocaeli University, Kocaeli,Umuttepe,41380, Turkey; 2) Department of Neurology, Faculty of Medicine, University of Istanbul, Capa, 34280, Istanbul, Turkey.

Amyotrophic lateral sclerosis (ALS) is a rare progressive and eventually fatal neurodegenerative disorder where motor neurons of the motor cortex, brainstem,and spinal cord degenerate, causing muscle wasting, weakness and profound paralysis. The 5,10-methylenetetrahydrofolate reductase (MTHFR) is the only enzyme in Hcy metabolism, which catalyzes the conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, the predominant circulating form of folate in blood. The MTHFR gene has at least two functional polymorphisms, 677C>T and 1298A>C.The MTHFR 677T allele is associated with reduced enzymatic activity, decreased concentrations of folate in serum, plasma, and red blood cells, and mildly increased plasma total Hcy (tHcy) concentrations.We genotyped 398(245 male; 153 female) sporadic amyotrophic lateral sclerosis(SALS)and 439(276 male;163 female) healthy controls to show whether there is an association between MTHFR polymorphisms and SALS. In female SALS, 677T allele is associated with SALS(X2=3.610; P=0.057; OR=1.536; 95%CI=0.986,2.395). TT genotype is also associated with SALS in females (X2=4.649; P=0.031; OR= 2.426; 95%CI=1.062,5.543).CCAA compoud genotype is also protective against SALS in females(X2=4.841;P=0.028; OR=0.426;95%CI= 0.195,0.927). TTAA compound genotype is also associated with SALS in females(X2=5.697; P=0.017; OR=2.747; 95%CI= 1.165, 6.478). In conclusion, MTHFR gene polymorphisms are associated with female SALS in a gender specific manner.

Association analysis of SMOC2 gene Variant in Jordanian Arab Vitiligo Patients. *A. Alkhateeb[1], F. Qarqaz[2], N. Marzoqa[1].* 1) Dept Biotechnology and Genetics, Jordan Univ Science & Tech, Irbid, Jordan; 2) Dept Dermatology, Jordan Univ Science & Tech, Irbid, Jordan.

Generalized vitiligo is a common autoimmune disorder, characterized by patchy loss of pigmentation due to melanocyte death. It is a multifactorial disorder in which multiple genes and environmental triggers contribute to the expression of the phenotype. Different genetic variants can have varying effects on having vitiligo. Recently, an SMOC2 variant (rs13208776) was reported to be associated with vitiligo in Caucasian patients from an isolated founder population. In this study, we investigate the association of SMOC2 variant with Jordanian Arab vitiligo patients. Forty-four patients with generalized vitiligo and 151 matched normal controls were recruited. DNA samples were obtained from patients and controls and samples were genotyped for SMOC2 variant by restriction fragment length polymorphism. Allelic frequency of the less common allele (A allele) was 29.5% in patients compared to 19.6% in the controls (p=0.27). Genotypic frequency for AA was 4.5% in patients and 7.9% in controls while heterozygous genotypes were 50% for patients and 33.1% in controls. Genotypes did not show statistical difference in patients versus control (p=0.12). Our data shows that the variant rs13208776 in SMOC2 gene does not play a major role in increasing the risk of vitiligo in Jordanian Arab patients. This is in contrast to the previous association reported for Caucasian patients from an isolated patient population in Romania. This signifies genetic differences in the two populations.

Identification of susceptibility variants for maxillary lateral incisor agenesis: a case-control study. *M. Alves-Ferreira[1,2], T. Pinho[3], A. Sousa[1,4], J. Sequeiros[1,2,4], C. Lemos[1], I. Alonso[1,2].* 1) UnIGENe, IBMC, University of Porto, Portugal; 2) CGPP, IBMC, University of Porto, Portugal; 3) CICS, ISCS-N/CESPU, Portugal; 4) Department of Population Studies, ICBAS, University of Porto, Portugal.

Agenesis of maxillary lateral incisors (MLIA) is the absence of formation of deciduous or permanent lateral incisors. Individuals with MLIA may present phonetic and masticatory dysfunction and also emotional development impairment. MLIA is the most frequent form of hypodontia with prevalence, estimated by us, of 1.3% in the Portuguese population. In a previous study, we found evidence of familial aggregation of MLIA in a sample of Portuguese families suggesting the presence of a strong genetic component for this trait. Odontogenesis is a complex mechanism mediated by genetic factors and is responsible for the determination of the position, number, shape and tooth size. Several genes have been identified as being expressed during odontogenesis and variations in these genes could lead to abnormalities in odontogenesis, resulting in tooth agenesis. Mutations in several genes have been identified in various forms of tooth agenesis or in syndromes in which tooth agenesis is a regular feature. New findings on the function of these genes that are mutated in certain human syndromes further strengthen the important role of these genes in tooth agenesis. Therefore, our aim was to study the association of polymorphisms in seven odontogenesis-related genes with MLIA susceptibility. Association studies are an essential approach in the research of candidate genes involved in MLIA susceptibility in our patients, allowing the identification of common variants associated with this trait. We are currently performing a case-control study, with a case:control ratio of 1:2, to increase the statistical power of our study. We focused on a candidate gene strategy, selecting genes based on their function on odontogenesis and possible involvement in MLIA susceptibility. The selection of the tagging single nucleotide polymorphisms (SNPs) was performed based on the degree of linkage disequilibrium (LD) between the SNPs. This study will comprise a total of 44 SNPs, which will be genotyped by SNaPshot, using a multiplex approach. We are starting the genotyping of 40 SNPs in the 300 individuals ascertained. Next, we will optimize the remaining SNPs and proceed to statistical analysis, comparing SNPs' frequencies in the two groups, in order to identify variants associated with MLIA susceptibility. The data obtained from this study will be useful to better understand the genetic basis of dental agenesis and the pathways underlying MLIA susceptibility.

946/W

Analysis of the variety of sequence variants of SOS1 gene in cleft lip and/or palate patients of Lithuania. *L. Ambrozaityte[1], I. Uktveryte[1], A. Timinskas[2], A. Utkus[1], A. Matuleviciene[1], V. Kucinskas[1].* 1) Human & Med Gen, Vilnius Univ, Vilnius, Lithuania; 2) Institute of Biotechnology, Vilnius, Lithuania.

Orofacial clefting (OFC) is developmental malformation during embryogenesis. It is one of the most common birth defects. Incidence of OFC varies from 1/500 to 1/1000 births and in the population of Lithuanian it is 1/700 - 800 that is akin to Caucasian (European) populations statistics. There are different genes and environmental forces involved in the formation of cleft lip with or without cleft palate (CL/P) and isolated cleft palate (CPO). Up to date more than 20 candidate genes are known which may contribute to non-syndromic CL/P (NS - CL/P). The goal of this study was to identify sequence variants of SOS1 gene (son of sevenless homolog 1 (Drosophila)) that may contribute to NS - CL/P phenotype in Lithuanian population. According to the performed bioinformatic analysis SOS1 gene interacts with 4 CL/P and 50 non CL/P genes. For the detection of risk factors all 23 exons of SOS1 gene were sequenced for 84 patients with NS - CL/P and 84 controls to find variants not only in coding but also in flanking sequences as NS - CL/P risk factors most probably are non patogenic mutations which usually cause complex phenotypes. 19 different variants were identified, 15 of which are SNPs and four in/del polymorphisms. According to the $\chi 2$ test results variant 100711insGTG (c.1075-98_1075-97 insGTG; rs56299761) showed statistical significance ($\chi 2$=4.841; p=0.028), 127470 -/insA (c.2792-51_2792-50 insA) was close to significance ($\chi 2$=3.388; p=0.066). Calculation of partial identity of population using hypergeometrical distribution did not confirm previous results but showed 11 sequence variants or its combinations statistically significant in different NS - CL/P subtypes: 139450G/G (p= 0.041 and p=0.024); 66325C/C (p=0.0179); 66325C/G (p=0.0179); 135314A/G-135350C/T-135389delT-135488T/C (p=0.0179); 135350C/T (p=0.0179); 135488T/C (p=0.0179); 70008C/C-70182C/T-70357G/G (p= 0.0259); 70182C/T (p=0.0259); 112515C/G-112516C/T (p=0.039); 112516C/T (p=0.039). Results of this study demonstrate association of SOS1 gene with NS - CL/P or it's subtypes. SOS1 gene can be considered as candidate gene for NS - CL/P according to this study results and known interaction with other CL/P candidate genes FGFR1 (fibroblast growth factor receptor 1), ERBB2 (v-erb-b2 erythroblastic leukemia viral oncogene homolog 2), EGFR (epidermal growth factor receptor) confirms SOS1 gene's importance to NS - CL/P phenotype.

Association analysis of Adiponectin and Sulphonylurea Receptor gene polymorphisms with Type 2 Diabetes (T2D) in North Indian Punjabi population. *A.J.S. Bhanwer, K. Matharoo.* Department of Human Genetics, Guru Nanak Dev University,Amritsar, Punjab, India.

Type 2 diabetes (T2D) is emerging as a major health concern in the North Indian Punjabi population which has undergone major change in the life style due to rapid growth in economy after green and white revolution; urbanization and industrialization. There is dearth of data pertaining to molecular genetic studies on predisposition to T2D in this population. To fill the existing lacunae the present case-control study was initiated to analyse single nucleotide polymorphisms (SNPs) in the adiponectin (APM) and sulphonylurea receptor (SUR1) genes with susceptibility to T2D in Punjabi population. 200 T2D patients and 200 non-diabetic age and sex matched healthy controls were recruited for the study with informed consent. Genomic DNA was extracted by phenol-chloroform method and PCR-RFLP procedure was used for genotyping of APM 45 (T®G) and SUR1 Exon16 (-3C®T) & Exon18 (C®T) SNPs. The distribution of APM 45 genotypes (TT, TG and GG) was 45.5%, 51% and 3.5% in T2D and 61.5%, 34% and 4.5%, in controls, respectively. The frequency of T and G allele was 71% and 29% in T2D and 78.5% and 21.5% in controls, respectively. The difference in the genotypes (p=0.003) and alleles was statistically significant [p=0.02; OR=0.67 (0.49-0.93)]. Analysis as per genetic models revealed a protective association of TT genotype against T2D [(p=0.034; OR=0.61 (0.39-0.96)] adjusted for age, sex, BMI. TG-genotype appeared to provide increased risk [p= 0.014; OR=1.78 (1.12-2.82)]. The resulting population attributable risk (PAR) of the G-allele was 9.55% (1.69-18.56). In the analysis of Exon 16 polymorphism, the frequency of C and T-allele in the T2D cases (56.8% and 43.2%) and controls (57.5% and 42.5%) was not significantly different (p=0.83). The frequency of T-allele of Exon-18 was very low in both cases and controls (1.8% and 0.8%, respectively) with insignificant difference (p= 0.20). Adiponectin stimulates glucose uptake and fatty acid oxidation. In the present study, the presence of G allele confers an increased risk to T2D while T-allele provides protection against T2D. Lower adiponectin levels are considered strong predictors for future development of T2D in Asian Indians. Probably, the SNP45 in linkage disequilibrium with other functionally relevant SNPs might affect the levels of protein. Thus, the study suggests that the APM 45 (T®G) polymorphism in the adiponectin gene seems to play a role in susceptibility of T2D in the Punjabi population.

Analysis of candidate genes for generalized vitiligo in a GWAS dataset supports additional susceptibility loci. *S. Birlea, Y. Jin, P. Fain, R. Spritz.* Human Medical Genetics Program, University of Colorado School of Medicine, Aurora, CO.

Generalized vitiligo (GV) is the most frequent pigmentation disorder, in which white patches of skin, hair, and mucous membranes result from autoimmune loss of melanocytes from involved areas. We previously carried out a genomewide association study (GWAS) of GV in Caucasians, identifying 13 loci involved in disease susceptibility. To identify additional GV susceptibility loci not detected by the GWAS, we re-analyzed the genomewide dataset (1392 cases, 2629 controls) to specifically test association of 20 candidate genes previously suggested to be involved in GV pathogenesis, followed by meta-analysis incorporating the current data and any previous published data. We confirmed association of three of these candidate genes at a Bonferroni-corrected significance threshold P < 2.50E-03. At 5q22.1 we detected association with *TSLP* (rs764916, P = 3.03E-04, OR = 1.60; combined P for published SNP rs3806933 = 3.15E-03, OR= 1.13) encoding thymic stromal lymphoprotein, which induces release of T cell-attracting chemokines from monocytes and enhances the maturation of CD11c(+) dendritic cells. At 22q12.1 we detected association of *XBP1* (rs6005864, P = 3.65E-04, OR = 1.17; combined P for published SNP rs2269577 = 9.50E-09, OR = 1.21), encoding a bZIP transcription factor that regulates immune function and expression of *HLA-DRA*. At Xp11.23 we detected association of *FOXP3* (rs11798415, P = 7.26E-04, OR = 1.19), which encodes a forkhead box transcription factor that is the master regulator of regulatory T cell development and is the gene underlying the IPEX multiple autoimmune disease syndrome. We found no apparent association of GV with the candidate genes *FOXD3, GSTM1, PTGS2, IL10, FBXO11, NFE2L2, ESR1, MBL2, FAS, CAT, VDR, C12orf10, ACE, CLEC11A, AIRE, COMT* and *GSTT1*. Our findings thus extend our previous GWAS results, supporting involvement of *TSLP*, *XBP1*, and *FOXP3* in the pathogenesis of GV and implicating new immunologic pathways in disease pathogenesis.

949/W

Study of association of K121Q and A-G1044TGA polymorphisms of ENPP1 gene with clinical markers of insulin resistance and obesity-related phenotypes in Mexican-mestizo children and adolescents. *A. Del Toro-Valero[1], MG. López-Cardona[6,3], E. Romero-Velarde[2], Y. Saldaña-Alvarez[4], M. Escalante Pulido[5], L. Aguirre-Salas[2,3], L. Orozco-Orozco[4], G. Salas[4], D. Carmona-Navarro[6], N. Davalos-Rodriguez[6,3], J. Armendariz-Borunda[6].* 1) Doctorado en Genetica Humana, CUCS. Universidad de Guadalajara, Guadalajara, Jalisco, México; 2) O.P.D. Hospital Civil de Guadalajara, Dr. Juan I. Menchaca. Guadalajara, Jalisco, México; 3) HR "Dr. Valentín Gómez Farías", ISSSTE. Zapopan, Jalisco, México; 4) Instituto Nacional de Medicina Genómica. DF, México; 5) Unidad Metabólica, CMNO, IMSS, Guadalajara, Jalisco, México; 6) CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México.

Background: Glucose metabolic disturbances and insulin resistance (IR) are closely related to obesity, diabetes mellitus and cardiovascular disease. The etiology involves cultural and environmental factors, as well as strong genetic predisposition, presenting high global prevalence. Recent reports state that ENPP1 gene encodes a protein that inhibits the alfa subunit of the insulin receptor, suggesting that the ENPP1 gene could be a candidate for IR. Objective: To analyze the relationship of K121Q and A-G1044TGA polymorphisms of ENPP1 gene with clinical markers of IR and obesity-related phenotypes in Mexican children and adolescents. Material and methods: We selected 123 children and adolescents with obesity (BMI $\geq$ 97th percentile) from 2-19 years old and 154 healthy adults. We analyzed the presence of acanthosis nigricans, glucose and insulin serum levels, HOMA index, only in the obese. The SNPs K121Q and A-G1044TGA were genotyped with allelic discrimination by TaqMan. Applying x2, OR and ANOVA for statistical analysis. Results: Of the 123 obese individuals, 48% were female and 52% male. 64% were between 11 and 19 years, 33% between 6 and 10 years and 3% between 2 and 5 years. 76% of patients had acanthosis nigricans. Serum glucose levels equal or greater than 100 mg / dl in 4% of the individuals. Over 70% had insulin levels >15 μU/ml and HOMA index >3. The genotype frequencies presents in patients for SNP K121Q were AA 0.62, AC 0.36 and CC 0.2; and for A-G1044TGA were AA 0.16, GA 0.57 and GG 0.27. For A-G1044TGA SNP in obese individuals the mean HOMA index for homozygous GG was significantly higher (6.6), unlike the genotypes AA and AG (5.9 and 4.7 respectively), with significant differences of p=0.029. The rest of the variables were not statistically significant. The genotype frecuency between healthy adults and obese individuals was no significant. Conclusions:Only GG genotype from A-G1044TGA polymorphism, present in obese children and adolescents was related to higher HOMA index, no relationship was found with acanthosis nigricans, insulin and glucose elevated serum levels. On the other hand, no association was found between K121Q polymorphism and the four variables. The presence of GG genotype from A-G1044TGA polymorphism could be associated with a higher risk of IR in Mexican obese children and adolescents.

Genome-wide linkage and association analyses in uterine leiomyomata reveals candidate gene on chromosome 17. *S.L. Eggert[1], R. Kavalla[2], K.L. Huyck[4], P. Somasundaram[2], E.A. Stewart[5], A. Lu[6], J.N. Painter[7], G.W. Montgomery[7], S.E. Medland[7], S.A. Treloar[7], L. Rose[8], P.M. Ridker[8,9], D.I. Chasman[8,9], N.G. Martin[7], R.M. Cantor[6], C.C. Morton[2,3,9].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Department of Obstetrics, Gynecology and Reproductive Biology, Brigham and Women's Hospital, Boston, MA; 3) Department of Pathology, Brigham and Women's Hospital, Boston, MA; 4) Department of Pathology, University of Vermont, Burlington, VT; 5) Department of Obstetrics and Gynecology, Mayo Clinic, Mayo Medical School, Rochester, MN; 6) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 7) Queensland Institute of Medical Research, Brisbane, Australia; 8) Division of Preventive Medicine, Brigham and Women's Hospital, Boston, MA; 9) Harvard Medical School, Boston, MA.

Uterine leiomyomata (UL), commonly known as fibroids, are the most prevalent pelvic tumors in women. UL pose a major public health problem given their prevalence (>70%) and rate of symptoms (~20-25%) in women of reproductive age and their indication for >200,000 hysterectomies in the U.S. annually. A genetic basis for tumor development is supported by the observation of recurrent chromosomal aberrations. Further, analyses of ethnic predisposition, twin studies, and familial aggregation indicate a genetic component to UL predisposition, but no genome-wide study for heritable variants has been reported. A genome-wide SNP linkage panel was applied to 261 white UL sister pair families from the Finding Genes for Fibroids study. Two significant linkage regions were detected; the highest LOD score discovered is in 10p11 (LOD=4.15) while the second significant peak is in 3p21 (LOD=3.73). Five additional linkage regions were identified with a suggestive LOD score over 2.00. These regions are in 2q37 (LOD= 2.41), 5p13 (LOD=2.13), 11p15 (LOD=2.53), 12q14 (LOD=2.62), and 17q25 (LOD=2.15). Fine mapping was performed with an independent sample of white women from the Women's Genome Health Study (WGHS) and 39,115 SNPs positioned under the linkage regions. Cases were defined as women who reported being diagnosed with fibroids under age 40 years, and/or had a hysterectomy, and have a mother or sister also diagnosed with fibroids. A standard case/control analysis was performed with 746 cases and 4487 controls; 44 SNPs were identified with p-values £ 0.001. Replication was performed with the 44 suggestive SNPs in a third independent sample of white women from an Australian twin cohort in which cases are defined as women who have been diagnosed with fibroids. A standard case/control analysis was performed with 484 cases and 610 controls; seven SNPs were identified with p-value £ 0.05. Of the seven candidate SNPs, six are in linkage disequilibrium with each other in 17q25.3 and are located in *CCDC57*. The p-values of the six SNPs in *CCDC57* reach genome-wide significance after meta-analysis of the WGHS and Australian samples. Functional studies will be performed to determine the possible role of these candidate SNPs in UL predisposition. Further understanding of genetic variants associated with UL will provide insight into the biology of tumor development and may lead to improved management or novel therapy.

Support for involvement of CIITA gene variants in rheumatoid arthritis in a Norwegian material and in an updated meta-analysis of 15 cohorts. *M.C. Eike[1], B. Skinningsrud[1,2], T.K. Kvien[3], A. Stormyr[2], D.E. Undlien[1,2], B.A. Lie[4].* 1) Dept of medical genetics, University of Oslo, Oslo, Norway; 2) Dept of medical genetics, Oslo university hospital, Ullevål, Oslo, Norway; 3) Dept of rheumatology, Diakonhjemmet hospital, Oslo, Norway; 4) Inst of immunology, Oslo university hospital, Rikshospitalet, Oslo, Norway.

The class II major histocompatibility complex (MHC) transactivator (CIITA) is a crucial regulator of MHC class II gene expression. Due to the established role of MHC class II in autoimmunity, CIITA is therefore an excellent candidate for involvement in autoimmune diseases. Accordingly, the rs3087456 A>G promoter SNP in this gene has been reported associated with rheumatoid arthritis (RA) and the intronic rs8048002 T>C SNP with autoimmune Addison's disease (AAD). In this study, we genotyped 819 Norwegian RA patients and 2149 controls for both of these SNPs. The rs3087456 GG genotype was significantly associated with RA in a recessive model, both in our material (OR 1.50 [95% CI 1.10-2.05], P=0.0093) and in an updated meta-analysis of 15 cohorts, totalling 13154 RA patients and 16351 controls (OR 1.15 [95% CI 1.01-1.31], P=0.031). However, no significant association was found at the allele level (P>0.05). Moreover, the recessive association appeared to be restricted to Scandinavian cohorts (P=0.0011 vs. 0.24 in other studies combined). The rs8048002*C allele was suggestively associated with RA both at the allele level (OR 1.25 [95% CI 1.00-1.56], P=0.046) and in a dominant model (OR 1.30 [95% CI 1.03-1.63], P=0.026) in our material. Linkage disequilibrium (LD) between the rs3087456 and rs8048002 SNPs was estimated to D'=0.98 and r^2=0.21. Haplotype analysis revealed that rs8048002*C was virtually always carried together with rs3087456*G on a susceptible haplotype (P=0.050), while the latter allele also occurred on non-risk haplotypes. Together with results of regression analyses, this indicates that the RA association of rs3087456 can be explained by LD with rs8048002. CIITA is the only known gene in the LD block harboring rs8048002 in European HapMap populations. Moreover, both rs3087456 and rs8048002 were in low LD with the rs6489169 SNP in the neighbouring C-type lectin domain family 16 member A (CLEC16A) gene previously associated with RA in our material (D'<0.12, r^2<0.002), indicating that the CIITA associations were independent of this effect. Our results provide support for the involvement of CIITA gene variants in RA, but suggest that variants other than the rs3087456 promoter SNP are involved in disease susceptibility. This provides a possible explanation for the diverging results for the rs3087456 SNP in previous studies of RA patients, and warrants follow-up studies that aim to genotype a spectre of SNPs tagging the CIITA harboring LD block.

952/W

Further evidence for the important role of apoptosis in clubfoot. *A.R. Ester[1], S. Richards[2], D. Barnes[3], C. Alvarez[4], S.H. Blanton[5], J.T. Hecht[1,3].* 1) Univ Texas Medical Sch, Houston, TX, 77030; 2) Texas Scottish Rite Hospital for Children, Dallas, TX 75219; 3) Shriners Hospital for Children, Houston, TX, 77030; 4) University of British Columbia, Vancouver, BC, Canada; 5) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL 33136.

Isolated clubfoot, a common birth defect occurring in more than 135,000 live births worldwide each year, is associated with significant health care and financial burdens. Clubfoot is a complex defect caused both genetic and environmental factors, most of which are yet to be defined. Brewer et al. (1998) identified six chromosomal deletion regions associated with syndromic clubfoot, and suggested that genes in these regions may contribute to isolated clubfoot. Previously, we found evidence for association with genes in the mitochondrial-mediated apoptotic pathway. The goal of this study was to further explore the association between apoptotic genes and clubfoot. Fifty-eight SNPs in eight mitochondrial-mediated apoptotic genes were genotyped in our expanded nonHispanic white (NHW) and Hispanic simplex and multiplex families, as were one hundred and ninety-two SNPs spanning twenty-nine apoptotic genes from the six clubfoot deletion regions. The mitochondrial-mediated apoptotic gene SNPs showed moderate association similar to that previously reported. For the chromosomal deletion region apoptotic genes in the NHW group, a SNP in TNIP2 showed the most significant association while SNPs in NFAT2 were most significant in Hispanics. Importantly for both ethnic groups, gene interactions involving many of the same genes and pathways were identified. Many of these SNPS were in promoter regions and would affect expression of the gene. Apoptosis is involved in muscle development, and the non-rotation of the clubfoot to plantar grade may be due to the disruption of normal muscle development. These results support a significant biologic mechanism for clubfoot that involves a high-risk haplotype composed of different genetic variants that create a higher genetic liability that may increase susceptibility to environmental influences.

953/W

***LOXL1* promoter region SNPs modify risk of exfoliation syndrome and exfoliation glaucoma.** *B.J. Fan[1], L.R. Pasquale[1], D. Rhee[1], J.L. Haines[2], J.L. Wiggs[1].* 1) Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA; 2) Center for Human Genetic Research, Vanderbilt University School of Medicine, Nashville, TN.

LOXL1 is necessary for elastogenesis and elastin homeostasis and is a major risk factor for exfoliation syndrome (ES), an ocular condition predisposing to glaucoma. Two highly associated *LOXL1* SNPs are missense changes in exon 1 (R141L, G153D). The risk allele frequency for both SNPs varies among different populations; the R141L risk allele flips in Japanese and Chinese and the G153D risk allele flips in the black South Africans, suggesting that these variants are not biologically causative but are in linkage disequilibrium with other variants affecting gene expression or protein function. To identify other ES-predisposing *LOXL1* variants, we evaluated SNPs across the whole gene region for association in a U.S. sample. **16** *LOXL1* tag SNPs, and six 5' SNPs near transcription factor binding sites, were genotyped in 196 Caucasian cases and 201 controls. Single-SNP association was initially analyzed using the chi-square test and further evaluated using logistic regression after adjusting for the effects of age and the R141L, G153D missense variants. **13** *LOXL1* SNPs were initially associated with ES after correction for multiple testing, however after adjusting for the effects of age and the R141L and G153D variants only rs12914489 remained associated (p=0.04). Logistic regression showed an additive effect between rs12914489 and G153D with an increased risk of ES (OR=20.40) in individuals carrying risk alleles in both SNPs compared to individuals carrying only the G153D risk allele (OR=8.73) suggesting that variants in the region 5' to the gene may independently influence disease progression. Of the 6 significant SNPs located in the 5' region rs16958477 demonstrated the best association ($p=6.4\times10^{-7}$). The haplotype consisting of risk alleles for rs16958477 and G153D was significantly associated with ES ($p=1.1\times10^{-7}$). rs12914489 is located approximately 30kb from the transcription start site in a conserved region containing at least one transcription factor binding site. Joint analyses with the G153D variant suggest that rs12914489 may contribute to ES risk as an independent additive factor. rs16958477 is located near the transcription start site, and previously the rs16958477 A allele has been shown to have significantly less transcription activity than the C allele. Our results showing association between the A allele and ES suggests that rs16958477 could contribute to ES by reducing *LOXL1* gene expression. **Grant support:** NEI R01EY015872, P30EY014104; RPB, MLERF.

ALX4 Variants in Nonsyndromic Sagittal Craniosnosynostosis. *A.S. Ghuman[1], L. Qi[2], J. Liu[1], G. Yagnik[1], E. Cherkez[1], M.L. Cunningham[3], V. Kimonis[4], S.A. Boyadjiev Boyd[1].* 1) Dept Pediatrics, SOM, University of California Davis, Sacramento, CA; 2) Rowe Program in Human Genetics, University of California Davis, Davis, CA; 3) Dept Pediatrics, Division of Craniofacial Medicine, University of Washington, Seattle, WA; 4) Dept Pediatrics, University of California Irvine, Irvine, CA.

Premature fusion of one or more cranial sutures is defined as craniosynostosis (CS) and this defect occurs in one of 2,000 live births. Nonsyndromic cases occur when the suture synostosis is an isolated anomaly (85% of reported cases, vs. 15% syndromic). Sagittal craniosynostosis (SCS) comprises 50% of all nonsyndromic CS patients. ALX4 plays the general role as a transcription factor involved in skull development and specifically, in controlling the proliferation-differentiation balance in the coronal suture. Loss of function (LOF) mutations of ALX4 result in parietal foramina. Similarly, LOF mutations of MSX2 result in parietal foramina, while gain of function (GOF) of MSX2 causes craniosynostosis. Based on that, we hypothesize that ALX4 GOF polymorphisms will result in SCS. Sequencing of ALX4 in 140 probands with nonsyndromic SCS identified three rare missense variants that are not present in the existing genetic databases and involve highly conserved residues. These polymorphisms are then to be tested for expression levels via dual luciferase assay. In addition, thirteen variants were identified in a larger SCS cohort (n=229) of which seven were present in controls and six were novel. Tests for associations documented statistically significant over representation of two non-synonymous variants in probands, suggesting that they confer increased susceptibility to SCS. In summary, our data suggests that unique and common ALX4 variants may contribute to a proportion of SCS cases through a GOF effect.

955/W

Gene-targeted (by MLPA) quantitative analysis in Autism Spectrum Disorders. *F. Gurrieri, N. Cannelli, G. Neri.* Genetica Medica, Univ Cattolica, Rome, Italy.

Autistic disorders (ASD) are a group of childhood neurodevelopmental disorders characterized by difficulties in socialization and communication and stereotypic behaviors. Array-CGH has recently allowed the identification of CNVs in 10% of ASD cases, often non randomly. Nevertheless, this high-throughput approach is limited by the resolution and assembly of the array-chip used in which some genes or genomic regions, still involved in ASD, may not be represented. In addition, alterations can be detected in regions not known to be related to ASD and therefore difficult to interpret as meaningful results. With the aim to develop a targeted quantitative genetic test for ASD we built an "in-house" MLPA assay with probes covering 9 candidate genes for ASD and tested it on 115 ASD patients. METHODS: All patients tested negative for Fragile-X syndrome, Rett syndrome and SHANK3 deletions/mutations. Candidate genes included in the MLPA assay were: FOXP2 (7q31), UBE2H (7q32), CALU (7q32.1), GRM8 (7q31), GRM5 (11q14), DOC2B (17p13), HOMER1 (5q14), NLGN3 (Xq13), FHIT (3p14). Probes were designed for each gene, according to MRC-Holland on-line manual and MLPA reactions were performed using EK1 reagent kit (MRC Holland, Amsterdam). Results were analysed by a developed spreadsheet in Microsoft Excel. All test/reference ratio values below 0.7(0.35 for NLGN3 in males) or exceeding 1.3 (0.65 for NLGN3 in males) were considered as CNA. The assay was first validated on 30 controls. RESULTS:We found a CNV in 4 patients (3.5%). In two of those, brother and sister, we detected an extra copy of NLGN3 probe. In another female patient we found a value of 0.57 in NLGN3 probe and in an additional unrelated female we found a similar value for the CALU gene, both values suggestive of a probable allele loss. These probes are not included in the array-chips currently in use in our laboratory (44K and high-definition 105K from Agilent). CONCLUSIONS:Our results indicate that a targeted MLPA assay could allow detection of intragenic CNVs that might have been missed with array-CGH, even at high resolution. This approach needs to be validated in higher cohorts of patients and other combinations of candidate genes might be assembled for a targeted diagnosis in ASD patients. Whereas NLGN3 alterations confirm already known associations of neuroligins to autism, the CALU alteration is interesting and can open further future investigations about its role in autism pathogenesis.

956/W

Fine Mapping of Regions Linked to Type 2 Diabetes and Admixture Mapping of Type 2 Diabetes in African American Families: The American Diabetes Association GENNID Project. *S. Hasstedt[1], C.L. Hanis[3], S.C. Elbein[2].* 1) Dept Human Genetics, Univ Utah, Salt Lake City, UT; 2) Section on Endocrinology and Metabolism, Dept of Medicine, Wake Forest Univ. School of Medicine, Winston-Salem, NC; 3) Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX.

The Genetics of NIDDM (GENNID) study was established by the American Diabetes Association as a resource for the discovery of genes related to diabetes and its complications. Autosomal linkage analysis of type 2 diabetes (T2D) and age of diagnosis (AOD) on a subset of the GENNID sample, which included 1344 (1082 with T2D) members of 524 African-American families, identified 4 candidate regions for T2D susceptibility genes (chromosomes 2 at 68-121 MB, 7 at 50-79 MB, 13 at 19-32 MB, and 18 at 33-67 MB) [Elbein et al Diabetes 58:268, 2009]. To follow up on these findings, we selected 10,650 single nucleotide polymorphisms (SNPs) to tag each gene under the 4 linkage peaks, in addition to 1600 SNPs from a panel of admixture informative markers. Genotyping was performed by CIDR. Admixture linkage analysis using ADMIXMAP identified 4 SNPs with suggestive P-values ($p<0.0005$) on chromosomes 13 (2 SNPs; 10 cM; 23.9 Mb, PARP4 gene), 12 (138 cM; 115 Mb; intergenic region), and 16 (0 cM; 0 Mb; MPG gene), but no SNP achieved genome-wide significance. The two SNPs on chromosome 13 fell within the region of linkage. We tested tag SNPs under each linkage peak for association with T2D, T2D adjusted for BMI, and age of diagnosis using jPAP, and also tested the change in LOD score for each associated SNP. Nominally significant associations were found for 14 SNPs on chromosome 2, 8 on chromosome 7, 13 on chromosome 13, and 7 on chromosome 18. Although no SNP reached experiment-wide significance, we found suggestive associations of rs7349979 (CALN1 gene) and rs2691529 (MAGI2 gene) with T2D and age of diagnosis on chromosome 7, and rs1893430 in transcription factor TCF4 with T2D on chromosome 18. The largest changes in LOD score were for rs7582241 (chromosome 2, CTNNA2; 0.51), rs3789073 (chromosome 2, ACOXL, 0.59), rs9318100 (chromosome 13, MIPEP, 0.66), and rs4770868 (chromosome 13; ATP8A2, 0.57). Given the paucity of T2D loci in African Americans, these studies are an important step in mapping susceptibility genes for African American diabetes. Additional analyses and testing in additional populations is needed to confirm the suggestive findings.

957/W

Investigation of European-derived adiposity loci in African Americans. *J.M. Hester[1,2,3], M.R. Wing[1,2,3], N.D. Palmer[1,2,4], P.J. Hicks[1,2,4], B.H. Roh[1,2], C.D. Langefeld[5,6], B.I. Freedman[7], D.W. Bowden[1,2,4,7], M.C.Y. Ng[1,2].* 1) Center for Diabetes Research, Wake Forest University; 2) Center for Genomics and Personalized Medicine Research, Wake Forest University; 3) Program in Molecular Genetics and Genomics, Wake Forest University; 4) Department of Biochemistry, Wake Forest University; 5) Department of Biostatistical Sciences, Wake Forest University; 6) Division of Public Health Sciences, Wake Forest University; 7) Department of Internal Medicine, Wake Forest University.

Obesity is a major public health problem in the United States with substantial racial differences in prevalence. To date, many GWAS have been performed to identify novel adiposity-associated variants in different European-derived populations, but few have attempted to replicate these associations in African Americans. We have conducted a genome-wide association study (GWAS) on body mass index (BMI) in 1715 unrelated African Americans (816 healthy subjects and 899 subjects with type 2 diabetes and nephropathy) using the Affymetrix 6.0 platform. Single SNP association analyses were conducted on 746,626 good quality autosomal SNPs with adjustment for age, gender and first principal component reflecting admixture proportion. Based on the GWAS results from previous studies in European populations, we have compiled a list of 23 adiposity loci for evaluation in our African American population. Of the 58 known index variants reported in European populations, only rs17782313, rs477181, and rs17700633 in *MC4R* and rs7498665 located between *SH2B1* and *ATP2A1* showed evidence of nominal association in our samples ($0.01<p<0.05$). A locus-wide analysis was performed by examining associations at a ±10kb flanking region around the genes or ±50kb flanking the intergenic index variants. This approach takes advantage of the fact that association signals may vary among different populations, and the smaller LD blocks in our African American population may help to fine map variants that could be causally related to disease. Using this approach, 577 SNPs were nominally associated with BMI ($p<0.05$). The strongest association was observed at rs2887941 ($p=2.5x10^{-4}$) located in the *NRXN3* gene. Nominal associations were also observed at *PARD3B* (rs12622484, $p=2.69x10^{-4}$), *MC4R* (rs639193, p=0.0013), *TFAP2B* (rs9349560, p=0.0018), *NEGR1* (rs7552295, p=0.0019), *MAF* (rs7195737, p=0.0019), *PRL* (rs9366426, p=0.003), and *MTCH2* (rs4752783, p=0.003). These results suggest that common genetic variants at loci that modulate adiposity in European-derived populations have only modest impact in African Americans. The ethnic differences in genetic susceptibility may partly account for the ethnic disparities in obesity-related traits. These putative associated SNPs warrant further investigation in additional African American populations.

Association of *ADAM33* polymorphisms with asthma in African Americans. *E.Y. Jingwi[1], L. Ricks-Santi[2,3], M. Abbas[2], T. Mason[2], C. Jackson[2], B. Arrey[2], V. Apprey[2,4], G. Bonney[2,4], A.A. Adeyemo[6], C.N. Rotimi[6], C.M. Lee[1], G.M. Dunston[2,5], M.U. Faruque[2,4].* 1) Department of Biology, Howard University, Washington DC; 2) National Human Genome Center, Howard University, Washington DC; 3) Cancer Center, Howard University, Washington DC; 4) Department of Community and Family Medicine, Howard University College of Medicine, Washington DC; 5) Department of Microbiology, Howard University College of Medicine, Washington DC; 6) Center for Research on Genomics and Global Health, National Institutes of Health, Bethesda, MD.

Background and Purpose: Asthma is a chronic inflammatory disease of the airways that has reached epidemic proportions in the US and other parts of the world. It appears to vary phenotypically according to ancestry. African Americans show higher incidences and clinically more severe asthma, with different patterns of allergic sensitization, higher IgE levels and bronchial hyperresponsiveness, when compared with Americans of European ancestry. Asthma is caused by the interaction of multiple genes and environmental factors. Our laboratory uses common variants to interrogate the biology of health disparities like asthma. Single nucleotide polymorphisms (SNPs) in *ADAM33* gene have been consistently associated with asthma in European and Asian populations in independent studies. We studied the association of SNPs in *ADAM33* with asthma in African Americans. Materials and Methods: A total of four single nucleotide polymorphisms (rs2787094, rs612709, rs2280091, rs2280090) were examined in 496 African Americans including 296 asthma cases and 200 geographically matched non-asthmatic controls from the Washington DC metropolitan area. Association was tested by logistic regression analysis under an additive genetic model with adjustment for age and gender. A replication p-value of <0.05 was considered significant. Results: rs2787094 in the 3' untranslated region of the *ADAM33* gene was significantly associated with asthma (OR = 1.51, 95% CI: 1.03 -2.20; p = 0.032). None of the other three SNPs (rs612709, rs2280091, rs2280090) was significantly associated with the disease risk. Conclusions: Out of four SNPs previously reported to be associated with asthma in non-African populations, one was replicated in this study of African Americans. This finding shows the functional significance of common variants in dissecting the biology of health disparities and may be instructive in genotype-based diagnosis and target intervention in the emergence of personalized genomic medicine.

SLE is a chronic, heterogeneous autoimmune disorder characterized by inflammation, loss of tolerance to self-antigens and dysregulated interferon responses. In this study, we sought to replicate a putative association at 11p13 from a genome-wide association (GWA) study not yet exceeding the stringent threshold for genome-wide significance (typically $P<5x10^{-8}$). Genotyping was performed using Illumina iSelect technology. Stringent quality control measures were applied for Hardy-Weinberg proportions, proportion of missing genotypes and missingness between cases and controls. After quality control filtering, 3562 SLE cases and 3491 controls of European ancestry, 1527 cases and 1811 controls of African-American (AA) descent and 1265 cases and 1260 controls of Asian origin were included in the replication analysis. Dominant, recessive and additive genetic models were computed under a logistic regression model, adjusting for gender and three principal components (to adjust for admixture). Stouffer's weighted Z_{trend} scores were calculated for a meta-analysis between the GWA and replication results. Our GWA scan identified two SNPs in strong linkage disequilibrium (LD, $r^2=0.94$) located ~74kb telomeric to *CD44* showing suggestive evidence of association with SLE in cases of European descent (rs2732552, $P=0.004$, OR=0.78, 95%CI=0.69-0.93; rs387619, $P=0.003$, OR=0.78, 95%CI=0.68-0.91). We observed independent replication at both rs2732552 ($P=9.03x10^{-8}$, OR=0.83, 95%CI =0.77-0.88) and rs387619 ($P=7.7x10^{-7}$, OR=0.83, 95%CI=0.77-0.90) in the European samples with a $P_{combined}=1.82x10^{-9}$ for rs2732552. The AA and Asian SLE cases also demonstrated association at rs2732552 ($P=5x10^{-3}$, OR=0.81, 95%CI=0.70-0.94 and $P=4.3x10^{-4}$, OR=0.80, 95%CI=0.70-0.91, respectively). The Asian SLE cases were associated with rs387619 ($P=0.001$, OR=0.8 95%CI=0.70-0.91), but not the AA SLE cases, consistent with differences in the haplotype patterns between racial groups. The meta-analysis at rs2732552 for all 4 ethnic groups produced $P_{combined}=3.00x10^{-13}$. We have established genetic association with SLE to a haplotype near *CD44*. Imputation and trans-ethnic mapping focus the effect on a ~14kb haplotype in a region of strong regulatory potential that may influence expression of the centromeric gene *CD44*. This locus contains multiple regulatory sites that could potentially affect expression and functions of *CD44*, a cell-surface glycoprotein influencing immunologic, inflammatory and oncologic phenotypes.

CYP4F2 genetic variant and the risk of stroke. *A. Munshi[1], V. Sharma[1], S. Kaul[2], A. Jyothy[1].* 1) Molecular Biology, Institute of Genetics and Hospital for Genetic Dis, Hyderabad, Andhra Pradesh, India; 2) Nizams Institue of Medical Sciences, Panjagutta , Hydearbad, India.

Stroke is a complex disease caused by combination of multiple risk factors. Recent findings have suggested that stroke has a strong genetic component. Evidence suggests that variations in CYP4F2 gene may influence stroke risk. CYP4f2 is an enzyme of cytochrome P450 enzymes which metabolize arachidonic acid to 20-hydroxyeicosatetraenoicacid (20-HETE).On the CYP4f2 gene , a guanine to adenine missense transition at1347 nucleotide results in valine to methionine amino acid substitution at residue 433(rs2108622). The present study was carried out to investigate the role of this gene variant with stroke and stroke subtypes in a South Indian population from Andhra Pradesh. Five hunderd patients with ischemic stroke and four hundred and eighty control subjects were enrolled in this case-control study. Ischemic stroke subtypes were classified according to TOAST (Trial of Org 10172 in Acute Stroke Treatment) classification. The results will be discussed.

961/W

Analysis of common *SCN9A* polymorphisms in clinical pain phenotypes. *S. Paciga[1], R. Lowe[2], J. Wheeler[2], G. Johnston[3], S. John[1], K. Tan[4], D. Williams[5], C. Hyde[6].* 1) Molecular Medicine, Pfizer Global Research & Development, Groton, CT; 2) Quanticate Ltd, Hitchin, UK SG5 1LH; 3) Molecular Medicine, Pfizer Global Research & Development, Sandwich, UK, CT13 9NJ; 4) Translational Medicine, Pfizer Global Research & Development, Sandwich, UK, CT13 9NJ; 5) Pain Research Unit, Pfizer Global Research & Development, Sandwich, UK, CT13 9NJ; 6) Clinical Research Statistics, Pfizer Global Research & Development, Groton, CT.

Previous research has mapped familial cases of congenital inability to experience pain to loss of function mutations in the gene *SCN9A*, which encodes the α-subunit of $Na_V1.7$, a sodium channel expressed in peripheral nerves. Subsequently, common polymorphisms in *SCN9A* have been reported to be associated to pain perception and sensitivity in general populations of patients with osteoarthritis and other pain conditions. We genotyped 32 single nucleotide polymorphisms spanning the *SCN9A* locus, including 5 markers previously reported by Reimann *et al.* (PNAS 107:5148-5153, 2010), in 2461 subjects of European ancestry with a clinical diagnosis of osteoarthritis (OA), Post-Herpetic Neuralgia (PHN), or Diabetic Peripheral Neuropathy (DPN). All patients were recruited into clinical trials where pain was self-reported at baseline or upon entry to the clinical trial. Each quantitative pain phenotype was analyzed independently, and within each phenotype a meta-analysis was conducted across studies. None of the 32 SNPs were significantly associated with pain severity in any of the three phenotypes after adjustment for multiple testing. The missense SNP rs6746030, with a reported functional impact, had the following unadjusted association results: for PHN, p=0.658; for OA, p = 0.54; and for DPN, p=0.038. This study had 94-98% power to nominally replicate the previous findings for the 5 markers in the OA pain phenotype, but all had unadjusted p > 0.1, and the effect estimate in rs6746030 for OA was in a direction opposite to what was previously reported. These data do not provide additional evidence supporting the role for common polymorphisms in *SCN9A* in osteoarthritis-induced pain. Further, we were unable to detect any significant associations in neuropathic pain when accounting for multiple testing. The ability to detect such associations may have been reduced due to the inclusion criteria of the studies eliminating subjects with lower pain scores. Additional comprehensive genotyping in clinically well characterized data sets will be required to determine if common alleles in this gene are associated with pain severity.

Genetic susceptibility profiles are different between pulmonary and extrapulmonary injury-related acute respiratory distress syndrome. *P. Tejera[1], F. Chen[1], C.C. Sheu[1], R. Zhai[1], Z. Wang[1], L. Su[1], E. Bajwa[2], A. Ahasic[2], P. Clardy[3], D. Gallagher[3], M. Gong[4], A.J. Frank[2], T.B. Thompson[2], D.C. Christiani[1,2].* 1) Environmental, Harvard Sch Pub Hlth, Boston, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Beth Israel-Deaconess Hospital, Boston, MA; 4) Montefiore Hospital, Albert Einstein School of Medicine, New York, NY.

Rationale: Acute respiratory distress syndrome (ARDS) can result from a direct (pulmonary) injury or an indirect (extrapulmonary) injury. Previous studies have suggested that the pathophysiological, biochemical, radiological, and mechanical patterns between ARDS derived from these two types of injury are different. However, genetic backgrounds underlying the differences between ARDS resulting from pulmonary and extrapulmonary injury are unknown. This work is intended to identify genetic variants that contribute to susceptibility to pulmonary and extrapulmonary injury-related ARDS. **Methods**: 1717 Caucasian critically ill patients at risk for ARDS were included in the present study. Patients with pneumonia, aspiration, pulmonary contusion or sepsis and/or bacteremia from pulmonary sources as risk factor for ARDS were categorized as having pulmonary injury. Patients with extrapulmonary injury were those with trauma, multiple transfusion or sepsis and/or bacteremia originated from extrapulmonary sources. Patients with both types of lung injury were excluded from the study. Genotyping was carried out using Illumina HumanCVD BeadChip. SNPs with MAF < 0.05 were removed. Genetic association with ARDS risk was analyzed using multivariate logistic regression (additive model) adjusted for age, gender, and APACHE III score. **Results**: 417 ARDS cases (126 with pulmonary injury and 291 with extrapulmonary injury) and 1300 controls (741 with pulmonary injury and 559 with extrapulmonary injury) were included in the study. After quality control, 31530 SNPs were analyzed. Top SNPs associated with pulmonary injury-related ARDS were found in *PRKAG2* (rs7807769; p = 1.6 x 10-5, rs7801616; p = 4.4 x 10-5) and *BVES* (rs1190286; p = 5.3 x 10-5). Two SNPs in *VWF* and two SNPs on chromosome region 19q13.3-13.42 (*KLK2-ISG15*) were associated with extrapulmonary injury-related ARDS at p < 4 x 10-4 (top SNP rs198977, p = 2.1 x 10-4). Interestingly, none of the 29 SNPs (in 21 genes) associated with pulmonary injury-related ARDS (p < 10-3) was associated with extrapulmonary injury-related ARDS (p > 0.200). On the other hand, none of the 27 SNPs (in 19 genes) associated with extrapulmonary injury-related ARDS (p < 10-3) was associated with pulmonary injury-related ARDS (p > 0.054). **Conclusion**: Our study suggests that injury-related genetic variants may contribute to ARDS risk. Further validation of our findings in independent populations is ongoing. FUNDED BY:NIH (HL60710, ES00002).

Evaluation of MMP-1 and MMP-3 Gene Promoter polymorphisms in Chronic Pancreatitis. *A. Venkateshwari[1], K. Srimanjari[1], D. Krishnaveni[1], A. Vidyasagar[2], K. Prabhakar[3], P. Nallari[4], A. Jyothy[1].* 1) Cell Biology, Institute of Genetics and Hospital for Genetic Diseases,Osmania University, Hyderabad; 2) Department of Gastroenterology,Gandhi Hospital ,Hyderabad; 3) Department of Gastroenterology,Osmania General Hospital,hyderabad; 4) Department of Genetics ,Osmania University, Hyderabad.

Chronic Pancreatitis is a progressive disease characterized by irreversible destruction of exocrine pancreatic tissue and extensive fibrosis. Matrix metalloproteinases (MMP) belong to a large group of proteases capable of breaking essential components of extracellular matrix. Polymorphism in the promoter region of MMP1 and MMP3 gene leads to a variation in its level of expression and found to be associated with various disorders. The aim of study is to investigate possible genetic associations of matrix metelloproteinase-1(MMP1) and matrix metelloproteinase-3 (MMP3) gene polymorphism with chronic pancreatitis. A total of 96 chronic pancreatitis patients and an equal number of unrelated age and gender matched control subjects were included in the present study. MMP1 (-1607) 1G/2G and MMP3 (-1171) 5A/6A polymorphisms were determined using standard Polymerase chain reaction- Restriction fragment length polymorphism and ARMS -PCR methods respectively. Differences in allele and genotype distributions were analyzed using appropriate statistical methods. A significant increase in the frequency of 2G/2G genotype of MMP1 polymorphism was observed in patients compared to control subjects, whereas there was no significant difference for the MMP3 5A/6A polymorphism. These findings suggest the possible association of MMP 1 gene polymorphism in the development of disease.

964/W

Association between Common Polymorphisms of COCH and Primary Open-angle Glaucoma in a U.S. Caucasian Population. *D.Y. Wang[1], L.R. Pasquale[1], D. Rhee[1], J.L. Haines[2], J.L. Wiggs[1].* 1) Department of Ophthalmology, Harvard Medical School, Massachusetts Eye & Ear Infirmary, Boston, MA; 2) Center for Human Genetic Research, Vanderbilt University School of Medicine, Nashville, Tennesse.

Purpose: Primary open-angle glaucoma (POAG) is the second leading cause of blindness worldwide and is characterized by degeneration of the optic nerve that is usually associated with elevated intraocular pressure. Twenty genetic loci have been linked to POAG, from which three causative genes are identified, however mutations in these genes only account for about 10% of patients with POAG. Genome-wide association studies have identified several single nucleotide polymorphisms (SNPs) associated with POAG but no annotated genes are linked to these SNPs. Our previous genome-wide scan of Caucasian siblings with POAG identified a linkage locus on 14q11, and fine-mapping of this region has identified a 3.5 Mb region likely to harbor a susceptibility gene. Twelve genes are located in this region and of these, the coagulation factor C homolog (COCH) gene has been shown to have increased expression in glaucoma in mouse and human eyes. The purpose of this study is to investigate common COCH polymorphisms for association with POAG. **Methods**: Fifteen tagging SNPs in the vicinity of COCH, capturing 100% of alleles with mean r-square of 0.95 were genotyped in 539 Caucasian patients with POAG and 336 controls, as well as SNPs located in the 5' promoter region (rs3759777 and rs8015095). SNP association analysis was performed for POAG by Fisher's exact test and Wald test. **Results**: All SNPs followed Hardy-Weinberg equilibrium in both cases and controls. No significant association was found between the tagging SNPs or the promoter region SNPs and POAG overall ($p>0.16$). However, subgroup analysis showed that rs8015095 was significantly associated with higher intraocular pressure and increased disease severity ($p\text{-trend}=0.0058$). **Conclusions**: Previous studies have suggested that transcriptional upregulation of COCH may occur in glaucoma. SNP rs8015095 is located 500 bp from the transcription start site and about 1500 bp from conserved binding sites for transcription factors FOXO3, FREAC4 and FREAC2. Our results suggest that rs8015095 may influence COCH gene expression or may be in linkage disequilibrium with other variants that could affect promoter efficiency. Further studies of COCH promoter activity in glaucoma patients could define a role for Cochlin in the disease. **Grant support**: NEI Grants R01EY015872 and P30EY014104, Research to Prevent Blindness and The Massachusetts Lions Eye Research Fund.

965/W

Association of variants in the NF-kB regulatory pathway loci with systemic lupus erythematosus in multiple populations. *F. Wen[1,21], G. Wiley[1,21], I. Adrianto[1,21], K.M. Kaufman[1,2,3], J.M. The transcription factor NF-kB is an important factor in inflammation and the immune response. Unrestrained NF-kB response has previously been associated with autoimmune disease, sepsis, and some cancers. It is therefore not surprising that NF-kB signaling is tightly regulated within the cell through a pathway of protein-protein interaction and post-translational protein modification. One key component of this pathway is the *TNFAIP3* complex consisting of *TNFAIP3*, *TNIP1*, *TNIP2*, *TAX1BP1*, *ITCH*, and *RNF11*. This complex, along with the ubiquitin-conjugating enzyme *UBE2L3*, deactivates NF-kB pathway proteins through deubiquitation of K63 polyubiquitin chains and subsequently targets those proteins for degradation via K48 ubiquitination. Recent GWAS have revealed that genetic variants in the *TNFAIP3*, *TNIP1*, and *UBE2L3* regions are associated with systemic lupus erythematosus (SLE) in subjects of European and Asian ancestry. SLE is an autoimmune disease characterized by loss of tolerance to self-antigens and dysregulated interferon responses. To further characterize and localize the effect of the *TNFAIP3* regulatory complex, we genotyped and imputed single-nucleotide polymorphisms (SNPs) within and flanking *TNIP1* on 5q33, *TNIP2* on 4p16, *UBE2L3* on 22q11, *TAX1BP1* on 7p15 in multiple populations: African-Americans (1,569 cases, 1,893 controls), Asians (1,328 cases, 1,348 controls), Europeans (4,248 cases, 3,818 controls), Gullah (155 cases, 131 controls), and Hispanics enriched for Amerindian-European admixture (1,622 cases, 887 controls). Using the Illumina iSelect system, we genotyped a total of 231 SNPs in and around those loci and 343 ancestry-informative markers (AIMs). We then imputed untyped SNPs at those loci using HapMap Phase III and 1000 Genomes Project data. We assessed single marker association to SLE using logistic regression with sex and global ancestry adjustments. We observed strong associations between SLE and multiple SNPs within *TNIP1* in Europeans, Hispanics, African-Americans, and Asians ($P_{combined}<5 \times 10^{-8}$) with the strongest signal at rs7708392 ($P_{combined}=2.53 \times 10^{-19}$). We also identified strong associations within *UBE2L3* in Europeans, Asians, African-Americans and Hispanics with the most significant association at rs7444 ($P_{combined}=1.25 \times 10^{-14}$). These results establish that variants within *TNIP1* and *UBE2L3* contribute to differential risk of SLE in multiple populations.

Evaluation of muscle contraction genes role in isolated clubfoot. *K.S. Weymouth[1,2], S.H. Blanton[3], M.B. Dobbs[4], C.A. Gurnett[4], L.E. Mitchell[5], J.T. Hecht[1,2].* 1) Dept Pediatrics, Univ Texas Medical Sch, Houston, TX; 2) Graduate School of Biomedical Sciences, Houston, TX; 3) University of Miami Miller School of Medicine, Miami, FL; 4) Washington School of Medicine, St. Louis, MO; 5) University of Texas School at Public Health, Houston, TX.

Clubfoot is a common birth defect that affects 4000 newborns in the US each year. Isolated clubfoot is characterized by an inward turning of the foot towards the midline of the body that is held in a rigid, downward position. Calf muscles in the affected leg(s) are underdeveloped and remain small even after corrective treatment. Syndromes with a complex phenotype have been used to identify candidate genes for isolated conditions. Distal Arthrogryposis (DA) is a rare genetic disorder that is characterized by congenital contractures with clubfoot associated with some DA subtypes. Mutations in five different genes encoding proteins that play key roles in muscle contraction cause four types of DA. Interrogation of fifteen muscle contraction genes in our discovery clubfoot population identified positive associations with twelve genes. Six SNPs in TNNC2 were out of Hardy Weinberg Equilibrium (HWE) in our NHW discovery population with only the mothers deviating from HWE, suggesting a maternal effect. Relative risk and likelihood ratio tests showed evidence for a maternal genotype effect with two SNPs, rs4629 and rs383112. The strongest associations were with TPM1, MYH13 and TNNT3. Single SNP, 2-SNP haplotypes and gene interactions found evidence of an association with potential regulatory SNPs located near fourteen of the fifteen muscle contraction genes. This suggests that perturbation of gene expression in muscle contraction genes contributes to clubfoot and is being examined in functional assays. To confirm these findings, validation studies were performed in case-control and second clubfoot family-based (144 NHW) populations. Positive associations were again identified for TPM1 in both populations (rs12148828/p=0.04 and rs1972041/p=0.000074, respectively). In addition, the association with rs2734495 in TNNT3, was also validated (p=0.04). Four TPM1 2-SNP haplotypes, all containing rs1972041 (p<0.001) were overtransmitted in the validation population. In complimentary studies, we have found association with apoptotic genes. Apoptosis and muscle contraction are two key components in limb development. Gene interactions between apoptotic and muscle contraction genes are being evaluated. Altogether, these results further suggest that perturbation of muscle contraction genes play a role in clubfoot and define an etiologic pathway for clubfoot.

967/W

RUNX2 Polymorphisms in Patients with Nonsyndromic Sagittal Craniosynostosis. *G. Yagnik[1], H. Drissi[2], C. Stevens[1], S. Boyadjiev Boyd[1].* 1) University of California, Davis, Davis, CA; 2) Department of Orthopedics, University of Connecticut, Health Center.

Craniosynostosis (CS), the premature fusion of one or more cranial sutures, is a common malformation occurring in 3 to 5 per 10,000 live births. In 85% of the cases, it occurs as an isolated (i.e. nonsyndromic) anomaly. RUNX2 is a transcriptional activator of osteoblast differentiation and thus a potential candidate gene for nonsyndromic CS. Our work to date has shown that polymorphisms within RUNX2 may lead to gain-of-function (GOF) of the protein, as demonstrated by dual-luciferase analysis of the RUNX2 R237C polymorphic variant. Based on this work, we hypothesize that GOF variants in RUNX2 may contribute to the development of nonsyndromic sagittal CS. We are currently screening a large cohort of patients for additional polymorphisms to support this, as well as interrogating a previously described RUNX2 isoform with an 18 bp deletion leading to a truncated Q/A domain.

Allelic Expression Imbalance Analysis under the Chromosome 1q21-24 Linkage Peak for Type2 Diabetes Shows Cis- Regulatory SNPs. *AK. Mondal, SK. Das, NK. Sharma, KA. Langberg, SC. Elbein.* Int Med,Endocrinology, Wake Forest University Health Sciences, Winston-Salem, NC.

Linkage of the chromosome 1q21-24 region to T2D has been demonstrated in multiple ethnic groups, but fine-mapping failed to identify common variants contributing to the linkage. We hypothesized that the linkage signal resulted from multiple common, noncoding regulatory variants, many of which act in cis to regulate adjacent transcripts. We designed a screening strategy based on allelic expression imbalance (AEI), which examines relative levels of maternal and paternal alleles in transcribed single nucleotide polymorphism (cSNP) from heterozygous individuals. We compared AEI for heterozygous individuals in cDNA derived from transformed lymphoblastoid (TL) cell line RNA to allelic imbalance calculated from genomic DNA (gDNA) using pyrosequencing. We identified 176 genes under the 22 Mb linkage peak that were both expressed in TL and had a known cSNP with minor allele frequency over 5%. From these, we have tested 69 cSNPs for 69 genes in 95 European American (EA), and in 95 African American (AA) TLs. We considered significance based on comparison of cDNA to gDNA in at least 4 heterozygous individuals using the nonparametric Wilcoxan sign rank test at nominal p£ 0.05. We observed significant AEI for 33 cSNPs in EA of which 20 cSNPs also showed AEI in AA. An additional 13 cSNPs showed AEI only in AA cell lines. Among the genes showing AEI in both populations were *SLAMF7, THEM4, ADAR, RIT1, EFNA1, ATF6, UBAP2L, SCYL3, SNAPIN, SELL, MEF2D, SLC25A44, SLC39A1, CD84, DAP3, ARHGAP30, PKLR/HCN3 , SYT11* and *PMVK*, with EA p values of 0.05 to 7x10-8. Additional genes seen only in EA included *USF1, RFX5, CD48, CD244, EFNA3, POGK, CRLA, SNX27, ADAM15, MPZL1, PBXIP1, SLAMF8* and *GATAD2B*. Genes showing highly significant (p <2 x10-4) allelic imbalance only in AA population were *IL6R, CRTC2, ZBTB7B, CRTC2, ISG20L2* and *IQGAP3*. Using a conservative test for AEI (Bonferroni corrected p£0.05), we find evidence for cis-acting variants in approximately 23% of the EA SNPs, with replication in two populations for 7/69 SNPs with more testing ongoing. These results support our hypothesis that cis-acting regulatory variants under linkage peaks are common, and include known genes with metabolic effects (*ATF6, USF1, THEM4, SLC39A1*, and others). Studies of remaining genes are in progress. Further functional analysis and fine mapping studies are needed to identify functional SNPs for type 2 diabetes.

969/W

Association of RNASEH1 SNPs with Type 1 Diabetes in Colombian families. *N. Pineda-Trujillo[1], A. Rodriguez-Acevedo[1], J. Gutierrez-Achury[1], G. Bedoya[2], F. Uribe[3], A. Ruiz-Linares[2, 4], V. Balthazar[1], J-M. Alfaro[1].* 1) Mapeo Genetico, Department of Pediatrics, University of Antioquia, Medellin- Colombia; 2) GENMOL, University of Antioquia. Medellin-Colombia; 3) Endocrinologia y Metabolismo, Medicine Faculty, University of Antioquia. Medellin-Colombia; 4) Department of Biology, University College London, UK.

Type 1 diabetes (T1D) is a complex trait in which genetic and environmental factors are involved. We have previously found linkage and association of T1D to 2p25. Our purpose was to analyze the role of the gene RNASEH1 in the susceptibility to T1D in one hundred Colombian families. RNASEH1 locates at 2p25. One hundred familial trios with T1D from Antioquia-Colombia were analyzed. In patients sera autoantibodies against anti-GAD, anti-IA2 and anti-TPO were tested. We began typing the RNASEH1 intragenic SNPs rs10186193 and rs7563960. According to the first results we then typed four extra SNPs in RNASEH1. These SNPs were rs11538545, rs760788, rs 6730126 and rs55981318. SNPs typing was done by PCR-RFLP and Tetraprimer-ARMS methods. Genetic association analysis was done by the transmission disequillibrium test (TDT). Positive autoantibodies were found in 73%, 41% and 17% for anti-IA2, anti-GAD and anti-TPO, respectively. Together, 86% of the affected individuals were positive for at least one auto-antibody. SNP rs10186193 showed significant association with T1D (p=5.3x10-3). Further SNPs typing in RNASEH1 showed that SNP rs760788 was also associated (p value= 9,6x10-4). Even though the significance decreased, a stratified analysis by autoimmune and idiopathic cases was still significant. Autoimmunity was found in similar proportions to previous reports. It was also found that two out of six SNPs tested at RNASEH1 gene are associated with T1D in the sample analized. Haplotype analysis is currently being done. Our results indicate a causative participation of the gene RNASEH1 in T1D. Evaluation of these three SNPs in an independent sample, from the same region in Colombia, is underway. It is interesting that this region has not been shown in previous GWAS. This study was funded by COLCIENCIAS grants # 111534319156 and 111540820532.

Keating[10].* 1) Center for Human Genetic Research & DACCPM, Massachusetts General Hospital, Boston, MA; 2) Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 3) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN; 4) Department of Epidemiology, Johns Hopkins School of Medicine, Baltimore, MD; 5) NHLBI's Framingham Heart Study, NIH, Boston, MA; 6) Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 7) Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 8) University of Mississippi Medical Center, Jackson MS; 9) Center for Clinical Investigation, Case Western Reserve University, Cleveland, OH; 10) Center for Applied Genomics, Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 11) Dept. of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia PA; 12) Department of Internal Medicine, University of South Alabama College of Medicine, Mobile, AL; 13) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC; 14) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 15) Division of Epidemiology, Mayo Clinic College of Medicine, Rochester, MN; 16) Medical Genetics Institute and Division of Medical Genetics, Cedars-Sinai Medical Center, Los Angeles, CA; 17) Department of Medicine, Harvard Medical School, General Medicine Division, Massachusetts General Hospital, Boston MA; 18) Cardiovascular Health Research Unit, Departments of Medicine and Epidemiology, University of Washington, Seattle, WA.

Type 2 diabetes (T2D) poses a large public health burden. Although candidate gene and genome-wide association analyses (GWAS) have found >30 T2D loci primarily in European populations, these variants explain <10% of the genetic contribution to inter-individual risk. Examination of candidate genes in multi-ethnic populations may identify additional variants and pathways dysregulated in T2D. Through a collaborative effort, the Candidate Gene Association Resource (CARe), we combined results for T2D across nine cohort studies genotyped for ~50,000 SNPs in 2016 candidate genes. Forty-nine candidate genes (~5000 SNPs) were specifically selected based on prior evidence in Mendelian diabetes, diabetes patho-physiology, linkage studies and meta-analyses of GWAS. Component studies included ARIC, CARDIA, CFS, CHS, FHS, JHS and MESA comprising 1794 cases and 7485 controls of African-American ancestry and 2636 cases and 21,944 controls of European-American ancestry. An additive genetic model with age, sex and 10 principal components to adjust for ancestry was used to test for genetic association, and results were combined by a fixed-effects inverse variance meta-analysis. In African-Americans, study-wide significant ($P<2x10^{-6}$) association after Bonferroni correction was observed for SNPs at *TCF7L2* ($P=3x10^{-11}$) and *HMGA2* (rs9668162 $P=6x10^{-8}$). *HMGA2* is a transcription factor that regulates a known diabetes gene, *IGF2BP2*, and a T2D signal near *HMGA2* ($r^2=0.005$ in CEU, $r^2=0.35$ in YRI) has recently been identified in Europeans. Rare SNPs (<5% MAF) in *EDN2*, *KCNQ1* and *ARNT* showed suggestive ($P<1x10^{-4}$) evidence of association with T2D in African-Americans. In European-Americans, we confirmed known loci, with SNPs at *TCF7L2*, *GCKR*, *IGF2BP2*, *FTO*, chr11p12 and *CDKAL1* exceeding study-wide significance, and found novel SNPs at *MSRA*, *HSF1* and *KCNJ1* with suggestive evidence. Little overlap of signals was found between the ethnicities, even though the African-American sample had ~80% power to detect European risk alleles on the array at α=0.05. Meta-analyses with additional T2D case control studies in samples of European and African-American ancestry are ongoing and should increase power to discriminate true T2D genes from false positives. In summary, meta-analysis of IBC chip data from nine CARe cohorts identified several putative novel associations in African- and European-Americans that should provide additional biological clues about the pathogenesis of type 2 diabetes.

Genotype score of common susceptible genotypes for prediction of type 2 diabetes in Japanese: the J-SHIPP study. *y. tabara, h. osawa, r. kawamoto, h. onuma, k. kohara, h. makino, t. miki.* Ehime University Graduate School of Medicine, Toon, Japan.

BACKGROUNDS: Recent genome wide association studies (GWAS) have successfully identified several genotypes susceptible for type 2 diabetes (T2DM). These associations have been replicated in various populations including East-Asians. In contrast to the accumulated evidence for a cross-sectional association, however, only a few studies have investigated whether these variations confer a risk of the future development of T2DM. Here, to clarify the prognostic significance of these T2DM-associated variants, we conducted a longitudinal genetic epidemiological study in a community-dwelling general population.

RESULTS: Among 21 recently identified candidate SNPs, significant association was observed in the KCNQ1, TCFL72, CDKAL1, HHEX, IGF2BP2, CDKNN2B, SLC30A8, KCNJ11, PPARG and GCKR in replication analysis in the 506 T2DM case and 402 non-diabetic control subjects. To clarify the prognostic significance of the T2DM SNPs in the development of diabetes, we retrospectively analyzed the association between genetic risk score calculated by adding the risk allele number of these 10 SNPs and the development of T2DM with 9.4 years follow-up. Among the 1,824 subjects who were not T2DM at baseline, 95 cases of T2DM were newly diagnosed during the follow-up period. These subjects were slightly older (58±9 vs. 56±10 years, p=0.091) and more frequent in male (50.5%; vs. 39.6%;, p= 0.035). The mean risk score in these subjects was significantly higher than that in the 1,729 subjects who remained non-diabetes (9.5±1.8 vs. 9.1±2.0, p=0.042). Although the initial mean BMI (24.7±3.2 vs. 23.0±2.8, p<0.001) and initial glucose (106±18 vs. 90±13 p<0.001) were also significantly higher in those subjects who developed T2DM, the genetic risk score remained an independent determinant of the future development of T2DM after adjustment for these possible confounding factors. Per-allele odds ratio for the development of T2DM was 1.12 (95% C.I. 1.00-1.25), p=0.049. Although none of 10 SNPs showed significant correlation with plasma levels of glucose, as well as insulin levels, HOMA-IR and HOMA-β, the genetic risk score showed stepwise association with plasma glucose levels ($1.2*10^{-6}$) and HOMA-β (p=0.006) after adjustment for possible covariates.

CONCLUSION: A genotype score based on 10 risk alleles predicted new cases of diabetes in the community but provided only a slightly better prediction of risk than knowledge of common risk factors alone.

Epistatic effects between variants of the high affinity IgE receptor (*FCER1A*) confers to eczema risk. *H. Baurecht[1,2], E. Rodríguez[1], A. Naumann[1,3], S. Wagenpfeil[2,3], N. Klopp[4], H.-E. Wichmann[4], K. Van Steen[5], S. Weidinger[1,6].* 1) Department of Dermatology and Allergy , Technische Universität München, Munich, Germany; 2) Graduate School of Information Science in Health (GSISH), Technische Universität München, Munich, Germany; 3) Institute for Medical Statistics and Epidemiology IMSE, Technische Universität München, Munich, Germany; 4) Institute of Epidemiology, Helmholtz Zentrum München, Neuherberg, Germany; 5) Systems and Modeling Unit, Department of Electrical Engineering and Computer Science, University of Liège, Liège, Belgium; 6) Department of Dermatology, University Hospital Schleswig-Holstein, Campus Kiel, Germany.

Atopic diseases (eczema, asthma, rhinitis) are often driven by high levels of total and allergen-specific IgE levels. The high-affinity receptor for IgE, which is composed of one alpha (*FCER1A*), one beta (*FCER1B*), and two gamma (*FCER1G*) subunits, represents the central receptor of IgE-induced reactions. Recently, a genome-wide association analysis identified associations between functional *FCER1A* variants and total serum IgE levels. For the *FCER1B* gene linkage and association with total IgE and atopic traits has been reported previously. So far the *FCER1G* subunit has not been examined on the genetic level with regard to atopic traits. Filaggrin (*FLG*) is the strongest known risk gene for eczema, in particular the allergic subtype of eczema.

We investigated the association of the *FCER1*, *FCER1B* and *FCER1G* variants with total IgE levels in a large population-based cohort and in a large eczema case-control sample. We used the model-based multifactor dimensionality reduction method (MBMDR) to test for epistatic effects. For further exploration, variable importance measures were computed by means of the random forest method.

We could not confirm associations for *FCER1B*, neither did we detect associations with *FCER1G*. However, three strongly correlated *FCER1A* polymorphisms were significantly associated with total and specific IgE levels. After adjustment for *FLG*, we found epistatic effects of the *FCER1A* variants rs10489854 and rs2511211 on eczema risk. In the random forest approach both variants showed positive variable importance values. These results suggest that *FCER1A* variants by themselves and in combination influence IgE levels and act synergistically to influence eczema risk.

Analysis of Genetic Variation in genes associated with Liver Disease in the Mexican Population. *D. Lau-Corona[1,2], J.C Fernandez-Lopez[2], G. Gutierrez-Reyes[1], G. Jimenez-Sanchez[2], D. Kershenobich[1], I. Silva-Zolezzi[2].* 1) Experimental Medicine, UNAM-Hospital General de México, México DF, Mexico; 2) National Institute of Genomic Medicine, Mexico DF, Mexico.

Two recent GWAS found SNPs in 8 genetic regions (*CPN1, CHUK, PNPLA3, SAMM50, HNF1A, GGT1, GPLD1, ABO*) associated to plasma levels of liver enzymes, additionally rs738409[G] variant in *PNPLA3* has been associated with susceptibility to nonalcoholic fatty liver disease and fibrosis progression. In a stratified analysis of these SNPs, US Hispanics had the highest frequency of the risk allele. In Mexico, chronic liver disease (CLD) is the third cause of death in the general population and the first in Amerindian men; in the US it is the twelfth death cause in the general population, sixth in Hispanics and fifth in Native Americans. Our study aims to explore the potential impact of these genetic variants as liver disease risk factors in Mexican Mestizos, as well as their relationship to the Amerindian contribution in this group. We have analyzed the frequency distribution of 12 SNPs associated to liver traits in the Mexican population. We determined their allele frequencies in 243 non-related Mexican Mestizos and 182 Mexican Amerindians of 3 different ethnic groups (Mayas, Zapotecos, Tepehuanes) from the Mexican Genome Diversity Project (MGDP) and included data of the CEU HapMap group. Genotypes were obtained from results of the MGDP with the Affy 500K, and using allelic discrimination assays. We estimated the contribution of the 12 SNPs to individual risk by calculating the number of accumulated risk- or protection-associated alleles. “Risk” was defined as the association either to a positive β coefficient in the analysis of liver enzyme levels, or to a higher liver fat content, while “protection” was defined as a negative β coefficient or lower liver fat content. We observed differences in 10 of 12 risk and protection-associated alleles between Mexican Amerindians and CEU (p£2.8E-7), and in 9 of 12 between Mestizos and CEU (p£1.7E-2). The proportion of individuals with 10 or more risk-associated alleles was, 32% in Amerindians 5% in Mestizos and 0 in CEU, in contrast the proportion of individuals with more than 4 protection-associated alleles was 2% in Amerindians, 8% in Mestizos and 18% in CEU. These results suggest an important contribution of genetic factors with ethnic related differences in CLD. Further analysis will require a comprehensive assessment in Latin American populations of the contribution of variants related to Amerindian ancestry on liver enzyme levels and clinical outcomes, as well as its potential relationship to natural selection.

974/W

High density genomewide linkage analysis of exceptional human longevity identifies multiple novel loci. *S. Boyden[1,2], L. Kunkel[1,2,3].* 1) Dept Genomics, Children’s Hosp, Boston, MA; 2) Dept Genetics, Harvard Medical School, Boston, MA; 3) Howard Hughes Medical Institute, Children’s Hosp, Boston, MA.

Human lifespan is approximately 25% heritable, and genetic factors may be particularly important for achieving exceptional longevity. Accordingly, siblings of centenarians have a dramatically higher probability of reaching extreme old age than the general population. To map the loci conferring this survival advantage, we performed the second genomewide linkage scan on human longevity and the first using a high density marker panel of single nucleotide polymorphisms. By systematically testing a range of minimum age cutoffs in 279 families with multiple long-lived siblings, we identified a locus on chromosome 3p24-22 with a genomewide significant allele-sharing LOD score of 4.02 (empirical P = 0.037) and a locus on chromosome 9q31-34 with a highly suggestive LOD score of 3.89 (empirical P = 0.054). The empirical P value for the combined result was 0.002. A third novel locus with a LOD score of 4.05 on chromosome 12q24 was detected in a subset of the data, and we also obtained modest evidence for a previously reported interval on chromosome 4q22-25. These linkage peaks should facilitate the discovery of both common and rare variants that determine genetic variability in lifespan.

975/W

Evidence of genetic linkage of the Class III Malocclusion phenotype with human chromosome 7 in 35 South American families. *G. Falcao Alencor[1,2,3], L. Otero[4], R.M. Cruz[3], T.M. Foroud[5], L. Dongbing[5], D. Koller[5], L.A. Morford[1,2], I. Ferrari[3], S.F. Oliveira[3], J.K. Hartsfield[2,5,6].* 1) Dept of Oral Health Practice, Univ Kentucky College of Dentistry, Lexington, KY; 2) Hereditary Genomics Laboratory, Center for Oral Health Research, Univ Kentucky College of Dentistry, Lexington, KY; 3) Dept of Genetics and Morphology, Universidade de Brasília - Brazil; 4) Dept of Orthodontics, Pontificia Universidad Javeriana, Bogotá - Colombia; 5) Dept of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 6) Dept Oral Health Science, Division of Orthodontics, Univ Kentucky College of Dentistry, Lexington, KY.

Introduction: Class III Malocclusion is when the sagittal position of the permanent mandibular first molars is more anterior than usual, typically with the mandibular incisors beyond the maxillary incisors. This dental relationship is usually caused by overgrowth of the mandible, undergrowth of the maxilla or a combination of both. Recent studies have indicated genetic linkage of Class III Malocclusion in humans with chromosomes 1p, 3q, 11q, and 12q in four Colombian families, and chromosomes 1p, 6q and 19p in Japanese and Korean brothers. **Aim:** Identify the genetic loci that contribute to Class III Malocclusion in 35 Colombian and Brazilian families using linkage analysis. **Methods:** The project was approved by: the National Committee on Research Ethics, Brazil; the Research and Ethics Committee of Pontificia Universidad Javeriana, Colombia; and the University of Kentucky IRB. Blood and saliva from 156 individuals belonging to 21 unique families in Colombia, and 77 individuals belonging to 14 unique families in Brazil, were collected for DNA isolation. Each family contained at least two Class III-affected members within the pedigree. DNA from 40 individuals in the most informative family (#9 from Colombia) was analyzed on the *Illumina® Infinium HumanLinkage-12* SNP-based array panel and suggested linkage of a region of chromosome 7 to the Class III phenotype. Based on the array results, three SNPs on chromosome 7 (rs1044701, rs1299548, and rs1882600) that showed evidence of linkage within Family 9, and five additional (rs1294611, rs9640034, rs9640038, rs11526212, and rs7800782), were genotyped in the remaining 34 Colombian and Brazilian families using TaqMan-based single point genotyping and were statistically analyzed for linkage to the Class III phenotype. **Results:** Suggestion of linkage (LOD= 2.36) was found at SNP rs1882600 for all the families. rs1882600 is an intergenic SNP, residing between the *C1GALT1* and *COL28A1* genes on chromosome 7, specifically 7p21.3. The *Sp8* gene is also located in this region, which may play a role in chondrogenic and osteoblastic differentiation. **Conclusion:** The Class III phenotype is a heterogeneous autosomal dominant trait with variable expressivity and incomplete penetrance. This study demonstrates the novel finding that a region of human chromosome 7 near SNP rs1882600 may contribute to this phenotype. Studies are underway to fine map this region of chromosome 7 within the 35 families described in this study.

976/W

Analysis of SNPs with an effect on gene expression identifies UBE2L3 and BCL3 as risk genes for Crohn's disease. *K. Fransen[1,2], M.C. Visschedijk[2,3], S. van Sommeren[1,2], J.Y. Fu[1], L. Franke[1], E.A.M. Festen[1,2], P.C.F. Stokkers[4], A.A. van Bodegraven[5], J.B.A. Crusius[6], D.W. Hommes[7], P. Zanen[8], D.J. de Jong[9], C. Wijmenga[1], C.C. van Diemen[1], R.K. Weersma[2].* 1) Department of Genetics, University Medical Centre Groningen, Groningen, Groningen, Netherlands; 2) Department of Gastroenterology and Hepatology, University Medical Centre Groningen, University of Groningen, Groningen, the Netherlands; 3) Department of Gastroenterology, Isala Klinieken, Zwolle, Overijssel, the Netherlands; 4) Department of Gastroenterology and Hepatology, Academic Medical Centre, Amsterdam, the Netherlands; 5) Department of Gastroenterology and Hepatology, VU University Medical Centre, Amsterdam, the Netherlands; 6) Laboratory of Immunogenetics, Department of PathologyVU University Medical Centre, Amsterdam, the Netherlands; 7) Department of Gastroenterology and Hepatology, Leiden University Medical Centre, Leiden, the Netherlands; 8) Department of Pulmonology, University Medical Center Utrecht, Utrecht, the Netherlands; 9) Department of Gastroenterology and Hepatology, Radboud University Nijmegen Medical Centre, Nijmegen, the Netherlands.

Background and Aims: Genome-wide association studies (GWAS) for Crohn's disease (CD) have identified loci explaining ~20% of the total genetic risk of CD. Part of the other genetic risk loci is probably partly hidden among signals discarded by the multiple testing correction needed in the analysis of GWAS data. Strategies for finding these hidden loci require large replication cohorts and are costly to perform. We adopted a strategy of selecting SNPs for follow-up that showed a correlation to gene expression (cis-eQTLs) since these have been shown more likely to be trait associated. Materials and methods: First we show that there is an overrepresentation of cis-eQTLs in the known CD-associated loci. Then SNPs were selected for follow-up by screening the top-500 SNP hits from a CD GWAS dataset. We identified 10 cis-eQTL SNPs. These 10 SNPs were tested for association to CD in two independent cohorts of Dutch CD patients (1539) and healthy controls (2648). Results: Three SNPs were significantly associated to CD in the initial replicaton phase, these were selected for follow-up. In a combined analysis two of these cis-eQTL SNPs were associated to CD rs2298428 in UBE2L3 ($p=5{,}22 \times 10^{-05}$) and rs2927488 in BCL3 ($p=2{,}94 \times 10^{-04}$) After adding additional publicly available data from previously reported meta-analysis the association with rs2298428 almost reached genome wide significance with a p-value of 2.40×10^{-07} and the association with rs2927488 was corroborated($p=6.46 \times 10^{-04}$) Discussion: We have identified UBE2L3 and BCL3 as novel risk genes for CD. UBE2L3 is also associated to other immune-mediated diseases. These results show that eQTL-based pre-selection for follow-up is a useful approach for identifying risk loci from a moderately sized GWAS.

977/W

Evidence of a novel candidate gene at 7q11 regions in Intracranial aneurysm based on positional screening in patients from South India. *M. Banerjee[1], L.V. Koshy[1], H.V. Easwer[2], S. Premkumar[3], J.P. Allapatt[3], R.N. Bhattacharya[2].* 1) Dept Human Molecular Genetics, Rajiv Gandhi Center Biotechnology, Thiruvananthapuram Kerala, India; 2) Department of Neurosurgery, Sree Chitra Tirunal Institute for Medical Sciences and Technology, Thiruvananthapuram, Kerala; 3) Dept. Of Neurosurgery, Calicut Medical College, Calicut.

Intracranial aneurysm is a fairly common condition that is often asymptomatic until the time of rupture, resulting in Aneurysmal subarachnoid hemorrhage (aSAH), ensuing significant morbidity and mortality. The reported prevalence rate of intracranial aneurysms in India varies from 0.75% to 10.3 % as determined in angiographic and autopsy studies. The pathogenesis of intracranial aneurysms has a multifactorial origin, where the essential defect of the arterial wall may, at least in part be genetically determined. Till date, 13 different susceptibility loci have been identified for intracranial aneurysm in different populations, which suggests its complex nature as well as the likelihood of clinical and genetic heterogeneity among populations. In, the present study we tested for association based on positional screening of 7q11 region using 12 STR markers spanning 33.67 cM in south Indian patient population. The study design was a case-control based association study comprising of 150 patients having angiographically documented saccular aneurysms with SAH and 175 controls selected from ethnically and geographically matched subjects. A positive association was detected for D7S2421 microsatellite marker positioned in intron 21 of the MAGI2 gene. Additionally 13 SNPs spanning 1.1 Kb surrounding the D7S2421 marker were further genotyped to identify risk conferring alleles in MAGI2 gene, which may be in LD with this microsatellite marker. rs12539225 and rs12531571 revealed significant association with IA both at an allelic and genotypic level (p=0.006 and 0.005, respectively). Haplotype analysis also revealed evidence of association with with two locus and three locus combinations of rs12539225 and rs12531571. The rs12539225 though present in the intron, has been found to function as an intronic enhancer, which alters the binding site of a transcription factor in the intronic region. This novel association of MAGI2 gene could open up new avenues for investigation. MAGI2 has been reported to be involved in the tight junction pathway (KEGG: hsa04530). Down-regulation of tight junction proteins has been suggested to trigger and promote cerebral aneurysm formation in rats. Studies have also shown that MAGI2 associates with the tumor suppressor PTEN and enhance PTEN-dependent inactivation of AKT, thus favoring apoptosis. Apoptosis has also been suggested to play a role in the development and rupture of intracranial aneurysms.

978/W

Copy Number Variations in Shortsightedness (Myopia). *M. Schache, M. Dirani, A.J. Richardson, P.N. Baird.* Centre for Eye Research Australia, University of Melbourne, Royal Victorian Eye and Ear Hospital, Melbourne, Australia.

Myopia is a complex disease influenced by genetic and environmental factors. Many genome-wide linkage and candidate gene association studies have been undertaken for myopia but these have had little impact on our understanding of its causative genetic variants. We hypothesize that copy number variations (CNVs) may play a role in myopia and to date the role of CNVs in myopia is relatively unexplored. To test this hypothesis we undertook a pilot study using a subset of twins from the Genes in Myopia (GEM) study. For the pilot study, 87 unrelated individuals including 51 myopic cases and 36 controls were genotyped using the Illumina Human610-Quad BeadChips. Output data was analyzed using the PennCNV software package for CNV calling. Frequencies of CNVs were compared between cases and controls using the Fisher Exact test. The quality of data from the pilot study was high with the average oligonucleotide call rate for each sample being 99.84%±0.07. A total of 3,250 CNVs were identified. Of these, 14 CNVs showed a statistically significant difference ($p > 0.05$) between myopic cases and controls including 8 deletions and 6 duplications. These CNVs were located in 11 chromosomal regions including 1p13, 2p21, 2q33, 3q26, 4p16, 4q32, 4q32, 6p21, 6p21, 14q11, 15q11. One of these CNVs appears to be novel whilst the remaining 13 have been previously reported in the Database of Genomic Variants. In conclusion, this pilot study suggests that CNVs do play a role in the development of myopia.

Age-varying association of a SNP at 2p16 with primary open angle glaucoma. *L. Chen[1], P.O.S. Tam[1], D.Y.L. Leung[1,2], S.W.Y. Chiang[1], Y.Q. Zheng[3], M.Z. Zhang[3], C.P. Pang[1].* 1) Department of Ophthalmology & Visual Sciences, the Chinese University of Hong Kong, Hong Kong, China; 2) Hong Kong Eye Hospital, Hospital Authority, Hong Kong S.A.R, China; 3) Joint Shantou International Eye Center of Shantou University and the Chinese University of Hong Kong, Shantou, China.

Purpose: Recently, whole-genome linkage analysis and regional fine-mapping have revealed strong association of primary open-angle glaucoma (POAG), a leading cause of irreversible blindness, with two SNPs at the 2p16.3 region in the Afro-Caribbean population of Barbados. In this study, we evaluated these two SNPs (rs1533428 and rs12994401) in Chinese. Methods: Totally 1,245 unrelated Chinese subjects in 3 cohorts were involved: a Hong Kong sample of 184 patients with high-tension POAG (HTG), 206 with normal-tension POAG (NTG) and 230 controls, a Shantou sample of 102 HTG patients and 147 controls, and a Beijing sample of 176 HTG patients and 200 controls. The SNPs were genotyped using TaqMan technology. Results: No significant association was observed between rs12994401 and POAG. In contrast, rs1533428 showed consistent association patterns in all three cohorts. Moreover, an age-varying association was detected for rs1533428 with both HTG and NTG. In the pooled sample, the higher risk genotype (TT+CT) conferred a 2.28- and 1.74-fold of increased risk to late-onset HTG (P=5.03×10-5) and NTG (P=0.011) for patients with age at diagnosis >60 years, whilst the genotypes were not associated with juvenile-onset POAG (aged at diagnosis <35 years). Conclusions: We have identified discrepant association patterns from the initial study and confirmed rs1533428 to be a common genetic marker for POAG. Our results revealed for the first time that a common SNP can predict the risk of late-onset POAG.

980/W

Interaction between rs2476601 SNP of PTPN22 gene and rs10818488 of TRAF1 gene in causing risk for rheumatoid arthritis. *S. Ahmadloo[1], H. Shomali[1], A. Salimzadeh[2], M. Akhyani[3], M. Keramatipour[1].* 1) Department of Medical Genetics, School of Medicine,Tehran University of Medical Sciences, Tehran 14176-13151, Iran; 2) Rheumatology Department, Sina Hospital, Tehran University of Medical Sciences, Emam Khomeini St., Tehran, Iran; 3) Rheumatology Department, Alborz Hospital, Baghestan e gharbi St., Karaj, Iran.

Rheumatoid arthritis (RA) is a common autoimmune disease with a complex etiology affecting 1% of the world population. It appears that RA requires the complex interaction of genetic and environmental factors with the immune system, and ultimately in the synovial tissues. The role of genetic elements in determining both the risk of developing RA and the severity of the disease had already been acknowledged. Association studies in various populations have reported a number of genetic variations affecting the individual susceptibility to RA. The strongest association has been reported from genes within the HLA region, particularly the HLA-DRB1 gene. The rs2476601 SNP of PTPN22 (protein tyrosine phosphatase nonreceptor 22) gene can be named as the second polymorphism that has been repeatedly reported to be associated with RA. The association of another SNP, rs10818488 located near TRAF1 gene, has been recently picked up by genome wide association studies. So far there is no report investigating the possible association of rs2476601 and rs10818488 SNPs with RA in Iranian population. Therefore the aim of this study is to determine the possible association of these SNPs with RA in Iranian population using family-based (parents-child trios) as well as population-based case-control studies. In addition to testing for association, analysis of interaction between the two SNPs will be performed on obtained data. Currently the genotyping of samples are being carried out. The results will be presented at the meeting.

Polymorphisms of the *HLA-DP* locus are associated with hepatitis B virus infection and clearance in Han Chinese. *P. An[1], Z. Zeng[3], L. Guan[1], S.J. O'Brien[2], C.A. Winkler[1], the HBV study consortium.* 1) Lab Genomic Diversity, SAIC-Frederick Inc, Frederick, MD; 2) Lab of Genomic Diversity, National Cancer Institute-Frederick, Frederick,MD; 3) Department of Infectious Diseases, Peking University First Hospital, Beijing, P.R. China.

Background. Hepatitis B Virus (HBV) infection infects 10% of Asian populations, and is the leading cause of chronic hepatitis, cirrhosis and hepatocellular carcinoma (HCC). The impact of host genetic control of HBV infection is largely unknown. Several single nucleotide polymorphisms (SNPs) in the *HLA-DP* locus were recently shown by a genome-wide association study (GWAS) to be associated with chronic HBV infection in Japanese and Thai (Kamatani et al., 2009). This study sought to assess the role of *HLA-DP* SNPs in modulating HBV outcomes in a Han Chinese population. Methods. We replicated two HLA-DP) in a Chinese cohort consisting of all major HBV outcomes: viral clearance, uninfected hypernormals, chronic diseases, cirrhosis and HCC (N=1700). Results. We extended the *HLA-DPA1* rs3077 association to Han Chinese for decreased risk of chronic HBV infection (OR=0.62, P=0.001), consistent with the previous report, and showed for the first time that rs3077 is a predictor for HBV clearance (OR=2.41. P= $4.7x10^{-10}$). The *HLA-DP* SNPs were not associated with development of cirrhosis or HCC. In Han Chinese, the *HLA-DPA1* rs3077 accounts for 36% of the population fraction for HBV infection and 56% for people who fail to clear HBV infection. Among global populations, the frequency of the risk allele tends to be higher in African and Asian populations (20-90%) with high HBV prevalence, but is less frequent in European populations (<20%) with low HBV prevalence, suggesting this allele may in part account for differential geographic distributions of HBV in the world. Conclusion. *HLA-DP* variation is a major genetic determinant of HBV infection and clearance in Asian populations. [Funded by NCI Contract HHSN261200800001E].

Fine-mapping linkage and family-based association of idiopathic scoliosis and chromosome 1. *D. Behneman[1,2], C. Justice[1], T. Beaty[2], K.Y. Liang[2], N.H. Miller[3], A.F. Wilson[1].* 1) Genometrics Section, IDRB/NHGRI/NIH, Baltimore, MD; 2) Johns Hopkins University, Bloomberg School of Public Health, Baltimore, MD; 3) University of Colorado Health Science Center at Aurora, Aurora, CO.

Idiopathic scoliosis is a lateral curvature of the spine with unknown etiology. Previous studies have reported linkage to several regions across the genome, as well as linkage and association with several candidate genes. In this study, we tested for association in two regions on chromosome 1 that were previously identified and replicated with genome-wide linkage analysis. Region 1 is 8 Mb on the p arm; Region 2 is 19 Mb on the q arm. Linkage analysis and family-based tests of association were performed in two samples: 95 families most-likely to have autosomal-dominant mode of inheritance (Sample 1) and 187 families selected for parent-child trios (Sample 2). Scoliosis was defined as two qualitative traits (lateral curvature ≥10° and ≥30°) and as a quantitative trait (the degree of lateral curvature). Model-independent sib-pair linkage analysis, as well as allelic, genotypic and haplotypic tests of association, were performed on 110 SNPs in Sample 1 and 18 SNPs in Sample 2 within Region 1, and among 202 SNPs in Sample 1 and 214 SNPs in Sample 2 from Region 2.

For Region 1, 13 SNPs showed evidence of linkage and another 9 SNPs showed evidence of association in Sample 1, and in Sample 2 linkage was found with 2 SNPs and association was found to another 5 SNPs, for at least one scoliosis phenotype. At the 30° threshold, linkage and association were observed for rs4512614 and rs4654549 in Sample 1 and rs10915548 in Sample 2.

For Region 2, 16 SNPs showed evidence of linkage and another 13 SNPs showed evidence of association in Sample 1, and in Sample 2 linkage was found with 45 SNPs and association was found to another 20 SNPs, for at least one scoliosis phenotype. In Sample 2, linkage and association were observed for rs11586173, rs7519036, rs12117045 and rs6428417 at the 10° threshold. However, in Sample 1 none of the SNPs were significant for both linkage and association.

Candidate genes were identified within 1 Mb of these linked SNPs and within 0.1 Mb of associated SNPs then prioritized by statistical evidence (p-values) and biologic plausibility (gene function). These findings suggest gene(s) in these regions may contribute to scoliosis, an important step in determining genetic etiology for this disorder.

983/W

Leptin and its receptor are not associated with the co-occurrence of mood and BMI in adolescent females. *S. Louise[1], L. Briollias[2], P.A. McCaskie[1], E. Mattes[3], L.J. Beilin[4], C.E. Pennell[5], L.J. Palmer[1].* 1) The Centre of Genetic Epidemiolgy and Biostatistics, The University of Western Australia, Perth, Australia; 2) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, University of Toronto, Canada; 3) Telethon Institute for Child Health Research, Centre for Child Health Research, The University of Western Australia, Perth, Australia; 4) School of Medicine and Pharmacology, Royal Perth Hospital Unit, The University of Western Australia, Perth, Australia; 5) School of Women's and Infants' Health, The University of Western Australia, Perth, Australia.

Purpose: Negative moods, such as depression, have been associated with obesity in multiple child and adolescent studies. Common genetic factors have been hypothesised as an explanation for this co-occurrence. While the co-occurrence of obesity and depression has been observed many times, the potential genetic basis of this co-occurrence has not yet been thoroughly investigated. This study therefore aims to investigate the genetic basis, specifically whether leptin (LEP) and leptin receptor (LEPR), underlie the co-occurrence of depressive and/or anxious mood and Body Mass Index (BMI)in adolescent females. Leptin is a key regulator of body weight and has been separately associated with mood in both animal and human studies. **Methods:** This study uses data on female participants from the Western Australian Pregnancy Cohort (Raine) Study at the 14 year follow-up (n= 545). Tagged SNPs for LEP and LEPR were identified from HapMap Phase II (CEU) data using a pairwise approach (minor allele frequency(MAF)>0.05%; and r^2>0.8). Regions analysed include the entire gene, plus additional sequences 10 kb upstream and downstream of the gene. Adolescent weight and height were assessed by trained assessors. BMI was then calculated. Depressive and/or anxious mood scores were available from the Youth Self Report (YSR) and Beck Youth Depression Inventory (BDI-Y). A linear regression model was used to examine cross sectional associations between BMI (outcome) and tagged SNPs within LEP and LEPR. Mixed distribution models were used to account for the extra zero counts in our data and examine associations between depressive and/or anxious mood scores (outcome) and tagged SNPs within LEP and LEPR. **Results:** SNPs within LEP and LEPR were not associated with both BMI and depressive and/or anxious mood (p>0.05). SNPs within LEPR (RS10493380, RS1171267, RS7602, RS9436740, RS1171271,RS17127618, RS3762274, RS4655537 and RS9436301)were associated with depressive and/or anxious mood. These associations however did not persist after correcting for multiple testing. **Conclusion:** Tagged SNPs within LEP and its receptor (LEPR) did not underlie the co-occurrence of depressive and/or anxious mood and BMI in adolescence females within the Raine study. However larger cohorts may be needed to explore this possible association. LEPR may be associated solely with depressive and/or anxious mood.

Intergenerational allelic interaction: Excess maternal-fetal allele sharing in the HLA genomic region is associated with preterm birth. *J.R. Shaffer[1], E. Feingold[1], K. Ryckman[2], F. Begum[1], B. Feenstra[3], F. Geller[3], H.A. Boyd[3], D.E. Weeks[1], M.M. Barmada[1], C. Laurie[4], Q. Zhang[4], K. Doheny[5], E. Pugh[5], M.L. Marazita[1], M. Melbye[3], J.C. Murray[2].* 1) University of Pittsburgh, Pittsburgh, PA; 2) University of Iowa, Iowa City, IA; 3) Statens Serum Institut, Copenhagen, Denmark; 4) University of Washington, Seattle, WA; 5) Johns Hopkins, Baltimore, MD.

MOTIVATION: The incidence of preterm birth (PTB; gestation <37 weeks), which is the leading cause of mortality and adverse health complications among newborns, has increased in the US in recent decades. Previous studies have suggested that excess maternal-fetal sharing at loci in the HLA genomic region is associated with poorer pregnancy outcomes, which supports the hypothesis that maternal response to paternally-derived fetal HLAs may be beneficial to implantation and/or maintenance of pregnancy. However, little is known about the effect of maternal-fetal HLA sharing on PTB as a pregnancy outcome. We examined HLA sharing among 642 PTB case and 943 control mother-child pairs enrolled in the Danish National Birth Cohort Study as part of the inter-NIH sponsored GENEVA consortium. METHODS: Subjects were genotyped by CIDR on the Illumina 660W platform, which included 1,334 SNPs meeting genotyping quality criteria in the HLA genomic region (i.e. all SNPs between HLA-F and HLA-DPB1 on chromosome 6). Maternal-fetal genotype combinations at each SNP were dichotomized as to whether or not the fetus carried a paternally-derived allele absent in the mother. This binary measure of allele sharing was tested against PTB case/control status. RESULTS: Allele sharing at the HLA region as a whole, which contains blocks of strong linkage disequilibrium, showed excess association at the alpha=0.01 significance level (i.e. p<0.01 for 26 of 1334 SNPs compared to 13 SNPs expected by chance; lambda=1.164). This is in marked contrast to the whole genome which did not show excess association between allele sharing and PTB (514,200 autosomal SNPs; lambda=0.979). Moreover, for 23 of the 26 nominally significant (p<0.01) SNPs, greater allele sharing was a risk for PTB. Further exploration of all possible maternal-fetal genotype combinations in the three "top hits" (i.e. p<0.001; within or near the ABCF1 gene) showed that all like genotype combinations (e.g. mom=AA, fetus=AA) were risk factors for PTB, whereas unlike genotype combinations (e.g. mom=AA, fetus=AB; or mom=AB, fetus= AA) were protective. CONCLUSIONS: Our interpretation of these findings is that excess maternal-fetal allele sharing in the HLA region is a risk factor for PTB; this result supports the hypothesis that maternal response to foreign HLA alleles may be favorable for successful pregnancy. Direct and Comprehensive Genotyping of Classical HLA Loci Reveals a Distinct Spectrum of Alleles Associated with Graves' Disease in Asians. *P. Chen[1,2], C. Fann[3,4], C. Chu[5], C. Chang[3], S. Chang[3], H. Hsieh[3], W. Yang[2,6,7], T. Chang[2,7].* 1) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan, Taiwan; 2) Division of Endocrinology and Metabolism, Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 3) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 4) Institute of Public Health, National Yang-Ming University, Taipei, Taiwan; 5) Transfusion Medicine Laboratory, Medical Research Department, Mackay Memorial Hospital, Taipei, Taiwan; 6) Graduate Institute of Clinical Medicine, College of Medicine, National Taiwan University; 7) Department of Medicine, College of Medicine, National Taiwan University.

Graves' disease (GD) is the leading cause of hyperthyroidism and thyroid eye disease inherited as a complex trait. There has been no conclusion concerning which human leukocyte antigen (HLA) loci or alleles are associated with GD in populations other than Caucasians. We conducted a case-control association study (499 unrelated GD cases and 504 controls) and a replication in an independent family sample (419 GD individuals and their 282 relatives in 165 families). To minimize genetic and phenotypic heterogeneity, we included only ethnic Chinese Han population in Taiwan and excluded subjects with family history of hypothyroidism. We performed direct and comprehensive genotyping of six classical HLA loci (*HLA-A*, *-B*, *-C*, *-DPB1*, *-DQB1* and *-DRB1*) to 4-digit resolution. Combining the data of two sample populations, we found that *B*46:01* (odds ratio under dominant model [OR] = 1.33, combined *P* [*Pc*] = 3.4×10^{-4}), *DPB1*05:01* (OR = 2.34, *Pc* = 7.6×10^{-12}), *DQB1*03:02* (OR = 0.62, *Pc* = 5.8×10^{-4}), *DRB1*12:02* (OR = 0.51, *Pc* = 3.4×10^{-3}), *DRB1*15:01* (OR = 1.68, *Pc* = 3.6×10^{-4}) and *DRB1*16:02* (OR = 2.63, *Pc* = 4.3×10^{-7}) were associated with GD. *HLA-DPB1*05:01* is the major gene of GD in our population and singly accounts for 48.4% of population-attributable risk. These alleles, with considerable supporting evidence from previous studies in Asians, are distinct from the known associated alleles in Caucasians. Identification of population-specific association alleles is the critical first step for individualized medicine. Furthermore, comparison between different alleles across populations provides a great opportunity for better understanding of GD pathogenesis.

Candidate genes associated with non-diabetic end stage renal disease in African Americans: analysis of a pooled DNA-based genome wide association study. *M. Bostrom[1, 4, 5], L. Lu[2], J. Chou[2], P. Hicks[1], J. Xu[5], C. Langefeld[2], D. Bowden[1,4,5], B. Freedman[3].* 1) Dept Biochem, Wake Forest Univ, Winston-Salem, NC; 2) Biostatistical Sciences, Wake Forest Univ, Winston-Salem, NC; 3) Internal Medicine/Nephrology, Wake Forest Univ, Winston-Salem, NC; 4) Center for Human Genomics, Wake Forest Univ, Winston-Salem, NC; 5) Center for Diabetes Research, Wake Forest Univ, Winston-Salem, NC.

African Americans (AA) have increased susceptibility to non-diabetic (non-DM) etiologies of end-stage renal disease (ESRD), particularly attributed to hypertension and glomerular disease. Studies have shown that this susceptibility has a genetic component. To identify genes associated with non-diabetic ESRD in African Americans, we performed a genome wide association study (GWAS) on 1000 African American non-diabetic ESRD cases and controls. DNA from 500 case and 500 control samples was quantified using gel electrophoresis and spectrophotometric analysis. Samples were pooled to create 10 case pools and 10 control pools with each pool containing 50 samples. DNA pools were genotyped in duplicate on the Illumina HumanHap550-Duo BeadChip. Top scoring SNPs from the GWAS were genotyped on 966 African American non-DM ESRD cases and 953 non-nephropathy controls using the Illumina 1536 GoldenGate custom genotyping chip at the Center for Inherited Disease Research. 1420 SNPs were successfully genotyped on 962 African American non-DM ESRD cases and 947 non-nephropathy controls. SNPs were tested for association with non-DM ESRD with covariate adjustment for age, gender, logBMI, and percentage of African Ancestry (as determined by 70 admixture informative markers). The top six most associated SNPs were located on chromosome 22 in the region of the *MYH9* gene, which has been previously associated with non-DM ESRD (p = 4.87E-20 - 6.15E-5, odds ratio (OR) = 0.47 - 0.74; additive model). Other top SNPs included rs379489, in the *CFH* gene (p = 1.02E-4, OR = 0.72, confidence interval (CI) = 0.61-0.85; additive model) and rs3798696, located in *UGT2A3* (p = 8.04E-4, OR = 0.64, CI = 0.49 - 0.83; additive model). Case-only interaction analysis for risk status resulted in association at rs9808028 in the *ERBB4* gene (p = 5.04E-4, OR = 1.58, CI = 1.22 - 2.04, additive model), rs9687184 in an intergenic region (p = 6.07E-4, OR = 0.56, CI = 0.40 - 0.78, dominant model), and rs4682417 in the *CCDC80* gene (p = 6.19E-4, OR = 1.6, CI = 1.22 - 2.10, dominant model). We have performed the first genome-wide association study for non-DM ESRD in African Americans and have replicated association in the *MYH9* region of chromosome 22 and identified several additional candidate loci for follow-up studies.

IRF6 and 8q24 SNPs contribution to nonsyndromic cleft lip with or without cleft palate predisposition varies according to the geographic region in Brazil. *L.A. Brito[1,2], C.B.F. Silva[1,2], K.M. Rocha[2], L.A. Cruz[1,2], D. Meyer[1], D. Schlesinger[1,2], L.B. Kobayashi[1,2], M. Aguena[1,2], D. Bertola[3], D.F. Bueno[1,2], N. Alonso[3], M.R.S. Passos-Bueno[1,2].* 1) Department of Genetics, Institute of Biosciences, University of São Paulo, São Paulo - SP, Brazil; 2) Human Genome Research Center, University of São Paulo, São Paulo-SP, Brazil; 3) School of Medicine, University of São Paulo, São Paulo-SP, Brazil.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P), the most common craniofacial birth defect, is a complex disease with multifactorial inheritance, and its prevalence varies among populations (1:1000 in Europeans (EU), 0.3:1000 in Africans (AF) and 3.6:1000 in Amerindians (AI)). IRF6 (1q32) SNPs, including one within an enhancer (rs642961), has been the locus of more replicated associations with NSCL/P. Studies also have pointed 8q24.21 as a candidate region to harbor a susceptibility locus to NSCL/P, and the SNP rs987252 in that region has been associated to the disease in some studies. As Brazilians constitute an admixed population mainly from EU, AF and AI, approaches such as admixture mapping and structured association are more recommended in order to avoid false correlations. In this study, the SNPs rs642961 and rs987252 were tested for association NSCL/P in our population. We performed the genotyping of the SNPs and of 40 biallelic insertion-deletion ancestry informative markers in 611 patients and 284 controls. Patients were from 5 different regions of Brazil (Rio de Janeiro, n=116; Maceio, n=107; Barbalha, n=63; Fortaleza, n=234 and Santarem, n=91). Ancestry contributions and association tests were performed with Admixmap, Structure 2.3.3 and STRAT softwares. Frequency of rs642961 risk allele was estimated at 0.181 (cases) and 0.131 (controls), whereas frequency of rs987252 risk allele was 0.357 (cases) and 0.330 (controls). Overall ancestry contributions were 58% EU, 29% AF and 13% AI for cases and 66% EU, 23% AF and 11% AI for controls. Individual admixture were used to stratify the association analysis and correct for effects of admixture in case-control comparison, resulting in significant association only for rs642961 in overall sample (P=0.013). Analyzing each region separately, rs642961 did not reach significance level in Rio de Janeiro and Maceio; in contrast, rs987252 showed significant association in Barbalha and Santarem (P<0.01). In summary, we corroborated the association of IRF6 and NSCLP in Brazilian population, and the 8q24.21 at risk alleles showed an important contribution only in some groups. Different results among the regions indicate that susceptibility to NSCLP is heterogeneous in Brazilian population. In order to further validate these results, admixture mapping is being conducted. FAPESP, CNPq.

The Signal vs. Noise Balance: Exploring Gene Summary Methods. *A.E. Hendricks[1], J. Dupuis[1], M. Gupta[1], E.J. Benjamin[3], R.H. Myers[2], K.L. Lunetta[1].* 1) Biostatistics, Boston University School of Public Health, Boston, MA; 2) Neurology, Boston University School of Medicine, Boston, MA; 3) Cardiology and Preventive Medicine Sections, Boston University School of Medicine, Boston, Massachusetts.

As Genome-Wide Association Studies have become common, many research groups want to explore the full potential of their data by conducting complex analyses such as gene-gene interaction or gene pathway analysis. Due to the large number of SNPs in most gene regions, multi-gene analyses share a common obstacle of how to represent or summarize each gene region at the subject level. Creating a summarized value for each subject, rather than one value or statistic for each gene over all subjects, retains variation at the subject level enabling the summary values to be used in established analyses such as gene pathway analysis. A common per subject gene-region summary method uses the genotypes of the SNP with the lowest association p-value. However, this method may not be effective when a gene region has more than one trait associated variant and other summary methods exist that may better capture this type of variation. Most summary methods can be reduced to a weighted sum of SNP genotypes with the goal to assign the true risk SNPs (signals) the highest weights and to give all other SNPs (noise) weights of zero. Some methods, such as choosing the top associated SNP, put weight on a very small proportion of SNPs in the region and thus likely eliminate many false signals, but may also leave out SNPs with true effects. Other methods assign a non-zero weight to a much larger proportion of markers, which likely keeps more truly associated SNPs, but also includes more noise SNPs. Here, we use a simulation study to compare several summary methods: a) single SNP, b) haplotype, c) principal component, d) LASSO regression, e) BIC model selection, and f) Bayesian model averaging. We compare type I error and power of the methods over many simple and complex risk scenarios and simulate our replicates using a method that retains the LD structure of the gene region. We also modify the LD structure of the gene region by changing the SNPs available for analysis (for example, only SNPs on the Affy 6.0 chip or on the Illumina Omni-Quad chip). We find that in most simple risk scenarios and many complex risk scenarios choosing the top associated SNP has the highest power, with haplotype, LASSO regression, and BIC selection also performing well. Future research includes looking at the performance of these gene summary methods in gene x gene interaction analysis with the goal to scan the genome to identify SNPs that interact with the summarized gene region of interest.

Genotype-phenotype relationships of susceptibility loci from genome-wide association studies in intracranial aneurysm. *H. Miura, H. Nakaoka, K. Akiyama, T. Cui, A. Tajima, I. Inoue.* Division of Molecular Life Science, School of Medicine, Tokai University, Isehara, Kanagawa, Japan.

Recently, a genome-wide association study identified associations between single nucleotide polymorphisms (SNPs) on chromosome 8q11, 9p21, 10q24, 13q13 and 18q11 and risk of harboring intracranial aneurysm (IA). Aneurysm characteristics or subphenotypes of IAs such as history of subarachnoid hemorrhage (SAH), presence of multiple IAs and location of IAs are clinically important but the genotype-phenotype relationships have not been approached yet. We investigated whether the association between variation in these loci and risk of IA varied among these subphenotypes.

We conducted a case-control study of 981 cases and 699 controls in Japanese. SNPs tagging these five risk loci were genotyped. The odds ratios (ORs) and 95% confidence intervals (CIs) were estimated using logistic regression analyses. To estimate subphenotype-specific ORs, the frequency of the 9p21 variant in each case-subgroup (e.g. patients with ruptured or unruptured IA) was compared with the frequency in controls using a polytomous logistic regression.

Among SNPs on the five loci, a SNP on 9p21 (rs1333040) showed the strongest evidence of association with IA (P=1.5x10-6; per allele OR=1.43; 95% CI: 1.24-1.66). None of the patient characteristics (sex, age, smoking and hypertension) was a significant confounder or effect modifier of the association. Subgroup analyses of IA subphenotypes showed that among the most common sites of IAs, the association was strongest for IAs of the posterior communicating artery (PcomA) (OR=1.69; 95% CI, 1.26-2.26) and not significant for IAs in the anterior communicating artery (OR=1.22; 95% CI, 0.96-1.57). When dichotomizing IA sites, the association was stronger for IAs of the posterior circulation-PcomA group (OR=1.73; 95% CI, 1.32-2.26) versus the anterior circulation group (OR=1.28; 95% CI: 1.07-1.53). The associations did not vary when stratifying neither by history of SAH nor by multiplicity of IA. A similar approach would be undertaken for other loci.

Our results suggest that genetic influence on formation may vary between IA subphenotypes.

Experimental follow-up of the *TCF7L2* association with type 2 diabetes. *D. Savic[1], H. Ye[2], S.Y. Park[2], G.I. Bell[2], M.A. Nobrega[1].* 1) Department of Human Genetics, The University of Chicago, Chicago, IL; 2) Department of Medicine, The University of Chicago, Chicago, IL.

Several genome wide association studies (GWAS) have identified a 92.1-kb block of strong linkage disequilibrium (LD) within the *TCF7L2* locus associated with type 2 diabetes (T2D). How *TCF7L2* affects risk and which tissues are involved are areas of active investigation by many laboratories. Coding variations within *TCF7L2* were not identified, raising the possibility that regulatory variations in distant enhancers may underlie the disease risk. Using a combination of bioinformatics, comparative genomics and mouse genetic engineering, we have identified a variety of tissue-specific enhancers within a region spanning the diabetes-associated interval that recapitulate the endogenous pattern of *Tcf7l2* expression. Several of these *TCF7L2* enhancers exhibit expression in tissues with established roles in maintaining glucose homeostasis, including brain, pancreas, stomach, bones and intestines, strengthening the hypothesis that sequence variants within these enhancers might underlie the association signal seen in the GWAS. In order to functionally establish *TCF7L2* as a T2D gene, we have developed *Tcf7l2* knockout mice using zinc finger nuclease technology. Preliminary analyses have shown that *Tcf7l2* heterozygous knockout mice display lower body weight, bone mineral density and fat mass but increased basal metabolic rate compared to wild-type littermates. Our study supports the notion that distant *cis*-regulatory elements are often present in regions associated with common diseases and suggests a role for *TCF7L2* in metabolism.

991/W

Possible roles of macrophage migration inhibitory factor and mannose-binding lectin gene polymorphisms in Turkish children with acute rheumatic fever. *N. Col Araz[1], S. Pehlivan[2], O. Pinarbasi[3], T. Sever[2], S. Oguzkan Balci[2], A. Balat[4].* 1) University of Gaziantep, Faculty of Medicine, Department of Pediatrics, Gaziantep, Turkey; 2) University of Gaziantep, Faculty of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey; 3) University of Gaziantep, Faculty of Medicine, Department of Pediatric Cardiology, Gaziantep, Turkey; 4) University of Gaziantep, Faculty of Medicine, Department of Pediatric Nephrology, Gaziantep, Turkey.

Objectives of Study: Acute rheumatic fever (ARF) is the most important immune-mediated sequela of upper respiratory tract infection with group A, β-hemolytic streptococci, and the immune mechanisms that provoke concomitant inflammation of synovial joints and cardiac valves remain poorly defined. Macrophage migration inhibitory factor (MIF) is recognized as a soluble factor produced by sensitized T lymphocytes and inhibits the random migration of macrophages. Mannose-binding lectin (MBL) is a central component of the innate immune response. They play important roles in the pathogenesis of several acute and chronic inflammatory / autoimmune disorders. Our aim was to investigate any possible association between MBL and MIF gene polymorphisms and ARF in a group of Turkish children. **Methods:** The study was approved by the local ethical committee and informed consents were obtained from the patients. Genomic DNA was extracted from peripheral blood using the salting out procedure. Thirty-eight children with ARF and 40 age-and sex-matched healthy controls were analyzed for codon 54 A/B polymorphism in MBL gene and -173 G/C polymorphism in MIF gene by using PCR-RFLP methods. **Results:** The distribution of AA, AB, and BB genotypes for MBL codon 54 were 55.3 %, 38.9 % and 35.2 % in ARF compared with 65%, 35 % and 0 % in the controls (p= 0.372). BB genotype was higher than AA and AA+AB genotypes in patient group (p=0.033, p=0.035, respectively). The allele frequency of A/B in MBL was 72.4 %, 27.6 % in ARF compared with 82.5 %, 17.5 % in the controls. (p=0.129). The distribution of GG, GC, and CC genotypes for MIF (-173) were 47.4 % , 31.6 %, and 21 % in ARF compared with 57.5 %, 40 % and 2.5 % in the controls (p=0.047). CC genotype was found higher than GG and GG+GC genotypes in patient group (p=0.014, p=0.010, respectively). The allele frequency of G/C in MBL was 63.2 %, 36.8 % in ARF compared with 77.5 %, 22.5 % in the controls. (p=0.049). The observed genotype counts were not deviated significantly from those expected according to the Hardy- Weinberg Equilibrium for MBL and MIF gene polymorphisms (P>0.05). **Conclusions:** The present study is the first to investigate the MBL and MIF gene polymorphisms in children with ARF. We conclude that BB genotype of MBL (codon 54) and CC genotype of MIF (-173) may have a role in the immunoinflammatory process of ARF. However, further studies in a larger population are needed to confirm the results.

992/W

Deleterious allele of olfactory receptor gene *OR51J1* is associated with specific inability to smell the musty odor of 3-methyl-2-hexenoic acid. *A. Knaapila[1], Y. Hasin[2], D. Reed[1], F. Duke[1], J. Louie[1], D. Lancet[2], C. Wysocki[1].* 1) Monell Chemical Senses Center, Philadelphia, PA; 2) Dept. of Molecular Genetics, the Weizmann Institute of Science, Rehovot, Israel.

Olfaction, the sense of smell, is important for detecting dangers (fire, spoiled food) and for enjoying pleasant odors from food, flowers, and perfumes. The lowest concentration at which an odorant can be perceived (detection threshold) can vary more than 10000-fold among human subjects. In an extreme case, an individual whose sense of smell is generally normal is unable to detect a specific odorant even at a very high concentration (specific anosmia). The gene family encoding olfactory receptors (ORs) is one of the largest in the genome with more than 400 potentially functional OR genes, but how polymorphism in the OR genes relates to the phenotypic variation in odor perception remains largely unknown. The aim of the study was to explore associations between 62 selected OR coding region polymorphisms, that segregate between intact and deleterious alleles (segregating pseudogenes), and specific anosmia, detection threshold, and perceived pleasantness of 9 odorants (androstenone, benzyl salicylate, Galaxolide™, isovaleric acid, isoamyl acetate, Jeger's ketal, 3-methyl-2-hexenoic acid [3M2H], muscone, and pentadecalactone). The analyses were based on data from 413 individuals (aged 18 to 62 years, mean age 27 years; 64.4% women). The statistical software Plink was used to screen the data for significant associations. Bonferroni correction for multiple testing was applied to adjust the criterion for statistical significance to $\alpha = 3.0e\text{-}5$. Specific anosmia to 3M2H (musty/sweaty odor) was associated with SNP *rs1909261* (nucleotide change G/A corresponding to a strong missense amino acid change C105Y) within gene *OR51J1* (unadjusted p = 6.0e-6). The frequency of 3M2H anosmia was significantly higher in subjects who were either homozygous for the allele or heterozygous (AA/GA; n = 67, of whom 38.8% were anosmic) as compared to individuals homozygous for the intact allele (GG; n = 301, of whom 14.6% were anosmic) (unadjusted Pearson Chi-squared p = 5.1e-6). *OR51J1* is located on chromosome 11p15.4 in the middle of a large OR gene cluster, that includes 74 OR genes. Thus, it is possible that *OR51J1* and/or another OR gene in linkage disequilibrium with *OR51J1* encode receptor(s) that respond to 3M2H, as implied by the theory of combinatorial receptor codes for odors. Although the functionality of these receptors remains to be demonstrated, the results of the present study suggest that the product of *OR51J1* is involved in detection of 3M2H.

993/W

Epistatic Interactions Among Genes for Athleticism. *E. McRae[1], J.R. Ruiz[2], F. Gómez-Gallego[3], C. Santiago[3], A. Buxens[4], A. Lucia[3], M. Ruvolo[1,5].* 1) Dept. of Organismic and Evolutionary Biology, Harvard University, Cambridge, MA; 2) Dept. of Biosciences and Nutrition, Karolinska Institute, Stockholm, Sweden; 3) Universidad Europea de Madrid, Madrid, Spain; 4) Progenika Biopharma, Zamudio, Spain; 5) Dept. of Human Evolutionary Biology, Harvard University, Cambridge, MA.

Human athleticism is a complex trait, influenced by many genes as well as the environment. Hundreds of alleles have been identified as being associated with athletic performance and fitness, and the number continues to grow. For the majority of the history of this field, such work has focused on the influence of individual genes. While such studies inform us about what genes could be involved in athleticism, they do not help us understand the complex nature of the trait. The goal of this study was to look for genes that interact epistatically in determining elite athlete status. We examined 37 health-related genes, 13 of which had previously been associated with athleticism, in 253 males of Spanish ancestry - 100 elite endurance athletes, 53 elite power athletes, and 100 sedentary controls. We used several methods to look for these interactions, including multifactor dimensionality reduction (MDR), generalized MDR (GMDR), and entropy-based methods. We found a significant interaction between the Met235Thr SNP of angiotensinogen (AGT) and the C-786T SNP of the endothelial nitric oxide synthase 3 (NOS3) gene that strongly distinguishes endurance athletes from power athletes. We found that an interaction between these same SNPs also distinguishes elite athletes as a group from sedentary controls, along with a second interaction between myostatin (GDF8) and the Ile105Val polymorphism of glutathione S-transferase π1 (GSTP1). We also found a suggestive four-way interaction between AGT, GSTP1 (105), NOS3 (-786), and superoxide dismutase 2 (SOD2). We found no significant interactions distinguishing endurance athletes and controls, only main effects from α-actinin 3 (ACTN3) and the β3 adrenergic receptor (ADRB3) gene. Finally, in examining power athletes and controls, we found a significant two-way interaction between the Cys112Arg SNP of apolipoprotein E (APOE) and the Glu298Asp polymorphism of NOS3. This comparison also yielded a suggestive four-way interaction among angiotensin I-converting enzyme (ACE), the Arg268Lys SNP of N-acetyltransferase 2 (NAT2), interleukin-6, and NOS3 (-786). This study allows us, for the first time, to look at specific gene interactions that are associated with elite athletic performance. Most of the polymorphisms identified have previously been associated with athleticism, but others had not, and should therefore be studied more closely.

994/W

Application of the *Gentrepid* candidate gene prediction system to Genome-Wide Association Studies. *S. Ballouz[1,2], J.Y. Liu[1], M. Oti[1], B. Gaeta[2], D. Fatkin[1,3], M. Bahlo[4], M.A. Wouters[1,3].* 1) The Victor Chang Cardiac Research Institute, Sydney, NSW, Australia; 2) School of Computer Science and Engineering, University of New South Wales, Sydney, NSW, Australia; 3) School of Medical Sciences, University of New South Wales, Sydney, NSW, Australia; 4) The Walter and Eliza Hall Institute, Melbourne, VIC, Australia.

Genome-wide association studies (GWAS) aim to identify the genetic architecture of complex diseases by using genotyping arrays to test a large number of SNP markers for disease correlation. However the data is very noisy and identifying the relevant disease gene is not straightforward. Here we analysed data from the Wellcome Trust Case Control Consortium on seven disease phenotypes: bipolar disorder, coronary artery disease, Crohn's disease, hypertension, rheumatoid arthritis, and type I and type II diabetes. We used the *Gentrepid* candidate gene prediction system to select likely gene candidates associated with SNPs of less stringent statistical thresholds than applied in the original analysis, using multiple SNP to gene mapping assumptions. Mapping assumptions resulted in search spaces ranging in size from 2 to 4431 genes for specific phenotypes. Under the common nearest neighbour SNP mapping assumption, only 76% of characterized genes are associated with a SNP on the Affymetrix 500K chip set. Gene coverage increases to 99% using other mapping assumptions tested. However, even when the entire genome is considered, only 57% of characterized genes have *Gentrepid* annotations and are thus potentially predictable as candidates. Predictions were made using protein domains and pathway information of known disease genes or by searching for enrichment of these features within the search space. *Gentrepid* was able to extract known disease genes and predict novel plausible disease genes in known and novel, WTCCC-implicated loci for the seven phenotypes. The results show the approach is feasible and may be a valuable way to analyse other GWAS data.

995/W

Genetic and molecular basis of QTL of alcohol preference in mice: genes and polymorphisms. *W. Gu[1], Y. Cao[2], Q. Xiong[3], Y. Jiao[1], B. Bennett[4], Y. Wang[5].* 1) Dept Orthopedic Surgery, Univ. of Tennessee Health Sci Ctr., Memphis, TN; 2) 2 Institute of Kaschin-Beck Disease, Center for Endemic Disease Control, Centers for Disease Control and Prevention, Harbin Medical University, Harbin, 150081, PR China; 3) Institute for Genome Science and Policy, Duke University, Durham, NC 27708, USA; 4) Department of Pharmacology, Universitty of Colorado Denver, Aurora, CO 80045-0508, USA; 5) Department of Neurology, Beijing Tiantan Hospital, Capital University of Medical Sciences, Beijing, 100050, PR China.

Alcoholism is a complex disease that is affected by multiple genetic and environmental factors. To understand the genetic and molecular basis of alcoholism, a large number of quantitative trait loci (QTL) that regulate experimental alcoholic preference have been identified using various mouse models for alcoholism. However, identifying the particular responsible genes within these QTL remains a major challenge. Using currently available genomic data and gene annotation information, we systematically examined alcoholic preference-associated genes and polymorphisms within and outside previously-reported QTL over the whole mouse genome. We found significantly more alcoholism-associated genes in QTL regions as contrasted with non-QTL regions. Rapid development of high throughput screening technology and genomic resource in the near future will determine whether these known alcoholism-associated genes or polymorphisms are genetic components causing the QTL effect.

996/W

Behçet's disease (BD) and the mitochondrial genome. *A. Rosa[1], J.M. Xavier[2,3], N.M. Shafiee[4], F. Ghaderi[4], B.S. Abdollahi[4], F. Shahram[4], F. Davatchi[4], S.A. Oliveira[2,3].* 1) Unidade de Ciências Médicas, Centro de Competências das Ciências da Vida, Universidade da Madeira, Funchal, Portugal; 2) Instituto de Medicina Molecular, Lisbon, Portugal; 3) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 4) Rheumatology Research Center, Tehran University of Medical Sciences, Tehran, Iran.

BD is a chronic inflammatory disorder, classified within the group of vasculitides, that may involve several organs, such as skin, mucocutaneous membranes (oral and genital aphtae), eyes, joints, lungs, gastrointestinal and central nervous systems. Only nuclear genes have been investigated thus far for BD risk, while the role of the mitochondrial DNA (mtDNA) has been completely neglected. In our expression profiling study of BD patients, we found an over-representation of nuclear genes linked to oxidative stress among those differentially expressed. Mitochondrial normal functioning is required for cellular respiration and vascular cell growth and function. mtDNA coding region polymorphisms (encoding for 13 oxidative phosphorilation polypeptides, 22 tRNAs and 2 rRNAs) may enhance oxidative stress by increased production of mitochondrial reactive oxygen species (ROS), which cause damage to DNA, proteins, and lipids. Since its dysfunction may underlie a multitude of clinical features in multifactorial and multisystemic diseases, we assessed whether mtDNA SNPs and haplogroups confer susceptibility to BD. Patients were selected as consecutive patients, according to ICBD criteria. 22 mtDNA tagging-SNPs sufficient for classifying our Iranian samples into the most prevalent regional haplogroups (West Eurasian H, pre-R0/R0, J, T, U, K, N1(I) and W; Eastern Eurasian M (xD), N (xN1, I, W and X) and R (xJT and UK); African L, and Asian D haplogroups) were genotyped in 550 BD patients and 436 controls, and their association with BD tested individually or in combination into haplogroups, adjusting for gender. mtDNA SNP 709G/A in the 12S rRNA was found to have a modest association with BD (adjusted p=0.052, and unadjusted p=0.03). None of the haplogroups tested were associated with BD. Since 12S RNA molecules participate in assemble of amino acids into functioning proteins that carry out oxidative phosphorylation inside the mitochondria, this modest association suggests a potential role of oxidative stress in BD pathogenesis. mtDNA SNP 709G/A association with BD requires further validation and investigation.

997/W

Association of the matrix metalloproteinase 13 gene with child-onset asthma. *Y. Suzuki[1], Y. Mashimo[1], S. Hattori[1], K. Takeuchi[1], N. Shimojo[2], T. Hirota[3], K. Fujita[4], A. Miyatake[5], S. Doi[6], Y. Okamoto[7], Y. Kohno[2], M. Tamari[3], A. Hata[1].* 1) Department of Public Health, Chiba University Graduate School of Medicine, Chiba, Japan; 2) Department of Pediatrics, Chiba University Graduate School of Medicine, Chiba, Japan; 3) Laboratory for Respiratory Diseases, Center for Genomic Medicine, RIKEN, Tsurumi, Japan; 4) School of Human Nursing, The University of Shiga Prefecture, Shiga, Japan; 5) Miyatake Asthma Clinic, Osaka, Japan; 6) Department of Pediatric Allergy, Osaka Prefectural Medical Center for Respiratory and Allergic Diseases, Osaka, Japan; 7) Department of Otolaryngology, Graduate School of Medicine, Chiba University, Chiba, Japan.

Background: Matrix metalloproteinases (MMP) are a family of zinc- and calcium- dependent endopeptidases that are involved in various physiological processes. Several MMP genes such as MMP9 and MMP12 have been shown to be involved in pathogenesis of asthma. However, little is known about roles of MMP13.

Methods: We recruited 1039 Japanese atopic asthma patients (age mean: 23.2 years; range: 3 to 83 years), 333 child (6 to 12 years) controls, and 628 adult (20 to75 years) controls. Onset of 64% of the patients was younger than 15 years of age. In this study, these patients were defined as child-onset asthma (COA). Patients with onset of 16 years or older were defined as adult-onset asthma (AOA). We investigated linkage disequilibrium (LD) status of 38 polymorphisms in the MMP13 gene region. Eight tag SNPs were genotyped in the entire samples. The promoter activity of the gene region was determined with a luciferase assay. Expression of MMP13 mRNA and protein in the small airway epithelial cells (SAEC) was measured before and after the addition of pathogen associated molecular patterns, interferons (IFN), or cytokines.

Results: Out of 8 tag SNPs, 3 SNPs were in moderate to strong LD (LD group 1) and the other five were in weak LD. None of the SNPs showed different genotype frequencies between the child control and adult control; thereby we compared genotypes of AOA or COA group with the combined control group. The SNPs of LD group1 were significantly associated with COA group. P values of association test in dominant model of -2976G/A (SNP2), -290G/A (SNP5), and 16385C/A (SNP7) were 0.000055, 0.000065, and 0.000011, respectively. The odds ratio and its 95% confidence interval of SNP5 were 1.90 and 1.37-2.55, respectively. SNP2 and SNP5 were located in the promoter region, while SNP7 were in the 3' downstream of the last exon. Only SNP5 significantly affected the promoter activity. Lung and bone marrow express MMP13 mRNA much higher than any other normal tissues. IFN beta and poly(I:C) were potent inducers of MMP13 in SAEC.

Conclusion: The MMP13 gene may be involved in defense mechanisms to viral infection in airway epithelial cells and play a role in pathogenesis of child-onset asthma.

998/W

Meta-analysis of the major histocompatibility complex in systemic lupus erythematosus. *K.E. Taylor[1], D. Morris[2], M.M. Fernando[2], J. Nititham[1], R.R. Graham[3], J.B. Harley[4,5], B.P. Systemic lupus erythematosus (SLE) is a genetically complex disease with heterogeneous clinical manifestations. Alleles of the *HLA-DRB1* locus in the major histocompatibility complex (MHC) are known to increase risk of SLE; previous studies have found additional but inconsistent risk signals in other areas of the MHC, and extensive linkage disequilibrium (LD) in the region makes it difficult to identify true risk loci. In order to more precisely understand the role of the MHC region in SLE etiology, we have collected data for the most comprehensive study to date on the MHC and SLE. We have acquired MHC single-nucleotide polymorphism (SNP) genotypes for 3,812 cases from four whole-genome scans and two recent MHC studies. We have also obtained genotype data on 12,817 controls, from those six studies and from additional publicly-available controls. In addition to the MHC we have collected available whole-genome data or ancestry-informative markers (AIMs) for detection of unknown duplication or relatedness and ancestry analysis. We identified duplicates and first-degree relatives by identifier and identity-by-state similarity; one subject of each relative pair or set was retained; for duplicates, genotypes were merged by consensus call. Quality-control filters were applied before merging; loci were removed for Hardy-Weinberg disequilibrium in controls by study source, removing those resulting in a false-discovery rate of greater than 0.05. Ancestry outliers (i.e. likely non-European ancestry, n=58) were removed using a series of principal component analyses performed using each type of available whole-genome or AIM data. As the six parent studies were performed on six different platforms without a high degree of overlap, we are imputing up to a common set of SNPs for analysis. Due to overlapping subjects and different genotyping platforms, each study will be re-analyzed after removal of duplicates and with adjustment for ancestry, and per-study results combined via Mantel-Haenszel statistics. We anticipate that multiple signals, some due to LD, obtained in the initial association screen will be tested for independence with each other and with *HLA-DRB1* alleles using multiple conditional analysis methods such as multivariate logistic regression and log-ratio testing of haplotypes. In sum, we are using a series of rigorous methods to investigate SLE in the largest collection of MHC data ever assembled for SLE.

999/W

Multiple independent major histocompatibility complex associations with nephritis and autoantibody production in systemic lupus erythematosus (SLE). *S.A. Chung[1], K.E. Taylor[1], S.L. May[2], P.P. Ramsay[2], H.L. Quach[2], J.A. Lane[3], J. Nititham[1], J.A. Noble[3], D.L. Quach[2], J.A. Kelly[4], K.L. Moser[4], T.W. Behrens[5], M.F. Seldin[6], J.B. Harley[7], P.M. Gaffney[4], L.F. Barcellos[2], L.A. Criswell[1].* 1) Rosalind Russell Medical Research Center for Arthritis, University of California, San Francisco, CA; 2) University of California, Berkeley, CA; 3) Children's Hospital Oakland Research Institute, Oakland, CA; 4) Oklahoma Medical Research Foundation, Oklahoma City, OK; 5) Genentech, Inc., South San Francisco, CA; 6) University of California, Davis, CA; 7) Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

The major histocompatibility complex (MHC) on chromosome 6p21 is the most significantly associated genomic region with systemic lupus erythematosus (SLE). Prior attempts to identify MHC associations independent of *HLA-DRB1* (the most consistently associated locus) have been limited, in part, by the region's extensive linkage disequilibrium. In addition, MHC associations with specific SLE manifestations such as lupus nephritis, anti-double-stranded DNA (anti-dsDNA), and anti-Ro/La (SSA/SSB) autoantibody production have not been fully explored. To identify independent MHC associations with these SLE manifestations, we genotyped 1,610 SLE cases of European descent for 2,360 MHC single nucleotide polymorphisms (SNPs), *HLA-DRB1* alleles, and 384 ancestry informative markers. Lupus nephritis and autoantibody status were obtained from medical record review. After applying stringent quality control criteria (including removal of SLE cases with <90% northern European ancestry), we analyzed 1,974 SNPs in 1,125 SLE cases. Thirty-two percent (32%) had lupus nephritis, 50% had anti-dsDNA autoantibodies, and 27% had anti-Ro/La (SSA/SSB) autoantibodies. Relative predispositional effects analysis showed that different *HLA-DRB1* alleles were associated with lupus nephritis as compared to anti-Ro/La (SSA/SSB) autoantibody production (**1501* and **1302* for nephritis vs. **0301*, **0401*, **0404*, **1301*, and **0101* for anti-Ro/La). No *HLA-DRB1* alleles were significantly associated with anti-dsDNA autoantibody production (global χ^2 p>0.05). Forward selection with conditional logistic regression based on haplotypes identified associations independent of *HLA-DRB1* in the *HLA-DOB*, *HLA-A/HCG9*, and *LEMD2* regions with lupus nephritis (OR for the most associated haplotype [OR_{hs}] 3.04, haplotype-specific p [p_{hs}]= 3.1E-04). *HLA-DRB1*-independent associations were observed in the *HLA-DPA1/HLA-DOA*, *C6orf205*, and *OR2H2* regions with anti-Ro/La (SSA/SSB) autoantibody production (OR_{hs} 3.23, p_{hs}=1.6E-08). SNPs in or near the *TAP2*, *C6orf10*, and *TRIM40/TRIM15* regions were associated with anti-dsDNA autoantibody production (OR_{hs} 2.82, p_{hs}=1.5E-08). In conclusion, we have identified several significant MHC associations with lupus nephritis and autoantibody production that are independent of *HLA-DRB1*. Of interest, different genes/genetic regions were associated with these specific SLE manifestations. These results indicate that MHC genetic variation contributes significantly to disease heterogeneity in SLE.

1000/W

Fine-Mapping the 13q21 Specific Language Impairment Locus in Extended Pedigrees. *T.R. Simmons[1], J.F. Flax[2,3], A.S. Bassett[4], P. Tallal[2], L.M. Brzustowicz[3], C.W. Bartlett[1].* 1) Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital & Department of Pediatrics, The Ohio State University, Columbus, OH 43203, USA; 2) Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102, USA; 3) Department of Genetics, Rutgers University, Piscataway, NJ 08854; 4) Department of Psychiatry, University of Toronto, Ontario M5T 1R8 and, Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario M5S 2S1 Canada.

Specific language impairment (SLI) is defined by the failure to develop language at the expected rate in the absence of cognitive, neurological, or psychological explanations. SLI is characterized by significant problems of comprehension and/or expression of spoken language though it is commonly comorbid with reading difficulties. Our previous linkage studies in 4 multiplex pedigrees implicated 13q21 as a critical region for an SLI susceptibility allele in those pedigrees selected for SLI and including family members with a significant reading impairment. To further refine localization in these pedigrees, dense SNP array genotyping was performed on one of two Illumina BeadArray systems. A total of 1865 SNPs with minor allele frequency > 5% in 13q21 were analyzed with the same reading impairment phenotype that was originally associated with the 13q21 locus. PPL linkage analysis of individual SNPs is in agreement with overall multiple linkage analysis with a peak posterior probability of 81%. Ongoing gene-gene interaction analysis using a functional coding SNP in the brain-derived neurotrophic factor (BDNF) gene increases the peak PPLs in the region to 99.9% in a narrowly defined region. These largest gene-gene interaction linkage signals span approximately 2 cM, thus narrowing down the critical region approximately 1.5 Mb. This region encompasses one known gene, protocadherin 17 (PCDH17), and ~1Mb upstream of the documented transcription start site. As the largest BDNF gene-gene interaction PPL results are upstream of PCDH17, rather than within the gene, it is possible that the SLI susceptibility allele will be present within the tissue-specific regulatory elements of PCDH17.

1001/W

A Genome-Wide Linkage Search for Genetic Loci Controlling Resistance to Tuberculosis. *E. Hoal[1], A. Cobat[2,3], C. Gallant[4], L. Simkin[4], G. Black[1], K. Stanley[1], J. Hughes[5], M. Doherty[6], W. Hanekom[5], B. Eley[7], N. Beyers[8], J. Jaïs[3], A. Boland-Auge[10], P. van Helden[1], J-L. Casanova[2,3,9], L. Abel[2,3,9], A. Alcaïs[2,3,9], E. Schurr[4].* 1) Molecular Biology and Human Genetics, Stellenbosch University, Tygerberg, South Africa; 2) Laboratory of Human Genetics of Infectious Diseases, Necker Branch, Institut National de la Santé et de la Recherche Medicale, Paris, France; 3) University Paris Descartes, Necker Medical School, Paris, France; 4) McGill Centre for the Study of Host Resistance & Departments of Human Genetics and Medicine, McGill University, Montreal, Canada; 5) South African Vaccine Initiative, Institute of Infectious Diseases and Molecular Medicine, Health Sciences Faculty, University of Cape Town; 6) Statens Serum Institute, Copenhagen, Denmark; 7) Paediatric Infectious Diseases Unit, Red Cross Children's Hospital, School of Child and Adolescent Health, University of Cape Town, South Africa; 8) Desmond Tutu TB Centre, Department of Paediatrics and Child Health, Faculty of Health Sciences, Stellenbosch University, Tygerberg; 9) Laboratory of Human Genetics of Infectious Diseases, Rockefeller Branch, Rockefeller University, New York, NY 10065; 10) Centre National de Génotypage, Institut de Génomique, Commissariat à l'energie atomique, Cedex Evry 91057, France.

Two-thirds of the global population is infected with Mycobacterium tuberculosis, yet tuberculosis (TB) disease manifests in less than 10% of infected individuals. TB is highly endemic in the Western Cape, South Africa, and this population is therefore very suitable to study genetic susceptibility. We found high heritability (>50%) for in vitro secretion of tumor necrosis factor a and interferon γ (IFNγ), and the frequency of antigen-specific IFNγ+CD4+ and IFNγ+CD8+ cells in the response of whole blood to mycobacterial challenge. In principal component analysis, the first 3 components explain 78% of the overall variance consistent with the effect of pleiotropic regulatory genes of human antimycobacterial immunity. We then set out to find genetic variants controlling susceptibility to infection by studying about 400 children and young adults in 128 families by means of a genome-wide linkage search. Most of the subjects tested were likely to have been exposed to TB, but about 20% did not show delayed type hypersensitivity (DTH) in a skin antigen test, appearing to be naturally resistant to infection by M. tuberculosis. This strong resistance mapped to a 6-Mbp chromosome region, 11p14 ($p = 1.5x10-5$) called TST1. The existence of this locus suggests that we could one day manipulate cellular mechanisms to achieve TB prevention - an important goal given the lack of an effective vaccine and the rise in drug-resistant strains. The second locus, in the 2.9-Mbp 5p15 region ($p < 10-5$) called TST2, segregated with differing extents of TB skin test response or the intensity of T-cell-mediated DTH to tuberculin. These genetic factors might contribute to whether an infected individual keeps the bacterium dormant or develops the disease. The measurement of TST did not correlate with IFNγ release, indicating that other pathways could be more important than this well-known cytokine. Fine mapping of the 5p15 region identified SLC6A3 as a promising candidate gene. This gene is a solute carrier (SLC) family member, which could influence granuloma responses to mycobacteria, and loss of the mouse SLC6A3 protein reduces DTH response to ovalbumin. We therefore identified one major locus that determines innate resistance to M. tuberculosis infection in endemic areas and a second that controls the extent of that response via critical regulators of T-cell dependent DTH. These results indicate that one major genetic locus may control resistance to the pathogen in humans.

1002/W

Variants in the neuregulin 1 gene are associated with nicotine dependence. *K. Jackson, J. Chen, K. Kendler, X. Chen.* Virginia Commonwealth University 800 E. Leigh St, Suite 390A Richmond, VA 23298.

Neuregulin 1 (NRG1), located on chromosome 8p12, encodes a protein that acts as a signaling molecule involved in cell-cell interactions and glutamatergic neurotransmission. NRG1 is a leading candidate gene in schizophrenia, and has been implicated in bipolar disorder. While smoking is highly comorbid with many mental disorders, including schizophrenia and bipolar disorder, the role of NRG1 in smoking and nicotine dependence (ND) is unclear. Thus, the goal of this study was to determine if variants in the NRG1 gene are associated with ND. We first tested the association of SNP markers with ND, the Fagerström Test for ND (FTND) and the number of cigarettes smoked per day (numCIG) in the control subjects of the study of Molecular Genetics of Schizophrenia supported by the Genetic Association Information Network (MGS-GAIN) and MGS-nonGAIN European-American samples. Four representative SNPs were selected to be replicated in selected subjects from the Virginia Adult Twin Study of Psychiatric and Substance Use Disorder (VA-Twins). Of the 4 markers tested, 2 markers (rs2976514 and rs16879814) were significantly associated with ND and FTND score. After correction for multiple testing, one marker (rs2976514) reached experiment wide significance for both phenotypes. The markers were also tested for association in MGS-GAIN African-American subjects. Two markers were found to be significant for ND or FTND, and one marker was marginally significant after correction for multiple testing for both phenotypes. These results suggest that variants in NRG1 are associated with ND.

Identifying The Mitochondrial Genetic Contribution To Metabolic Syndrome. *P. Bonnen[1], I. Pe'er[2], M. Stoffel[3], J. Friedman[3], J. Breslow[3], D. Murdock[1].* 1) Baylor College Med, Houston, TX; 2) Columbia University, New York, NY; 3) Rockefeller University, New York, NY.

Metabolic Syndrome (MetS) is the clustering of obesity, diabetes, hypertension, and dyslipidemia in one individual and is thought to affect over 50 million people in the United States. Mitochondrial function is central to energy metabolism. Rare mutations in the mitochondrial genome cause diabetes with deafness and other metabolic phenotypes. We are conducting family-based studies aimed at determining the mitochondrial genetic contribution to MetS and its component disorders. The Micronesian island of Kosrae is a rare genetic isolate that offers significant advantages for genetic studies of human disease. Kosrae suffers from one of the highest rates of MetS (41%), obesity (52%), and diabetes (17%) globally and has a homogeneous environment making this an excellent population in which to study these significant health problems. We have generated mitochondrial genotype and sequence data on over 3,000 individuals and are conducting family-based analyses aimed at identifying specific mitochondrial variants that contribute to obesity and other co-morbid conditions.

1004/W

A mitochondrial polymorphism 12361A>G is associated with non-alcoholic fatty liver disease. *M. Lu[1], J. Huang[1], Y. Liao[1], R. Bai[2], R. Trieu[2], W. Chuang[1], M. Yu[1], S. Juo[1], L. Wong[2].* 1) Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, USA.

Background Non-alcoholic fatty liver disease (NAFLD) can range from simple hepatic steatosis, nonalcoholic steatohepatitis (NASH) to cirrhosis. Insulin resistance and oxidative stress are responsible for the pathogenesis of NAFLD. Mitochondrial dysfunction is one of the causes of insulin resistance and impairment of oxidative phosphorylation. We hypothesized that mtDNA polymorphisms are associated with the development of NAFLD. **Methods** We conducted a two stage case-control study with 1281 participants to investigate the association between mtDNA variants and NAFLD in a Chinese population. The diagnosis of NAFLD was based on the presence of fatty liver by ultrasound sonography, and exclusion of alcohol abuse and other secondary factors. We initially screened 79 selected mitochondrial single nucleotide polymorphisms (mtSNPs) in 279 subjects (NAFLD n=160; control n=119). The most significant SNP (mt12361A>G) was validated in 1002 additional subjects (NAFLD n=477, control n=525). **Results** In the screening dataset, two mtDNA variants (mt12361A>G and mt709A>G), haplogroups D4 and M8 were found to be associated with the predisposition to NAFLD. In the follow-up dataset, the individuals carrying the mt12361G variant had an odds ratio (OR) of 8.61 for the severe NAFLD group (95% confidence interval [CI] = 2.85~26.05, adjusted p-value=1.4x10-4) and an OR of 4.13 for the moderate NAFLD group (95% CI =1.64~10.38, adjusted p-value=2.6x10-3) compared with those carrying the mt12361A variant. Moreover, the mt12361 G carriers had a 4.19-fold risk for NASH compared to mt12361 A carriers (95% CI=1.12~12.95, p-value=0.031). **Conclusions** Subjects carrying the mt12361G variant had higher risk to develop moderate/severe NAFLD and NASH.

1005/W

GENETIC POLYMORPHISMS OF WNT INHIBITORS ARE ASSOCIATED WITH BONE MASS: A GENE-WIDE STUDY. *J.A. Riamcho[1], C. Valero[1], B. Pineda[2], J.L. Hernandez[1], J.M. Olmos[1], A. Cano[2], M.A. Garcia[2], M.T. Zarrabeitia[1].* 1) Hospital U.M.Valdecilla, Santander, Spain; 2) Hospitales Clinico and Pesset, Univ. Valencia, Valencia, Spain.

Wnt agonists stimulate bone formation and have an anabolic effect on bone. Their activity is modulated by a number of extracellular inhibitors, including SFRP3 and sclerostin, the products of FRZB and SOST genes. The objective of this study was to explore the relationship of common allelic variants of these genes with bone mineral density (BMD). Twelve tagging SNPs of the FRZB gene and 7 of the SOST gene were analyzed in 1043 Spanish postmenopausal women over 50 years of age (mean 66±8). Women with present or past diseases or treatments known to influence skeletal homeostasis were excluded. BMD was measured by DXA. Several FRZB polymorphisms and haplotypes were associated with BMD in the discovery cohort, particularly at the spine (p=0.002), but the results were not confirmed in the replication cohort. On the other hand, several polymorphisms located in the 5' region of the SOST gene, within 1.1 kb of the translation start site, were associated with BMD in both the discovery and replication cohorts, in the single locus and the haplotypic analyses. The strongest association was found with the G/C rs851056 polymorphism. The combined standardized weighted mean difference between women homozygotes for the minor allele and those with other genotypes was 0.3 standard deviations (95% confidence interval 0.2-0.5; p<0.0001). Bioinformatic tools suggested that a putative c-Myc binding site was lost in G alleles. In summary, this study confirms that polymorphisms in the 5' region of the SOST gene are associated with BMD in postmenopausal women. We also found an association of some FRZB polymorphisms with BMD, but it could not be replicated in an independent cohort. Therefore, its actual biological relevance is uncertain.

1006/W

The genetic polymorphisms of Apelin are associated with obesity phenotypes in Chinese women but not men. *Y.T. Wang[1], Y.C. Liao[2,3], Y.N. Li[1], S.H.H. Juo[1,4].* 1) Department of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Graduate Institute of Medicine, Kaohsiung Medical University, Taiwan; 3) Section of Neurology, Taichung Veterans General Hospital, Taichung, Taiwan; 4) Department of Medical Research, Kaohsiung Medical University Hospital.

Background: Obesity is a risk factor for cardiovascular related diseases and cancers. Adipocytes play an important role in obesity. Recent research on adipocyte biology has revealed that adipocytes produce and secrete a variety of bioactive substances, named ''adipokines''. Apelin is a newly found adipokine and apelin serum levels have been reported to be associated with obesity. We aimed to test whether genetic polymorphisms at the apelin gene is associated with obesity and waist circumference. Methods: We selected four common (MAF > 10%;) tagging SNPs (rs3115757, rs2235310, rs3761581 and rs2235307) and used the TaqMan assay for genotyping. A total of 1041 women and 790 men were recruited in this study. Two obese phenotypes were used: waist circumference (less than 80 cm in women, less than 90 cm in men as Asian criteria in metabolic syndrome), and BMI (BMI < 24 normal, 24-27 overweight, > 27 obesity according to the guideline by the Taiwan government). Results: The mean age is 51.7 (13.0) for women and 53.5 (13.9) for men. Forty-four percent (n=460) of women and 44.6% (n=352) of men had over waist circumference. For women, 51.5% (n=467), 28.0% (n=262) and 19.6% (n=178) were in normal, over-weighted and obese categories, respectively. For men, 36.5% (n=261), 34.1% (n=244) and 29.4% (n=210) were in normal, over-weighted and obese categories, respectively. Both waist circumference and obesity are associated with SNP rs3115757 (p=0.002 and 0.009, respectively, after adjusting for age, DM, hypertension and hyperlipidemia) in women. However, this SNP was not significant in men (p > 0.1). SNP rs2235310 was associated with waist circumference (p=0.007) but not obesity in women. Again, this SNP is not significant in men (p>0.7). Conclusion: Apelin genetic variants can predict the obesity phenotypes in women but not in men. Since this gene is located on X chromosome, we are investigating whether there is a chromosome dose effect.

1007/W

Polymorphisms in Heat Shock 70kDa Protein 4 Gene Are Associated with Severity of Sepsis and Acute Lung Injury in African Americans. *N.M. Rafaels[1], L. Gao[1], T. Murray[1,2], R.A. Mathias[1], J.P. Maloney[4], M. Moss[4], G. Martin[5], C. Shanholtz[6], J.G.N. Garcia[7], J. Sevransky[3], T.H. Beaty[2], R. Brower[3], P.H. Hassoun[3], K.C. Barnes[1].* 1) Division of Allergy and Clinical Immunology, Department of Medicine, Johns Hopkins, Baltimore, MD; 2) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins, Baltimore, MD; 3) Division of Pulmonary and Critical Care Medicine, Department of Medicine, Johns Hopkins, Baltimore, MD; 4) University of Colorado Health Sciences Center, Denver, CO; 5) Emory University School of Medicine, Atlanta, GA; 6) University of Maryland School of Medicine Baltimore, MD; 7) Department of Medicine, Pritzker School of Medicine, University of Chicago, Chicago, IL.

Rationale: Acute lung injury (ALI) and sepsis are significant causes of morbidity and mortality worldwide. Severe sepsis (and sepsis-associated ALI) is characterized by increased inflammation throughout the entire body and an elevated white blood cell count. Short term highly intense physiological stress has been shown to increase levels of heat shock proteins in leukocytes. In this study, we tested the hypothesis that single nucleotide polymorphisms (SNPs) in Heat Shock70kDa Protein, *HSPA4*, are associated with severity (characterized by APACHE II score) in a population of 976 subjects.

Methods: We genotyped 9 *HSPA4* SNPs using the Illumina GoldenGate platform of 1536 SNPs in a primary population of 925 European American patients with severe sepsis (N=326), sepsis-associated ALI (N=297) and 302 control subjects. An independent population of 759 African American subjects (195 severe sepsis patients, 158 ALI patients, and 406 controls) served as the replication group. SNP associations were tested under a logistic regression model using PLINK adaptive permutations model.

Results: Analysis of APACHE II score using 1536 SNPs revealed four *HSPA4* intronic SNPs (rs4705990, rs10075878, rs4367292, and rs4574536) were associated with higher APACHE II scores in African Americans (P= 0.0008, 0.0011, 0.0011, and 0.0097, respectively). When comparing severe sepsis patients to controls, these same 4 SNPs were associated with greater risk of sepsis but the risk allele for APACHE II score was protective against sepsis in African Americans (0.021, 0.037, 0.035, and 0.010, respectively). No associations were found in European Americans, however, allele frequencies between European American and African American controls were quite different: for rs4705990 (AA: 0.29 (C), EA: 0.74 (C)), rs10075878 (AA: 0.28 (A), EA: 0.48 (A)), and rs4367292 (AA: 0.41 (C), EA: 0.72 (C)).

Conclusions: Our findings suggest *HSPA4* is a putative candidate gene for severity of sepsis and sepsis-associated ALI in African Americans but the different frequencies and linkage disequilibrium patterns in the *HSPA4* gene between European American and African American groups warrant further investigation.

1008/W

ADHD genes are associated with being born small for gestational age: Results from the Auckland Birthweight Collaborative study. *A.R. Morgan[1,2], J.M.D. Thompson[3], K.E Waldie[4], C.M. Cornforth[5], D. Turic[5], E.J.S. Sonuga-Barke[5], W.J. Lam[1,2], L.R. Ferguson[1,2], E.A. Mitchell[1,2].* 1) Discipline of Nutrition, FMHS, The University of Auckland, New Zealand; 2) Nutrigenomics New Zealand; 3) Department of Paediatrics, FMHS, The University of Auckland, New Zealand; 4) Department of Psychology, The University of Auckland, New Zealand; 5) Institute for Disorders of Impulsivity and Attention, School of Psychology, The University of Southampton.

Children born small for gestational age (SGA) are at increased risk for developing Attention-Deficit Hyperactivity Disorder (ADHD), symptoms of which include inattention, overactivity and impulsivity. Altered neurotransmitter activation in frontal brain structures, accompanied by an imbalance of activity in frontostriatal regions, is thought to characterise this genetically complex disorder. Here we present data from the Auckland Birthweight Collaborative (ABC) Study in which we investigated possible association between ADHD susceptibility genes involved in neurotransmission and being born SGA. After controlling for gestational age, gender, socio-economic status, maternal education, marital status, antenatal class attendance, primiparity, maternal tobacco / marijuana smoking during pregnancy and maternal hypertension, the COMT, HTR2A, SLC1A3, and SLC6A1 genes continued to show significant associations with SGA. Although these have been linked to ADHD in earlier research, this is the first report to date to reveal associations for these genes with SGA.

1009/W

A functional variant within the ubiquitin-associated domain-containing protein 2 gene (UBAC2) is associated with increased risk of Behçet's disease. *A. Sawalha[1], T. Hughes[1], A. Nadig[1], V. Yilmaz[2], K. Aksu[3], G. Keser[3], A. Cefle[4], A. Yazici[4], A. Ergen[5], H. Direskeneli[6], G. Saruhan-Direskeneli[2].* 1) Dept Rheumatology & Arthritis and Immunilogy, OUHSC/VAMC/OMRF, Oklahoma City, OK; 2) Department of Physiology, Istanbul University, Istanbul School of Medicine, Istanbul, Turkey; 3) Department of Rheumatology, Ege University, School of Medicine, Izmir, Turkey; 4) Department of Rheumatology, Kocaeli University, School of Medicine, Kocaeli, Turkey; 5) Ophthalmology Clinic, Okmeydani Research and Education Hospital, Istanbul, Turkey; 6) Department of Rheumatology, Marmara University, School of Medicine, Istanbul, Turkey.

Objectives: Using a genome-wide association scan and DNA pooling, we previously identified 5 novel genetic susceptibility loci for Behçet's disease. Herein, we fine-map the genetic effect within the UBAC2 gene, replicate this genetic association in an independent cohort of Behçet's disease patients and controls, and identify a functional polymorphism in this locus. Methods: Two independent cohorts of Behçet's disease patients and controls from Turkey were studied. The discovery and replication cohorts included 152 patients and 172 controls, and 376 patients and 369 controls, respectively. Genotyping of 14 SNPs within and around UBAC2 was performed using TaqMan SNP genotyping assays. Results: The genetic association between Behçet's disease and UBAC2 was established and confirmed in two independent cohorts of patients and controls (Meta-analysis OR= 2.05, meta-analysis P= 1.75X10-7). Haplotype analysis identified both a disease risk and a protective haplotype (P= 0.00014 and 0.0075, respectively). Using conditional haplotype analysis we identified that the SNP rs7999348 (A/G) within UBAC2 is the most likely SNP to explain the genetic effect in this locus. Indeed, we demonstrate that rs7999348 is a functional SNP that results in increased mRNA expression of a UBAC2 transcript variant in PBMCs of individuals homozygous for the Behçet's disease-associated "G" allele. Conclusion: We establish and confirm the genetic association between UBAC2 and Behçet's disease in two independent cohorts of patients and controls. Fine mapping of this genetic effect and conditional analysis followed by functional studies identified the minor allele in rs7999348 as a disease-risk allele that alters UBAC2 expression.

1010/W

Localization of psoriasis candidate gene product CCHCR1 at centrosomes. *M.H. Tervaniemi[1,2], C. Söderhäll[3], H.A. Siitonen[1,2], L. Samuelsson[5], S. Suomela[4], U. Saarialho-Kere[4], J. Kere[1,2,3], O. Elomaa[1,2].* 1) Department of Medical Genetics, Haartman Institute, University of Helsinki, Helsinki, Finland; 2) Folkhalsan Institute of Genetics, Biomedicum Helsinki, Helsinki, Finland; 3) Department of Biosciences and Nutrition, Karolinska Institutet, Stockholm, Sweden; 4) Department of Dermatology, Helsinki University Central Hospital and University of Helsinki, Helsinki, Finland; 5) Department of Clinical Genetics, Sahlgrenska University Hospital, Gothenburg, Sweden.

Psoriasis is a common dermatological disorder, affecting 2-3 percent in Caucasians. It is characterized by abnormal proliferation, differentiation of keratinocytes and infiltration of inflammatory cells. This multifactorial disease is caused by both genetic and environmental factors. Several candidate gene loci for psoriasis (PSORS1-9) have been identified. *CCHCR1* (coiled-coil alpha-helical rod protein 1) is a plausible candidate gene in the PSORS1 locus (6p21.3) whose role as a psoriasis effector gene is unsettled although it resides in the region of strongest associations even in GWA studies. CCHCR1 has different expression pattern in psoriatic vs. healthy skin and is suggested to have a role in cell proliferation. We have recently cloned a novel variant of CCHCR1 (isoform 1) in which the N-terminal domain is 89 amino acid residues longer than in the previously studied form (isoform 3). In the present study we have genotyped the SNP (rs3130453) that controls the formation of the alternative isoforms using samples from 435 Finnish and Swedish psoriasis families. The allele for the variant 3 shows preferential transmission from heterozygous parents to affected offspring ($p<10^{-5}$). Here we show by immunofluorescent staining that both CCHCR1 isoforms have a centrosomal localization. They co-localize with a centrosome marker γ-tubulin but not with microtubule proteins α- and β-tubulin. However, the localization of CCHCR1 is partially dependent of microtubules indicated by Nocodazole treatment that disrupts the microtubules. After the treatment CCHCR1 can still be observed in association with centrosomes but also as granules in the cytoplasm. Stable over-expression of CCHCR1 in HEK293 cells results in nuclear aberrations, suggesting abnormalities in cell cycle control. As centrosomes are cell organelles that have a role in organization of the microtubules, cell cycle and division, centrosomal localization of CCHCR1 provides a connection to the abnormal proliferation. This novel hypothesis offers a link to the cellular pathways that are altered in psoriasis.

1011/W

Association of Calpain 10 (CAPN10) gene polymorphisms with Type 2 Diabetes (T2D) in the Population of Punjab. *K. Matharoo, I.S. Sidhu, R. Sharma, A.J.S. Bhanwer.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

The polymorphisms of Calpain 10 (CAPN 10)gene has been associated with T2D. Calpain10 is a member of a large family of intracellular proteases and resides in the 2q37.3 region. Variation in the calcium-activated neutral protease 10 gene (CAPN 10) was identified as a possible T2D susceptibility gene through positional cloning in Mexican-Americans. However, large differences were shown between ethnic groups at risk alleles and haplotypes as well as in their attributable risk. There is dearth of data pertaining to association of Calpain10 risk alleles with T2D in the North Indian Punjabi population, which is experiencing a considerable increase in the prevalence of T2D due to economic shift. Thus, it is important to determine the role of calpain 10 in the North Indian Punjabi population. We examined three SNPs in the Calpain10 gene (-43, -19, and -63) in case control cohort comprising 200 T2D cases and 200 age and sex matched controls from Punjabi population. Genomic DNA was extracted from peripheral blood (obtained with informed consent) by phenol-chloroform method. Genotyping for SNP19 (insertion/deletion polymorphism) was done PCR followed by detection on agarose gel while SNP43 and 63 were genotyped by PCR-RFLP method. The genotype and allele frequency distribution did not reveal any statistically significant difference for SNP19 (p=0.653, 0.357, respectively) and SNP 43 (p=0.507, 0.301). For SNP63, a significant association of genotypes was observed (p=0.009). However, no significant association could be documented after correction for age, sex and BMI using linear regression in CC vs CT&TT [p=0.295; 1.45(0.72-2.93)] and comparison of CT with CC&TT [p= 0.11; 0.59(0.31-1.12)]. Further analysis in males and females revealed a significant association in genotype distribution between cases and controls in males for SNP63 (p=0.000). After correction for age, BMI and WHR a protective association of CT vs. CC+TT was observed against T2D in males [p=0.002; 0.22(0.08-0.57)]. However, no association was observed in females. Haplotype analysis revealed highest frequency of 112/112 (0.229) followed by 111/111(0.217). Conversely, none of the haplotype combinations were found to be associated with T2D. The results of the present study suggest a sex specific protective association of SNP63 genotypes with T2D. However, analysis on a larger number of samples is required to determine the association of Haplotype at the CAPN 10 locus.

1012/W

Variants in Dynamin Binding Protein Increase Risk of Glaucoma. *M. Hauser[1], Y. Liu[1], X.-J. Qin[1], M. Ulmer[1], B.-J. Fan[3], J.-D. Ding[2], L. Pasquale[3], C. Bowes Rickman[2], J. Wiggs[3], E. Oh[4], N. Katsanis[4], S. Schmidt[1], R. Rand Allingham[2].* 1) Ctr Human Gen, Duke Univ Med Ctr, Durham, NC; 2) Department of Ophthalmology, Duke Univ Med Ctr, Durham, NC; 3) Department of Ophthalmology, Harvard Med Sch, Boston MA; 4) Department of Cell Biology, Duke Univ Med Ctr, Durham, NC.

Genes identified to date account for only a small proportion of primary open angle glaucoma (POAG). We report here the identification of a C1413W coding variant of dynamin binding protein (DNMBP) that confers risk of POAG (OR=1.26; 95%CI=1.07-1.47). Evidence for association increases in a subset of patients characterized by onset of disease prior to age 53 (OR= 1.61; 95%CI=1.28-2.02), and increased intraocular pressure as compared to other cases (p=0.0002). DNMBP is a multifunctional docking protein that could modulate glaucoma risk by affecting vesicle transport, cell signaling, axon and dendrite growth and cell motility in the neural retina and the trabecular meshwork. The C1413W variant conveys a population attributable risk percentage of 17%, the largest genetic effect in POAG described to date. A knockdown of DNMBP in primary cultures of murine neonatal cortical neurons induces statistically significant neurite extension and arborization phenotypes, making it likely that allele-specific disruptions of DNMBP activity could be resonsible for glaucoma-related neuropathology.

1013/W

Type 2 Diabetes (T2D) Associated SNPs Regulate Expression of Adjacent Transcripts in Subcutaneous Adipose Tissue and Muscle from Caucasian and African American Subjects. *S.K. Das, N.K. Sharma, K.A. Langberg, A.K. Mondal, S.C. Elbein.* Internal Medicine/Endocrinology, Wake Forest University Health Sciences, Winston-Salem, NC.

Published genome wide association scans have identified regions with single nucleotide polymorphisms (SNPs) that increase T2D susceptibility, alter glucose homeostasis, or both. Because most variants are noncoding and of unknown function, we hypothesized that these SNPs act by modulating the transcription of nearby genes in adipose and muscle. To address this hypothesis, we tested the association of these SNPs with the expression of their nearest transcripts in subcutaneous (sc) adipose and muscle from individuals who spanned a broad range of insulin sensitivity (SI) and body mass index (BMI). We successfully tested association of 22 SNPs with 21 transcripts in sc. adipose from 153 individuals [13 T2D, 140 nondiabetic; 106 Caucasian (C), 47 African American (AA)] and 17 SNPs with 15 transcripts in 168 individuals [13 T2D, 155 nondiabetic; 122 C, 46 AA]. Expression values from qRT-PCR were normalized with 18S control and log transformed for analysis. Association was tested with or without adjustment for age, sex, BMI and ethnicity. *SYN2* expression in adipose was associated with rs17036101 in nondiabetic C, with lower expression among homozygous carriers of the risk allele (p_{adj}= 0.001). *DNAJC11* expression in adipose was similarly reduced in C in rare homozygotes for rs1043681 (p< 0.05), as was *TSPAN8* with rs7961581 (p< 0.05). *NOTCH4* expression was strongly associated in sc adipose from all individuals and C, with lowest expression in the rare allele homozygotes (p= 0.0003, p_{adj}= 0.001). Nominal associations were also seen for rs906216 and *HK1* expression (p<0.05). No association was observed with nearby SNPs for genes for *ADAMTS9, CAMK1D, CDC123, CDKAL1, FTO, HHEX, IDE, JAZF1, NOTCH2, PPARG, SMARCAD1, TCF7L2, THADA, VEGFA*, or *WFS1* in adipose. *PKN2* transcript levels were associated with rs6698181 in both adipose (p= 0.009, p_{adj}= 0.004) in C and muscle (p= 0.00004, p_{adj}= 0.001) in all subjects with reduced expression in risk allele homozygotes. Nominal associations of SNPs with muscle transcript levels were also seen for rs864745 and *JAZF1* in all subjects (p= 0.02); for rs7578597 and *THADA* in C (p= 0.05); and rs10010131 and *WFS1* in C (p= 0.05). We show that a subset of T2D associated SNPs likely increase T2D susceptibility by directly or indirectly modulating expression of neighboring transcripts. Our studies in diabetes-relevant tissues provide the basis for mapping the functional variants and determining the role of these genes in adipose and muscle.

1014/W

Sex Hormone Binding Globulin (*SHBG*) $(TAAAA)_n$ polymorphism is associated with SHBG levels and measures of fetal size in a Hispanic cohort. *C. Ackerman[1], M.G. Hayes[1], L.P. Lowe[2], H. Lee[1], A.R. Dyer[2], B.E. Metzger[1], W.L. Lowe[1], M. Urbanek[1], HAPO Study Cooperative Research Group.* 1) Division of Endocrinology, Dept of Medicine, Northwestern University, Chicago, IL; 2) Dept of Preventive Medicine, Northwestern University, Chicago, IL.

Sex hormone-binding globulin (SHBG) is a glycoprotein that binds sex hormones and regulates their biological activity. Low circulating levels of SHBG are associated with altered glucose levels and an increased risk of type 2 diabetes (T2D). Given the known impact of maternal glycemia and fetal insulin production on fetal size at birth, we hypothesized that genetic variation in *SHBG* may impact circulating SHBG levels and subsequent size at birth.

The $(TAAAA)_n$ repeat in the *SHBG* promoter affects transcription of the gene and serum SHBG levels. To determine whether the $(TAAAA)_n$ repeat is associated with fetal size, we genotyped 3422 Caucasian babies, 2066 Thai babies, 1203 Afro-Caribbean babies, and 768 Hispanic babies at the *SHBG* $(TAAAA)_n$ repeat in the multi-ethnic Hyperglycemia and Adverse Pregnancy Outcome (HAPO) cohort, and tested for associations between *SHBG* $(TAAAA)_n$ genotype and fetal traits (birth weight, birth length, head circumference, sum of skinfolds, fat mass, percent bodyfat, cord C-peptide, and neonatal 2-hr plasma glucose). Associations were assessed through linear regressions with single outcomes under an additive model and adjusted for covariates. We found evidence for associations between *SHBG* allele 7 (A7, 7 TAAAA repeats) and measures of fetal growth and adiposity in the Hispanic population. Specifically in the Hispanic male babies, after adjusting for covariates, *SHBG* A7 was negatively associated with birth weight (β= -72.23g per allele, *P*=0.02), head circumference (β= -0.22cm, *P*=0.02), log-transformed sum of skinfolds (3.92% decrease in sum of skinfolds per allele, *P*=0.01), fat mass (β= -27.1g, *P*=0.03), and percent body fat (β= -0.57%, *P*=0.001). Trends in the same direction were also observed in the Hispanic females and Caucasian males, but did not reach significance.

To determine if *SHBG* $(TAAAA)_n$ genotype had an impact on SHBG levels, we assayed 255 Hispanic babies for serum SHBG. We tested for associations between *SHBG* $(TAAAA)_n$ repeat length and SHBG levels. We found significant negative associations between average *SHBG* $(TAAAA)_n$ repeat length and log-transformed SHBG levels (4.88% decrease in SHBG level per repeat, *P*=0.003) in male babies, and similar but nonsignificant trends in the females. Our results indicate that genetic variation at the *SHBG* promoter $(TAAAA)_n$ repeat is inversely correlated with circulating SHBG levels and fetal size at birth.

1015/W

Genetic basis of Common Human Disease: Insight into the role of non-synonymous SNPs from Genome Wide Association Studies. *L.R. Pal[1], J. Moult[1,2].* 1) Institute for Bioscience and Biotechnology Research, University System of Maryland, Rockville, MD; 2) Department of Cell Biology and molecular Genetics, University of Maryland at College Park.

Recent genome wide association studies have led to the reliable identification of multiple common SNPs associated with increased incidence of a number of common human diseases. These results offer the tantalizing prospect of major new insights into disease mechanisms. A variety of mechanisms may link the presence of a SNP to altered in vivo gene product function and hence contribute to disease risk. We have explored the role of one of these mechanisms, non-synonymous SNPs in proteins, for associations found in the Wellcome Trust Case Control Consortium (WTCCC) seven disease study and follow-up work. Using Hapmap data, we first identified all non-synonymous SNPs in linkage disequilibrium with those associated with increased disease risk. We then applied two computational methods to determine which of these SNPs has a significant deleterious effect on in vivo protein function (SNPs3D, http://www.snps3d.org). A number of these disease loci are found to be linked to one or more deleterious non-synonymous SNPs. In some cases, these SNPs are in well known proteins, such as HLAs. In others, they are in less well established disease genes (for example, MST1 for Crohn's disease) and in still others, they are in so far little investigated proteins (for example gasdermin B, also for Crohn's disease). Together, these data suggest a very significant role for this class of SNPs in common human disease susceptibility.

1016/W

A 3'UTR Variant Is Associated with Impaired Expression of CD226 in T and NK T Cells and Susceptibility to Systemic Lupus Erythematosus. *S.E. Löfgren[1], A.M. Delgado-Vega[1], C.J. Gallant[1], E. Objective. CD226 has recently been associated with a number of autoimmune diseases with the SNP rs763361 been proposed as the putative causative variant. We here report a fine mapping of the gene locus and the genetic association of several SNPs with systemic lupus erythematosus in Europeans, together with functional analyses to give a better understanding on the mechanisms behind the gene association and potential contribution of these variants. Methods. Genetic association of 12 SNPs in the CD226 gene was conducted using 1194 SLE patients and 1454 healthy controls from a European multicenter collection. Genotyping was performed using a GoldenGate Custom Genotyping Assay and a BeadXpress Reader from Illumina or Taqman assay and the statistical association analyzed with PLINK v1.07. Gene expression was analyzed by quantitative real-time PCR and SYBR Green for signal detection, using total RNA purified from PBMCs from healthy donors. Surface detection of the protein was performed by a three-color flow cytometry using leukocytes isolated from healthy donors, where total lymphocytes, CD3+CD4+, CD3+CD8+, CD3-CD56+, CD3-CD19+ and CD3+CD56+ cells were analyzed. Expression analysis of reporter plasmids including different alleles of the risk haplotypes of the CD226 3'-UTR region was assessed by transfection of HEK293 cells and dual luciferase assay. Results. A risk haplotype ($P = 3.96 \times 10^{-6}$) was detected in the 3'-UTR region of the gene, and revealed rs727088 as the strongest associated variant ($P_{CMH\text{-}adjusted} = 0.0098$). Expression analysis showed that the risk haplotype correlated with decreased levels of CD226 transcripts and protein levels in the surface of T helper cells (CD4+), Cytotoxic T cells (CD8+) and NK T cells (CD3+CD56+), but not NK cells (CD3-CD56+) or B cells (CD19+). Luciferase assays suggest that rs727088 is the main polymorphism responsible for altered gene expression. Conclusion. Our data does not support Gly307Ser as main functional variant within CD226 gene and indicates rs727088 located in the 3'UTR region as the potential causative SNP, by a mechanism that alters protein expression in T cells, potentially involving mRNA processing and/or stability.

1017/W

The evaluation of a loss-of-function GBA variant found in patients with Parkinson disease. *N. Tayebi, Y. Blech-Hermoni, JH. Choi, W. Westbroek, BK. Stubblefield, E. Sidransky.* Section on Molecular Neurogenetics, Medical Genetics Branch/NHGRI, NIH, Bethesda, MD.

Recent studies demonstrate an increased frequency of mutations in the gene encoding glucocerebrosidase (GBA), the enzyme deficient in Gaucher disease, among patients with Parkinson disease. One particular GBA mutation, c.84dupG, a founder mutation in the Ashkenazi Jewish population, was found with a frequency of 2.1% among Ashkenazi patients with Parkinson disease as compared to 0.27% in controls. In this mutant allele, the insertion of a G introduces a frameshift in the signal peptide sequence of glucocerebrosidase, causing a complete deficiency of the enzyme and generating a STOP codon ,TAA, 25 amino acids downstream from the insertion. The mutation has never been encountered in the homozygosus state and is presumed to be lethal. We evaluated the consequences and potential toxicity resulting from this alteration. RNA was extracted from fibroblasts from patients heterozygous for c.84dupG and controls. An RNA protection assay, RT-PCR using different primer sets, and subcloning followed by sequencing of each allele were performed, excluding an alternative exonic splice site. In vitro translation assays indicated no translation of the predicted 25 amino acid peptide. The small peptide was synthesized and an antibody was generated. Using the conjugated peptide as a positive control, the small peptide as not detected in Western blots of fibroblasts from patients with the c.84dupG allele. Moreover, the peptide was not seen in these fibroblasts on confocal microscopy. No morphological changes were observed in Cos-7 and CHO cell lines transfected with a pcDNA3.1 GBA construct expressing c.84dupG, excluding a toxic effect of the peptide. These studies indicate that c.84dupG is a loss-of- function mutation, implicating the deficiency of enzymatic activity in Parkinsonian patients carrying this mutation.

1018/W

A functional polymorphism at 3' UTR of the PAX6 gene confers risk for extreme myopia in Chinese. *E. Hsi[1,2], C. Liang[3], K. Chen[4], Y. Pan[4], Y. Wang[4], S. Juo[2,4].* 1) Dept Med, Kaohsiung Med Univ, Kaohsiung, Taiwan; 2) Dept Med Research, Kaohsiung Med Univ, Kaohsiung, Taiwan; 3) Bright-Eyes Clinic, Kaohsiung, Taiwan; 4) Dept Med Genetics, Kaohsiung Med Univ, Kaohsiung, Taiwan.

Purpose: The *paired box 6* (*PAX6*) is involved in eye development and associated with several ocular diseases. Conflicting results were reported regarding the association between *PAX6* polymorphism and myopia. We conducted a case-control study and functional assay, and identified a functional risk polymorphism for myopia. **Methods:** We enrolled 1083 cases (£ -6.0 D) and 1096 controls (≥ -1.5 D) from a Chinese population residing in Taiwan. Four common tagging single nucleotide polymorphisms (SNPs) and a SNP at the 3' untranslated region (UTR) were selected. The chi-square test was performed to assess the genetic effect and permutation was used to adjust for multiple testing. Luciferase reporter assay was conducted for the 3' UTR SNP to assess the allelic effect on gene expression. **Results:** SNPs rs644xxx and rs622xxx had marginal significance and further analyses showed that these SNPs were associated with extreme myopia (£ -11 D). The OR for extreme myopia was 2.1 (nominal p=0.012; empirical p=0.008) for the CC genotype at SNP rs662xxx at 3' UTR. Functional assay for SNP rs662xxx demonstrated that the C allele had a significantly lower expression level than the T allele (P=0.0001). SNP rs662xxx was predicted to be located in the microRNA-328 binding site and this mechanism may explain the differential allelic effect on gene expression. **Conclusion:** We conducted a large study to identify a functional SNP located at the 3' UTR influencing the risk for extreme myopia. The functional assay suggested the risk allele can reduce *PAX6* protein level leading to a high risk for myopia.

1019/W

Inhibition of the Angiotensin Pathway Increases Bone Mass by Reducing Osteoclastogenesis. *S. Chen, T. Sibai, T. Yang, J. Tao, D. Napierala, B. Dawson, J. Black, Y. Chen, M. Jiang, B. Lee.* Howard Hughes Medical Institute and Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Hypertension and osteoporosis are common diseases affecting an increasingly aging population. The angiotensin pathway plays a central role in controlling blood pressure and is an important target for anti-hypertension drugs. Interestingly, through epidemiological studies in human as well as animal experiments, it has been found that the blockage of this pathway is associated with reduced risk of fractures, while activation of this signaling leads to bone loss. However, the mechanistic basis is largely unknown. Our aim in this study is to understand the effects of inhibiting the angiotensin pathway on bone homeostasis using the mouse model. We administered Losartan, an angiotensin II type I receptor antagonist in both wild-type (WT) and the ovariectomized (OVX) mice. After 6 weeks, Losartan-treated WT mice showed a significant increase in femoral cortical thickness, increased in trabecular bone volume/total bone volume (BV/TV), trabecular thickness, and trabecular number, and corresponding decrease of trabecular separation. Interestingly, we observed that osteoclast numbers were significantly decreased whereas osteoblast numbers did not change. Similarly, OVX mice treated with Losartan showed a significant improvement in trabecular BV/TV, trabecular thickness and bone mineral density. In conclusion, the inhibition of Angiotensin signaling by Losartan shows beneficial effects on bone mass via reduction of bone resportion secondary to a decrease in osteoclast numbers. These data suggest that use of angiotensin receptor antagonists may have added beneficial effects beyond treatment of hypertension.

Association study of MMP 13 gene polymorphisms and Kawasaki disease in Taiwanese children. *H. Chi[1,5,6], LY. Chang[2], FY. Huang[1,4], MR. Chen[1,6], NC. Chiu[1,6], HC. Lee[1,4], SP. Lin[1,3,6,7], WF. Chen[3], CL. Lin[3], HW. Chang[3], HF. Liu[3], LM. Huang[2,5], YJ. Lee[1,3,4].* 1) Pediatrics, Mackay Memorial Hosp, Taipei, Taiwan; 2) Pediatrics, National Taiwan University Hospital, Taipei, Taiwan; 3) Medical Research, Mackay Memorial Hospital, Tamshui, Taipei, Taiwan; 4) Pediatrics, Taipei Medical University, Taipei, Taiwan; 5) Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 6) Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 7) Department of Infant and Child Care, National Taipei College of Nursing, Taipei, Taiwan.

Introduction Kawasaki disease (KD) is a systemic vasculitis. Coronary artery lesions (CALs) complicate 15%-25% of cases of untreated KD. Matrix metalloproteinases (MMPs) have been considered to play pathophysiologic roles of CALs and the MMP-13 gene appears to be a susceptibility gene to the development of CALs in patients with KD in Japanese children. The aim of this study was to investigate if the single-nucleotide polymorphism (SNP) rs2252070 (A>G) and rs675392 (C>G) of the MMP 13 promoter gene is associated with susceptibility to KD or with CALs in Taiwanese children. Materials and Methods All patients with KD were from the Department of Pediatrics at Mackay Memorial Hospital and National Taiwan University Hospital, Taipei, Taiwan. A total of 170 unrelated Taiwanese children (101 boys and 69 girls) with KD were included, 66 of whom had CALs. Mean age at diagnosis was 1.8 ± 1.6 (0.1 - 7.4) years. rs2252070 and rs675392 were genotyped in children with KD and 344 ethnically matched healthy controls using the TaqMan Allelic Discrimination Assay. Results The genotype frequencies of the controls and patients were in Hardy-Weinberg equilibrium (P>0.05). The frequencies of the AA, AG, and GG genotypes for the rs2252070 were 24.1%;, 48.2%; and 27.6%; in the KD group, while they were 25.3%;, 46.5%; and 28.2%; in the control subjects, respectively. No significant differences in genotype, allele, and carrier frequencies of the SNP rs2252070 were found between healthy controls and children with KD (P=0.93, P=0.92 and P=0.95, respectively) or those with CALs (P=0.63, P= 0.64 and P=0.78, respectively). The frequencies of the CC, CG, and GG genotypes for the rs675392 were 40.0%;, 48.8%; and 11.2%; in the KD group, while they were 40.4%;, 43.3%; and 16.3%; in the control subjects, respectively. No significant differences in genotype, allele, and carrier frequencies of the SNP rs675392 were found between healthy controls and children with KD (P=0.25, P=0.46 and P=0.74, respectively) or those with CALs (P=0.72, P=0.99 and P=0.96, respectively). Three haplotypes with frequencies of more than 0.10 were estimated and accounted for about 99% of all haplotypes in both KD patients and controls. Discussion Despite the association of MMP13 gene polymorphism and KD with CALs in Japanese children, we did not find a similar association in our series. A more extensive array of SNPs may need to be assessed to find such an association.

1021/W

NXF/ARNT2/SIM2, RET expression regulation and specific HSCR associated DNA variants. *Y. Sribudiani[1], M. Metzger[2, 3], J. Osinga[1], A. Rey[1], A.J. Burns[2], N. Thapar[2], R.M.W. Hofstra[1].* 1) Genetics, University Medical Center Groningen, Groningen, Groningen, Netherlands; 2) Gastroenterology and Neural Development Units, Institute of Child Health, University College London, London, United Kingdom; 3) Translational Centre for Regenerative Medicine, University of Leipzig, Philipp-Rosenthal-Strasse 55, 04103 Leipzig, Germany.

Two non-coding RET variations, the T allele of SNP rs2435357 (Enh1-T) and the A allele of SNP rs2506004 (Enh2-A), are strongly associated with Hirschsprung (HSCR) susceptibility. These SNPs are in strong linkage disequilibrium and located in an enhancer element in intron 1 of the RET gene. For Enh1 it has been shown that the disease-associated T allele results in reduced expression in Luciferase experiments, via reduced SOX10 binding, compared to the non-disease associated C allele. We aimed to determine whether Enh2-A is also a functional variant by generating reporter constructs containing both alleles, separately or in combinations, coupled to the Luciferase gene. Luciferase assays showed that not only the Enh1-T allele but also the Enh2-A allele decreased Luciferase expression, thus both SNPs can contribute independently to HSCR development. Our results show that more than one SNP on an associated haplotype might influence disease development. MatsInspector software identified the sequences of Enh2-C (non-disease associated variant) and its surroundings sequences (-ACGTG-) as a potential binding site for the heterodimer transcription activator NXF/ARNT2, and the heterodimer transcription repressors SIM2/ARNT2. The binding affinity of NXF/ARNT2 to Enh2-C was confirmed by Electrophoresis Mobility Shift Assays and Supershift. Transfections of NXF/ARNT2 or SIM2/ARNT2 into neuroblastoma cell lines increase and decrease RET expression, respectively. Therefore, these data strongly indicated an involvement of NXF, ARNT2 and SIM2 in the development of HSCR through RET expression regulation. Furthermore, as SIM2 is located on chromosome 21, SIM2 overrepresentation might explain the high occurrence of HSCR in Down syndrome patients.

1022/W

Functional screening of genes at loci associated with type 2 diabetes using glucose-stimulated insulin secretion assays. *J.R. Kulzer, M.P. Fogarty, K.L. Mohlke.* Department of Genetics, UNC Chapel Hill, Chapel Hill, NC.

Genome-wide association (GWA) studies have identified at least 39 genetic loci associated with type 2 diabetes (T2D), but for almost all of them, the biological mechanisms relating the DNA variants to T2D remain to be determined. We hypothesize that some of these loci contain genes that influence glucose homeostasis by altering glucose-stimulated insulin secretion (GSIS) in pancreatic beta cells. To identify these genes, we are screening plausible positional candidates at GWA loci by decreasing gene expression in cultured cells and evaluating the effect on GSIS. Positional candidate genes were selected for study based on evidence of SNP association with T2D or fasting glucose levels, relative level of expression in pancreas or islets, biological function based on literature review, and gene density at a locus. We used siRNA to reduce gene expression in the rat insulinoma-derived cell line 832/13, incubated the cells in basal (3 mM) or high (15 mM) levels of glucose, and measured the amount of insulin secreted after two hours. Insulin levels were quantified by ELISA and normalized to total protein, and transcript levels were measured by quantitative real time PCR (qPCR). We tested positional candidate genes *ARAP1* and *PDE2A* with this approach. Both genes are located at the same human T2D association locus. Biologically, ARAP1 associates with the Golgi apparatus and plays a role in cell receptor trafficking and signaling. PDE2A is a phosphodiesterase that removes phosphate groups from cAMP and cGMP to degrade these signaling molecules within the cell. Transfection with siRNAs targeting *Arap1* and *Pde2a* reduced gene expression by 38% and 65%, respectively. Insulin response to high glucose after siRNA knockdown was compared to the 4.4-fold response observed with a control siRNA that does not target any known genes. Preliminary results showed that decreased *Arap1* gene expression reduced insulin response to 1.6-fold (P=0.07), while decreased *Pde2a* gene expression reduced insulin response to 3.2-fold (P=0.34). If these results are verified, we may be able to conclude that differential *Arap1* expression influences GSIS, suggesting *ARAP1* as the more likely T2D susceptibility gene at this locus. Identification of additional genes that affect GSIS will improve our understanding of glucose metabolism and regulation, and may lead to the discovery of novel biochemical pathways that can be targeted for the development of new T2D therapies.

1023/W

A Functional Haplotype in *EIF2AK3*, an ER Stress Sensor, is Associated with Lower Bone Mineral Density. *J. Liu, N. Hoppman-Chaney, J.C. McLenithan, D.J. McBride, J.R. O'Connell, H. Wang, E.A. Streeten, B.D. Mitchell, A.R. Shuldiner.* Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD.

EIF2AK3 is a type I transmembrane protein that functions as an endoplasmic reticulum (ER) stress sensor to regulate global protein synthesis. Rare mutations in *EIF2AK3* cause Wolcott-Rallison syndrome (OMIM 226980), an autosomal recessive disorder characterized by diabetes, epiphyseal dysplasia, osteoporosis, and growth retardation. To investigate the role of common genetic variation in *EIF2AK3* as a determinant of bone mineral density (BMD) and osteoporosis, we genotyped 6 common SNPs in this gene in 997 Amish subjects and performed association analysis. We found that the minor allele A of nonsynonymous SNP rs13045 was associated with decreased forearm BMD (P=0.036 and β=-0.007) in the Amish. This association was replicated in 887 Mexican American subjects (P=0.031 and β=-0.008). Rs13045 was in high linkage disequilibrium (r^2 > 0.98) with three other potentially functional SNPs, including one promoter SNP (rs6547787) and two nonsynonymous SNPs (rs867529 and rs1805165), forming two haplotypes (denoted low-BMD associated haplotype A (MAF = 0.319) and common haplotype B). Allele-specific expression of mRNA from lymphoblastoid cell lines did not detect any evidence for differential expression between the two haplotypes. However, lymphoblastoid cell lines from individuals with haplotype A showed increased sensitivity to ER stress induced by thapsigargin treatment (P=0.014), compared to cell lines with haplotype B. Our results suggest that common nonsynonymous sequence variants in *EIF2AK3* have a modest effect on ER stress response and may contribute to risk for low BMD through this mechanism.

1024/W

High temperature requirement factor A1 is a potential disease-causing gene for age-related macular degeneration: evidences from the protective effect of a variant. *TszKin. NG, ChiPui. PANG.* Department of Opthalmology & Visual Sciences, The Chinese University of Hong Kong, Hong Kong, Hong Kong, Hong Kong.

Age-related macular degeneration (AMD) is a leading cause of severe visual impairment and blindness in most developed countries, affecting about 50 million elderly worldwide. Chromosome 10q26 has long been suggested to be an AMD-associated locus; however, the disease-causing gene (*LOC387715* or *HTRA1*) has yet to be identified. A recent study suggested that the *LOC387715* gene might not be a potential disease-causing gene. In this study, the genotyping of a previously described *HTRA1* insertion-deletion (indel) variant (34delCinsTCCT) was replicated, and the characteristics of the HtrA1 variant were also investigated. It was confirmed that the prevalence of 34delCinsTCCT indel allele was higher in control subjects than in exudative AMD patients (p = 0.002), indicating a protective effect. This protective effect was validated by the differential haplotypes of the 34delCinsTCCT indel allele with the risk A allele of rs11200638. This variant was predicted to have a serine amino acid insertion in and influence the recognition of signal peptide. Compared to recombinant wildtype HtrA1, the variant protein was more ER localized and its secretion was deterred. Moreover, the cell viability was higher and the cell apoptosis was lower in ARPE-19 cells expressing HtrA1 variant than wildtype protein. This confirmed the protective effect of HtrA1 variant and suggests that *HTRA1* is a potential disease-causing gene for AMD in the 10q26 region.

1025/T

Genome-wide association study for age-related hearing impairment. *R.A. Friedman[1], J. Ohmen[1], C. White[1], J. Corneveaux[2], A. Allen[2], S. Bonneux[3], E. Fransen[3], G. VanCamp[3], M. Huentelman[2], European Age-related Hearing Impairment (ARHI) project.* 1) Cell Biology and Genetics, House Ear Institute 2100 West Third Street Los Angeles, CA 90057; 2) Neurogenomics Division The Translational Genomics Research Institute (TGen), 445 N 5th Street, Suite 600 Phoenix, AZ 85004; 3) Medical Genetics Centre Dept. of Biomedical Sciences University of Antwerp Universiteitsplein 1 2610 Antwerp Belgium.

Age-Related Hearing Impairment (ARHI), or presbycusis, is the most prevalent sensory impairment in the elderly. ARHI is a complex disease caused by an interaction between environmental and genetic factors. While the environmental factors conferring altered risk for ARHI have been extensively studied, investigations into the genetic risk factors have only recently been initiated. Here we describe the results of the first whole genome association study for ARHI using individual samples. Our previous GWAS for this disease with pooled DNA samples resulted in the identification of a highly significant and replicated SNP located in GRM7, the gene encoding the metabotropic glutamate receptor type 7 (mGluR7) protein. The current study used a two phase study design. Phase 1 consists of a cohort with over 1100 samples assayed by whole-genome genotyping. No single SNP was associated with ARHI after correcting for multiple comparisons. There were several genes that are attractive candidates that await confirmation in phase II. The results of phase I and current progress will be presented.

1026/T

Functional Linear Model in Inferring the Relationship between a set of Variants and Quantitative Phenotype. *Y. Zhu, L. Luo, M. Xiong.* University of Texas School of Public Health, Houston, TX.

To better understand the path from genomic information through intermediate traits, such as lipid levels, to the disease outcome, we need to identify DNA variants which predict variation in the intermediate quantitative traits. The traditional quantitative genetic analysis has mainly focused on investigation of a single variant one at a time. While the genetic effect for each single variant may be too small to be detected, we seek to find a method for testing a region of DNA variants. The multiple linear regression model might have higher power to detect a quantitative traits than simple linear regression model since it jointly uses multiple marker information. However, as the number of marker increases, the degree of freedom of the test statistics will also increase. To reduce the degrees of freedom in the model and variances of the estimators due to presence of rare variants in the model, we developed a functional linear model for a quantitative trait. Its type 1 error rates were not appreciably different from the nominal levels by simulation studies. The proposed statistic was applied to Framingham Heart Study (FHS). We observed that 20% of the genes associated with glucose and 15% of the genes significantly associated with TG contain no single significant SNPs by conventional methods. For example, the P-values of the best associated with glucose in the genes TMEM16C, TULP4, SMPD3 and CNTLN, and the P-values of the best SNPs associated with TG in the genes RUOS, GRK4, and PRAGMIN were 1.52×10-3, 4.57×10-4, 5.80×10-5, 2.76×10-5, 5.38×10-3, 4.29×10-3 and 3.08×10-4, respectively, but the overall P-values of these genes were 1.20×10-10,1.17×10-12, 5.62×10-9, 6.66×10-16, <1.00×10-17, <1.00×10-17 and 2.37×10-7. These examples demonstrate that Functional Linear Model is powerful in inferring the relationship between a set of SNPs and quantitative phenotype.

1027/T

Mutation screen of significant GWAS signal implicates *ARHGAP29* in nonsyndromic cleft lip and/or palate. *E.J. Leslie[1], M.A. Mansilla[1], M.L. Marazita[2], T.H. Beaty[3], J.C. Murray[1].* 1) Department of Pediatrics, University of Iowa, Iowa City, IA; 2) University of Pittsburgh, School of Dental Medicine, Pittsburgh, PA; 3) Johns Hopkins University, School of Public Health, Baltimore, MD.

Nonsyndromic cleft lip and/or cleft palate (CL/P) is a common birth defect with complex etiology due to multiple genetic and environmental factors. Multiple genome wide association studies have been successful in identifying novel loci associated with CL/P including a locus on 1p22.1. The association signal resides in the *ABCA4* gene, which is associated with retinal disease, however neither expression analysis nor mutation screening support a role for this gene in the etiology of CL/P. We have investigated an adjacent gene, *ARHGAP29*, which encodes a Rho GTPase activating protein. This protein has been shown to have activity towards Rho and is an effector of Rap2. Rho (and ARHGAP29, by association) can be placed in many signaling pathways related to cell shape, movement, cell-cell interactions, and cell proliferation. The *ARHGAP29* gene is adjacent to a linkage disequilibrium (LD) block containing the most significant SNPs for this association but the region surrounding this gene has little LD with the associated block, making it difficult to identify associated SNPs. Sequencing of this gene in individuals from the Philippines with CL/P revealed a nonsense mutation and several missense mutations. The nonsense mutation, K326X, was identified in one individual with bilateral cleft lip with cleft palate. The mutation was also found in his unaffected mother and grandfather. A missense mutation, R616H, was found in cases and controls with a minor allele frequency of approximately 5%. This amino acid change is predicted to be “possibly damaging” by Polyphen. The identification of a rare, damaging mutation, such as the K326X nonsense mutation, provides evidence to implicate this gene in cleft lip and palate. Additional sequence, genotyping and expression analysis will allow us to determine if there is additional support for its etiologic role. Studies of model systems will allow us to understand the role of this gene in the development of the face.

1028/T

Genetic association analysis highlights new loci that modulate hematological trait variation in Caucasians and African Americans. *G. Lettre[1,17], K.S. Lo[1], J.G. Wilson[2], L.A. Lange[3], A.R. Red blood cell, white blood cell, and platelet measures, including their count, sub-type and volume, are important diagnostic and prognostic clinical parameters for several human diseases. To identify novel loci associated with hematological traits, and compare the architecture of these phenotypes between ethnic groups, the CARe Project genotyped 49,094 single nucleotide polymorphisms (SNPs) that capture variation in ~2,100 candidate genes in DNA of 23,439 Caucasians and 7,112 African Americans from five population-based cohorts. We found strong novel associations between erythrocyte phenotypes and the glucose-6 phosphate dehydrogenase (*G6PD*) A- allele in African Americans (rs1050828, $P<2x10^{-13}$), and between platelet count and a SNP at the tropomyosin-4 (*TPM4*) locus (rs8109288, $P=1.2x10^{-7}$ in Caucasians; $P=2.5x10^{-7}$ in African Americans). We strongly replicated many genetic associations to blood cell phenotypes previously established in Caucasians. We also specifically explored the role in hematological trait variation of known rare functional SNPs that had been included on the array (nonsense, missense, and splice site markers with minor allele frequency £1%). Our results show similarities but also differences in the genetic regulation of hematological traits in European- and African-derived populations, and highlight the role of natural selection in shaping these differences.

1029/T

The perception of quinine taste intensity is associated with common genetic variants in a bitter receptor cluster on chromosome 12. *D. Reed[1], G. Zhu[2], P. Breslin[1,3], F. Duke[1], A. Henders[2], M. Campbell[2], G. Montgomery[2], S. Medland[2], N. Martin[2], M. Wright[2].* 1) Monell Chem Senses Ctr, Philadelphia, PA; 2) Queensland Institute of Medical Research, Brisbane, Australia; 3) Rutgers University, New Brunswick, NJ,.

The perceived taste intensities of quinine HCl, caffeine, sucrose octaacetate (SOA), and propylthiouracil (PROP) solutions were examined in 1,457 twins and their siblings. Previous heritability modeling of these bitter stimuli indicated a common genetic factor for quinine, caffeine, and SOA (22-28%), as well as separate specific genetic factors for PROP (72%) and quinine (15%). To identify the genes involved, we performed a genome-wide association study with the same sample as the modeling analysis, genotyped for ~610,000 single nucleotide polymorphisms (SNPs). For caffeine and SOA, no SNP association reached a genome-wide statistical criterion. For PROP, the peak association was within *TAS2R38* (*rs10246939*, I296V, P=1.1x10-101), which accounted for 45.9% of the trait variance. For quinine, the peak association was centered in a region that contains bitter receptor as well as salivary protein genes and explained 5.8% of the trait variance (*TAS2R19*, *rs10772420*, R299C, P=1.8x10-15). We confirmed this association in a replication sample of twins of similar ancestry [p=0.00001]. The specific genetic factor for the perceived intensity of PROP was identified as the gene previously implicated in this trait (*TAS2R38*). For quinine, one or more bitter receptor or salivary proline rich protein genes on chromosome 12 have alleles which affect its perception but tight linkage among very similar genes precludes the identification of a single causal genetic variant.

1030/T

Identification of a Novel Obesity-Related QTL Using a Genome-Wide Association Approach in Mexican American Families. *C. Bellis[1], MA. Carless[1], E. Drigalenko[1], MP. Johnson[1], HHH. Goring[1], TD. Dyer[1], LA. Almasy[1], MC. Mahaney[1], JB. Jowett[2], EK. Moses[1], AG. Comuzzie[1], J. Blangero[1], JE. Curran[1].* 1) Dept Gen, SFBR, San Antonio, TX; 2) Baker IDI Heart and Diabetes Institute, Melbourne, Australia.

Obesity, like most other common complex human diseases possesses a genetic signature that has largely eluded identification of specific causal genes and their underlying polymorphisms. A complex disease inheritance pattern, elaborate interactions with other metabolic disorders such as diabetes, heart disease and hypertension, and a host of environmental factors all contribute to variation in obesity measures. We are currently entering a generation where demand on the health budget has never been more critical, mainly due to escalating rates of cardiovascular diseases and related traits including obesity. Therefore, identification of genes influencing risk of obesity will be useful to enhance pharmacological target development. In this study we performed a genome-wide association scan to search for obesity-related QTLs on 1,189 Mexican Americans from approximately 40 extended pedigrees. Associations were evaluated using a variance component-based measured genotype approach implemented in SOLAR. Using 550,000 SNPs genotyped on the Illumina HumanHap550 BeadChip, we localized a QTL at chromosome 8q12 near the *SDCBP* (syntenin) gene, a gene thought to influence critical cell adhesion and cell signalling processes. Multiple obesity-related phenotypes exhibited signal at an intronic SNP (rs7833413) in the *SDCBP* gene. Obesity measures showing genome-wide significant or genome-wide suggestive associations included waist ($p=4.0 \times 10^{-8}$) and hip ($p=9.1 \times 10^{-8}$) circumferences, percentage body fat as measured by bioimpedance ($p=3.6 \times 10^{-7}$), and BMI ($p=6.0 \times 10^{-7}$). The minor allele frequency in this population was 0.06 and corresponded with an increased level of obesity in all of these traits. Genome-wide gene expression, obtained from lymphocytes from these same individuals, revealed that the rarer SNP allele is associated with a decrease in *SDCBP* gene expression ($p=0.0089$), directly supporting *SDCBP* as a causal player in the observed QTL. These novel results suggest a role for syntenin in obesity-related phenotypes. Our current sequencing effort, aimed at identifying the *SDCBP* causal variant/s through interrogation of all coding and potentially functional gene regions, will further elucidate the role for this novel gene in obesity.

1031/T

A genome wide association study of body mass index in African Americans. *M.C.Y. Ng[1,2], J.M. Hester[1,2,3], M.R. Wing[1,2,3], J. Li[1,2], N.D. Palmer[1,2,4], P.J. Hicks[1,2,4], B.H. Roh[1,2], L. Lu[5,6], L.E. Wagenknecht[6], J. Divers[5,6], C.D. Langefeld[5,6], B.I. Freedman[7], D.W. Bowden[1,2,4,7].* 1) Center for Diabetes Research; 2) Center for Genomics and Personalized Medicine Research; 3) Program in Molecular Genetics and Genomics; 4) Department of Biochemistry; 5) Department of Biostatistical Sciences; 6) Division of Public Health Sciences; 7) Department of Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

Obesity is a major public health problem in the US, exhibiting racial differences in obesity prevalence of 44% and 32% in African Americans (AA) and European Americans, respectively. We have completed a genome-wide association study (GWAS) on body mass index (BMI) in 1715 unrelated AA (S1: 816 healthy subjects; S2: 899 subjects with type 2 diabetes and nephropathy) using the Affymetrix 6.0 platform. Single SNP association analyses were conducted on 746,626 good quality autosomal SNPs with adjustment for age, gender and first principal component reflecting admixture proportion. Meta-analysis revealed 75 SNPs showing nominal significance ($4.4X10^{-9} < P_{ADD} < 1X10^{-4}$) with the same direction of association in S1 and S2 samples.

We further genotyped these SNPs in 3224 AA subjects (S3: 611 healthy subjects and S4: 1490 diabetic subjects from Wake Forest University, S5: 286 subjects from Diabetes Heart Study (DHS) and AA DHS, S6: 837 subjects from Insulin Resistance Atherosclerosis Study (IRAS) study and IRAS family study) for replication. The analysis was conducted in each of the four replication samples adjusted for age, gender, admixture and/or disease status using a variance component approach. Five SNPs at four loci near *TMEM212* (rs6794092), *ZNF518B* (rs7691990), *MFAP3-GALNT10* (rs2033195, rs815611) and *FER1L4* (rs6088887) were nominally associated with BMI in the meta-analysis of replication samples ($0.003 < P_{ADD} < 0.05$). They also showed consistent direction of association in all GWAS and replication samples. Meta-analysis of 4939 GWAS (S1 and S2) and replication samples (S3 to S6) showed increased association signals in these five SNPs ($2.1X10^{-6} < P_{ADD} < 2.3X10^{-5}$). The functions of most of these nearby genes are unknown except that *GALNT10* encodes a member of the GalNAc polypeptide N-acetylgalactosaminyltransferases involved in the synthesis of mucin-type oligosaccharides. Our results in AA suggest four novel putative BMI loci in African Americans that warrant further replication studies.

1032/T

Genetics of Meiotic Recombination: Genome Wide Association Studies for recombination phenotypes. *F. BEGUM[1], E. FEINGOLD[1,2], S.L. SHERMAN[3], V.G. CHEUNG[4], R. CHOWDHURY[5].* 1) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA, USA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA, USA; 3) Department of Human Genetics, Emory University School of Medicine, Atlanta, Georgia, United States of America; 4) Department of Genetics, University of Pennsylvania, Philadelphia, PA, USA; 5) Department of Pediatrics, University of Pennsylvania, Philadelphia, PA, USA.

Meiotic recombination is critical to successful human reproduction. Absence of recombination and recombination in certain high-risk locations are both associated with aberrant meiotic outcomes, including trisomy and monosomy. Several genes have recently been associated with variability in meiotic recombination, including RNF212 for total recombination and PRDM9 for recombination hotspot usage. We have combined several large family GWAS datasets to confirm these associations and to find additional regions that are associated with various recombination phenotypes. Family datasets are necessary because recombination phenotypes are estimated for each parent in the dataset, based on their children. We have also expanded the sample size available for studying recombination by developing methods for using many different pedigree configurations for estimating recombination phenotypes; previous recent papers have relied on methods that only score recombination for parents in nuclear families with two or more children. Our goal is to identify genetic determinants of recombination in order to better understand the biology of recombination and its role in meiosis.

1033/T

Validation of a computationally feasible method for imputation in African Americans in the NHLBI CARe Project. *C.D. Palmer[1,2], G. Lettre[3,4], J.N. Hirschhorn[1,2,5] for the NHLBI CARe Consortium.* 1) Program in Genomics and Divisions of Genetics and Endocrinology, Children's Hospital Boston, Boston, MA, 02115, USA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, 02142, USA; 3) Faculté de médecine, Université de Montréal, Montréal, Québec, Canada H3C 3J7; 4) Institut de cardiologie de Montréal, Montréal, Québec, Canada H1T 1C8; 5) Department of Genetics, Harvard Medical School, Boston, MA, 02115, USA.

Genotype imputation has become a common tool in the analysis of genome-wide association studies and medical resequencing, but imputation in admixed populations presents additional challenges. Imputation involves generating probabilistic genotypes for densely genotyped individuals using a reference panel such as HapMap, but imputation quality is highly dependent on well-matched ancestry between sample and reference individuals. This is not always possible in data such as HapMap2 or current releases from 1000 Genomes, which are enriched for Northern European (CEU), West African (YRI) and East Asian (JPT+CHB) populations. For admixed populations with representation of ancestral populations in reference panels, such as African Americans (~80% African and ~20% European ancestry), an ideal solution involves dynamically selecting reference haplotypes based on local ancestry estimates. However, these methods are not yet computationally feasible.

Here, we present validation of a simpler method for imputation of an admixed sample. This method, similar to that of Huang et al. (2009), uses a combination of HapMap haplotypes broadly matched to the sample's ancestral populations. We imputed five African American cohorts from the NHLBI CARe (Candidate gene Association REsource) Project. Over 8000 individuals were represented from the ARIC, CARDIA, CFS, JHS, and MESA cohorts. Each cohort was genotyped on Affymetrix 6.0 (Affy6) and Illumina IBC (ITMAT, Broad, CARe) iSelect Infinium chips. Imputation was performed using MACH and combined HapMap2 CEU and YRI reference panels, to reflect the admixture in the samples. This method generated genotype estimates at ~2.7 million SNPs. For SNPs genotyped on one chip but absent from the other, the estimated allele dosages for the missing SNPs were compared to genotype calls for the same individuals on the other platform. With the Affy6 chip (~800K SNPs), imputed SNPs had ~95.6% concordance with genotypes at an expected-to-observed variance ratio (RSQ_HAT) ≥0.3, compared to published ~96% concordance in European samples. The combined reference panel yielded higher minor allele concordance than either CEU or YRI alone. With the IBC chip (~40K SNPs), allelic concordance was lower (~90%), and required RSQ_HAT ≥0.6 to match the concordance of the Affy6 imputation. These results demonstrate that imputation of admixed populations is computationally feasible using available software.

1034/T

Using whole-genome sequence data to expand the search for asthma risk variants: Australian Asthma Genetics Consortium. *M.A. Ferreira[1], M.C. Matheson[2], C.F. Robertson[3], G.B. Marks[4], L.J. Palmer[5], S.C. Dharmage[2], P. Le Souef[6], D.L. Duffy[1], M.J. Abramson[7], G.W. Montgomery[1], P.J. Thompson[8] on behalf of the Australian Asthma Genetics Consortium.* 1) Queensland Institute of Medical Research, Brisbane, Australia; 2) Centre for MEGA Epidemiology, The University of Melbourne, Australia; 3) Royal Children's Hospital, Melbourne, Australia; 4) Woolcock Institute of Medical Research, Sydney, Australia; 5) Genetic Epidemiology, University of Western Australia, Perth, Australia; 6) School of Paediatrics and Child Health, Princess Margaret Hospital for Children, Perth, Australia; 7) Department of Epidemiology & Preventive Medicine, Monash University, Melbourne, Australia; 8) Lung Institute of Western Australia, Perth, Australia.

Most genetic risk factors for asthma remain to be identified and it is now clear that these can only be detected through large international collaborative studies. In 2010 we established the Australian Asthma Genetics Consortium to generate and analyse whole-genome genotype data on up to 3,000 doctor-diagnosed cases and 4,000 controls of European descent. All samples have been genotyped using the Illumina platform. We expanded the genomic coverage by imputing ~8 million SNPs using the phased data for 56 unrelated CEPH individuals sequenced at a low coverage by the 1000 Genomes Project. Based on preliminary analyses of a subset of 986 cases and 1,846 controls, we have confirmed the association between variants in ORMDL3 and asthma (rs6503525, P=4.8x10-7). We also identified a new risk variant in IL1RL1 that is independent of that reported in a previous study (rs1420101), suggesting the presence of multiple independent risk variants for asthma in this region. We found no evidence for an increased number or size of copy number variants (CNVs) in cases when compared to controls, when considering large (>100kb), uncommon (MAF<0.05) CNVs. Genotype data from the remaining 2,000 cases and 2,000 controls, together with whole-genome sequence data that we are currently generating with deep coverage (30x) for a carefully selected reference panel of asthma cases, will be used to confirm these results and extend our analyses of rare variants.

1035/T

Phenotypic differences in genetically identical Monozygotic Twins. *L. Martelli[1,3], G. Maire[2], D.P. Pereira[3], R.S. Simao[3], J. Huber[3], A.L. Simoes[1], S. Choufani[4], R. Weksberg[4], J.A. Squire[5], M. Yoshimoto[5].* 1) Dept Genetics - School of Medicine, University of Sao Paulo, Ribeirao Preto, SP, Brazil; 2) Dept Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Division of Medical Genetics, Hospital das Clinicas - School of Medicine, Ribeirao Preto, SP, Brazil; 4) Dept Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 5) Dept Pathology and Molecular Medicine, Queen's University, Kingston, Ontario, Canada.

Monozygotic (MZ) twins represent an important resource in genetic studies related to normal development and disease. Consequently, studies of MZ twins have become a powerful tool for studying disorders and endophenotypes, highlighting the genotype-phenotype differences, and testing hypotheses regarding gene-environment interactions. Recently, CNV analysis of phenotypically discordant MZ twins has been applied for identifying disease predisposition loci. In this case report, we evaluated obesity-discordant MZ twins to determine whether distinct genetic events can influence the pathophysiological feature and characterize genetic predisposition factors. The proband (twin A), product of the second gestation of a 37 yo woman, was born at 38 weeks gestation after an uncomplicated pregnancy. The boy was delivered by C-section, weighting 3,340g and height of 49cm. Twin B birth weight was 2,360g and H= 47cm. Twin A weight with 17mo was 16,100 g (average for 47months), H = 75cm (p3-10) and OFC = 50,5 cm (p50-98). With 27 mo: W= 22,200 g (>> p97), H= 87,5 cm (p25-50). At the same age, twin B presented normal growth parameters, weighting 12,800g. Non dysmorphic features were detected. DNA zygosity test was compatible with monozygotic twins. Laboratorial tests showed normal basal ACTH levels; IGF1=12ng/mL; lipidogram with elevated triglycerides levels. Thyroid, renal and liver function tests were normal as well as basal cortisol, calcium, phosphorus, basal glucose and GTT. Leptin= 20 ng/ml and BMI> 23 (RV= 10-20). Serum copper was slightly elevated. Abdominal ultrasonography revealed discrete hepatomegaly. Both karyotypes were normal. The primary platform for analysis of genetic variants was the 6.0 SNP array (Affymetrix) using peripheral blood derived DNA obtained from the twin pair. We compared one twin versus its co- twin to assess the accurate genotype of the twins and putative imbalance within each twin pair. Importantly, the SNP analysis confirmed the monozygosity. However, the findings indicated that obesity-discordant MZ twins were genotypically concordant for all CNVs. According to the enrichment analysis, the CNV events were random and phenotypically neutral, as no obesity-related pathways were detected. Thus, a genetic mechanism origin for obesity-discordance in MZ twins was not detected in our study by SNP arrays methodology and further epigenetics or transcriptome investigations are necessary to yield molecular mechanisms underpinning disease.

1036/T

Identification of novel type 2 diabetes susceptibility loci by large-scale replication using the "Metabochip". *A. Kumar[1,2], A. Mahajan[1,3], I. Prokopenko[1,4], V. Lagou[1], N. Robertson[1], N.W. Rayner[1], R. Magi[1], C. Groves[4], K. Stirrups[5], S.E. Hunt[5], A. Bennett[4], S. Wiltshire[1], J. Trakalo[1], G. Mirza[1], D. Buck[1], K. Zhou[6], C.N.A. Palmer[6], A.D. Morris[6], T.M. Frayling[7], A. Hattersley[7], M. Weedon[7], A. Wood[7], C. Langford[5], S. Potter[5], P. Deloukas[5], P. Donnelly[1], A.P. Morris[1], C.M. Lindgren[1], M.I. McCarthy[1,4], The Wellcome Trust Case Control Consortium, The DIAGRAM Consortium.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Swiss Tropical and Public Health Institute, University of Basel, Basel, Switzerland; 3) Institute of Genomics and Integrative Biology, CSIR, Delhi, India; 4) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 5) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 6) Biomedical Research Institute, University of Dundee, Ninewells Hospital and Medical School, Dundee, United Kingdom; 7) Institute of Biomedical and Clinical Science, Penninsular Medical School, Exeter, United Kingdom.

Over 30 common variant signals influencing type 2 diabetes (T2D) susceptibility have been identified, most through meta-analysis of genome-wide association studies. However, replication efforts have focussed only on the strongest associations, and have failed to fully exploit large-scale discovery meta-analyses such as that undertaken by the DIAGRAM consortium (12,057 cases, 56,071 controls of European descent). The Metabochip, a custom iSELECT array containing ~195,000 SNPs, was designed to support large-scale follow up of putative associations for T2D and other metabolic and cardiovascular traits.

We analysed Metabochip genotype data, called using GenCallv1.1, for an additional 4,434 T2D cases and 7,932 controls from UK cohorts (UK T2D Genetics Consortium, Warren 2 Collection and 1958 British Birth Cohort). We analysed 4,790 high-quality, statistically-independent SNPs which capture >95% of the strongest ~5,000 autosomal signals from the DIAGRAM meta-analysis. Association analyses in each cohort were performed under an additive model and combined via fixed effects meta-analysis.

We first compared patterns of replication between "Stage 1" DIAGRAM and "Stage 2" Metabochip data. Of 37 established autosomal T2D loci, 36 showed directional consistency (i.e. same high risk allele in both stages) including *TCF7L2* (p=7.3x10^{-30}), *FTO* (p=4.6x10^{-10}) and *KCNQ1* (p=2.4x10^{-9}). After excluding SNPs at these loci, there was a highly significant concordance in the direction of effects (2,569 [59.3%] of 4,332 SNPs, binomial test p=8.8x10^{-35}). The concordance was even stronger among the 314 SNPs demonstrating nominal evidence of association (p<0.05) in Stage 2 (233 [74.2%] concordant, binomial test p=4.8x10^{-18}). Subsequent meta-analysis of the two stages of our study revealed 5 novel loci exceeding genome-wide significance mapping near: *SPRY2* (p=5.5x10^{-11}, OR= 1.11[1.08-1.15]); *ANK1* (p=2.0x10^{-10}, OR=1.11[1.08-1.15]); *LINGO1* (p=5.6x10^{-10}, OR=1.10[1.07-1.14]); *ZMIZ1* (p=3.1x10^{-9}, OR=1.09[1.06-1.12]; and *BAT3* (p=3.1x10^{-8}, OR= 1.10[1.06-1.13]).

The concordance of results in the two stages of our study is consistent with a long-tail of modest effect common variant associations with T2D. Metabochip-genotyping underway in >30,000 T2D cases and >50,000 controls should add considerably to the tally of proven T2D-susceptibility loci.

1037/T

A Genome-wide association analysis in over 187,000 individuals identifies 14 loci contributing to variation in central obesity and fat-distribution. *C.M. Lindgren[1, 2, 3].* 1) on behalf of the GIANT (Genetic Investigation of ANthropmetric Traits) Consortium; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 3) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Churchill Hospital, Oxford, United Kingdom.

Obesity is an increasing public health issue, but not all forms of obesity carry the same risk. Individuals with high waist-to-hip ratio (WHR) have an increased risk of Type 2 Diabetes (T2D), hypertension, heart disease, stroke and certain cancers. WHR is one of the primary measures of fat distribution and has a substantial heritability (~50%), independent of overall adiposity. Hitherto, the genetic variants that contribute to variation in WHR have not been well characterized. To detect common variants we performed a meta-analysis of 32 genome-wide association studies comprising >77,000 individuals of European ancestry as part of the GIANT consortium. We tested ~2.8 million imputed and genotyped SNPs for association with WHR using an additive model, adjusted for age, BMI and sex. Our discovery analysis identified 16 independent loci associated with WHR with p<5x10-6. We took these loci forward for replication (*de-novo* and *in-silico*) in 30 additional cohorts (>110,000 individuals). In our analysis combining discovery and follow-up studies 14 loci reached genome-wide significance (p<5x10-8). We confirmed the known locus near *LYPLAL1* (1q41; p=6.9x10-21) and identified 13 novel associations, including: near *VEGFA* (6p12; p=5.9x10-25), *TBX15* (1p11; p=8.7x10-25), *GRB14* (2q24.3; p=2.1x10-24) and near *ADAMTS9* (3p14; p=9.8x10-14). *TBX15* is differentially expressed between subcutaneous and visceral fat and the expression is correlated with WHR. *GRB14* is reported to be a regulator of insulin-mediated signaling and is significantly associated with triglycerides in our data (p=7.4x10-9). *VEGFA* is a growth factor that has been suggested to play a role in diabetic nephropathy and retinopathy. *ADAMTS9* is significantly associated with T2D, possibly mediating an effect through decreased insulin sensitivity of peripheral tissues. Further, we find a directionally consistent enrichment of associations (P-nominal <0.05) with increased triglycerides, LDL-cholesterol, fasting insulin, HOMA-IR and T2D. We also observed a marked gender difference in our results; 7 of the 14 loci showed a stronger association in women than in men. Taken together, these results promise to enhance our knowledge of underlying biological pathways involved in fat-distribution and propose a genetic overlap with metabolic risk and T2D. Hopefully these advancements will support functional and translational advances in the management of obesity through development of novel diagnostic and therapeutic options.

Rare variant SNP calling; performance of current genotype calling algorithms. *N.W. Rayner[1,2], N. Robertson[1,2], I. Prokopenko[1,2], C. Groves[2], C.M. Lindgren[1], G. Mirza[1], J. Trakalo[1], D. Buck[1], M.A. Eberle[3], T. Royce[3], K. Zhou[4], C.N.A. Palmer[4], A.D. Morris[4], T. Frayling[5], A. Hattersley[5], A. Woods[5], P. Deloukas[6], S. Potter[6], M.I. McCarthy[1,2].* 1) WTCHG, Univ Oxford, Oxford, United Kingdom; 2) OCDEM, Univ Oxford, United Kingdom; 3) Bioinformatics Department, Illumina Inc, San Diego, USA; 4) Biomedical Research Institute, University of Dundee, Ninewells Hospital & Medical School, Dundee, United Kingdom; 5) Institute of Biomedical and Clinical Science, Peninsula Medical School, Exeter, UK; 6) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

With the growing focus on studies of low-frequency and rare alleles, the performance of alternative genotype-calling algorithms in this part of the allele frequency spectrum becomes critical. We evaluated three such algorithms (Illuminus, GenoSNP, Gencall) on data generated on the "metabochip" (a custom iSELECT array containing ~197k SNPs, of which 62,494 have MAF<1%, according to CEU HapMap data). The programs were all run with default settings, except GenoSNP (0.95 probability threshold cutoff). Genotypes were obtained for 30 CEPH HapMap Trios, and for 7,984 unrelated samples from the Dundee T2D case-control collection, and analysed without further QC for metrics including genotyping rate, mendelian inconsistencies (MI: in trios, contingent on both parents having genotypes) and between-methods concordance. Of the three methods, Illuminus performed least well judged by genotyping rate (94.9%) and MI count (59,229 MI counts across all SNPs, 51,396 of these in MAF<1% SNPs). The MI count was significantly reduced when we reclustered the trios with up to 17,000 other samples (2,954; 939 in MAF<1% SNPs), but still higher than the other methods. Gencall (run without Gentrain to reduce overfitting given overlap in the samples typed) achieved higher genotyping rate (99.2%) with relatively low MI counts (544 overall, 152 in MAF<1% SNPs), but discordancy analyses suggested that Gencall was generally conservative with respect to calling of small heterozygote clusters. GenoSNP might be expected to outperform other methods for rare SNPs: it clusters data on an "all SNPs per sample" basis (rather than "all samples per SNP"), and therefore is less reliant on observing all three genotype clusters for a given SNP. Indeed, we found that GenoSNP combined respectable genotyping rates (96.7%) with low MI rates (235 overall, 44 in MAF<1%), despite being less conservative than Gencall at defining small heterozygote clusters. Overall, therefore Gencall and GenoSNP performed well across all metrics, even for low-frequency SNPs. In the case-control data, Gencall and GenoSNP calls were highly concordant (99.8% where both made calls in 185,802 high-quality SNPs; 99.9% in MAF<1%) though there were more serious disparities at the remaining ~11k. One further attractive feature of GenoSNP is that the "per-sample" calling strategy makes calls more stable when new data are integrated.

1039/T

META-ANALYSIS OF GENOME-WIDE ASSOCIATION STUDIES OF DIABETIC NEPHROPATHY. *R.M. Salem[1,2,8], N. Sandholm[5,6], A.J. McKnight[3], T. Isakova[7], E. Brennan[4], C. Palmer[1,2], D. Sadlier[4], A. Taylor[1,7], V. Harjutsalo[5,6], C. Guiducci[1], W. Williams[1,7], S. Bain[3], M. Parkkonen[5,6], D. Savage[3], F. Martin[4], C. Forsblom[5,6], J. Florez[1,7], C. Godson[4], A.P. Maxwell[3], J. Hirschorn[1,2,8], P.H. Groop[5,6].* 1) Broad Institute, Cambridge, MA, US; 2) Children's Hospital, Boston, MA, US; 3) Queen's University of Belfast, NI, UK; 4) Conway Institute of Biomolecular and Biomedical Research, University College, Dublin, ROI; 5) Biomedicum Helsinki, Helsinki, FI; 6) Helsinki University Central Hospital, Helsinki, FI; 7) Massachusetts General Hospital, Boston, MA; 8) Harvard Medical School, Boston, MA.

Diabetic nephropathy (DN), often leading to end-stage renal disease (ESRD), is a significant complication of type 1 diabetes (T1D), with lifetime risk of approximately 30% among persons with T1D. We sought to improve understanding of the genetic contribution to DN by assembling the largest collection of individuals with T1D (n=6,462), with and without nephropathy. These samples are part of the GENIE (GEnetics of Nephropathy, an International Effort) Consortium and include the All Ireland-Warren3-UK GoKinD (UK/ROI, 823 cases and 903 controls) and FinnDiane (FD, 1,411 cases and 1,708 controls) collections, as well as publicly available data from the US GoKinD study obtained from dbGAP (US, 782 cases and 835 controls). Cases were patients with T1D and nephropathy (macroalbuminuria or ESRD) and controls were patients with T1D for at least 15 years and no evidence of renal disease (no microalbuminuria). The UK/ROI was genotyped on the Illumina Omni1-quad chip and FD on the Illumina 610Quad, while US was genotyped previously on the Affy 5.0 platform. We imputed genotypes using MACH with the HapMap2 CEU panel, and performed association tests using PLINK, with principal components of ancestry, age at recruitment, duration of diabetes, gender and study site as covariates. We meta-analyzed association statistics using METAL. In total, ~2.4 million single nucleotide polymorphisms (SNPs) with minor allele frequency > 1% and passing QC were analyzed. A total of 15 SNPs achieved a P-value of less than 10^{-6} in the combined analysis. Of these, multiple SNPs mapped to 2q34, 3q13.31, 4q34.3 and 20q11.21. Four of these SNPs were observed in a biologically plausible gene at 2q34. We are assembling additional samples to follow up the top SNPs and test whether any reach genome-wide significance. We are performing additional related analyses of extreme phenotypes and DN-related quantitative traits. FD also has longitudinal follow-up data that will facilitate investigation of the initiation and progression of diabetic nephropathy. Finally, we will compare our list of top signals with data from microarray analyses of in vitro models of DN. By combining genetic and expression data, this research has the potential to highlight novel biological pathways and improve our understanding of DN.

Educational attainment: from a single marker association approach toward pathway analysis. *N.W. Martin[1,2], K.H. Verweij[1,2], S.E. Medland[1], D.R. Nyholt[1], P.A. Madden[3], A.C. Heath[3], G.W. Montgomery[1], M.J. Wright[1,2], N.G Martin[1,2].* 1) Genetic Epidemiology Laboratory, Queensland Institute of Medical Research, Brisbane, Australia; 2) School of Psychology, University of Queensland, Brisbane, Australia; 3) School of Medicine, Washington University, St Louis, Missouri, USA.

Background: Educational Attainment (EA) is measure of interest across multi-disciplinary research in economics, health and cognitive functioning. Correlations between EA and measures of cognitive performance are as high as 0.8. This makes EA an attractive alternative phenotype for studies willing to map cognitive genes due to the ease of collecting EA data compared to other cognitive phenotypes such as IQ. Methodology: In an Australian family sample of over 10000 individuals we performed a genome-wide association scan (GWAS) using the genotypes of ~2,5 million single nucleotide polymorphisms (SNP) for a 6-point scale measure of EA (from 1 = 7 years or less of schooling to 6 = university postgraduate training). A gene-based test of association was then applied to the GWAS results, followed by pathway analyses of the most associated genes. Results/Significance: No SNP reached a genome wide significant p-value (p £ 10-8) with the best SNP having a p-value of 1.1x10-6. The gene-based test of association showed only one gene with a p-value that passed correction got multiple testing, however, it had no relevance to brain phenotypes. Similarly, the pathway analyses of the top associated genes were mostly inconclusive with the exception of a hypothetical role for the glycosaminoglycan degradation pathway in the etiology of EA. However, this result should be taken with caution as further replications and meta analyses will be needed to draw firm conclusions. Despite having performed the largest GWAS for EA to our knowledge, our study demonstrated the high polygenic architecture of EA. Our results show that EA does not escape the debate of whether common variants of small effect or rare variants of large effect are responsible for explaining the phenotypic variance in complex traits.

HLA Stratification Analysis of the Finnish Coeliac Disease GWAS Data. *K.I. Loytynoja[1], E. Einarsdottir[1], K. Kurppa[2], K. Kaukinen[3], M. Maki[2], A. Aromaa[4], V. Salomaa[4], L. Peltonen[5], P. Dubois[6], D.A. van Heel[7], P. Saavalainen[1].* 1) Medical Genetics, University of Helsinki, Helsinki, Helsinki, Finland; 2) Paediatric Research Centre, University of Tampere Medical School and Tampere University Hospital, University of Tampere, Finland; 3) Department of Gastroenterology and Alimentary Tract Surgery, Tampere University Hospital and Medical School, University of Tampere, Finland; 4) National Institute for Health and Welfare, Helsinki, Finland; 5) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK, and Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland; 6) Blizard Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK; 7) Centre for Gastroenterology, Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, United Kingdom.

Introduction: Coeliac disease (CD) is a multifactorial disorder caused by the ingestion of gluten in genetically susceptible individuals. The genes encoding the HLA-DQ2 and HLA-DQ8 heterodimers are the strongest genetic risk factors for the disease. Roughly percent of patients carry DQ2 in cis (DQ2.5) or trans (DQ2.2 and DQ7) and 5-10 percent have DQ8. These HLA variants are also common in the general population, implicating additional genetic factors in disease susceptibility. **Materials and methods:** A recent GWA study on CD in four European populations revealed multiple risk loci for CD, and included samples from 642 cases and 1 834 controls from the Finnish population (Dubois et al. 2010). Based on HLA-tagging SNPs (rs2187668 for DQ2.5 and rs3957148 for DQ8), 560 cases and 349 controls were DQ2.5 positive, and 56 cases and 405 controls were DQ8 positive/DQ2.5 negative. In addition, 26 cases and 1080 controls carried neither of these alleles. We performed independent analyses for DQ2.5 positive and DQ8 positive/DQ2.5 negative carriers, and also compared DQ2.5 positive and DQ8 positive/DQ2.5 negative cases against each other. For follow-up purposes we selected only those signals that reached p-values < 1.0*10-5. **Results:** We found novel associations on chromosomes 3 and 15 in DQ2.5 positive group and a significantly strengthened association for IRF4 gene on chromosome 6. In DQ8 positive/DQ2.5 negative group, novel associations located on chromosomes 1, 5, and 11. Novel associations on chromosomes 2, 3, and 17 were found in DQ2.5 positive versus DQ8 positive cases -analysis. **Conclusions:** In addition to the previously identified HLA-haplotype independent loci, there may be additional and unique susceptibility loci in carriers of specific HLA-haplotypes. HLA-stratification also strengthened signals in several previously found loci. Our data therefore suggests that HLA-stratification may reveal particularly interesting subgroups of patients, that helps understanding the interactions and shared biological pathways of the CD risk genes.

Genetic variation that predicts white blood cell count and its differential, a marker of the health of the immune system. *D.R. Crosslin[1], N. Weston[2], K. Ehrlich[2], G. Hart[2], A. McDavid[3], K. Newton[2], C.S. Carlson[3], E.B. Larson[2], G.P. Jarvik[1], . eMERGE Network[1,2,3].* 1) Department of Medicine, University of Washington, Seattle, WA; 2) Group Health Research Institute, Center for Health Studies, Seattle WA; 3) Fred Hutchinson Cancer Research Center, Public Health Sciences Division, Seattle WA.

White blood cell count (WBC) is unique among the identified inflammatory predictors of chronic disease in that it has been routinely measured in healthy patients in an unbiased way for the duration of the electronic medical record (EMR) data at Group Health Cooperative (GH) and other eMERGE Network participating sites. We led genome wide association studies (GWAS) to identify variation that predicts WBC and its differential (neutrophils, lymphocytes, monocytes, eosinophils and basophils). As well as being a marker of the health of the immune system, WBC is emerging as a risk factor for chronic diseases, including vascular disease and renal failure. GWAS of total WBC and its differential counts can identify genes that predict WBC as the end result of a variety of inflammatory pathways. Within the eMERGE network, the GH, Marshfield Clinic and Mayo Clinic sites have >98% of subjects with WBC. Northwestern University has 92% and Vanderbilt University has 91%. In total, there were 19,000 subjects with WBC, and >18,000 with differential. The sample at GH was older (74.5±7.9), and subjects had multiple visits for the duration of the EMR, with a median number of visits of nine. The goal was to select WBCs that were not inflated by acute processes. We developed an algorithm to extract WBC and differential repeated measures from the EMR using subject-level and visit-level inclusion/exclusion criteria. All subjects in the eMERGE Network were genotyped on the Illumina Human660W-Quadv1_A platform. For the genetic association, we compared and contrasted different approaches utilizing repeated measures. These summary measures provided a cleaner set of phenotypes to analyze than cross-sectional data. The within-subject measures included the following: 1.median value for a subject; 2.within-subject predicted value at the overall mean age; 3.within-subject slope; and 4.the best unbiased linear predictor. WBC is a complex phenotype to analyze, and we have provided the framework and model for extracting and summarizing subject-level data from a repeated-measure EMR. Our algorithm has successfully been translated to other eMERGE sites. Initial association analyses are ongoing and replication is planned with other Network data, but preliminary results at GH are encouraging. There were ten genes mapped to SNPs with p-values <0.0001 across the phenotypes. Assessment of the contribution of top hits to inflammatory pathways and gene set enrichment will complete the analyses.

Whole genome-scan of genetic determinants for dental caries in the primary dentition. *E. Feingold[1], J.R. Shaffer[1], X.J. Wang[1], M.K. Lee[1], F. Begum[1], D.E. Weeks[1], M. Barmada[1], K. T.Cuenco[1], S. Wendell[1], D. Crosslin[2], C. Laurie[2], K. Doheny[3], E. Pugh[3], F. Geller[4], B. Feenstra[4], H. Zhang[4], H. Boyd[4], M. Melbye[4], R.J. Weyant[1], R. Crout[5], D. McNeil[5], S.M. Levy[6], R.L. Slayton[6], M. Willing[7], B. Broffitt[6], M.L. Marazita[1].* 1) Univ Pittsburgh, Pittsburgh, PA; 2) Univ of Washington, Seattle, WA; 3) Johns Hopkins University, Baltimore, MD; 4) Statens Serum Institut, Copenhagen, Denmark; 5) University of West Virginia, Morgantown WV; 6) University of Iowa, Iowa City, IA; 7) Washington University, St. Lous, MO.

Objective: Despite advances in dental care, dental caries (also known as tooth decay) remains one of the most common chronic diseases of human beings, and the incidence of caries in young children has actually increased in recent years. The etiology of dental caries is thought to involve a complex interplay of environmental and genetic factors, with heritabilities of caries phenotypes ranging from 30-60%. As part of the NIH Genes and Environment Initiative (GENEVA), we performed the first genome-wide association study (GWAS) of dental caries in the primary dentition to identify genomic regions harboring genes responsible for caries susceptibility or resistance in children. Subjects and Methods: 1,643 subjects between the ages of 3 and 12 years with primary teeth were drawn from larger family cohort studies in Pennsylvania, West Virginia, and Iowa. The majority of subjects were Caucasian. All tooth surfaces were evaluated by trained dental examiners, and scored as sound, white spot (non-cavitated), decayed (cavitated), or filled. Individuals with > 1 lesion were considered “affected” (n=705), and those with no lesions were considered “unaffected” (n=938). Each subject was genotyped for the Human610-Quad SNP panel by the Center for Inherited Disease Research, and the data were cleaned in collaboration with the GENEVA Data Coordinating Center. Associations between dental caries and each SNP were first assessed using the trend test (PLINK) ignoring familial relationships, then repeated with adjustments for relatedness (variance components-SOLAR). Finally, we stratified the sample based on household water fluoride levels, and repeated the analyses in each subset as a preliminary investigation of gene by environment interaction. Results: A region on chromosome 11 was significantly associated with caries, with several SNPs showing unadjusted p-values < 10-6. Regions on chromosome 1 and 17 also showed multiple SNPs with p-values < 10-5 in the vicinity of plausible candidate genes. After stratification on household water fluoride levels, a region on chromosome 9 was also significant ((p-values < 10-6). Replication is now in progress in an additional cohort. Rare variant analysis of the mitochondrial genome in age-related hearing impairment. *E. Fransen, S. Bonneux, G. Van Camp.* Center for Medical Genetics, University of Antwerp, Antwerp, Belgium.

Age-related hearing impairment (ARHI) is a condition whereby hearing acuity declines with ageing. Heritability studies indicated that about half of the phenotypic variance is attributable to genetic factors. Previous studies on nuclear genes showed association with GRHL2 and GRM7, but much of the variance remains unexplained. Since alterations in the mitochondrial genome have been implicated in various ageing diseases, we also performed an analysis of mitochondrial variants by completely resequencing the mitochondrial genome in 200 affected persons and 200 controls. In a first round of analyses, we tested association between the phenotype and the common mt variants or mt haplogroups, but no significant associations were found. Moreover, we did not find any common variant to be associated with ARHI. The average mutation load per individual, calculated as the number of rare alleles carried by an individual, did not differ significantly between cases and controls, even when common variants (MAF>0.05) were excluded from this calculation. The previous tests have limited power to detect the influence of rare variants on disease risk. Here we have used the collapsing technique proposed by Li and Leal (2010), to perform a gene-based analysis of rare mitochondrial variants. For each of the mitochondrial genes separately, we subdivided the individuals into two groups according to their mutational status: individuals carrying no minor allele were scored as wildtype, whereas individuals with at least one mutation were scored as mutant. This analysis was performed on i) all variants, ii) only rare variants (MAF<0.05) and iii) variants only found once in the entire dataset. Within each mt gene, association between mutational status and case control status was tested using the Fischer’s exact test. Reference Li, B. and Leal, S.M. (2008) “Novel Methods for Detecting Associations with Rare Variants for Common Diseases: Application to Analysis of Sequence Data.” Am. J. Hum. Genet. 83(3): 311-21.

The period between late adolescence and young adulthood is a period with a high risk for weight gain and development of obesity. Information on genetic determinants of body mass index (BMI) or change in BMI during this particular period of life may yield important insight into the etiology of obesity. The purpose of the current study was to identify genetic loci influencing cross-sectional observations of BMI (BMI level) and change in BMI (BMI change), during late adolescence and early adulthood in Caucasians considering potential gender differences. We performed a meta-analysis of 9 genome-wide association studies that included observations of BMI level between ages 16 and 21 years (N = 13530) and BMI change between ages 16 and 35 years (N = 6626). Each study imputed~2.5 million SNPs in HapMap and tested for association assuming an additive genetic model, stratified by gender and/or case-control status and adjusted for age, center, and principal components reflecting racial variation. Family studies also adjusted for relatedness. Multiple BMI observations at different ages were used to perform a growth curve analysis for BMI change. Inverse normal transformed residuals were used for level and change as the outcomes. The meta-analysis was conducted using the inverse variance weighted method. For BMI level, we identified 5 independent loci (P< 5.0 x 10-8) in men and women combined near TNNI3K (p=1.9x10-12), TMEM18 (p= 3.0x10-11), MC4R (p=3.4x10-09), FTO (p=2.2x10-09), and PMAIP1 (p= 4.2x10 -09); 2 in men only (near PMAIP1, p=5.5x10-10 and MC4R, p= 3.2x10-08); and 1 in women only (near TNNI3K, p=9.6x10-09)In the smaller longitudinal sample, we found no significant loci for BMI change. In summary, TNNI3K and PMAIP1 are novel hits, whereas FTO, MC4R, and TMEM18 are already well replicated. During a narrow period of the life course, late adolescence and early adulthood, we find several significant loci related to body mass index that partly vary by gender. These results suggest that the expression of genetic effects may relate to particular periods of the life course and can vary by gender.

Does the Bunion come from the Genes or High Heels? The Healthy Twin Study, Korea. *D.H. Lee[1], J. Sung[1], M.K. Lee[1], Y.M. Song[2], K. Lee[3], J.H. Hwang[4].* 1) Complex Disease and Genetic Epidemiology Branch, Department of Epidemiology and Institute of Environment and Health, School of Public Health Seoul National University; 2) Department of Family Medicine, Samsung Medical Center, and Center for Clinical Research, Samsung Biomedical Research Institute, SungKyunKwan University School of Medicine, Seoul, Korea; 3) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Korea; 4) Department of Rehabilitation Medicine, Samsung Medical Center, SungKyunKwan University School of Medicine, Seoul, Korea.

Buion, or hallux valgus is a common foot condition characterized by lateral displacement deformity of the first metatarsophalangeal joint in great toe. Hallux valgus is associated with wearing high-heeled shoes especially in women, but its genetic susceptibility is not well known. We are determined to estimate genetic contributions to the hallux valgus angle (HVA) and the hallux valgus (defined by HVA >15 degree in either foot) after considering the individual preference to the heel size.1,288 Korean adult twins and their families (183 monozygotic and 32 dizygotic twin pairs, and 857 individuals of their family took foot examination, (502 men and 786 women, average age 44.06 years). The HVA was radiologically evaluated from the weight-bearing anteroposterior (AP) foot X-ray views. The mean HVA was 14.15 degree for men, and 16.63 degree for women, and 47.0 % of men (236 persons), and 55.9 % of women (439 persons) were classified as hallux valgus. A variance component method was used to estimate heritability. After consideration of shared environmental effects and adjustment for age and sex effects, the heritability estimates ± s.e. were 0.52 ± 0.047 for HVA, and 0.74 ± 0.063 for hallux valgus. When we considered the preferred heel height, asked as “what is your typical heel size?”, the women preferring higher (>5 cm) heels showed significant associations with the bunion status, and also showed evidence of the interaction between additive genetic effects Our findings suggest that HVA and hallux valgus have a strong genetic influence and for someone who are vulnerable to hallux valgus, wearing high heels will more likely to produce bunions.

1047/T

A two-stage genome-wide association study of mean telomere length. *K.A. Pooley[1], J. Morrison[1], A.A. Al Olama[1], M. Shah[2], B.A.J. Ponder[3], P.D.P. Pharoah[2], D.E. Neal[3,4], F.C. Hamdy[5], J.L. Donovan[6], Z. Kote-Jarai[7], R.A. Eeles[7,8], D.F. Easton[1], A.M. Dunning[2].* 1) CR_UK Genetic Epidemiology Unit, Dept of Public Health, University of Cambridge, Strangeways Res Lab, Cambridge, United Kingdom; 2) Dept of Oncology, University of Cambridge, Strangeways Res Lab, Cambridge, United Kingdom; 3) Cancer Research UK Cambridge Research Institute, Li Ka Shing Centre, Robinson Way, Cambridge, United Kingdom; 4) Depts of Oncology and Surgery, Addenbrooke’s Hospital, Hills Road, Cambridge, United Kingdom; 5) Nuffield Department of Surgery, University of Oxford, United Kingdom; 6) Department of Social Medicine, University of Bristol, United Kingdom; 7) Translational Cancer Genetics Team, The Institute of Cancer Research, Sutton, Surrey, United Kingdom; 8) Royal Marsden NHS Trust Foundation, Sutton, Surrey, United Kingdom.

Telomeres protect against DNA damage that may result in genome instability. Mean telomere length is heritable and progressively shortens with age, and there is evidence for marked telomere length attrition in cancer patients, post-diagnosis. Recently, loci have emerged that may start to explain telomere length homeostasis and biology. To investigate the genetic basis of mean telomere length, we performed a genome-wide association study (GWAS), using an Illumina 550K array. Participants were 1,540 disease-free men from the ProtecT prostate cancer case-control study on which we had also measured mean telomere length using a quantitative Real Time PCR assay. In the second stage, we genotyped by Taqman® assay the 12 loci most strongly associated with mean telomere length in stage 1, in a further 15,606 samples on which we also had telomere length measurements. This stage comprised cancer-free individuals (n=9,708) from the SEARCH study, the Sisters in Breast Screening (SIBS) study, and the MAPLES melanoma family study; SEARCH breast cancer cases (n=6,338) and MAPLES and SEARCH melanoma cases (n=560). Of the initial GWAS top 12 SNPs, 11 demonstrated a change in mean telomere length (ΔCt), whereby the rare allele was associated with shorter mean telomere length (p-trend=$1.7x10^{-6}$ to p-trend=$3.2x10^{-5}$, adjusted for age, study plate, gender and family). In the Stage 2 replication, one of the top 12 variants showed evidence of replication (stage 2, p-trend=0.007; combined stage 1 & 2, p-trend=$3.3x10^{-4}$). None of the 12 SNPs in the second stage of the study were significantly associated with risk of breast cancer (6,367 cases, 6,483 controls), or melanoma (562 cases, 778 controls). In addition to our GWAS hits, we also found weak evidence of association with mean telomere length for two recently published loci (rs12696304, p-trend=0.017; rs16847897, p-trend=0.014). These loci are worthy of further investigation, and if confirmed, may provide novel insights into the determinants of telomere length control and attrition, and its role in ageing and common disease progression.

Alopecia areata (AA) is among the most highly prevalent human autoimmune diseases, leading to disfiguring hair loss due to the collapse of immune privilege of the hair follicle and subsequent autoimmune attack. The genetic basis of AA is largely unknown. We undertook a genome-wide association study in an initial discovery sample of 250 unrelated cases and 1049 controls, and replicated our findings in an independent sample of 804 cases and 2229 controls. Joint analysis identified 139 SNPs that are significantly associated with AA (p£5x10-7) and which implicate at least eight genomic regions, including the HLA. The regions outside of the HLA harbor several key components of Treg activation and proliferation (CTLA4, IL-2/IL-21, IL-2RA, and Eos), as well as three ligands of NKG2D, an activating receptor of cytotoxic lymphocytes (MICA, ULBP3, and UPBP6). We also found evidence for genes expressed in the hair follicle itself (PRDX5 and STX17). Next, we reduced the stringency threshold (p<0.01) to identify a set of SNPs that mapped onto 2929 genes, on which we performed pathway analysis. This analysis identified several immune related pathways with significant representation in our data set, including NK cell mediated cytotoxicity, T cell receptor signalling, cytokine-receptor interaction, Jak-STAT signalling and antigen presentation. Additionally several pathways that appear to be aligned with hair follicle specification and maintenance were also identified, including WNT signalling, ErbB signalling, and cell adhesion. Finally, a subset of SNPs mapped onto disease processes for type I diabetes, autoimmune thyroid disease, systemic lupus erythematosus and asthma, supporting the common cause hypothesis of autoimmune diseases. We have defined the genetic underpinnings of AA, placing it within the context of shared pathways among autoimmune diseases, and implicating a novel disease mechanism, the upregulation of ULBP ligands, in triggering autoimmunity.

1049/T

Genomewide association study in Systemic Sclerosis. *Y. Allanore[1,2], M. Saad[3], P. Dieude[4], C. Boileau[5], M. Martinez[3], GENESYS consortium.* 1) INSERM U781, Hôpital Necker, Université Paris Descartes, Paris, France; 2) Rhumatologie A, Hôpital Cochin, Université Paris Descartes, APHP, Paris, France; 3) INSERM U563 Université Paul Sabatier, Toulouse, France; 4) Rhumatologie, INSERMU699, Hôpital Bichat, Paris Diderot université, Paris, France; 5) Université VSQ, Biochimie A, Hôpital A. Pare, Boulogne, France.

Systemic sclerosis (SSc) is an orphan multi-organ disease affecting the immune system, the microvascular network and the connective tissue. SSc leads to profound disability and premature death. Epidemiological data suggest a complex genetic etiology. To dissect genetic susceptibility to SSc we have performed a genome-wide association study in 654 SSc patients of French Caucasian origin from the GENESYS study, and 2,543 French controls (subjects without SSc from GENESYS and neurologically healthy subjects from the Three-City cohort- Lambert et al, Nat Genet. 2009;41:1094-9). Subjects were genotyped using the Illumina Human 610 QUAD bead chip. The final post-QC discovery (stage-1) sample comprised 564 SSc cases and 2,466 controls, and a total of 489,814 SNPs passed quality control criteria. Association was tested using logistic regression assuming additive genetic effects and adjusted for the two principal components to account for population substructure. The genome-wide association results revealed a number of SNPs with strong evidence (P<10-5) of association. Interestingly, in our discovery sample, stronger signals were detected for 6 non-HLA SNPs that spanned 5 distinct genomic loci. Two SNPs belong to a candidate gene previously reported associated to other autoimmune disease of high relevance with regards to SSc pathogenesis. Furthermore, the remaining 4 SNPs are located on 3 previously unreported putative SSc loci. 2 SNPs are close to genes coding for neuro-mediators and 1 SNP is close to a metabolic gene recently showed to deeply contribute to extra-cellular matrix remodeling. Follow-up and replication analysis of these promising and new association signals are under way in a second French/Italian/German case-control sample (>1,750 SSc cases and 3,200 controls). Our preliminary GWAS results identified a tractable number of novel candidate genes for SSc that warrant further investigation. All top best associated SNPs will be reported in the meeting.

1050/T

Genome-wide association study for sarcoidosis identifies novel risk locus at 12q14.1. *S. Hofmann[1], A. Fischer[1], M. Nothnagel[2], G. Jacobs[1], P. Rosenstiel[1], K. Gaede[3], M. Schuermann[4], J. Mueller-Quernheim[5], S. Schreiber[1].* 1) Institute of Clinical Molecular Biology, CAU Kiel, Germany; 2) Institute of Medical Informatics and Statistics, CAU Kiel, Germany; 3) Reserch Center Borstel,Germany; 4) Institute of Human Genetics, University Lübeck, Germany; 5) Department of Pneumology, Medical University Hospital Freiburg, Germany.

Genetic factors are important to the development of sarcoidosis, and recent advantages in genome-wide screening and candidate gene experiments have lead to the identification of several sarcoidosis susceptibility loci. Although, these loci have considerably improved and changed the understanding of the sarcoidosis pathophysiology they explain only a minor part of the heritability underlying the disease. We aimed on the identification of further susceptibility loci for sarcoidosis and performed a genome-wide association analysis of 934,968 SNPs in 641 German sarcoidosis cases and 1,263 control individuals. We discovered a new association at chromosome 12q14.1. Subphenotype-specific analysis revealed a stronger association of the lead SNP with acute sarcoidosis (OR=1.30) compared to the chronic phenotype (OR=1.16). Fine mapping of the novel locus and quantitative mRNA expression studies point to a candidate gene that plays an important role in the ER-associated degradation of misfolded or unassembled proteins and functions in the maturation of dendritic cells.

1051/T

A Genome-wide association study identifies susceptibility variants for Graves' disease. *J. Wu[1, 2], C. Yang[1], F. Tsai[2], R. Chen[2], C. Chen[1], Y. Chen[1].* 1) Institue Biomedical Sci, Academia Sinica, Taipei, Taiwan; 2) China Medical University Hospital, Taichung, Taiwan.

Graves' disease (GD) is a common autoimmune thyroid disease affecting 0.5-1% of the general population. To investigate susceptibility genes that increase the risk of GD in Han Chinese, a genome-wide association study was conducted in which 596 GD cases and 804 controls were genotyped with Affymetrix SNP6.0 genechips. Graves' disease was diagnosed according to the American Thyroid Disease Association Criteria. All cases were recruited from the China Medical University Hospital, Taichung, Taiwan. The controls were randomly selected from the Taiwan Han Chinese Cell and Genome Bank. All of the participating cases and controls were of Han Chinese origin, which is the origin of 98% of the Taiwan population. We excluded SNPs from further analyses by three major criteria: (1) total call rate <98%, (2) minor allele frequency <5%, and (3) p-value of Hardy-Weinberg Disequilibrium test <10-4. A total of 694,436 SNPs (79.99%) passed the quality control filter with an average call rate of 99.8% and subjected to association analysis using trend (Cochran-Armitage) test. Eleven SNPs within three loci outside the MHC showed associations with p value between 10-5and 10-6. Two of the three loci were novel and one was located within the thyroid stimulating hormone receptor (TSHR) gene that encodes the primary autoantigen in GD. We also demonstrated a positive association of GD with HLA-DQB1 and DRB1 alleles in Han Chinese. In summary, we have identified novel SNPs/loci associated with Graves' disease in Han Chinese. Our study may lead to a better understanding of the underlying mechanism of Graves' disease pathogenesis.

1052/T

Genome-wide association study with gender adjustment to search for genetic variants responsible for intracranial aneurysms in Japanese population. *K. Akiyama, A. Narita, H. Nakaoka, T. Cui, A. Tajima, I. Inoue.* Department of Molecular Life Sciences, Basic Medical Science and Molecular Medicine, Tokai University School of Medicine, Isehara, Kanagawa, Japan.

Intracranial aneurysm (IA) (MIM105800) is a cerebrovascular disease showing a reported prevalence of 3-6 %. The rupture of an IA leads to subarachnoid hemorrhage (SAH) which often results in death or severe physical disability, therefore the disease is a major public health concern. A large-scale GWAS in European cohorts has revealed SNPs responsible for predisposition to IA, locating on 18q11.2, 13q13.1, 10q24.32, 8q11.23-q12.1 and 9p21.3. To identify novel genetic susceptibility loci for Japanese IA, we carried out a multistage association study using genome-wide SNPs in Japanese case-control subjects.

IA is most likely a multifactorial etiology, involving complex interactions of genetic and environmental risk factors. There is a possibility that non-genetic risk factors for aneurysm formation, such as smoking habits, hypertension, frequent alcohol intake and female gender, might hinder the identification of genetic effects. Therefore, additional tests with adjusting sex effects which act between genetic effect and IA were performed at a genome-wide level.

In the first stage of our GWAS, we genotyped over 300,000 tag SNPs spanning the whole genome for 250 IA cases and 249 control subjects. In the second stage, we genotyped 2,304 SNPs in additional subjects. In the following intensified study, we genotyped 22 SNPs in further additional subjects. We assessed evidence for association using standard approaches, and additional tests by adjusting sex effects which act between the genetic effect and disease in order to evaluate the genuine genetic effect of SNPs on IA. Consequently, five SNPs ($p=1.31\times10^{-5}$ for rs1930095 of intergenic region; $p=1.32\times10^{-5}$ for rs4628172 of TMEM195; $p=2.78\times10^{-5}$ for rs7781293 of TMEM195; $p=4.93\times10^{-5}$ for rs7550260 of ARHGEF11; $p=3.63\times10^{-5}$ for rs9864101 of IQSEC1) with probabilities of being false positives < 0.5 were associated with IA in Japanese population. Furthermore, when performing a multivariate logistic regression with gender, hypertension and smoking habit as covariates, we still observed significant associations of the five SNPs. This study indicates the presence of several susceptibility loci which deserve further investigation in the Japanese population.

1053/T

Genome-wide association study identifies two novel regions at 11p15.5-p13 and 1p31 with major impact on acute-phase Serum Amyloid A. *E. Albrecht[1,20], C. Marzi[1,20], P.G. Hysi[2], V. Serum amyloid A (SAA), an acute-phase protein, is causally involved in the pathogenesis of amyloidosis and has been found to be implicated in obesity, atherosclerosis and its clinical complications, and various malignancies. We conducted the first genome-wide association study on baseline acute-phase SAA (A-SAA) concentrations in three population-based studies (KORA, TwinsUK, Sorbs) and one prospective case cohort study (LURIC) including a total of 4,212 participants of European descent and identified two genetic susceptibility regions at chromosome 11 and 1. The region at chromosome 11 contains serum amyloid A1 (SAA1) and the adjacent general transcription factor 2 H1 (GTF2H1), Hermansky-Prudlak Syndrome 5 (HPS5), lactate dehydrogenase A (LDHA), and lactate dehydrogenase C (LDHC). The high degree of explained variance (10.84%) of the total variation of A-SAA suggests that the region is of key importance in the regulation of inflammation. The second region encloses the leptin receptor (LEPR) gene at chromosome 1. As this region has been found to be associated with other acute-phase proteins in previous studies, our finding indicates a close interplay between A-SAA, leptin, and other inflammatory proteins and a larger role of the LEPR gene locus in inflammatory processes as it has been assumed in the past.

1054/T

Genome-wide association study identifies a second independent genetic variant in BCL11A influencing F cells in sickle cell disease. *P. Bhatnagar[1], S. Purvis[2], E. Barron-Casella[2], M.R. DeBaun[3], J.F. Casella[2], D.E. Arking[1], J.R. Keefer[2].* 1) McKusick-Nathans Institute of Genetic Medicine, School of Medicine, Johns Hopkins University, MD; 2) Department of Pediatrics, Division of Pediatric Hematology, School of Medicine, Johns Hopkins University, MD; 3) School of Medicine, Washington University, St. Louis, MO.

Sickle cell disease (SCD) is the most common autosomal recessive blood disorder in the United States, affecting about 1 in 400 African Americans. SCD is a widely studied with marked phenotypic heterogeneity that results from environmental as well as genetic factors. Variation in the level of fetal hemoglobin (HbF) accounts for much of the clinical heterogeneity associated with incidence of pain episodes. Therefore, HbF level has emerged as an important prognostic factor in SCD and can be measured by the proportion of Fcells. The genetic regulation of Fcells levels is complex and quantitative trait loci (QTLs) at chromosome 6q23, 11p15 and Xp22.2 have been reported. To map additional QTLs, we performed a genome-wide association study (GWAS) in 440 African-ancestry SCD patients from the Silent Infarct Transfusion Trial cohort. Genotyping was performed using Illumina HumanHap650Y arrays, and principal component analysis (PCA) was used to correct for potential population stratification. Fcells quantitation was done in a single laboratory. All the analyses were performed by adjusting age, sex and top ten principal components. The average age of the cohort was 9.15 yrs, with 53% males. Our results replicate the previously implicated chromosome 2p15 region that includes BCL11A, confirming the association of BCL11A in the modulation of HbF levels. In earlier GWAS, an intronic BCL11A SNP, rs766432 was the most significant SNP associated with Fcell levels. In our study, we mapped another novel BCL11A intronic SNP, rs6706648 (~2 kb downstream to rs766432, r^2=0.25), associated with lower Fcell counts (P=4.71x10^{-14}). Interestingly, the effect of this SNP is in the opposite direction observed for rs766432; the minor T allele of rs6706648 is associated with lower levels of Fcells, whereas minor C allele of rs766432 is associated with higher levels. Using conditional linear regression and haplotype analyses, we show that these two variants represent independent genetic effects. The variance explained independently by rs6706648 and rs766432 are ~12% and ~11%, respectively, and combined, these SNPs explain ~16%. These results highlight the importance of denser genetic screens, and suggest that analytical methods that specifically look for multiple genetic effects within a gene may improve the ability to detect genes associated with Fcell levels in SCD. Further exploration of the region containing rs6706648 may help explain negative regulation of Fcell production.

1055/T

Meta analysis of African American Genome Wide Association Studies of type 2 diabetes: The CARe T2D Plus Study. *D.W. Bowden[1], S.J. Bielinski[2], L. Kao[3], D. Siscovick[4], S.R. Patel[5], J.R. Medical Center and University of Mississippi Medical Center, Jackson, MS; 16) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN; 17) Department of Genetics, University of North Carolina, Chapel Hill, NC.

A meta-analysis of 6 African American genome wide association studies: Atherosclerosis Risk in Communities (ARIC), Coronary Artery Risk Development in Young Adults (CARDIA) Cleveland Family Study (CFS), Jackson Heart Study (JHS), Multi-Ethnic Study of Atherosclerosis (MESA), and Wake Forest University, has been performed for type 2 diabetes (T2D). Samples were genotyped on the Affymetrix 6.0 platform with imputation of genotypes performed with MACH using the HapMap Phase II CEU and YRI (1:1) haplotypes as reference resulting in ~3M SNP genotypes for analysis (MAF > 0.01). The initial analysis was performed on a total of 8936 DNA samples (2229 prevalent T2D cases at baseline and 6707 non-diabetic controls; Baseline analysis: BSL). A second analysis (Diabetes Working Group analysis: DWG) encompassed 3121 cases with prevalent and incident T2D and 3792 non-diabetic controls without impaired glucose tolerance (fasting glucose <100mg/dl and/or 2hr glucose<140mg/dl) or T2D. Association analysis was performed on 3 million directly genotyped and imputed SNPs in each cohort separately using PLINK or SNPGWA programs with adjustment for admixture using principal components. Meta-analysis was then carried out using METAL. There are both qualitative and quantitative differences between the BSL and DWG analyses. The TCF7L2 SNP rs7903146 was imputed and results in the strongest evidence of association in African Americans (P=4.3X10-12 and OR [95%CI]=1.35[1.24-1.47] BSL; P=1.7X10-9 and OR[95%CI]=1.32[1.20-1.44] DWG) consistent with numerous prior reports. Other, more nominal evidence of association was observed near TAS2R16-SLC13A1 (P=3.2X10-7; OR [95%CI]=0.74[0.66-0.83];BSL). With the exception of TCF7L2 there is limited evidence of association of T2D SNPs identified from prior studies in European-derived populations: CDKAL1, JAZF1, KCNQ1, KCNJ11-ABCC8 with index SNPs showing modest association with T2D (0.001<P<0.05). However, in gene or locus-wide analyses of these "European" loci, suggestive evidence for association was observed in KCNQ1 independent of the index SNP (most significant SNP OR=1.19(CI 1.09-1.29), P=0.0001). The common variant genetic architecture of T2D in African Americans remains elusive. Larger sample sizes achievable through meta analysis or independent replication analyses will be needed to follow-up borderline-significant genetic variants that appear to contribute to T2D susceptibility in the African American population.

1056/T

Meta-analysis of type 1 diabetes GWAS datasets reveals novel loci. *J.P. Bradfield[1], H.Q. Qu[2], K. Wang[1], H. Zhang[1], P.M. Sleiman[1], C.E. Kim[1], J.T. Glessner[1], H. Qiu[1], F. Mentch[1], K. Thomas[1], E.C. Frackelton[1], R. Chiavacci[1], M. Imielinski[1], D.S. Monos[3,4], S.F.A. Grant[1,3,5], H. Hakonarson[1,3,5].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Departments of Pediatrics and Human Genetics, McGill University, Montreal, QC, CA; 3) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA; 4) Department of Pathology and Laboratory Medicine, Abramson Research Center, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Division of Human Genetics, Abramson Research Center, Children's Hospital of Philadelphia, Philadelphia, PA.

Type 1 diabetes is an autoimmune disease leading to the destruction of the pancreatic islets. The prevalence of T1D in the United States in individuals below the age of 20 is 1.7 per 1000. Genome wide association studies (GWAs) have been particularly valuable in identifying the genetic susceptibility loci underlying type 1 diabetes with over 40 associations described in the last two years. One inherent limitation to GWAs is the large sample sizes required to detect loci of modest effect. Meta-analyses are the most efficient and economical way to assemble such large cohorts. In an effort to find more loci, we analyzed the largest combined T1D cohort to date, totaling 10,000 cases and 17,500 controls, comprising ~14000 samples (~3500 cases, ~10500 controls) genotyped on Affymetrix 500K chips (GoKinD, WTCCC) and ~13500 samples (~6500 cases, ~7000 controls) genotyped on Illumina 550K chips (McGill/CHOP, DCCT-EDIC, T1DGC). A cohort of ~1000 independent trios (T1DGC/McGill) was used for replication of all previously unknown T1D loci with p<1.0 x 10e-05. Power calculations based on these sample sizes indicate we have greater than 80% power to detect a variant with relative risk of 1.13 and above assuming a minor allele frequency of 20%. Methodologically, we initially imputed all datasets up to the 2 million CEU Hapmap SNPs using Mach 1.0 so that platform independent comparisons could be made. To control for population stratification, we used principal components anaysis (PCA) in the Illumina and Affymetrix cohorts separately. The results of the PCA analysis were then used as covariates in a logistic regression. Summary stats were then computed on the Illumina and Affymetrix cohorts and combined at all 2 million SNPs using fixed-effects meta-analysis. Three SNPs in previously unknown T1D loci replicated with a fishers combined p<5.0 x 10e-08 and four SNPs in previously unknown loci showed suggestive replication in which the replication p-value was less than 0.05 but the combined p-value was more than the genome wide cutoff. One replicated SNP resides in region 13q22.2 in the gene LMO7 and another in region 2p23.3 in the gene EFR3B. The last replicated SNP doesn't reside in a gene but is in region 6q27.

1057/T

Genomewide association study demonstrates the power of extreme truncate selection, identifying novel genes controlling bone mineral density and fracture. *M.A. Brown[1], E.L. Duncan[1], P. BMD is strongly correlated with fracture risk, and is highly heritable. This study aimed to identify genes associated with BMD, using a unique design of extreme truncate selection in a cohort ascertained for BMD at one skeletal site (total hip (TH)), and one gender and age/menopausal status group (postmenopausal women age 55-85 years). A GWAS was performed in 1952 women of white western European descent, with either extreme high (z=+1.5 to +4, n=1053) or low bone mineral density (BMD) (z=-1.5 to -4, n=899), with follow-up in a cohort of 14,396 participants, assessing both BMD and fracture risk. Following imputation, 2,543,109 SNPs were tested for association with TH BMD. 124 SNPs were studied in the replication cohorts. Our dataset replicated at P<0.05 previously associated SNPs in 21 of 26 BMD genes reported from previous GWAS (*ARHGAP1, CTNNB1, ESR1, FAM3C, FLJ42280, FOXL1, GPR177, HDAC5, JAG1, LRP5, MARK3, MEF2C, MEPE, OPG, RANK, RANKL, STARD3NL, SOST, SOX6, SP7 (Osterix)* and *ZBTB40*). Fracture association was observed (P<0.05) with SNPs at *GALNT3, CLCN7, FLJ42280* and *GPR177* loci. Two genes (*GALNT3, RSPO3*) were identified with $P<5x10^{-8}$ and independently confirmed, and three other genes (*LTBP3, CLCN7* and *SOX4*) were identified with suggestive association ($5x10^{-8}<P<5x10^{-5}$) and confirmed in the replication cohorts. *GALNT3* belongs to the FGF23 pathway, a key pathway involved in control of phosphate and vitamin D levels that has never previously been associated with any common human disease. Mutations of *GALNT3* cause familial tumoral calcinosis and hyperostosis-hyperphosphataemia syndrome through effects on FGF23 glycosylation. RSPO3 is a Wnt-pathway agonist which has not previously been associated with any human disease. Mutations of *LTBP3* cause dental agenesis and high BMD through effects on TGFB1 bioavailability. Mutations of *CLCN7* cause osteopetrosis due to effects on osteoclastic bone resorption. Our study also strongly confirms the previously reported suggestive association of *TGFBR3* with BMD (P=6.7x10-5), indicating that this is a true BMD-associated gene. The extreme-truncate ascertainment scheme used in this study resulted in markedly increased study power, with the GWAS having similar statistical power to studies of ~16,000 unselected cases, and gains further power relative to previous screens through its site, gender and age focus. This study design is efficient and effective for gene discovery in quantitative traits such as BMD.

1058/T

Biological Pathway-based Genome-wide Association Analysis Indentified the Importance of Inflam Pathway for Femoral Neck Bone Geometry in Chinese males. *J. Chen[1, 2], YJ. Liu[1], YF. Pei[1], J. Li[1], J. Hamilton[1], HW. Deng[1, 2].* 1) University of Missouri - Kansas City, School of Medicine, Kansas City, MO 64108, USA; 2) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P R China.

Femoral neck (FN) bone geometry parameters are an important predictor of bone strength and fracture risk. These bone geometry parameters, including CSA (Cross Sectional Area), CT (Cortical Thickness), ED (Endosteal Diameter), Z (Section Modulus) and BR (Buckling Ratio), are under strong genetic control. However, the majority of the underlying genetic factors remain to be identified. In this study, we performed pathway-based genome-wide association analysis in a cohort of 1627 (Male: 802; Female: 825) unrelated Chinese adults to search for genes underlying variation in FN bone geometry parameters. The pathway-based analysis method used in this study is a modification of the Gene Set Enrichment Algorithm. A total of 1007 pathways extracted from the MSigDB database (*http://www.broadinstitute.org/gsea/msigdb/index.jsp*) were analyzed. Among all of the pathways analyzed, the Inflam pathway was most strongly associated with FN CSA in males only even after multiple testing adjustments ($p = 0.0009$, $q_{fdr} = 0.001$, $p_{fwer} = 0.0009$). CSA refers to the area with mineralized bone tissue excluded bone marrow space. Earlier studies have demonstrated that the Inflam pathway is involved in Interleukins and TNF serve as signals to coordinate the inflammatory response, in which macrophages recruit and activate neutrophils, fibroblasts, and T cells. Some of the genes in the Inflam pathway (e.g., TGFB1, IL-6, TNF) play important roles in osteoblastogenesis or osteoclastogenesis. In summary, our study suggests the importance of the Inflam pathway on variation in FN bone geometry parameters of males.

1059/T

Genome-wide Copy-Number-Variation Analysis Identified the *DOK6* Gene to Be Associated with Obesity in Chinese. *Y. Cheng[1,2], T. Xu[1,2], TL. Yang[1,3], YF. Pei[1,3], L. Zhang[1,3], N. Yu[1], HB. Liu[1,4], J. Li[1], K. Redger[1], Q. Tian[1], P. Yu[1], J. Hamilton[1], C. Papasian[1], YJ. Liu[1], HH. Zhou[2], HW. Deng[1].* 1) School of Medicine, University of Missouri-Kansas City, Kansas City, MO; 2) Pharmacogenetics Research Institute, Institute of Clinical Pharmacology, Central South University, Changsha, Hunan 410078, P.R.China; 3) Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an 710049, P R China; 4) Key Lab of Agricultural Animal Genetics, Breeding and Reproduction of Ministry of Education, HuaZhong Agricultural University, 430070, PR China.

Obesity is a major public health problem with strong genetic determination. Copy number variations (CNVs) have been suggested to contribute to complex human diseases. However, whether CNV is associated with obesity remains largely unknown. In this study, we performed genome-wide CNV analyses for body mass index (BMI) and body fat mass in a sample of 1,627 unrelated Chinese subjects. All the subjects were genotyped for the Affymetrix genome-wide human SNP array 6.0 which includes more than 946,000 probes for the detection of CNVs. Body fat mass was measured by a dual-energy X-ray absorptiometry scanner (Hologic Discovery A system). Among the 217 CNVs that passed the quality control, we found that a CNV (CNP12610) located at chromosome 18q22.2 was associated with body mass index (BMI) and body fat mass. This CNV achieved an experiment-wise P-value of 4.61×10^{-5} for BMI and of 1.4×10^{-4} for body fat mass. Compared with normal diploid (copy number=2), CNV loss (copy number=0 or 1) confers an average increase in BMI and body fat mass of 2.27 kg/m^2 and 3.86 kg, respectively. CNP12610 covers the docking protein 6 (*DOK6*) gene which was reported to played a role in the *RET* (ret proto-oncogene) signaling cascade. The *RET* gene encodes one of the receptor tyrosine kinases, which are cell-surface molecules that transduce signals for cell growth and differentiation. Mutations in the *RET* gene were reported to be associated with endocrine disorders such as multiple endocrine neoplasia. Our study is the first suggesting the potential contribution of the *DOK6* gene to obesity in Chinese.

1060/T

Design of a replication study in advanced age-related macular degeneration Mexican patients based on genome-wide association studies. *A. Contreras[1], J.C. Fernandez-Lopez[1], F. Morales-Mandujano[1], L. Sebastian-Medina[1], U. Rodriguez-Corona[1], J.C. Canseco-Mendez[1], A. Ramos-Perez[1], J.C. Zenteno-Ruiz[2], D. Ochoa-Contreras[3], K. Estrada[1], S. March[1], E. Graue[2,4], G. JImenez-Sanchez[1], I. Silva-Zolezzi[1].* 1) INMEGEN, Mexico DF, Mexico; 2) Conde de Valenciana Hospital, IAP. Mexico DF, Mexico; 3) School of Medicine, UNAM, Mexico DF, Mexico; 4) Asociacion para Evitar la Ceguera en Mexico, AC., Mexico DF, Mexcio.

Age-related macular degeneration (AMD) is the most common cause of central blindness in the elderly population. Four genome-wide association studies, two with ~100,000 SNPs, one with ~600,000 SNP and one with ~2.5 x 106 SNPs (imputed) have demonstrated the clear association (p£7E-7) of 8 genes with AMD: Complement Factor H (*CFH*), complement component 2 and 3 (*C2* and *C3*), complement factor B and I (*CFB* and *CFI*), age-related maculopathy susceptibility (*ARMS2*), TIMP metallopeptidase inhibitor 3 (*TIMP3*) and Lipase C (*LIPC*). In order to search for new genes and variants associated to AMD in an admixed we genotyped ~1 x 10^6 SNPs in 100 unrelated Mexican patients with advanced AMD, 100 unrelated healthy controls and 300 population controls from the Mexican Genome Diversity Project (MGDP). Our GWAS results replicated the association found in ARMS2 rs1040924 (p-value<4.0E-7). Additional signals with suggestive p-values<5.0E-5 were identified in regions not previously associated to AMD in chromosomes 3, 5 and 7. The association all regions identified in Caucasians except rs10490924, did not achieve GWAS statistical significance because our GWAS study is underpowered. We are currently performing a replication study in a larger case-control group in candidate regions based on the results from GWAS in other populations and in Mexicans in 200 AMD patients, 200 healthy controls and 300 population controls from the MGDP. This study includes 134 SNPs in the candidate regions and 250 AIMs to correct for population stratification. Our study suggests that contribution of genetic variants to disease-risk in AMD in Mexicans may differ to that of other populations and that the genomic structure of admixed populations may allow the identification of new disease-associated genes.

General cognitive ability has a high heritability through the human lifecourse from adolescence to old age. The field of cognitive genetic research aims to identify the genetic variants responsible for high cognitive functioning and successful cognitive ageing. To date, there are almost no replicated variants from candidate gene studies that contribute to variation in cognitive functioning. An exception is the contribution of APOE at older ages. Genome-wide studies have been inconclusive, but suggest large numbers of genes with very small effect. Limitations with studies to date include inadequate sample size, population stratification effects, and differences in cognitive measurements. A collaborative project between the University of Edinburgh and the University of Manchester examines data from five Caucasian cohorts. Genotyping has been performed on approximately 3800 DNA samples obtained from elderly volunteers from the Greater Manchester, Tyne and Wear, Aberdeen and Lothian (Edinburgh) areas of the UK using the Illumina 610 microarray. Mental and physical health, personality traits and socioeconomic status are available in addition to detailed cognitive measurements. Initial analyses focused on fluid and crystallized intelligence phenotypes. Fluid intelligence was based on either latent traits from a number of non-verbal tests, or from reasoning tests. Crystallized intelligence was based on vocabulary tests. Fluid-type intelligence declines with age and crystallized intelligence holds up better. Association analysis, of each cohort, was performed in PLINK using linear regression analysis under an additive genetic model. Meta-analyses of these association results were then carried out in METAL, using an inverse standard error method. Preliminary GWAS meta-analysis results for fluid and crystallised intelligence suggest evidence of polygenic control. Replication in an independent Norwegian population has produced positive results.

Genome-Wide Association Scan Identified UQCC Locus for Spine Bone Size in Humans. *F.Y. Deng[1, 2], S.F. Lei[1, 2, 3], X.G. Liu[4], T.L. Yang[4], Y. Guo[4], S.S. Dong[4], X.H. Xu[4], Q. Tian[1, 2], Y.J. Liu[1, 2], Y.Z. Liu[1, 2], J. Li[1, 2], H. Shen[1, 2], H.W. Deng[1, 2, 3, 5].* 1) Human Genetics/Genomics Program, Department of Orthopedic Surgery, UMKC, Kansas City, MO; 2) Department of Basic Medical Science, School of Medicine, UMKC, Kansas City, MO; 3) College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P. R. China; 4) School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, Shaanxi 710049, P. R. China; 5) Center of Systematic Biomedical Research, Shanghai University of Science and Technology, Shanghai 200093, P. R. China.

Bone size (BS) is one of the major indexes for bone strength, and BS contributes significantly to the pathology of osteoporotic fracture. Osteoporotic fracture at spine is one of the most disabling outcomes of osteoporosis in humans. To identify genomic loci underlying spine BS variation, we performed a genome-wide association scan (GWAS) in a sample of 2,286 unrelated Caucasian subjects using Affymetrix 6.0 SNP arrays which cover 909,622 SNPs across the human genome. Areal BS (cm^2) at lumbar spine was measured using daily calibrated dual energy X-ray absorptiometry machines. PLINK tool set was used to conduct the genotypic association analyses. Principle component analyses method was utilized to correct for population stratification for the GWAS analyses. Out of a total of 92 SNPs with p <10e-4 in the initial GWAS test, a group of 8 contiguous SNPs (rs6060369, rs6088791, rs6060373, rs2425062, rs2248393, rs4911178, rs1570004, rs6142358), which cluster at UQCC gene locus (ubiquinol-cytochrome c reductase complex chaperone), was identified. The association of the above identified SNPs with spine BS were further replicated in a second independent sample of Caucasians (one-sided $p < 0.1$), as well as in a third sample of Chinese (one-sided $p < 0.05$). With meta-analyses, more significant p values were attained for the 8 SNPs, providing further evidence of their associations with spine BS in humans. The group of SNPs, with strong linkage disequilibrium with each other, tightly form one haplotype block. This study identified UQCC as a novel locus underlying spine BS variation in humans. The mechanism, by which the UQCC locus regulates bone growth and development, still awaits demonstration by future functional studies.

Bivariate Genome-Wide Association Analyses for Obesity and Osteoporosis in Chinese. *H.W. Deng[1,2,3], X. Li[1], L.J. Tan[1], X.G. Liu[1], S.F. Lei[1,2], X.D. Chen[1].* 1) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan, 410081, P. R. China; 2) School of Medicine, University of Missouri-Kansas City, 2411 Holmes Street, Kansas City, MO 64108, USA; 3) Systematic Biomedicine Research Center, University of Shanghai for Science and Technology, Shanghai, 200093, P.R. China.

Obesity and osteoporosis are two common and closely genetically correlated diseases of major public health importance. Although a number of genome-wide association studies (GWAS) have been conducted separately for one of these two diseases, GWAS considering the potential genetic correlation between obesity and osteoporosis are rare. In this study we have performed a bivariate GWAS of obesity and osteoporosis, in order to identify the pleiotropic genes and the genetic mechanisms linking these two diseases. With Affymetrix Genome-Wide Human SNP Array 6.0 genotyped in ~1,600 unrelated Chinese subjects, we focused on two phenotypes, body mass index for obesity and bone mineral density for osteoporosis. Our preliminary results found that a number of SNPs may play pleiotropic roles for obesity and osteoporosis such as rs9503404 on chromosome 6. Our findings, together with the prior biological evidence, will advance our understanding on the co-regulation of obesity and osteoporosis, and aid in the management and treatment for the two diseases.

1064/T

Empirical power of regression methods for cluster-correlated data of quantitative traits in GWAS Based on the Electronic Medical Record; A Mayo eMERGE Study. *K. Ding[1], K.R. Bailey[2], I.J. Kullo[1].* 1) Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 2) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN.

The Electronic Medical Record (EMR) is potential source of high throughput phenotyping to conduct genome-wide association studies (GWAS) including those of medically relevant quantitative traits. An important methodological challenge is dealing with multiple observations often noted in an EMR for a quantitative trait in an individual. We describe empirical power of regression methods for cluster-correlated data of quantitative traits, using six red blood cell (RBC) traits (hemoglobin, hematocrit, RBC count, MCV, MCH, and MCHC) as an example. For 3,012 patients in the Mayo electronic medical records and genomics (eMERGE) cohort, we extracted and compiled 20,650 measurements of six RBC traits from the Mayo EMR between 01/01/1994 to 09/30/2009. Several regression methods, including an aggregate regression analysis [ie, constructing a summary statistic (mean or median) in the same individuals], a weighted least square (WLS), and a generalized estimating equation (GEE), were used in cluster-correlated data analysis. In the context of GWAS, we used a variance-component model to simulate cluster-correlated data, and, for each method, construct the test statistic under the null hypothesis of no association. To quantify the statistical power of different methods, we simulated cluster-correlated data 1,000 times by incorporating the effect of a given genetic marker in the variance-component model. For most RBC traits, there was greater variance between than within clusters such that ~70% variation is attributed to differences between clusters. The exception was MCHC for which only ~45% variation could be attributed to differences between clusters. Under the null hypothesis of no association, we generated the distribution of test statistics under four different regression methods in 10 times simulation in the context of GWAS, i.e., 4,769,900 test statistics were generated for each trait under each regression method. We tabulated the empirical power of different methods by calculating the proportions of times that the critical value was exceeded at the significance level of 0.05 (two sided). We did not find that any one of the regression methods to be more powerful than the remaining methods by pairwise comparison using the McNemar's test. We suggest the use of empirical power to compare regression methods for cluster-correlated data of quantitative traits in GWAS.

Analysis of known asthma-associated variants in population-based cohorts. *Z.K.Z. Gajdos[1, 2, 3], A. Ramasamy[4], M. Kuokkanen[5], S. Vedantam[1,2], H. Lyon[2], C. Palmer[1,2], E. Widen[6], J. Eriksson[7], P. Jousilahti[5], T. Laitinen[7], V. Salomaa[5], J.N. Hirschhorn[1,2,3], M.-R. Jarvelin[4], APCAT Consortium.* 1) Broad Institute, Cambridge, MA; 2) Children's Hospital Boston, Boston, MA; 3) Harvard Medical School Department of Genetics, Boston, MA; 4) Imperial College London, London, UK; 5) The National Institute for Health and Welfare, Helsinki, Finland; 6) The Institute for Molecular Medicine, Helsinki, Finland; 7) University of Helsinki, Helsinki, Finland.

Asthma is a major public health concern. Although environmental factors play a prominent role, about half of asthma susceptibility is due to inherited factors. Discovery of the genetic contributors to asthma could provide important insights into why patients get asthma, with potential implications for prognosis, diagnosis, treatment and prevention. Genome-wide association (GWA) studies have identified a number of asthma-associated loci, primarily through studies of cohorts ascertained for asthma or of population-based studies of asthma-related traits such as eosinophil counts. As with most polygenic traits, the power of GWA studies of asthma is limiting. To see if we could improve power using existing data, we utilized the fact that many population-based studies with genome-wide genotype data have also asked participants about physician-diagnosed asthma. Analyzing these data could supplement current studies by helping to validate known loci and increasing power to identify novel loci. To explore this possibility, we formed the Analysis in Population-based Cohorts of Asthma Traits (APCAT) consortium, which currently includes participants from Finland (Northern Finnish Birth Cohort of 1996, Finrisk cohorts, Health 2000, Helsinki Birth Cohort, and Young Finns Study) and the United States (Framingham Heart Study). Information from 2,091 physician-diagnosed asthmatics and 15,463 healthy controls were available for analyses. We are currently analyzing the association of physician-diagnosed asthma with each of ~2.2 million SNPs, assuming an additive genetic model, and stratifying by smoking status (never, former, and current smokers). To confirm the utility of these population-based cohorts, we first examined eight variants with strong evidence from the literature for association with asthma, at or near ORMDL3, IL1RL1, WDR36, IL33, MYB, IL13, PDE4D, and DENND1B. The direction of association for all eight SNPs was consistent with the prior literature. Four of the eight SNPs were nominally associated with asthma (1-tailed P value < 0.05), with the most significant association at IL33 (rs3939286, 1-tailed $P = 8.63 \times 10^{-6}$). These results provide good evidence that population-based samples can be helpful to validate SNPs identified in case-control studies, and suggest that GWA studies in these samples can serve as a useful complement to GWA studies of samples specifically ascertained for asthma.

1066/T

Genes regulating skin color in Koreans: The Health Twin Study. *M. Han[1], J. Sung[1], Y.M. Song[2], K. Lee[3], M. Lee[1], D.H. Lee[1].* 1) Seoul National University, Seoul, Korea; 2) Department of Family Medicine, Samsung Medical Center, SungKyunKwan University School of Medicine; 3) Department of Family Medicine, Busan Paik Hospital, School of Medicine, Inje University.

Variations in human skin color are but only inborn, not also adaptive traits that correlate closely with the sun's ultraviolet (UV) radiation. The skin's pigment is Melanin that protects peoples from the many harmful effects of ultraviolet (UV) rays. But it is very diverse with individual life style besides race. Recently genetic studies have identified a subset of genes influencing the extent of skin pigmentation; MATP, IRF4, TYR, OCA2, and MC1R were associated with skin colors in a Genome-wide association studies (GWAS) in Europian population. But little is known about the genetic regulators in skin pigmentation difference in Asian family-based population. Specific aims of the study was 1) to test whether there are genetic influences on the skin colors of both ultraviolet light(UV)-exposed (cheek) and UV-unexposed (arm, flank) in Asians, and 2) to identify the genes which are responsible for the degree of skin pigmentation in both body areas. A total of 1440 individuals of Korean twins and their families (543 men and 897 women aged from 17 to 80 years, mean age: 44.1 ± 0.4) join this study. The skin surface pigmentation, were measured using MPA 5, Courage-Khazaka electronic. The average skin pigmentation in cheek, arm and flank were 166.01±55.5, 155.48±49.3 and 134.07±51.9. Pearson correlation coefficients between skin brightness on the cheek and arm, the flank and arm, the flank and cheek are respectively 0.62 , 0.47 and 0.35. The heritabilities of skin pigmentation were 0.55 (p = 6.63e-39) for cheek and 0.66 (p = 3.02e-67)for arm, 0.58 (p = 1.00e-44) for flank area. Genome-wide association test was conducted with Affymetrix GeneChip version 6 (with 541,000 effective SNP markers), using FBAT. We identified rs7956106(12, p12.3,) rs12117410(1,-p31.1), rs11162211(1,-p31.1) SNPs associated with the skin pigmentation on the cheek , rs17016276(1,-q32.2), rs2501892(1,+q32.2), rs1542140(1,-q32.3) SNPs on the arm, and rs8060157(16, q12.1), rs9940645(16, +q12.1), SNPs on the flank. While these genes await replication or further validation, we concluded that different sets of genes may regulate the skin pigmentation according to the UV exposure status.

1067/T

Neurotransmitter receptor gene polymorphisms are associated with widespread pain: findings from the first genome-wide association study of musculoskeletal pain. *K.L. Holliday[1], T. Neogi[2], D.T. Felson[1,2], K. Wang[3], W. Thomson[1], J. McBeth[1].* 1) Arthritis Research UK Epidemiology Unit, University of Manchester, Manchester, United Kingdom; 2) Boston University School of Medicine, Boston, Massachusetts, USA; 3) Department of Biostatistics, Boston University School of Public Health, Boston, Massachusetts, USA.

Purpose: Musculoskeletal pain disorders are prevalent with 10% of the general population reporting widespread pain. Heritability estimates for widespread pain are around 50% although the susceptibility loci have yet to be identified. The purpose of this study was to identify susceptibility loci by conducting the first genome-wide association study (GWAS) of widespread pain. Methods: As part of the Framingham SHARe project, subjects from 3 generations were genotyped using Affymetrix 500k and 50k gene-focused SNP chips. Samples were excluded for low call rate (<95%), excess heterozygosity and mendelian errors. SNPs were excluded for deviation from HWE ($p<10^{-6}$), low call rate (<97%), MAF<1% and mendelian errors (>100). Whole genome imputation was carried out using HapMap CEU data and MACH v1.0.15. Data on musculoskeletal pain was available for a subset of these subjects (n=3850) from 2 generations, which was used to classify cases with widespread pain (reporting pain in contra-lateral body quadrants above and below the waist and in the axial skeleton) and controls (reporting no pain). Generalised estimating equation regression analysis was used to perform a case-control GWAS analysis under an additive genetic model on autosomal SNPs with a MAF>3%, while accounting for relatedness between subjects and using genomic control to adjust for population stratification in R. Results: Imputation was conducted on 378,163 SNPs meeting quality control criteria providing 2,321,937 SNPs for analysis in 572 cases and 1587 controls. The genomic inflation factor was 1.02. Using a p-value cut off of 1×10^{-5}, we identified 52 SNPs in association with widespread pain which comprise 8 individual loci, many of which are strong candidate loci for susceptibility to widespread pain. In particular, an intronic SNP in the neurotransmitter receptor gene *GABA B receptor 2* (*GABBR2*) was associated with an increased risk of having widespread pain (OR=1.37 (1.24, 1.51) $p=6.7 \times 10^{-6}$). A SNP 100 Kb downstream of *glutamate receptor 2* (*GRIA2*), was also associated with an increased risk of having widespread pain (OR= 1.54 (1.35, 1.73) $p=8.96 \times 10^{-6}$). Conclusion: This study, the first GWAS of widespread pain, implicates a number of biologically relevant loci including neurotransmitter genes that are directly linked to pain pathways. Validation of these findings is required in independent cohorts to ascertain the true impact of these loci on widespread pain susceptibility.

1068/T

PRIMe: A Method for Characterization and Evaluation of Pleiotropic Regions from Multiple Genome-wide Association Studies. *J. Huang[1,2], A.D. Johnson[1,2], C.J. O'Donnell[1,2].* 1) Framingham Heart Study, National Heart Lung & Blood Institute, framingham, MA; 2) Center for Cardiovascular Genomics, Division of Intramural Research, National Heart, Lung and Blood Institute, Bethesda, MD.

Background: The concept of pleiotropy was first defined a century ago as one mutation resulting in multiple independent phenotypes. The current abundance of genome-wide association studies (GWAS) results provides an unprecedented opportunity to fully examine this phenomenon in a systematic manner. **Methods & Results**: We developed the Pleiotropic Region Identification Method (PRIMe) to systematically identify and characterize genomic regions where significant association p-values are observed with multiple traits. PRIMe iteratively finds SNPs with the lowest association p-value as the *driver*, and SNPs whose r^2 with the *driver* is above a user specified threshold (≥ 0.8 by default) as *passengers*. Regions are defined by one *driver* and zero or more *passengers*. We denote Pleiotropy Index as the number of traits with significant association p-values at an identified genomic region. For GWAS conducted on traits with known correlation coefficients and for SNPs with known linkage disequilibrium (LD) structure, simulations were performed to derive the statistical distribution of the Pleiotropy Index. The simulation is based on a mathematical derivation that the correlation matrix between all *K* x *M* test statistics is simply the (kronecker) product of the *K* dimensional correlation matrix of the traits (ρ) and the *M* dimensional correlation matrix of the SNPs (*r*). Separately, we evaluated an approximation approach for independent traits and SNPs. For *K* independent traits each with *M* independent SNPs in the region, the number of traits with at least one SNP below a p-value threshold P_S follows a binomial distribution $B(n,p)$, with *n* equal to *K* and *p* equal to $1 - (1- P_S)^M$. Using our simulation approach, we identified pleiotropic regions including *SH2B3* and *BRAP* (both at 12q24.12) for GWAS of hematological and blood pressure traits. By the approximation approach, we confirmed the genome-wide significant pleiotropy of these two regions based on the NHGRI GWAS catalog, and identified further plausible regions of potential pleiotropy including the *FTO* and *ABO* regions. **Conclusion**: Our method can be used to generate further gene hypotheses and may facilitate targeting of pleiotropic regions for resequencing and functional follow-up. This new approach, together with continuing efforts to centralize GWAS results into accessible repositories, is well suited to advance the study of the genetic architecture of complex diseases beyond individual investigators or individual datasets.

Discovering combined causal signals from genome-wide association studies by network module based approach. *P. Jia[1,2,3], S. Zheng[1,3], J. Sun[1,2,3], J. Rong[4], W. Zheng[4,5], Z. Zhao[1,2,3,5].* 1) Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Psychiatry, Vanderbilt University, Nashville, TN; 3) Bioinformatics Resource Center, Vanderbilt University, Nashville, TN; 4) Vanderbilt Epidemiology Center, Vanderbilt University, Nashville, TN; 5) Vanderbilt-Ingram Cancer Center, Vanderbilt University, Nashville, TN.

Genome-wide association studies (GWAS) have revealed hundreds of common variants susceptible to common diseases. While GWA studies have suggested hundreds of single markers/genes that are associated with various diseases, an important emerging question now is how to detect genetic signal beyond single markers/genes in order to explore their combined effects on mediating complex diseases/traits. Here, we introduced a module based method, dense module searching (DMS), to identify candidate subnetworks or genes for complex diseases by integrating the association signal from GWAS datasets into the human protein-protein interaction (PPI) network. The DMS method extensively searches for subnetworks enriched with low P-value genes in GWAS datasets. Specifically, we can apply this method to either single or multiple GWAS datasets. In the latter case, additional GWAS dataset(s) can be used for evaluation/validation of the modules found by the discovery GWAS dataset. The top ranked modules are evaluated by using permutation data so that significant modules can be selected for further analysis and validation. Compared with pathway-based approaches, this method introduces flexibility in defining a gene set and can effectively utilize local PPI information. We demonstrated DMS in two complex diseases, schizophrenia and breast cancer, which have different characteristics of pathology and heritability. We showed that disease candidate genes could converge on PPI subnetworks mediating critical biological functions. For each disease, the DMS method successfully identified a set of candidate genes, including some well studied genes that could not be detected in the original GWA studies. Our functional evaluation revealed that 1) for schizophrenia, several neurodevelopment-related functional categories were consistently enriched; and 2) for breast cancer, Wnt/β-catenin signaling and HER-2 signaling in breast cancer stood out as two of the most enriched pathways. These results indicate that the DMS method and strategy is effective in detecting real effect of susceptibility genes through their interaction in the context of PPI network.

A QTL in the MHC class II gene region influences generalized vitiligo age-of-onset. *Y. Jin, P.R. Fain, R.A. Spritz.* Human Med Gen, Univ Colorado School of Medicine, Aurora, CO 80045.

Generalized vitiligo is a common autoimmune disease in which acquired patchy depigmentation of skin, hair, and mucous membranes results from loss of melanocytes from involved areas. Age-of-onset of generalized vitiligo involves a substantial genetic component, but has not previously been studied systematically. To identify loci that influence generalized vitiligo age-of-onset, we carried out a genome-wide association study in 1339 Caucasian generalized vitiligo patients, with replication in an independent cohort of 677 cases, treating age-of-onset as a quantitative trait. We identified a major association signal in the MHC class II gene region, in the vicinity of c6orf10-BTNL2 (rs7758128; genome-wide association $P = 9.94 \times 10^{-9}$ and replication $P = 2.23 \times 10^{-3}$). We previously identified this same region as a locus contributing to generalized vitiligo susceptibility per se in the same patient cohort. These findings highlight the critical role of the MHC class II gene region in both the pathogenesis and natural history of generalized vitiligo, and perhaps other autoimmune diseases, possibly via mediating recognition and presentation of environmental triggers of disease by the immune system.

Trait-stratified genome-wide association study identifies novel and diverse genetic associations with serologic and cytokine phenotypes in systemic lupus erythematosus. *S.N. Kariuki[1], B.S. Franek[1], A.A. Kumar[1], J. Arrington[1], R.A. Mikolaitis[2], T.O. Utset[1], M. Jolly[2], M.K. Crow[3], A.D. Skol[4], T.B. Niewold[1].* 1) University of Chicago Pritzker School of Medicine, Section of Rheumatology and Gwen Knapp Center for Lupus and Immunology Research, 924 E 57th Street, Chicago, IL 60637; 2) Rush University Medical Center, Section of Rheumatology, 600 South Paulina Street, Chicago, IL 60612; 3) Hospital for Special Surgery, Mary Kirkland Center for Lupus Research, 535 East 70th Street, New York, NY 10021; 4) University of Chicago Pritzker School of Medicine, Section of Genetic Medicine, 5841 South Maryland Ave, Chicago, IL 60637.

Introduction: Systemic lupus erythematosus (SLE) is a highly heterogeneous disorder, characterized by differences in autoantibody profile, serum cytokines, and clinical manifestations. SLE-associated autoantibodies and high serum interferon alpha (IFN-α) are important heritable phenotypes in SLE which are correlated with each other, and play a role in disease pathogenesis. These two heritable risk factors are shared between ancestral backgrounds. The aim of the study was to detect genetic factors associated with autoantibody profiles and serum IFN-α in SLE. Methods: We undertook a case-case genome-wide association study of SLE patients stratified by ancestry and extremes of phenotype in serology and serum IFN-α. Single nucleotide polymorphisms (SNPs) in seven loci were selected for follow up in a large independent cohort of 538 SLE patients and 522 controls using a multi-step screening approach based on novel metrics and expert database review. The seven loci were: leucine-rich repeat containing 20 (LRRC20); protein phosphatase 1H (PPM1H); lysophosphatidic acid receptor 1 (LPAR1); ankyrin repeat and sterile alpha motif domain 1A (ANKS1A); protein tyrosine phosphatase, receptor type M (PTPRM); ephrin A5 (EFNA5); and V-set and immunoglobulin domain containing 2 (VSIG2). Results: SNPs in the LRRC20, PPM1H, LPAR1, ANKS1A, and VSIG2 loci each demonstrated strong association with a particular serologic profile (all OR>2.2 and p<3.5x10-4). Each of these serologic profiles was associated with increased serum IFN-α. SNPs in both PTPRM and LRRC20 was associated with increased serum IFN-α independent of serologic profile (p=2.2 x 10-6 and p= 2.6 x 10-3 respectively). None of the SNPs were strongly associated with SLE in case-control analysis, suggesting that the major impact of these variants will be upon subphenotypes in SLE. Conclusions: This study demonstrates the power of using serologic and cytokine subphenotypes to elucidate genetic factors involved in complex autoimmune disease. The distinct associations observed emphasize the heterogeneity of molecular pathogenesis in SLE, and the need for stratification by subphenotypes in genetic studies. We hypothesize that these genetic variants play a role in disease manifestations and severity in SLE.

Family-based genome-wide association study for length or height from infancy to early childhood. *H. Kim[1], E. Lee[2], H. Kim[1], S. Jung[1], B. Han[2], J. Lee[2], H. Chung[3].* 1) 1Department of Biochemistry, School of Medicine, Ewha Womans University, Seoul, Korea; 2) Center for Genome Science, Korea National Institute of Health, Korea Centers for Disease Control and Prevention, Seoul, Korea; 3) Department of Obstetrics and Gynecology, School of Medicine, Ewha Womans University, Seoul, Korea.

With increasing intermarriage and the number of admixed infants, understanding the anthropometric variation of admixed infants and children is important. To identify genetic factors that influence infant and childhood height, family-based genome-wide association analyses were conducted using 269,888 single nucleotide polymorphisms (SNPs) in 165 trios composed of a Korean father, a Vietnamese mother, and Vietnamese-Korean offspring of a marriage-based immigrant cohort in Korea. In a single-SNP-based analysis, the six SNPs in or near the genes BMP4, MAF, MAGI2, and PTPN7 showed consistent suggestive associations at all height standard deviation scores using Korean, World Health Organization, and Vietnamese growth references. We did not find genome-wide significant associations with height after multiple-testing correction in a single SNP-based analysis. However, the haplotypes in linkage disequilibrium block, which contained the SNPs near the suspected loci, were significantly associated with height. Similar to the results of contiguous haplotype analysis using tagged SNPs, noncontiguous haplotypes of variable length also showed a significant association near the suspected loci. Our results demonstrate that infant and childhood height may be regulated by genetic variations that differ from those of adults and remind us of the need to look at human height from a different perspective, namely age. This study is the first genetic association analysis on cross-sectional infant and childhood height in admixture families, and it provides a basis for future investigations into the genes acting at each stage of height growth.

1073/T

Using shared controls in genome-wide association studies. *R.J. Klein[1], S. Mukherjee[1,2], R. Kurtz[3], S.H. Olson[4].* 1) Program in Cancer Biology and Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Gerstner Sloan-kettering Graduate School of Biomedical Sciences, New York, NY; 3) Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 4) Department of Epidemiology and Biostatistics, Memorial Sloan-Kettering Cancer Center, New York, NY.

Though genome-wide association studies have successfully identified numerous susceptibility loci for common diseases, their use is limited due to the expense of collecting and genotyping large cohorts of individuals. In a hospital-based setting recruitment of controls to studies can be especially difficult. One potential solution to these problems is to use “shared controls,” or data from control individuals genotyped as part of other studies that have been deposited in public repositories. While such an approach has been successfully used by several groups, the genetically heterogeneous nature of the US population makes this approach potentially problematic in the US. Even if analysis is restricted to individuals with a single continental ancestry, if cases and controls are recruited from different places in the U.S. underlying population substructure may appear and lead to false positive findings. To investigate the utility of this approach in US-based GWAS, we applied this approach to an ongoing GWAS of pancreatic cancer. Using analytical calculations, we estimate that once the case:control ratio exceeds 1:10, additional controls do not significantly add to the power of the study. We demonstrate that in our cohort of 263 pancreatic cancer cases and 203 controls from the New York area, the proportions of individuals whose genetic data suggests southeastern Europe or Ashkenazi Jewish ancestry is larger than in individuals in the dbGaP database. When we add up to 5629 additional controls from dbGaP, we find that there is a large inflation of the test statistic that is properly corrected for using eigenvectors from principal components analysis as covariates. Most of this correction is achieved just by using the first six principal components. While the four SNPs identified as pancreatic cancer risk factors by the PanScan study show hardly any association with pancreatic cancer in our cohort alone, results that are trending significant are observed when we add in shared controls from dbGaP. While several SNPs reach a level of genome-wide significance in our analysis, none of them are significant at the P=0.05 level in the PanScan data, suggesting that false positives are a concern with this kind of approach. These data suggest a potential new approach to GWAS in which a smaller number of cases are genotyped genome-wide, analyzed in conjunction with controls from dbGaP, and then the top SNPs are genotyped in a larger case-control set.

Genetic factors contributing to Metabolic syndrome: the Healthy Twin Study in Korea. *J. Lee[1], J. Sung[1], Y.M. Song[2], K. Lee[3], M.K. Lee[1], D.H. Lee[1].* 1) Department of Epidemiology, Seoul National University of Public Health; 2) Department of Family Medicine, Samsung Medical Center, SungKyunKwan University School of Medicine; 3) Department of Family Medicine, Busan Paik Hospital, School of Medicine, Inje University.

Metabolic syndrome (MetS) is one of the major health problems, due to its increasing prevalence and association with chronic disease. Numerous studies have reported genetic and environmental contributions to MetS, and several susceptibility loci for MetS have been identified through genome-wide association (GWA) studies. While MetS definition is useful for educational and preventive purposes, the scientific validity of these criteria has been argued, and some suggested that MetS components can be classified into two heterogenous components; 1)obesity—glucose intolerance—dyslipidemia; 2)hypertension mainly by covariance analysis. This study aims to estimate genetic effects on each MetS trait—waist circumference, HDL cholesterol, triglycerides, blood pressure (BP), fasting blood glucose—and to test whether each component shares overall genetic effects or specific genetic loci. In addition, we attempted to replicate reported loci and identify new region for this end from the Healthy Twin Study in Korea. 1,857 individuals from 635 pedigrees were genotyped with Affymetrix GeneChip v6.0 (1M). Overall genetic influences on MetS were measured by heritabilities (h2), and correlation of MetS traits between cotwins was also considered. 4 traits except for TG showed significant h2 (>.5) after adjustment, and all traits showed higher correlation between MZ cotwins than between DZ cotwins, further suggesting influence of genetic factors on MetS. Since MetS traits tend to cluster in individuals, we generated new factors by Principal Component (PC) analysis, and PCs also showed high h2 (>.5). GWA analyses for each trait showed significant associations with SNP markers, some of which were replication. The 1p21.2 (rs11166440) and 13q13.3 (rs6563539) regions were associated with diastolic and systolic BP level in this study, which were previously reported associations with aortic root and heart-rate respectively. We also attempted to identify susceptibility loci using latent composite phenotypes of MetS and PC1 exhibited significant p-values in 2p22.1, implying there are latent factors in developing MetS. According to previous reports, genetic associations with MetS were found in chromosome 2p23 and 2p24, supportive to this finding in terms of physical distance on chromosome. Our results suggest some components of current MetS, but not all, may have specific genetic ground, especially between obesity and lipid levels, but another genetic component will regulate BP levels.

Genome-Wide Association Study of Saliva Flow Rates from the COHRA-GENEVA Study. *M. Lee[1], K.T. Cuenco[1], X. Wang[1], J.R. Shaffer[1], F. Begum[1], E. Feingold[1], D.E. Weeks[1], M.M. Barmada[1], S. Wendell[1], D. Crosslin[2], C. Laurie[2], B. Weir[2], K.F. Doheny[3], E. Pugh[3], R.J. Weyant[1], R.J. Crout[4], D.W. McNeil[4], M.L. Marazita[1].* 1) University of Pittsburgh, Pittsburgh, PA; 2) University of Washington, Seattle, WA; 3) Johns Hopkins, Baltimore, MD; 4) West Virginia University, Morgantown, WV.

Background and Objective: The Appalachian region experiences limited healthcare access and negative health outcomes including oral disease. As a result of disproportionate levels of dental caries found in the Appalachians, the Center for Oral Health Research in Appalachia (COHRA) began evaluating underlying risk factors for dental caries in families. COHRA participants, as part of the NIH Gene, Environment Association Studies Consortium (GENEVA), were included in a genome-wide association study (GWAS) to identify genetic variants and assess environmental factors related to dental caries. Dental caries are heritable (29%~40%) even after adjusting for shared environmental factors in this population. Caries risk may be influenced by saliva flow altering the oral environment. Saliva flow itself may also be under genetic influence. **Samples and Methods:** Measures included caries status, demographics, and unstimulated saliva flow rates (ml/min). The estimated heritability of saliva flow is 49% in COHRA subjects. A GWAS was conducted of unstimulated saliva flow rates (mean=0.581(ml/min), sd= 0.418) in COHRA-GENEVA subjects (n = 1506; 647 males and 859 females) who are self-reported Caucasian, and 5 to 75 years of age. The Center for Inherited Disease Research generated subject genotypes with the Illumina 610-Quad platform. Genotype quality control was performed by both GENEVA Coordinating Center and our analytic group (548,874 SNPs with Minor Allele Frequency (MAF)>0.02 and Hardy-Weinberg Equilibrium (HWE) p-value>0.0001). The association between each SNP and transformed saliva flow rate was assessed using regression analysis ignoring familial relationships but adjusted for gender and age under an additive genetic model and will be repeated with adjustments for relatedness (variance components-SOLAR). **Results:** Preliminary GWAS results suggest regions of chromosomes 2, 8, and 13 may be associated with a cubic-root transformed saliva flow rate. We are currently assessing the utility of applying a two-stage sampling methodology which involves repeated split samples. This method may be a useful alternative for other seldom measured traits for which independent replication populations are unavailable. These data also provide the initial findings for specific gene regions associated with unstimulated saliva flow rates in this underserved population. NIH grants DE014899, DE018903.

Identificaiton of candidate variant for Intraocular Pressure using Korean twin families and Mongolian large families: The Healthy Twin Project and GENDISCAN Project. *M. Lee[1], J. Sung[1], Y. Song[2], K. Lee[3], S. Cho[1], D. Ham[4], D.H. Lee[1], J. Seo[5].* 1) Complex Disease and Genetic Epidemiology Branch, Department of Epidemiology and Institute of Environment and Health, School of Public Health Seoul National University; 2) Department of Family Medicine, Samsung Medical Center, and Center for Clinical Research, Samsung Biomedical Research Institute, Sungkyunkwan University School of Medicine, Seoul, Korea; 3) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Korea; 4) Department of Ophthalmology, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea; 5) Department of Molecular Medicine, School of Medicine, Seoul National University, Korea.

Intraocular pressure (IOP) is one of the major risk factors for Primary open-angle glaucoma (POAG): the second most frequent cause for visual impairment worldwide. Genetic studies of IOP have been mainly accomplished in glaucomatous families among Caucasians therefore searching for causative variants for IOP variation using healthy population will provide further insight.Particularly, studies from Asians, who show different epidemiologic characteristics for IOP and glaucoma will bear academic and public health significance. The Healthy Twin study and The GENDISCAN study recruited large families from Korea and two isolated regions (Selenge and Dashibalbar) in Mongolia. Clinical information and epidemiologic data were collected and IOP values were measured using non-contact method. For Selenge population with 1451 individuals from 142 families we had genotyped 390 short tandem repeat (STR) markers and 370K genome-wide SNPs (Illumina). In Dashibalbar we collected 1490 individuals from 95 families and the genotyping was done with 1097 STR markers, and 610K genome-wide SNPs (Illumina) for 652 individuals. In Korean twin-families, 1502 individuals from 396 families were genotyped using Affymetrix GeneChip version 6.0 for 1376 individuals. Family-based genome-wide linkage and association approach was adopted for investigating causative variants regulating IOP variation. For regions with replicated by linkage analysis, we further tested for associations in both populations. The heritabilities of IOP level were 0.48, 0.50, and 0.62 adjusted for age, sex and age by sex interaction for two populations in Mongolia in Koreans. The GWAS analysis revealed several candidate genes. SNPs with genome wide significance in two populations were closely located to POAG candidate gene on Chromosome 5: Zinc Finger protein 608 (ZNF608) and WD repeat domain 36 (WDR36). In those two regions, there are several significant SNPs and haplotypes associated with IOP elevation: C alleles on rs7723819 increased IOP level by 7% and 2% for having one more C allele (WDR36, C allele frequency 39%). Our study showed that QTL regulating IOP in general populations from Korea and Mongolia are linked to regions harboring POAG genes. Furthermore we suggest that the QTL from our analysis can influence both normal variation and disease occurrence and some genes may regulate both normal variation and the development of disease.

Background: Chronic kidney disease (CKD) is an increasing global public health problem. Although hypertension and diabetes are major risks factors for CKD, there is considerable evidence that genetic factors also contribute. To date, most studies have reported results for individuals of European ancestry; few studies have reported results in those of non-European ancestry. Here we present the results of a genome-wide association (GWA) study from the CARe Renal Consortium in African Americans. Methods: Using estimated glomerular filtration rate (eGFRcrea) defined by the MDRD equation, we performed a meta-analysis of GWA data in 7382 individuals of African ancestry from four CARe studies (ARIC, CARDIA, JHS and MESA) to identify potentially susceptibility loci for eGFRcrea and CKD (eGFRcrea < 60 ml/min/1.73m2). We also developed an algorithm to interrogate and validate signals reported in European ancestry individuals by interrogating their associated regions in African ancestry participants. Results: No individuals SNPs reached genome-wide significance. However, we identified four potential novel SNPs, rs6581768 (chr 12, p=3.0E-07, eGFRcrea), rs7784820 (chr 7, p=5.3E-07, eGFRcrea), rs1257581 (chr 11, p=9.97E-07, CKD) and rs6428106 (chr 1, p=2.95E-07, CKD), which are respectively near DYRK2 (related to glycogen synthesis regulation), GNAT3 (related to gut capacity to absorb sugars), B3GAT1 and RGS1 (highly expressed in renal cell carcinoma tissues) region. We also interrogated 24 previously published loci associated with eGFRcrea identified by the CKDGen Consortium. Of the 24 lead SNPs identified in participants of European ancestry, 23 had direction-consistent beta coefficients among our AA samples. We subsequently interrogated the 250 kb flanking regions for the best SNP in each region, and identified 8 SNPs in participants of African ancestry that reached significance after Bonferroni correction by the number of independent corrected SNPs within the region. Conclusion: In 7382 African Americans, we identified 4 potential novel loci and replicated eight loci previously associated with eGFRcrea in whites. While our findings require replication, our study supports the importance of multi-ethnic GWAS in the identification of novel loci and underscores the similarity of genetic architecture among European and African populations.

Using data mining to detect main effects and interactions in GWAS. *G. Lubke, R. Walters, C. Laurin.* University of Notre Dame, Notre Dame, IN.

The common approach in genome-wide association studies (GWAS) is to test single nucleotide polymorphisms (SNPs) univariately, thus necessitating substantial corrections for multiple testing. We investigated the precision rate of a data mining procedure to detect small main effects ($<10^{-7}$) and 2-way interaction effects using simulated genome-wide data. The procedure is carried out in a parallelized way, and is computationally feasible on clusters with 32Gb RAM. The procedure can be used as a screen to select a small proportion of promising SNPs for further parametric testing.

1079/T

A genome-wide association analysis of gender-specific effects of fasting glycaemic traits. *R. Magi[1], J.J. Hottenga[2], I. Prokopenko[1,3], MAGIC investigators.* 1) WTCHG, University of Oxford, Oxford, United Kingdom; 2) Department of Biological Psychology, VU University Amsterdam, Amsterdam, Netherlands; 3) OCDEM, University of Oxford, Oxford, United Kingdom.

Meta-analyses of genome-wide association (GWA) studies for glycaemic traits have described 16 loci influencing fasting glucose (FG) and two loci influencing fasting insulin (FI) levels. Within the Meta-Analyses of Glucose and Insulin-related traits Consortium (MAGIC) we aimed to investigate gender-specific differences in genetic regulation of FG/FI levels. To do this, we performed gender-stratified meta-analyses of 36 genome-wide association (GWA) studies informative for FG and FI within MAGIC in up to 32,993 and 27,870 non-diabetic men and 42,149 and 34,940 non-diabetic women, respectively.

Among previously described loci *DGKB-TMEM195I* demonstrated the largest gender-specific effect (heterogeneity Q P=0.026, I^2=80%) showing stronger association in men (β=0.031 [SE=0.004], P=9.1x10^{-14}) than in women (β=0.019 [SE=0.004], P=1.1x10^{-7}). Gender-specific heterogeneity for *MTNR1B* was also high (Q P<0.05, I^2=75%) with larger effects for men (β=0.080 [SE=0.005], P=3.7x10^{-56}) than for women (β=0.067 [SE=0.004], P=3.3x10^{-51}). Effects estimates in women were higher for *C2CD4B* and *GCKR*, where the gender heterogeneity was present, but not significant (I^2~60%, Q P>0.05). *G6PC2* and *ADCY5* showed moderate and *GCK*, *PROX1*, *SLC30A8* low between-gender heterogeneity for FG (I^2£50% and I^2<25%, respectively). In the FG meta-analysis we uncovered a novel locus near *PCSK1* showing strong gender heterogeneity (Q P=0.055, I^2=73%) with women showing β=0.023 [SE=0.003], (P=3.0x10^{-9}) and men β=0.012 [SE=0.004], (P=0.008); overall β=0.018 [SE=0.003], (P=9.0x10^{-10}). The FI meta-analysis revealed higher effect estimates in men (β=0.034 [SE=0.006], P=3.3x10^{-8}) compared to women (β=0.018 [SE=0.006], P=0.001) at rs860598 near *IGF1* locus (overall β=0.024 [SE=0.004], P=3.6x10^{-9}, heterogeneity Q P=0.042, I^2=76%).

Our analysis showed the novel FG-associated locus near *PCSK1* and four known FG- or FI-associated loci have differential gender-specific effects. These findings may provide new insights into the physiological mechanisms linking these loci to the physiological regulation of fasting glycaemic traits and to gender-specific differences in T2D pathogenesis.

1080/T

Overcoming heterogeneity to indentify genes influencing handedness: results from the International Handedness Consortium. *S.E Medland[1,9], R. Magi[2,3,4], D.M Evans[5], A. Kumar[2,3,4], H. Stefánsson[8], B.M Neale[6,7], C.M Lindgren[2,3,4] for the International Handedness Consortium.* 1) Gen Epidemology, Queensland Inst Med Res, Brisbane, Australia; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 3) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, UK; 4) Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 5) MRC Centre for Causal Analyses in Translational Epidemiology, Department of Social Medicine, University of Bristol, Bristol, UK; 6) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA USA; 7) Program in Medical and Population Genetics, The Broad Institute, Boston, MA USA; 8) deCODE Genetics, Reykjavik, Iceland; 9) School of Psychology, University of Queensland, Brisbane, Australia.

Background: The prevalence of left-handedness (~10%) is increased in a number of psychiatric, neurologic, and learning disorders suggesting that cerebral asymmetry may play a role in these disorders. Handedness is moderately heritable and is related to the lateralization of language functions within the brain. The International Handedness Consortium was formed to conduct large scale meta-analyses to ameliorate the low power associated with GWAS in unselected samples with low prevalence. Here we present the results of the third round of analysis which included data from 32 samples comprising results from 55,399 individuals (5,429 cases, 49,970 controls). Methods: Writing hand was used to classify participants as left- or right-handers, and sex and year of birth were used as covariates. All samples were derived from European descent populations. We tested for trait associations under an additive model for a total of ~2.5 million common HapMap SNPs (directly genotyped and imputed). Weighted Z-score based meta-analysis was conducted using METAL with weights defined by effective sample size. Results: The initial meta-analysis results for the 32 samples were extremely disappointing (the strongest p-value was 1.197e-06). To ascertain whether we had a complex heterogeneity problem we undertook a series of novel multi-dimensional scaling analyses. The results of these analyses identified four samples which were outliers compared to the remaining 28. Re-running the analysis with these four samples removed vastly improved the results, yielding a p-value of 6.092e-08. Conclusions: We have identified a region on chromosome 5 that is potentially associated with handedness. The region encompasses SLIT3 which plays a role in the axon-guidance-pathways that guide motor neuronal development during fetal development. In addition, our study demonstrates that meta-analyses may benefit from examination of heterogeneity at the whole genome as well the SNP level.

1081/T

Efficient Testing of Gene-Environment Interactions Affecting Asthma Susceptibility in the Children's Health Study. *C.E. Murcray, J. Baurley, F. Gilliland, W.J. Gauderman.* University of Southern California, Los Angeles, CA.

Asthma is a growing health concern for children, with prevalence of asthma and asthma-related symptoms increasing over the last few decades. Although the etiology of asthma is largely unknown, it is widely accepted that asthma is a result of the interplay of environmental exposures and genetic factors. Genome-wide association studies of asthma have already uncovered novel genetic regions related to asthma susceptibility. However, little work has been done to allow for the possibility of heterogeneity of genetic risk by subgroups defined by environmental exposures in these large studies. Emerging evidence suggests that smoking, air pollution, traffic, and other personal exposures affect asthma risk and symptoms. It may therefore be important to include these environmental risk factors in the search for novel genetic variants. The Children's Health Study (CHS) is a prospective cohort study of southern California children that began in 1992. Children enrolled in the study have been followed for up to 8 years, with data collected on a large number of respiratory related exposures, including yearly regional air pollution measures, traffic-related exposures, and personal environmental factors, such as in utero and passive tobacco smoke exposure. In addition to this collection of comprehensive environmental data, genome-wide genotyping was conducted on the Illumina 550K genotyping chip for 2,841 children (1,248 asthmatic cases/1,593 non-asthmatic controls). This resource offers the unique opportunity to scan the genome for genes associated with asthma susceptibility whose effects are modified by environmental factors. To analyze this data, we apply a two-step procedure developed by Murcray et al (2009). Their method uses a screening step to prioritize SNPs that are likely to be involved in a GxE interaction by modeling the induced G-E association in the combined case-control sample. We optimize this procedure to efficiently scan for GxE interactions that affect asthma susceptibility for binary (e.g. in utero tobacco smoke, close proximity to a major road) and continuous (e.g. PM2.5, ozone, traffic-related pollution) exposures. For a scan of Gx in utero tobacco smoke exposure, we identify a genome-wide statistically significant SNP on chromosome 6, rs807532, using the Murcray et al two-step approach. This SNP fails to reach genome-wide significance using the standard GxE approach for case-control studies.

1082/T

Within the mTOR pathway, translation regulator EIF4EBP3 sequencey variants associate with healthy human aging. *S.S. Murray[1], B.A. Patay[1,2], E. Smith[1], S. Topol[1], M. Shaw[1], C. Bloss[1], A. Torkamani[1], N. Villarasa[1], K. Wang[3], G. Tranah[4], H. Hakonarson[3], E. Orwoll[5], S. Cummings[4], N. Schork[1], S. Levy[1], E.J. Topol[1,2].* 1) Scripps Genomic Medicine, Scripps Translational Science Institute, La Jolla, CA; 2) Scripps Clinic, La Jolla, CA; 3) Children's Hospital of Philadelphia, Philadelphia, PA; 4) California Pacific Medical Center Research Institute, San Francisco, CA; 5) Oregon Health Sciences University, Portland, OR.

While there has been considerable application of genome-wide association studies to elucidate genes and pathways related to diseases, this methodology has yet to be used to understand the phenotype of healthspan. We have used the Illumina Human1M to genotype over 1 million single nucleotide polymorphisms (SNPs) in 397 DNA samples from individuals who were at least age 80 and had no chronic disease ("wellderly" cases) and 386 individuals who were deceased from various chronic diseases, matched for birth year, gender and ancestry ("illderly" controls). We conducted a genome-wide association from the whole-genome genotyping data, and multiple SNPs in the translator regulator EIF4EBP3 were associated (peak SNP rs250431 P = 1.8 X 10^{-5}; 21 SNPs < 10^{-4}) where the allele frequency at rs250431 was higher in the "illderly" control versus the "wellderly" case groups (0.39 and 0.29, respectively). The top genome-wide associated SNPs were assessed in a second healthy aging cohort (N=284) and compared with the same set of illderly controls, and strengthened the evidence for association (peak SNP rs250431 P = 7.9 X 10^{-6}, combined sample P = 3.1 X 10^{-6}). The finding of significant association with EIF4EBP3 is particularly intriguing as there is an established strong relationship between dietary restriction and aging and longevity. EIF4EBP3 with EIF4EBP1 and EIF4EBP2 produce proteins that bind to eIF4E which prevent eIF4G binding thus inhibiting translation and affects cell proliferation. The ortholog to this gene is 4E-BP, which was recently demonstrated to regulate lifespan in Drosophila subjected to caloric restriction. Since the allele frequency of the associated SNPs is higher in the illderly versus the wellderly groups, this finding raises the possibility of an accelerated aging disorder with the illderly having a higher rate of increase in mortality with age. We are currently sequencing the EIF4EBP3 gene region as well as other key genes in the mTOR pathway in both wellderly and illderly samples. We will compare the spectrum of variants between both wellderly and illderly groups by using single locus tests for common variants, and methods to test association by collapsing rare variants based on function or being present in a contiguous window.

1083/T

Genome-wide association study identified the association of IL28B with response to PEG-IFN-α/RBV therapy for HCV patients. *N. Nishida[1], Y. Tanaka[2], M. Sugiyama[3], A. Koike[4], M. Sageshima[1], Y. Ogasawara[1], Y. Ishibashi[1], Y. Uehara[1], M. Mizokami[3], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 2) Department of Clinical Molecular Informative Medicine, Nagoya City University, Nagoya, Japan; 3) Research Center for Hepatitis and Immunology, International Medical Center of Japan Konodai Hospital, Ichikawa, Japan; 4) Central Research Laboratory, Hitachi Ltd., Kokubunji, Japan.

Together with technology developments on large-scale single nucleotide polymorphism (SNP) genotyping, genome-wide association studies (GWAS) with hundreds of thousands of SNPs allow the identification of candidate genetic loci for multifactorial diseases in different populations. We conducted GWAS to identify the host genes associated with response to PEG-IFN-α/RBV treatment in 142 Japanese patients with HCV genotype 1 (78 with null virological response (NVR) and 64 with virologic response (VR)). We found that the minor alleles of two SNPs near the gene IL28B (a member of interferon lambda family) on chromosome 19 were strongly associated with NVR (rs8099917; P = 3.11 × 10^{-15}, OR=30.0 and rs12980275; P = 1.93 × 10^{-13}, OR=20.3). We confirmed these associations with independent patient panels of 50 NVR and 122 VR (combined P = 2.68 × 10^{-32} (OR = 27.1) and 2.84 × 10^{-27} (OR = 17.7), respectively). In the fine mapping of the region, seven SNPs located in the IL28B region showed the strongest associations (P = 5.52 × 10^{-28}-2.68 × 10^{-32}; OR = 22.3-27.1). Quantitative PCR assays in peripheral blood mononuclear cells showed lower IL28 expression level in patients possessing the minor alleles, suggesting that variant(s) regulating interferon-lambda expression is associated with the response to PEG-IFN-α/RBV treatment. The strong association of IL28B with response to PEG-IFN-α/RBV treatment was also found among HCV-infected individuals of European and African ancestry. In these populations, the strongest association was observed from rs12979860 (located about 3 kb upstream of IL28B), which shows to be in linkage disequilibrium with rs8099917 (r^2=0.98). The frequency of minor allele-positive patients were much higher in the NVR group than in the VR group for both SNPs (74.3% in NVR, 12.5% in VR for rs12980275; 75.6% in NVR, 9.4% in VR for rs8099917). Further studies following our report of this robust genetic association to NVR may make it possible to develop a pre-treatment predictor of which individuals are likely to respond to PEG-IFN-α/RBV treatment. This would remove the need for the initial 12-24 weeks of treatment that is currently used as a basis for a clinical decision about whether treatment should be continued.

Genome-wide association studies of hematological, biochemical and physical traits in the Japanese population identified 49 novel loci. *Y. Okada[1,2], Y. Kamatani[3], A. Takahashi[1], K. Matsuda[4], N. Hosono[5], H. Ohmiya[1], Y. Daigo[4], K. Yamamoto[2], M. Kubo[5], Y. Nakamura[4], N. Kamatani[1].* 1) Lab for Statistical Analysis, CGM, RIKEN, Japan; 2) Department of Allergy and Rheumatology, Graduate School of Medicine, the University of Tokyo, Japan; 3) Centre d'Etude du Polymorphisme Humain (CEPH), Paris, France; 4) Lab of Molecular Medicine, HGC, IMS-UT, Japan; 5) Lab for Genotyping Development, CGM, RIKEN, Japan.

Recent development of genome-wide association studies (GWASs) led to the identification of numerous quantitative trait loci (QTL). Here, we report GWASs for hematological, biochemical and physical traits in the Japanese populations. We enrolled ~20,000 Japanese individuals under the support of BioBank Japan Project (http://biobankjp.org). We evaluated 9 hematological traits (white blood cell count: **WBC**, neutrophil count, red blood cell count: **RBC**, hemoglobin concentration: **Hb**, hematocrit: **Ht**, mean corpuscular volume: **MCV**, mean corpuscular hemoglobin: **MCH**, mean corpuscular hemoglobin concentration: **MCHC**, and platelet count: **PLT**), 15 biochemical traits (urate: **UA**, high-density lipoprotein: **HDL-C**, low-density lipoprotein: **LDL-C**, triglyceride: **TG**, gamma glutamyl transferase: **GGT**, alkaline phosphatase: **ALP**, aspartate aminotransferase: **AST**, alanine aminotransferase: **ALT**, creatine kinase: **CK**, total protein: **TP**, albumin: **ALB**, blood urea nitrogen: **BUN**, serum creatinine: **sCr**, serum Calcium: **Ca**, and serum Phospate: **P**), and 1 physical trait (adult height). We identified 99 significant associations ($P < 5\times10^{-8}$), including 49 novel associations.

Our study also provides the following topics. (i): Ethnically different genetic backgrounds of QTL. Although *IGF1* is a well-known gene that plays an important role in skeletal development, the association of *IGF1* with height had not been established in Europeans. Our study identified that the multiple SNPs were independently associated with height in *IGF1* locus, and their minor allele frequencies were high in Asian populations but quite low in Europeans and Africans. (ii): Most of the identified QTL included the genes that were functionally related with the traits. We identified that the SNP in *ABO* gene that determine ABO blood type of human was associated with RBC, Hb and MCHC. It suggested that the proportion of the individuals suffering from anemia would be different according to ABO blood type. (iii): Even though a number of QTL were identified, most of the QTL would be still unidentified. We evaluated the combined effects of the height-associated loci incorporating a total of 51 loci. However, the explained proportion of the variance of height was as low as 4.8%, suggesting the missing heritability of the trait. Our study would enhance our knowledge for QTL and motivate the accumulations of the further studies.

A Genome-wide Association Study of von Willebrand Factor Plasma Levels and other Hematological Traits in a Healthy Young Cohort. *A. Ozel[1], K. Desch[2], D. Siemieniak[3], D. Ginsburg[1,3], J. Li[1].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 3) HHMI, University of Michigan, Ann Arbor, MI.

von Willebrand factor (VWF) is an abundant plasma glycoprotein that regulates hemostasis. Plasma levels of von Willebrand Factor (VWF) are highly variable among healthy people, with ~70% of this variability attributed to heritable factors. von Willebrand disease (VWD), the most common inherited bleeding disorder in humans, results from deficiencies in VWF function. Conversely, elevated plasma VWF levels are associated with an increased risk for deep vein thrombosis. We performed a genomewide association study involving genotyping >800,000 common SNPs (Illumina Omni1-Quad) in a healthy sibling cohort of 1146 subjects (ages 14-35) in 499 sibships. Approximately 80% of subjects are of European ancestry. We collected a total of 62 traits, including plasma VWF antigen level, peripheral blood cell counts (RBC, WBC, platelets), blood cell indices (hematocrit, hemoglobin, MCV, MCH, MCHC, RDW, MPV), as well as common traits such as hair color, eye color, weight, height, and handedness. Many traits show strong familial clustering, suggesting substantial genetic contribution to their variation. Data clean-up for genotypes and phenotypes is near completion. Initial analyses reveal a significant association of plasma levels of VWF with the ABO locus ($p\sim10^{-30}$), consistent with previous reports. Suggestive evidence of association and linkage is found for the VWF gene and a number of other loci. Analyses of other hematological traits (peripheral blood cell counts and platelet factors) are currently underway, as are meta-analyses involving another healthy young cohort and data from the CHARGE consortium. These data provide new insight into the regulation of hemostasis and may identify novel genetic modifiers of bleeding and thrombosis risk. The study is supported by NIH grant HL039693 and is part of the GENEVA (Gene Environment Association Studies) Consortium.

Endometriosis is a common gynaecological disease associated with severe pelvic pain and sub-fertility. We conducted a genome-wide association (GWA) study using 540,082 SNPs in 3,194 surgically confirmed endometriosis cases and 7,060 controls from Australia and the UK. There is currently considerable debate as to whether different endometriosis stages represent disease progression or whether the milder form of the disease is an epiphenomonen. We used novel statistical methods to estimate the proportion of variation explained by all markers and perform polygenic predictive modelling for disease stage, both of which showed significantly increased genetic loading among the 42% of cases with moderate-severe endometriosis. The strongest signals of association were also observed for moderate-severe disease. We subsequently genotyped 72 SNPs in an independent US dataset consisting of 2,392 endometriosis cases and 1,646 controls. An association with rs7798431 on 7p15.2 for moderate-severe endometriosis (P = 6.0 x 10-8, OR = 1.34 (1.21-1.49)) was replicated, reaching combined genome-wide significance (P = 1.7 x 10-9; OR = 1.26 (1.17-1.35)). Following analysis of imputed SNPs the strongest evidence of association was seen for rs12700667. Both SNPs are located in a 48 kb segment of high LD in an intergenic region upstream of plausible candidate genes, NFE2L3 and HOXA10.

1087/T

Harley[15].* 1) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) University of Alabama at Birmingham, Birmingham, AL; 3) Division of Rheumatology, Department of Medicine, Johns Hopkins University, Baltimore, MD; 4) Northwestern University, Chicago, IL; 5) University of Texas Health Sciences Center, Houston, TX; 6) University of Puerto Rico School of Medicine, San Juan, PR; 7) Feinstein Institute of Medical Research, Manhasset, NY; 8) University of Southern California, Los Angeles, CA; 9) Medical University of South Carolina, Charleston, SC; 10) Imperial College London, UK; 11) University of Texas Southwestern Medical Center, Dallas, TX; 12) University of California San Francisco, San Francisco, CA; 13) University of California Los Angeles, Los Angeles, CA; 14) Wake Forest University Health Sciences, Winston-Salem, NC; 15) Cincinnati Children's Hospital, Cincinnati, OH.

Objectives: Systemic Lupus Erythematosus (SLE) is an autoimmune inflammatory disease with a strong genetic component, which predominantly affects women with a 9:1 female:male ratio. A genome wide association study (GWAS) and its replication cohort, the Large Lupus Association Study #1 (LLAS1), were performed in women of European-American (EA) ancestry and identified SLE susceptibility variants in ITGAM, PXK, KIAA1542 and confirmed several previously associated loci (Nat Genet 40:204-210, 2008). Here, we report confirmation of genetic associations with SLE in the EA males from LLAS1. Methods: We studied 8633 SNPs selected from the female LLAS1-GWA case-control study in a replication cohort of 213 EA males affected with SLE and 709 EA male controls. We performed a standard chi-square analysis in the males and conducted a Fisher's combined p-value for the combined result of males and females. We required primary associations to be significant for the risk allele in the males cohort at $P<0.05$ and $P<10^{-6}$ in the combined analysis of the four female cohorts plus male cohort. Results: The most significant associations were within the MHC region in chromosome 6p21, where all prior associations in females were confirmed in males; this was also the case for the association with IRF5. We also identified highly significant associations with markers in a 700 Kb segment on chromosome 8p23.1 containing XKR6, BLK and C8orf12. The associations with PXK and KIAA1542 did not reach statistical significance in the male-only cohort. Table 1 shows the most relevant associations identified. Conclusions: The EA male replication cohort supports many of the associations previously identified in the LLAS1-GWA study in females, and suggests that some sex differences may exist. These include a tendency for larger odds-ratios in males than those observed in females at several loci, and a candidate association to USH2A in males-only. Furthermore, we found significant association to multiple SNPs in a segment of 8p23.1 that encodes for at least three transcripts that are expressed in immune cells. This region has been proposed as a candidate for SLE-association mainly in Asian populations.

1088/T

Genome wide association study identifies three loci associated with psoriatic arthritis. *A. Reis[1], U. Hüffmeier[1], S. Uebe[1], A.B. Ekici[1], J. Bowes[2], E. Giardina[3], E. Korendowych[4], K. Psoriatic arthritis (PsA) is an inflammatory joint disease distinct from other chronic arthritides and frequently accompanied by psoriasis vulgaris and seronegativity for rheumatoid factor. In order to identify susceptibility genes, we performed a SNP array based genome wide association study in 609 German patients and 990 control individuals. Analysis of 1,585,307 confidently imputed SNPs revealed three loci achieving genome-wide significance ($p<5x10^{-8}$) that were replicated in independent study groups of 1,761 patients and 3,727 control individuals of European origin. We confirmed HLA-C ($p=2.63x10^{-23}$) and IL12B ($p=5.60x10^{-13}$) as PsA susceptibility genes and observed several independent signals within the HLA region. The most associated IL12B variant, located 72kb upstream of the gene, was independent of previously reported psoriasis-associated IL12B-SNPs. Association to several intragenic variants of the TRAF3IP2 gene ($p=5.48x10^{-9}$) including the missense-variant R74W (rs13190932) was detected implicating this component of the IL-17 receptor signalling pathway as a PsA susceptibility locus. Functional studies of two missense variants within this gene showed altered binding to molecules TRAF3 and TRAF6. Our study implicates new susceptibility variants at known susceptibility loci and in addition identifies a novel pathway for PsA.

1089/T

Variants within the *CBLB* gene are associated with multiple sclerosis. *S. Sanna[1], M. Pitzalis[2], M. Zoledziewska[2], I. Zara[3], C. Sidore[1,2], R. Murru[5], M.B. Whalen[4], L. Neurologia, Cagliari, Italy; 13) Laboratory of Genetics, National Institute on Aging, Baltimore, MD, USA.

Multiple sclerosis (MS) is a multi-factorial neuroinflammatory and autoimmune disorder. A primary cause of disability in young adults, it results from interactions between unknown environmental factors and alleles of many susceptibility loci across the genome. Recent investigations of the genetics of MS have resulted in important advances, driven largely by completion of the first genome-wide association scans (GWAS). To detect additional loci, we performed a GWAS in 882 Sardinian Multiple Sclerosis (MS) cases and 872 controls genotyped with the Affymetrix 6.0 chip, using 575,678 SNPs that passed quality checks. We then successfully imputed 6,031,588 SNPs using haplotypes available from HapMap II, HapMap III and 1000 Genomes projects, and tested for association ~6.6 million variants. The strongest signal (OR=2.05, $p=1.45x10^{-20}$) was observed at a SNP tag for the HLA-DRB1*0301-DQB1*0201 allele. We then selected 9 SNPs outside of the HLA locus for validation and follow-up, based on their level of significance, proximity to functional candidate genes, and quality of imputation. Of those, SNP rs9657904 on chr3q13 was successfully confirmed in the GWAS samples and replicated in an independent set of 1,775 MS cases and 2,005 controls ($p=9.4x10^{-6}$). Notably, this variant is absent from the HapMap II reference panel, and we were able to fully assess it only after imputation with HapMap III and 1000 Genomes haplotypes. Combining all available genotypes, the observed pvalue was $1.6x10^{-10}$ (OR=1.40). The most associated variants at this locus fall in the promoter of a gene, *CBLB*, which encodes a negative regulator of adaptive immune responses. In support of its involvement in MS, mice lacking the ortholog are prone to experimental autoimmune encephalomyelitis, the animal model of multiple sclerosis. The strongest associated variant was also replicated in 1,441 cases and 1,465 controls from central-northern Italy with a similar effect size, hence confirming the role of this marker in increased risk for multiple sclerosis in another southern European population. Finally, we sequenced by the Sanger method the coding regions and promoter of the gene in 96 patients, observing novel variants that are potentially causative, and will now be assessed with focused biological studies.

1090/T

A new method for association studies allowing for multiple causal alleles. *B. Servin[1], P. Scheet[2].* 1) Dept Animal Genetics, INRA, Castanet-Tolosan, France; 2) The University of Texas Health Science Center at Houston M. D. Anderson Cancer Center Department of Epidemiology, Houston, TX.

Although hundreds of variants for a variety of traits have been identified using genetic association studies, only a proportion of the genetic variance expected from familial clustering can be explained. Finding this "missing heritability" is a current challenge in the genetics of complex traits. One possible extension of current approaches for detecting association is to model more complex genetic architecture, in particular in allowing for multiple causal alleles. This will become particularly relevant for the analysis of large scale resequencing data that unravel the full genotypic diversity of the study sample. We present a contribution to the resolution of this problem with a new multipoint method for the analysis of genetic association studies that allows for multiple causal alleles. Current approaches, including imputation-based approaches, still usually rely on testing a SNP genotype, potentially imputed, for association with a phenotype. Our new approach uses a test that allows for multipe alleles in a genomic region. It exploits a model for haplotype diversity in a genomic region to extract relatedness between individuals, and test for its association with the phenotype using a variance components approach. We developped a new statistic for association (a Bayes Factor) for this model that can be computed rapidly. We will show how our method leads to (i) increased power and (ii) more clear association signals than current approaches. We show that out new method has equivalent power than current tests (BF or p-value based) when the causal variant is bi-allelic and a much greater power when a large number of alleles contributes to the trait, therefore providing a robust inference for the analysis of genetic association studies.

1091/T

Genome-wide studies of idiopathic scoliosis susceptibility implicate genes encoding neural cell adhesion proteins. *S. Sharma[1], X. Gao[1], D. Londono[2], S.E. Devroy[1], K.N. Mauldin[1], J.T. Frankel[1], J.M. Brandon[1], D. Zhang[1], Q. Li[3], M.B. Dobbs[4,5], C.A. Gurnett[4,6,7], S.F.A. Grant[8], H. Hakonarson[8], J.P. Dormans[9], J.A. Herring[10,11], D. Gordon[2], C.A. Wise[1,11,12].* 1) Seay Center for Musculoskeletal Research, Texas Scottish Rite Hospital for Children, Dallas, Texas, USA; 2) Department of Genetics, Rutgers, The State University of New Jersey, Piscataway, New Jersey, USA; 3) UTSW Microarray Core, University of Texas Southwestern Medical Center at Dallas, Dallas, Texas, USA; 4) Department of Orthopaedics, Washington University School of Medicine, St. Louis, Missouri, USA; 5) St. Louis Shriners Hospital for Children, St. Louis, Missouri, USA; 6) Department of Pediatrics, Washington University School of Medicine, St. Louis, Missouri, USA; 7) Department of Neurology, Washington University School of Medicine, St. Louis, Missouri, USA; 8) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, USA; 9) Department of Orthopaedic Surgery, The Children's Hospital of Philadelphia, Pennsylvania, USA; 10) Department of Orthopaedics, Texas Scottish Rite Hospital for Children, Dallas, Texas, USA; 11) Department of Orthopaedics, University of Texas Southwestern Medical Center at Dallas, Dallas, Texas, USA; 12) McDermott Center for Human Growth and Development, University of Texas Southwestern Medical Center at Dallas, Dallas, Texas, USA.

Idiopathic scoliosis (IS) affects ~3% of school age children and usually occurs coincident with adolescent growth. Heritability estimates are significant, yet pre-disposing alleles are lacking. We performed a genome-wide association study (GWAS) with the Illumina HumanCNV370-quad platform in 419 Texas trios, with follow-up in IS cases from Texas and other U.S. regions. For the discovery phase we applied the TDT statistic that is robust to population stratification and observed top IS-associated loci on chrs 3, 4, 5, 6, and 21. Restricting the analysis to genotyped and imputed SNPs in the non-Hispanic white subset, our largest ethnic group, produced top clustered signals on chrs 3, 7, 14, and 21, with strongest results for chr 3 loci in the proximity of the *CHL1* gene [rs1400180 $P=7.91 \times 10^{-8}$; OR(95%CI)= 2.13(1.60-2.82); rs10501081 $P=2.56 \times 10^{-6}$; OR(95%CI)=2.03(1.50-2.75)]. Genotyping chr 3 SNPs in independent, non-Hispanic white cohorts from Texas and other U.S. regions (total unrelated cases: controls = 562:666) produced the same direction of effect for each SNP, where combined evidence of replication was greatest for rs10510181 [$P_{Fisher}=2.58 \times 10^{-8}$; OR(95%CI)=1.49(1.29-1.73)]. However these SNPs were not significantly associated with IS in comparison with a separate GWAS (N=137 cases, 2,126 controls), likely reflecting disease complexity. *CHL1* encodes Close Homolog of L1, a neural cell adhesion protein involved in axon guidance and a plausible risk factor for IS, given the known causal relationship between Mendelian axon guidance deficiency and scoliosis. We obtained suggestive evidence of linkage (maximum HLOD = 1.93, P=0.001 at rs1400180) with IS in families (N>90) and expect that this cohort will be useful in sequence-based searches for disease alleles. We recently expanded our genome-wide studies (N=702 Texas trios) and noted top clustered associations with variants in additional neural cell adhesion and axon guidance genes including the gene encoding Down syndrome cell adhesion molecule (*DSCAM*) on chromosome 21. This is of particular interest, as increased incidence of scoliosis is reported in Down syndrome patients. Follow-up of promising loci is ongoing, including application of recent TDT and case-control methods that allow for locus heterogeneity to potentially increase power for association. Our data implicate variation affecting neural cell adhesion genes in IS susceptibility and suggest new testable hypotheses relating to disease pathogenesis.

1092/T

Genome-wide association study of the timing of the pubertal growth spurt in healthy children from the Fels Longitudinal Study. *B. Towne[1], J.W. Kent, Jr.[2], C. Bellis[2], J.E. Curran[2], E.W. Demerath[3], K.D. Williams[4], T.D. Dyer[2], A.C. Choh[1], W.C. Chumlea[1], R.M. Siervogel[1], J. Blangero[2], S.A. Czerwinski[1].* 1) Wright State University School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) University of Minnesota, Minneapolis, MN; 4) Temple University, Philadelphia, PA.

Stature is a highly heritable trait, and several recent genome-wide analyses have identified QTL and SNPs linked or associated with adult or childhood stature. But, very little is known of genetic influences on specific features of individual growth patterns during childhood. Presented here are results of an initial genome-wide association analysis of the timing of the pubertal growth spurt in healthy children from the Fels Longitudinal Study. We applied a triple logistic curve-fitting method to extensive serial stature data from 492 subjects aged 2 years to early adulthood (245 males and 247 females) to identify in each of them the timing of the initiation of the pubertal growth spurt (age at pre-pubertal minimum growth velocity or "age at take-off" - ATO) and the timing of the pubertal growth spurt while at its most intense (age at peak height velocity - APHV). Mean ATO and APHV in these males and females were 10.66 and 8.74 years, and 13.72 and 11.55 years, respectively. The heritability of ATO was high in magnitude and significance ($h^2 = 0.66 \pm 0.10$; $p < 0.0001$), as was the heritability of APHV ($h^2 = 0.70 \pm 0.10$; $p < 0.0001$). All 492 individuals were genotyped with the Illumina Human 610-Quad BeadChip containing more than 550,000 SNPs. Association analyses were conducted using measured genotype analysis implemented in SOLAR allowing for residual non-independence among relatives. In this sample, genome-wide significance was indicated by a chi-square $\geq$ 27.85 and suggestive evidence by a chi-square $\geq$ 22.70. Highly suggestive association of SNP rs6016887 (chromosome 20) with both ATO (chi-square = 25.54) and APHV (chi-square = 27.00) was found. Likewise, highly suggestive association of SNP rs1155563 (chromosome 4) with both ATO (chi-square = 26.14) and APHV (chi-square = 24.48) also was found. And, highly suggestive association of SNP rs7629566 (chromosome 3) with ATO was observed (chi-square = 27.07), as was a suggestive association of SNP rs4622992 (chromosome 4) with APHV (chi-square = 23.49). In previous analyses we had found suggestive linkages of both ATO and APHV to markers on chromosome 20 in the same region as SNP rs6016887, indicating that future combined linkage/association analyses may better clarify these findings. In sum, these results demonstrate the feasibility of locating and identifying genes that influence different aspects of childhood growth. Supported by NIH grants R01HD12252, R01HD40377, F32HD053206, and R37MH59490.

Whole genome-scan of genetic determinants for dental caries in the permanent dentition. *X. Wang[1], J.R. Shaffer[1], E. Feingold[1], M. Lee[1], K.T. Cuenco[1], F. Begum[1], D.E. Weeks[1], M.M. Barmada[1], S. Wendell[1], D. Crosslin[2], C. Laurie[2], K. Doheny[3], E. Pugh[3], R.J. Weyant[1], A.R. Vieira[1], R.J. Crout[4], D.W. McNeil[4], M.L. Marazita[1].* 1) Univ Pittsburgh, Pittsburgh, PA; 2) University of Washington, Seattle, WA; 3) Johns Hopkins, Baltimore, MD; 4) West Virginia University, Morgantown, WV.

Background and Objective: Despite advances in dental care, dental caries remains one of the most common diseases throughout the world. The etiology of dental caries is thought to involve a complex interplay of environmental and genetic factors, with heritability of caries phenotypes ranging from 30-60%. However, specific susceptibility genes affecting dental caries are not well studied. Moreover, recent findings have revealed that genes affecting susceptibility to caries in the permanent dentition (in adults) may differ from those in primary teeth (in children). Moreover, recent findings have revealed that genes affecting susceptibility to caries in the permanent dentition (in adults) may differ from those in primary teeth (in children). Therefore, we performed the first highly dense genome-wide association study (GWAS) of dental caries in the permanent dentition to identify genomic regions likely to harbor genes responsible for caries susceptibility or resistance, particularly in adults. **Methods**: Dental exams on 2,219 Caucasian subjects (ages 14+, a sub-cohort from NIH funded GENEVA caries project) were performed to assess evidence of caries (e.g., decay, missing due to decay, or fillings) on all surfaces of each permanent tooth. Trend tests for association between caries phenotypes and 548,948 SNPs (genotyped by CIDR on the Illumina Human610-Quad SNP platform and passing quality control filters) were performed first using PLINK for three different age groups, 14+, 17+, and 20-60 years (sample sizes range from 1,965 to 2,219). Then the repeated analysis in SOLAR with adjustments for relatedness was conducted to verify the significance of association signals. **Results**: Genome-wide scans for different caries phenotypes (e.g. total number of teeth or surfaces with caries, percentage of teeth or surfaces affected etc.) and for the three age groups were compared, and "top hits" (P<1.0 x 10^-05) were inspected for nearby genes with plausible effects on tooth decay. Several of these signals were consistent across the three age groups and across the different caries phenotypes. In addition, several of the top signals were found within or near genes previously shown to be involved in tooth development or the disease processes. Replication in three additional cohorts is ongoing. *NIH grants DE018903, DE 014899, HG004438, HG004446, RR024153,; NIH contract HHSN268200782096C.*.

Combining association evidence across populations with diverse LD patterns: an eigen-weighted regional method. *X. WANG[1], H.Y. XU[1], X.L. SIM[1], C. SUO[1], W.T. TAY[2], T.H. ONG[3], E.S. TAI[4,5], T.Y. WONG[2,6], K.S. CHIA[1,4], Y.Y. TEO[4,7].* 1) Centre for Molecular Epidemiology, National University of Singapore, Singapore; 2) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore; 3) NUS Graduate School for Integrative Science and Engineering, National University of Singapore, Singapore; 4) Department of Epidemiology and Public Health, National University of Singapore, Singapore; 5) Department of Medicine, National University of Singapore, Singapore; 6) Centre for Eye Research Australia, University of Melbourne, Australia; 7) Department of Statistics and Applied Probability, National University of Singapore, Singapore.

Meta-analysis of genome-wide association studies (GWAS) across tens to hundreds of thousands of samples from multiple populations is now the preferred strategy to locate and verify new loci for phenotype-genotype associations. This approach generally assumes that: (i) the same causal variants exist across multiple populations; (ii) the same SNPs are assayed in all the populations; (iii) the LD structure between the causal variants and the assayed SNPs is similar across the different populations. In practice, different studies may rely on different genotyping platforms with moderately low degree of overlapping SNPs across the different technologies. Imputation strategies are subsequently utilized to generate a standardized set of SNPs for meta-analysis, although this can be sub-optimal without the availability of population-specific reference haplotypes. Also, heterogeneous patterns of LD with the causal variants may result in different SNPs emerging from the individual GWAS, further confounding meta-analyses. Here we introduce a region-based analysis that does not require the latter two assumptions to be met, by effectively searching for an over-representation of genotyped SNPs with suggestive evidence of disease association in a genomic region. While such analyses can be affected by SNPs in LD, we implement a novel eigen-decomposition method to estimate variable SNP weightings in order to minimize "double counting" due to LD. Crucially, this method avoids the assumption that the same markers have to display similar disease effects across multiple populations - which can be penalizing for increasingly large meta-studies. In regions of large heterogeneous patterns of LD across multiple populations, this method has the statistical power to detect disease associations that standard meta-analysis will have missed.We first implemented a series of simulations under different scenarios to assess the power and false positive rates, observing significantly higher power to detect disease associations that will otherwise have been missed by standard meta-analytic approaches. We subsequently applied this method to genome-wide data to at least half a million SNPs across three populations in Singapore (with Southern Chinese, South-East Asian Malay and Asian Indian genetic ancestries) , identifying novel genomic regions that are putatively implicated with type 2 diabetes, hypertension and hyperlipidemia.

Common variants explain the same amount of variation in fasting glucose levels in Pakistani individuals as they do in Europeans. *A.R. Wood[1], M. Islam[2], B. Chaudhary[3], S. Hashmi[1], N. Chaturvedi[4], M.N. Weedon[1], T.M. Frayling[1], T.H. Jafar[2].* 1) Genetics of Complex Traits, Peninsula Medical School, Exeter, United Kingdom; 2) Department of Community Health Sciences, Aga Khan University, Karachi, Pakistan; 3) Department of Biological and Biomedical Sciences, Aga Khan University, Karachi, Pakistan; 4) International Centre for Circulatory Health, National Heart and Lung Institute, Imperial College London, United Kingdom.

It has recently been suggested that associations between common variants and phenotypes will differ between populations, for example due to "synthetic" common variant associations caused by multiple rare variants at any one locus, as well as differences in environmental factors between populations.

To test this hypothesis we genotyped 16 common variants associated with fasting glucose levels in Europeans in a population of 1500 individuals from Pakistan. We compared the total variation in fasting glucose explained by all 16 SNPs with that in Europeans.

We used a multiple linear regression with fasting glucose as the dependent variable with all 16 SNPs acting as the independent variables. Twelve of the 16 SNPs (P=0.038) had the same glucose raising allele as in Europeans and 4 of these were nominally significantly associated with fasting glucose levels in the expected direction (P<0.05). We found that the proportion of the variance explained was similar to that identified in the European population (3.2% - 4.4%), with an adjusted R^2 of 0.03 (95% CI: 0.01, 0.05).

This study provides evidence that the effects of SNPs associated with fasting glucose in the European population have similar effects in the Pakistani population. This finding suggests that population differences for common variants on complex traits may not be as dramatic as some have suggested.

1096/T

Genome-wide association study for adiponectin levels in Filipino women identifies *CDH13* and a novel uncommon haplotype at *KNG1* - *ADIPOQ*. *Y. Wu[1], Y. Li[1,2], E.M. Ethan[1,2], D.C. Croteau-Chonka[1], C.W. Kuzawa[4,5], T.W. McDade[4,5], L. Qin[1], G. Curochicin[1,6], J.B. Borja[7], L.A. Lange[1], L.S. Adair[3], K.L. Mohlke[1].* 1) Department of Genetics, Univ of North Carolina, Chapel Hill, Chapel Hill, NC; 2) Department of Biostatistics, Univ of North Carolina, Chapel Hill, Chapel Hill, NC; 3) Department of Nutrition, University of North Carolina, Chapel Hill, NC; 4) Department of Anthropology, Institute for Policy Research, Northwestern University, Evanston, IL; 5) Cells 2 Society: The Center for Social Disparities and Health at the Institute for Policy Research, Northwestern University, Evanston, IL; 6) Department of Family Medicine, State Medical and Pharmaceutical University, Chisinau, Moldova; 7) Office of Population Studies Foundation, University of San Carlos, Cebu City, Philippines.

Adiponectin is an adipocyte-secreted protein involved in a variety of metabolic processes, including glucose regulation and fatty acid catabolism. Plasma adiponectin is under substantial genetic influence, however, the common variants identified to date cannot explain the majority of the estimated 30-70% heritability. In addition, the loci associated with adiponectin remain unclear in populations of non-European ancestry. Therefore, we conducted a genome-wide association study (GWAS) to investigate the genetic loci associated with plasma adiponectin in 1,776 unrelated Filipino women from the Cebu Longitudinal Health and Nutrition Survey (CLHNS). A multiple linear regression model with covariates of age, age^2, socialeconomic status and menopausal status was used to evaluate the association between adiponectin and 2,073,674 SNPs. The strongest signal mapped to the gene *CDH13* (rs3865188, $P = 7.2\times10^{-16}$), which encodes a receptor for high-molecular-weight forms of adiponectin. Compared to *CDH13* variant rs7195409, which has been reported with nominal association evidence in a recent GWAS in Europeans but showed no association in CLHNS mother ($P = 0.16$), rs3865188 is located ~887 kb upstream ($D' = 0.06$, $r^2 = 0$, HapMap CHB+JPT) and represents a genome-wide significant and novel signal for adiponectin. Evidence for association was also detected near the *ADIPOQ* gene (rs864265, $P = 3.8\times10^{-9}$) and at a novel location 100 kb upstream of *ADIPOQ* near *KNG1* (rs11924390, $P = 7.6\times10^{-7}$). All three signals were subsequently observed in 1,774 young adult CLHNS offspring and in combined mixed model analyses that included all 3,550 mothers and offspring samples taking relatedness into consideration (all $P < 1.6\times10^{-9}$). Haplotype analysis performed using the haplo.glm function in the R haplo.stats package showed that an uncommon haplotype of rs11924390 and rs864265 (C-T haplotype frequency = 0.050) was strongly associated with lower adiponectin compared to the most common C-G haplotype in both CLHNS mothers ($P = 1.8\times10^{-25}$) and offspring ($P = 8.7\times10^{-32}$). Our findings provide convincing evidence that the *CDH13* locus is associated with plasma adiponectin. We also identify a novel uncommon haplotype strongly associated with adiponectin level in Filipinos, which may motivate future studies to investigate potential functional variants and to elucidate their molecular mechanisms.

1097/T

A genome-wide association scan identified sex-specific genes for obesity in Chinese. *T. Xu[1,2], Y. Cheng[1,2], YF. Pei[3], L. Zhang[3], N. Yu[1], TL. Yang[3], J. Chen[1,4], XH. Xu[3], SS. Dong[3], HB. Liu[1], J. Li[1], J. Hamilton[1], YJ. Liu[1], HW. Deng[1,2,3,4].* 1) School of Medicine, University of Missouri - Kansas City, Kansas City, MO 64108, USA; 2) Pharmacogenetics Research Institute, Institute of Clinical Pharmacology, Central South University, Changsha, Hunan, 410008, P. R. R. China; 4) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P. R. China.

Obesity is a serious public health problem which increases the risk of some diseases such as cardiovascular disease and diabetes. The genetic determination of obesity is strong, but the majority of underlying genetic factors remain to be discovered. In this study, we performed association analyses in a sample of 1627 unrelated Chinese subjects (802 males and 825 females) genotyped for Affymetrix genome-wide human SNP array 6.0. We focused our analysis on 20131 mitochondria SNPs and 4974 SNPs at the CpG island due to the important role of mitochondria on energy metabolism and the importance of CpG island on gene transcription. Obesity phenotypes analyzed included trunk fat mass and waist/hip ratio. In the total sample analysis, none of the SNPs reached genome-wide significant level. However, in sex-stratified analysis, we identified two mitochondrial SNPs (rs9395490 and rs2182011) that were significantly associated with trunk fat mass in females only (P-values of 7.07×10^{-7} and 1.34×10^{-6} respectively). These two female-specific SNPs were located in a mitochondrial gene, MUT (methylmalonyl CoA mutase). In the analysis of SNPs at CpG island, we identified a SNP rs12371091 that was significantly associated with waist/hip ratio in males only (P-value of 8.81×10^{-7}). This male-specific SNP is located at the STX2 (syntaxin 2) gene. The MUT gene encodes Methylmalonyle-CoA mutase, which involves in the degradation of odd-chain fatty acids and cholesterol and tricarboxylic acid cycle in mitochondria. The STX2 gene encodes syntaxin-2, which regulates epithelial-mesenchymal interactions. In summary, our findings suggest two novel genes that have sex-specific effects on obesity in Chinese.

Key words: Genome-wide association analyses, MUT, STX2, Sex-specific, Obesity.

1098/T

The value of mapping genome-wide associations across other ethnic groups: An analysis of BMD in Mexican Americans. *L.M. Yerges-Armstrong[1], J.R. Shaffer[2], J.M. Bruder[3], T.D. Dyer[4], M.A. Carless[4], J.E. Curran[4], HHH. Göring[4], J. Blangero[4], C.M. Kammerer[2], B.D. Mitchell[1].* 1) University of Maryland, Baltimore, MD; 2) University of Pittsburgh, Pittsburgh, PA; 3) University of Texas Health Science Center, San Antonio, TX; 4) Southwest Foundation for Biomedical Research, San Antonio, TX.

Recent GWA studies carried out in European Caucasians have identified at least 25 SNPs associated with bone mineral density (BMD), including one on chromosome 7p14 upstream of STARD3NL, which encodes a membrane protein of unknown function. It is unclear whether the association with BMD is due to altered regulation or function of this gene or to other nearby genes that are in linkage disequilibrium (LD). For this reason there can be great value in carrying out association studies in other populations with differing LD patterns. We conducted a GWA study of BMD at the femoral neck and spine in 797 men and women in multi-generational Mexican American families as part of the San Antonio Family Osteoporosis Study using 531,800 SNPs genotyped on the Illumina 500K genotyping platform. Analyses were adjusted for relevant covariates (age, age2, sex, and weight) and allowed for residual familial relatedness using a variance components model. We examined GWA signals within 100kb of the previously reported SNPs in particular detail. Of 988 SNPs falling within 100kb of the 25 previously reported GWA association signals, 69 SNPs in 13 gene regions were nominally associated ($p<0.05$) with lumbar spine BMD and 79 SNPs in 12 gene regions were nominally associated with femoral neck BMD. After applying a conservative Bonferroni adjustment for multiple comparisons, three SNPs (two for lumbar spine and one for femoral neck) were associated ($p<5x10-5$) with BMD. All three fell within 75kb in the 7p14 region, ~50 kb telomeric to the previously associated SNP. The signal identified by our GWA analysis is closer to the EPDR1 and SFRP4 genes than it is to the previously reported association near the STARD3NL gene. Similar to our study, a GWA study in Asians also identified a SNP on 7p14 that mapped closer to SFRP4 than STARD3NL. In fact, the SNPs in highest LD with the SNP originally identified in Caucasians were associated less strongly with lumbar spine BMD ($p= 5x10-3$) and not associated with femoral neck BMD at all ($p=0.5$). Depending on criteria used to consider an association replicated, this region may have been considered a non-replicating region if only the primary association signal from the Caucasian meta-analysis was analyzed. While the location of the true causative SNP is not known, our results highlight the utility of expanding the scope of inquiry for replication to a larger window, particularly in replication cohorts comprising other ethnic groups.

Genome-wide association analysis of Metabolic Syndrome and related quantitative traits in a Croatian island population. *G. Zhang[1,2], G. Sun[1], R. Karns[1], S. Indugula[1], N. Wen[1], H. Cheng[1], N. Narancic[3], N. Jeran[3], D. Havas[3], S. Missoni[3], Z. Durakovic[3], R. Chakraborty[4], P. Rudan[3], R. Deka[1].* 1) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, Ohio, United States of America; 2) Department of Family and Community Medicine, University of Cincinnati, Cincinnati, Ohio, United States of America; 3) Institute for Anthropological Research, Zagreb, Croatia; 4) Center for Computational Genomics, University of North Texas Health Science Center, Fort Worth, Texas, United States of America.

Genome-wide association (GWA) studies represent a powerful approach to the identification of genes involved in common human diseases. In this report, we describe a GWA study (using Affymetrix Genome-Wide Human SNP Array 5.0) of Metabolic Syndrome (MetS) and related quantitative traits (including 15 anthropometric and 11 blood biochemical traits) in a sample of ~1,500 individuals drawn from a homogenous population of Hvar Island off the eastern Adriatic coast of Croatia. Association tests of quantitative traits identified a large number of independent association signals (with single-point P values less than 10^{-6}). These signals include many previously reported loci such as SLC2A9 (uric acid), TCF7L2 (FBG and HbA1c), CETP (HDL), HMGA2 and UQCC (body height) as well as some novel loci which may represent genuine effects. Some notable examples include: rs17154194 (intergenic SNP) was associated with FBG ($P = 2.8\times10^{-9}$) and triglyceride ($P = 2.4\times10^{-8}$); rs200116 (downstream of SEMA5A) and rs833820 (intron of ARF3) were associated with uric acid ($P = 3.7\times10^{-8}$ and 9.2×10^{-8}); rs11030796 (intron of STIM1) was associated with fibrinogen ($P = 1.8\times10^{-8}$); rs3746410 (FER1L4) was associated with body weight ($P = 1.2\times10^{-6}$). We also detected rs1521282 (downstream of CPNE4) as a susceptibility locus for MetS as a binary trait by either ATP ($P = 1.1\times10^{-7}$) or IDF ($P = 3.6\times10^{-6}$) definition. In addition, using a principle component analysis of the quantitative traits used in MetS diagnostic criteria (waist circumference, triglyceride, HDL, blood pressure and FBG), we observed several genes implicated in blood glucose homeostasis (KCNJ11, TCF7L2, SLC30A8 and FBP2) were associated independently with individual principle components of MetS traits. In summary, our study yield additional genetic loci that may influence MetS susceptibility or related quantitative traits. These findings were either supported by high-level of statistical significance and/or functional implications which make them highly interesting for further replication and follow-up. Our results also suggest that the genes involved in blood glucose homeostasis may play important role in the development of MetS.

1100/T

Targeted Genomic Enrichment and Next-Generation Sequencing of An Autosomal Dominant Trait Linked to Chromosome 5p13. *L. Racacho[1,2], S.M. Nikkel[3], J. MacKenzie[4], A. Hunter[3], D.E. Bulman[1,2].* 1) Dept. Biochemistry, Microbiology and Immunology, University of Ottawa, Ottawa, ON; 2) Regenerative Medicine Program, Ottawa Hospital Research Institute, Ottawa, ON; 3) Dept. of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON; 4) Division of Genetics, Kingston General Hospital, Kingston, ON.

Targeted genomic enrichment, coupled with next-generation sequencing, represents a feasible resequencing strategy for monogenic loci in which no disease causing mutation has been identified. We tested this approach using brachydactyly A1 (BDA1) as a model. We previously identified a BDA1 locus on chromosome 5p13 segregating as an autosomal dominant trait in a single family. We hypothesize that a gene on chromosome 5p13 is necessary for proper bone development and a mutation in this gene will disrupt the Ihh-Pthlh signaling axis, causing the BDA1 phenotype. Two NimbleGen 385K arrays were designed to capture 3.2 Mb of the critical region from two affected individuals in our family. Next-generation sequencing of the enriched fragments was performed using Roche 454 Titanium pyrosequencing. A 30X coverage of the critical region yielded 205 novel and shared simple variants. More than 25 novel and shared breakpoints were identified on a separate genome analysis of single end reads. We are currently verifying and validating these sequence variants.

1101/T

A unified framework for testing multiple phenotypes for association with genetic variants. *M. Stephens.* Statistics & Human Gen, Univ Chicago, Chicago, IL.

In many ongoing genome-wide association studies, multiple related phenotypes are available for testing for association with genetic variants. In most cases, however, these related phenotypes are analysed independently from one another. For example, several studies have measured multiple lipid-related phenotypes, such as LDL-cholestrol, HDL-cholestrol, and Triglycerides, but in most cases the primary analysis has been a simple univariate scan for each phenotype. This type of univariate analysis fails to make full use of potentially rich phenotypic data. While this observation is in some sense obvious, much less obvious is the right way to go about examining associations with multiple phenotypes. Common existing approaches include the use of methods such as MANOVA, canonical correlations, or Principal Components Analysis, to identify linear combinations of outcome that are associated with genetic variants. However, if such methods give a significant result, these associations are not always easy to interpret. Indeed the usual approach to explaining observed multivariate associations is to revert to univariate tests, which seems far from ideal. In this work we outline an approach to dealing with multiple phenotypes based on Bayesian multivariate regression. The method attempts to identify which subset of phenotypes is associated with a given genotype. In this way it incorporates the null model (no phenotypes associated with genotype); the simple univariate alternative (only one phenotype associated with genotype) and the general alternative (all phenotypes associated with genotype) into a single unified framework. In particular our approach both tests for and explains multivariate associations within a single model, avoiding the need to resort to univariate tests when explaining and interpreting significant multivariate findings. We illustrate the approach on examples, and show how, when combined with multiple phenotype data, the method can improve both power and interpretation of association analyses.

1102/T

Celiac disease: can CNVs contribute to the genetic risk? *G. Trynka[1], PC. Dubois[2], L. Franke[1,2], A. Zhernakova[3,4], J. Romanos[1], R. McManus[5], D. Barisani[6], P. Saavalainen[7], DA. Van Heel[2], C. Wijmenga[1].* 1) Genetics, UMCG, Groningen, Netherlands; 2) Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, London, UK; 3) Medical Genetics Dept, University Medical Center Utrecht, the Netherlands; 4) Dept of Rheumatology, University Medical Center Leiden, the Netherlands; 5) Departments of Clinical Medicine, Institute of Molecular Medicine, Trinity College Dublin, Dublin, Ireland; 6) Department of Experimental Medicine, Faculty of Medicine University of Milano-Bicocca, Monza, Italy; 7) Department of Medical Genetics, and Research Program of Molecular Medicine, University of Helsinki, Finland.

Celiac disease is an autoimmune disorder with prevalence of 1-3% in the Caucasian population and high heritability of 80%. HLA is the major genetic risk factor but accounts only for 35% of the genetic risk. Recent genome-wide association study (GWAS) of 4,533 cases and 10,750 controls and its follow-up in additional 4,918 cases and 5,684 matched controls have identified 26 non-HLA risk loci (p-value<5x10e-08) and suggested associations for a further 13 loci. Over 50% of the associated single nucleotide polymorphisms (SNPs) correlate with cis gene expression and for 70% the effect of the risk allele results in lower expression. Celiac disease has a complex genetic background, HLA and the 26 non-HLA loci account for 40% of the genetic risk. We sought to investigate the involvement of other genetic variations in the pathogenesis of celiac disease. Recent studies show that majority of copy number variations (CNVs) can be captured by tagging SNPs. There are over 30,000 SNPs reported to tag CNV changes and nearly 18,000 of these SNPs were present in our imputed GWAS data of 15,283 individuals. Excluding HLA region, 30 SNPs representing 29 loci were associated at p<10e-03. When investigating the association strength within the LD regions harbouring the CNV tag-SNPs, we observed that eleven tag-SNPs were the most associated among all the other tested SNPs. Additionally 23% of these associated tag-SNPs showed significant cis e-QTL effects. Furthermore, eight SNPs were perfectly tagging CNVs with R2>0.8. Because the remaining SNPs showed imperfect LD with the tagged CNVs, we hypothesised that the CNV variants may be more strongly associated than their tagging SNPs. Currently, we are genotyping 21 CNVs in ~3000 samples from the Netherlands and Italy. Our results indicate that CNVs, next to the SNP variants, may contribute to the genetic risk predisposing to celiac disease.

Genome-Wide Association Study for Rheumatoid Arthritis in the Korean Population Points to Novel Candidate Loci and Indicates Overlap with European Susceptibility Loci. *J. Freudenberg[1], H.S. Lee[2], H.D. Shin[3], B.G. Han[4], Y.M. Kang[5], S.C. Shim[6], Y.K. Sung[2], C.B. Choi[2], A.T. Lee[1], P.K. Gregersen[1], S.C. Bae[2].* 1) Center for Genomics and Human Genetics Feinstein Institute for Medical Research North Shore LIJ Health System; 2) Hanyang University Hospital for Rheumatic Diseases, Seoul 133-792, Korea; 3) Sogang University, Seoul, Korea; 4) Korea National Institute of Health, Seoul, Korea; 5) Kyungpook National University School of Medicine, Daegu, Korea; 6) Eulji University Hospital, Daejeon, Korea.

To find novel susceptibility loci for Rheumatoid Arthritis (RA) and to compare the genetic basis of RA between populations, we performed a genome-wide association study (GWAS) in Korean individuals. We generated high quality genotypes for 441398 SNPs in 801 cases of RA and 757 controls. Genome-wide significance (P<5*e-08) was attained by markers from the MHC-region and at *PADI4*. We next partitioned SNPs into separate LD-blocks and quantified the observed excess of LD-blocks that contain associated SNPs by using permutation of the affection status (excluding the MHC-region). This showed an excess of 14 loci when calling SNPs associated using a threshold of P<1e-04 that increased to an excess of about 500 LD-blocks when calling SNPs associated with P<0.1. In the second stage, we genotyped 79 markers from 46 loci in a replication sample of 718 cases and 719 controls. The combined analysis of genotypes from both stages did not reveal any additional loci of genome-wide statistical significance. However, the replication data showed nominal association signals (P<5*e-02) for markers from 11 out of 46 loci. Genes that were most significant in the replication stage and in the combined analysis include the known European RA loci *BLK*, *AFF3* and *CCL21* as well as *PTPN2*, *FLI1*, *LCP2*, *GPR137B*, *TRHDE*, *CGA1* and *ARHGEF3*. Based on the P-value distribution of our replication genotypes, we estimate that at least four of these loci are genuine RA susceptibility genes. Finally, we systematically analyzed the overlap of association signals with previously established European RA loci. To this end we retrieved the set of LD-blocks that harbor associated SNPs in Europeans and estimated its odds ratio for showing a SNP-association in the Korean GWAS data. This odds ratio statistic was compared to its expected value as obtained from permutation of the affection status. This showed a significant enrichment of European RA loci, which became more pronounced with increasing stringency for calling loci associated with RA. We conclude that certain genetic RA susceptibility factors are shared between populations and that the use of independent knowledge provides a feasible way to exploit subthreshold association signals in GWAS datasets.

Introduction: Brachial circumference (BC), also known as upper arm or mid arm circumference, can be used as an indicator of muscle mass and fat tissue, which are differently distributed in men and women. The purpose of this study is to identify genetic variants associated with BC through a large-scale genome-wide association scan (GWAS) meta-analysis. Methods: To identify gender-specific effects underlying BC we used fixed-effects meta-analysis to synthesise data from 7 GWAS on 3551 males, 4152 females and on the combined set of 7703 individuals. Association analyses were adjusted for age and BMI. Reported investigations have been carried out following the principles of the Declaration of Helsinki. Results and Discussion: The male-specific meta-analysis identified a signal between the nuclear receptor co-repressor 2 (NCOR2) and scavenger receptor class B, member 1 (SCARB1) genes on chr12 (e.g. rs275771, β= 2.824, 95%CI [1.842, 3.806], p-value=1.74E-08). The NCOR2 gene has been suggested to play a role in the regulating adipose tissue accumulation and NCOR2 +/- mice develop increased adiposity on a high-fat diet but have normal weight on a regular diet. The SCARB1 gene acts as a high-density lipoprotein (HDL) receptor and is involved in both HDL and low-density lipoprotein (LDL) metabolism. The female-specific meta-analysis identified several associated variants within the SEC14-like 5 (S. cerevisiae) (SEC14L5) gene on chr16 (e.g. intronic SNP rs12444698, β= -2.382, 95%CI [-3.306,-1.458], p-value= 4.44E-07). A conserved domain of SEC14L5 gene, Sec14p-like lipid-binding domain, is found in secretory proteins and in lipid regulated proteins. Meta-analysis across males and females identified a region on chr9 spreading across 120kb (e.g. rs2383455, β= -2.025, 95%CI [-2.814, -1.238], p-value= 4.78E-07), with the closest gene 700kb away. Conclusion: In this first GWAS meta-analysis for BC to date, we have identified promising signals (below or close to the genome-wide significance level), which will require replication in independent datasets. These studies are currently underway.

Detection and Estimation of Identity by Descent with High Density Genotype Data. *L. Han, M. Abney.* Human genetics, University of Chicago, Chicago, IL.

Estimating identity by descent (IBD) sharing between individuals is of fundamental importance in genetics. It is important for a variety of problems including disease gene mapping, genotype imputation and haplotype inference, and detection of runs of shared genomic segments. We consider the problem of estimating IBD between pairs of individuals using dense SNP data. We describe a method that estimates IBD given a pedigree of arbitrary size and complexity. We extend the standard hidden Markov model using two different methods to incorporate linkage disequilibrium (LD). The first uses phased haplotypes and uses haplotype probabilities between pairs of SNPs. The second uses unphased genotypes and incorporates LD from multiple SNPs. We also describe an extension to our method that allows for IBD estimates when the pedigree is unknown. Our methods can estimate IBD at specific loci, chromosome-wide and genome-wide averages, and detect IBD segments shared between individuals. We demonstrate the accuracy of our methods using simulated data on pedigrees ranging from small (e.g. sib pairs) to large and complex. We consider both closely and distantly related pairs. We also estimate IBD for all pairs in a real data set consisting of 609 individuals (185,745 pairs) from a large and complex 13 generation pedigree, all of whom were genotyped on the 500k Affymetrix SNP chip. The software package IBDLD that implements our method is freely available.

Obesity is a well-established risk factor for a number of chronic diseases and presents a substantial public health challenge. While behavior and environment clearly play a role, strong evidence exists for a substantial genetic contribution to body mass index (BMI), a common measure of obesity. Previous genome-wide association (GWA) studies have identified a number of obesity-susceptibility loci. However, we expect that more loci, potentially leading to new biological mechanisms and therapeutic targets, can be identified from increased sample sizes. With this aim, we performed a meta-analysis of GWA data for BMI at 2.8 million SNPs in 123,865 individuals of European descent from 46 cohorts from the GIANT Consortium. We examined the most promising 42 SNPs in an additional set of follow-up samples (combined sample size up to 249,796 individuals). Combined analysis identified 18 new loci (p£5x10-8) that locate in or near *RBJ/ADCY3/POMC, MAP2K5/LBXCOR1, QPCTL/GIPR, FANCL, TNNI3K, LRRN6C, FLJ35779/HMGCR, SLC39A8, TMEM160/NDUFS3, CADM2, LRP1B, PRKD1, MTIF3/GTF3A, ZNF608, PTBP2, RPL27A/TUB, NUDT3/HMGA1,* and *GPRC5B*. We also confirmed 14 previously-identified obesity-related loci: *FTO, MC4R, TMEM18, GNPDA2, TFAP2B, BDNF, SH2B1, SEC16B, ETV5, NEGR1, MTCH2, FAIM2, NRXN3*, and *KCTD15*. Strongly associated SNPs near the novel locus GPRC5B are perfect proxies of a 21kb polymorphic deletion. Although these SNPs only explain ~1.5% of the variance in BMI, individuals with the highest genetic risk score (≥38 BMI-increasing alleles, 1.5% of individuals) had a mean BMI 2.7 kg/m^2 (typically corresponding to 15-19 lbs in weight) higher than individuals with the lowest genetic risk score (£21 BMI-increasing alleles, 2.2%). As previously, loci discovered indicate a CNS-mediated effect on obesity; however, the majority of new loci are as yet unannotated and likely represent novel biological mechanisms. Prediction modeling based on the observed effect sizes at these loci suggest that there are ~180 loci with similar effect sizes that have not yet been identified, and likely many more with smaller effect sizes. Ongoing and future research includes imputation based on the 1000 Genomes Project and follow-up of the top 5000 SNPs in hundreds of thousands of samples using a custom-designed Metabochip. These discoveries provide information about the allelic architecture and frequency spectrum of complex trait susceptibility variants and will guide the design of future sequencing studies.

Strongly-correlated quantum-system approach in association study of rheumatoid arthritis. *I. Sandalov[1], L. Padyukov[2].* 1) Condensed Matter Physics, Royal Institute of Technology, S-164 40 Kista- Stockholm, Sweden; 2) Rheumatology Unit, Karolinska University Hospital Solna SE-171 76 Stockholm Sweden.

To identify putative relations between different genetic factors in human genome in development of common complex disease we applied strongly-correlated quantum systems approach to genetic data. To test applicability of approach, we analyzed 1820 rheumatoid arthritis (RA) cases and 947 healthy controls by correlation functions with data for 7 SNPs from HTR2A locus. Each SNP can be considered as a "spin", with three pairs (genotypes) represented in each "cell" of the genotype state vector (GV) characterizing each person. For our experimental data this ensemble can be separated into 151 GV subgroups g=(n,n_ctrl,n_case,v), n=n_ctrl+n_case, where n_ctrl,n_case are numbers of persons with several particular GV, which are specific only for controls (2.3%) or for cases (1.37%) GVs.GVs with large odds ratio (OR) assumed to contain SNPs in question. The characteristic matrix for each state is designed to compare many-spin states, introduce three population numbers of "single-particle" states |i >, and check for HWE for each SNP. The 3x3 matrices of pair correlation functions (CF) for those SNPs, which are suggested by GVs with high OR are calculated for control and case sets separately. The correlations between different components of different cells may strongly differ from each other, but all are relatively low, less than 5%. The strongest correlations are found between SNPs AA rs977003 and CC rs6314 (0.0554 in control and 0.0457 in case groups), however, the ctrl-case difference of CFs dK=K(ctrl)-K(case) in SNP-SNP correlators is larger for other SNPs, e.g., for CA rs977003 and CC rs6311 it is -0.0184, CA rs977003 and GG rs6313 combined it is -0.0181, etc.. Comparison of most contrast GVs reveals quite large shift of pair-SNP population of cells from controls to case, namely the heterozygotic state may increase a risk of disease. The whole picture, however, is complex and determined by more than one particular SNP shift. From our test we conclude that a reformulation of quantum theory methods for needs of genetics provide not only a cheap and efficient way for analysis, but, also, opens a somewhat new interesting perspectives for quantitative description and modeling of genomic structure of populations.

1108/T

Bayesian Methods to Overcome the Winner's Curse in Genetic Studies. *L. Xu[1], R. Craiu[1], L. Sun[1,2].* 1) Department of statistics, University of Toronto; 2) Division of Biostatistics, Dalla Lana School of Public Health , University of Toronto, Toronto, Ontario, Canada.

Introduction: Parameter estimates for associated SNPs, reported in the discovery samples, the so-called naïve estimates, are often grossly inflated compared to the values observed in the follow-up samples. This type of bias is a consequence of the sequential procedure, because a declared associated variant must first pass a stringent significance threshold. This phenomenon is also known as the Winner's curse. Both likelihood-based and bootstrap-based bias reduction methods have been proposed in the literature but the variation in the estimates could be very high for practical use in replication sample size calculations. Methodology: We propose a Bayesian hierarchical model that takes advantage of available prior information producing estimators with a smaller bias and variance especially in low power studies. We use a spike-and-slab prior to account for the possibility that the significant association may be a false positive. To robustify the method to prior specification, we adopt a Bayesian Model Averaging (BMA) strategy that averages over models with different prior belief in the discovery finding's authenticity. The proposed method requires only the summary statistics such as the reported naïve estimate of the odds ratio and the corresponding association p-value. Results: Extensive simulations confirmed that the BMA method performs well in a variety of settings and that it outperforms the likelihood-based approaches in low power studies. For example, the standard error in the sample size prediction for a replication study (80% power at the 0.05 level) using the BMA estimate is almost twice as small as the replication sample size calculated based on the likelihood estimate. We also applied the methods to four different association studies, including a candidate gene study and three genome-wide association studies of binary case-control or quantitative outcomes. Application results demonstrate the importance of utilizing known prior information such as the study design and putative power of detecting a SNP association.

Validating and genotyping rare SNPs with Axiom™ microarray technology. *T.A. Webster, J. Gollub, E. Hubbell, Y. Zhan, Y. Lu, T. Asbury, L. Weng, M. Purdy, M. Shapiro.* Algorithms & DataAnalysis, Affymetrix, Santa Clara, CA.

Investigating the role of rare SNPs in common disease fuels the need for high-throughput, cost-effective, and accurate methods for validating and genotyping such SNPs. We present components of such a method that uses the Axiom™ Genotyping Solution, a high-performance microarray technology from Affymetrix. First, candidates from SNP discovery projects are screened by the Axiom system against samples from reference populations with enough diversity to elicit two to three examples of heterozygous genotype. Second, properties of the genotypes clusters produced by small number of heterozygous genotypes, along with the major homozygous genotypes, are used to validate that the SNP site is polymorphic. Third, the "Axiom GTv1" algorithm generates genotypes using a Bayesian procedure in which priors for the SNPs are combined with the data to obtain posterior estimates of genotype cluster centers and variance of the missing minor homozygous genotypes, as well as the heterozygous and major homozygous genotypes. This enables genotyping of rare SNPs in new data sets. Rare SNPs collected by this process fuel the Axiom database of validated SNPs. Genotypes from the reference populations in the screening data are used to estimate the contribution to coverage of rare SNPs in the genome. The current database covers more than 80% of rare CEU SNPs (MAF < 5%) in a reference set of HapMap plus validated SNPs from the 1000 Genomes Project. The resulting database is a resource from which multiple SNP panels can be derived, optimizing coverage of rare variants in studies seeking to understand the association of rare SNPs with common diseases.

Replication of GWAS loci for fasting plasma glucose in African Americans. *E. Ramos[1], G. Chen[1], A. Doumatey[1], D. Shriner[1], N.P. Gerry[2], A. Herbert[3], H. Huang[1], J. Zhou[1], M.F. Christman[2], A. Adeyemo[1], C. Rotimi[1].* 1) Center for Research on Genomics and Global Health, NIH/NHGRI, Bethesda, MD; 2) Coriell Institute for Medical Research, Camden, NJ; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA.

Chronically elevated blood glucose (hyperglycemia) is the primary indicator of type 2 diabetes, which has a prevalence that varies considerably by ethnicity in the United States with African Americans disproportionately affected. Genome-wide association studies (GWAS) have significantly enhanced our understanding of the genetic basis of diabetes and related traits including fasting plasma glucose (FPG). However, the majority of GWAS have been conducted in populations of European ancestry (EA), including a recent meta-analysis of multiple cohorts. Thus, it is important to conduct replication analyses in non-EA populations to both verify and identify shared loci associated with FPG across populations. We used data collected from nondiabetic individuals (n = 927) that participated in the Howard University Family Study, a cohort of African Americans, to replicate previously published GWAS of FPG. In addition to comparing SNPs directly, we queried a 500-kb window centered on each reported SNP for additional markers in linkage disequilibrium (LD). Using direct SNP and LD-based comparisons, we replicated multiple SNPs previously associated with FPG and strongly associated with type 2 diabetes in recently published meta-analyses and related GWAS in EA populations. The replicated SNPs included those in or near TCF7L2, SLC30A8, G6PC2, MTNR1B, DGKB-TMEM195, and GCKR. We also replicated additional variants in LD with the reported SNP in ZMAT4 and adjacent to IRS1. We replicated multiple GWAS variants for FPG in our cohort of African Americans. Using LD-based strategy, we also identified SNPs not previously reported demonstrating the utility of using diverse populations for replication analysis.

COPACETIC, a genome-wide association study on chronic obstructive pulmonary disease (COPD). *J. Smolonska[1,2], P. Zanen[3], D.S. Postma[4], B. van Ginneken[5], B. de Hoop[6], A.E. Dijkstra[4], M. Platteel[1], M. Oudkerk[7], J-W. Lammers[3], H.J.M. Groen[4], A. Dirksen[8], J.H. Pedersen[9], K. Forsman-Semb[10], M. Dahlback[10], P. Nastalek[11], F. Mejza[11], E. Nizankowska[11], J. Vestbo[12,13], B.G. Nordestgaard[14,15], H.M. Boezen[2], C. Wijmenga[1], . COPACETIC[16].* 1) Department of Genetics, University Medical Center Groningen, the Netherlands; 2) Department of Epidemiology, University Medical Center Groningen, the Netherlands; 3) Department of Pulmonology University Medical Center, Utrecht, the Netherlands; 4) Department of Pulmonology University Medical Center Groningen, the Netherlands; 5) Image Sciences Institute, University Medical Center Utrecht, the Netherlands; 6) Department of Radiology, University Medical Center Utrecht, the Netherlands; 7) Department of Radiology University Medical Center Groningen, the Netherlands; 8) Department of Pulmonary Medicine, Gentofte University Hospital, Hellerup, Denmark; 9) 44Department of Cardiothoracic Surgery, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark; 10) AstraZeneca R&D, Lund, Sweden; 11) Division of Pulmonary Diseases, Department of Internal Medicine, Jagiellonian University School of Medicine, Krakow, Poland; 12) Department Respiratory Medicine, Hvidovre Hospital, Denmark; 13) University of Manchester, Manchester, UK; 14) 14Department of Clinical Biochemistry, Herlev Hospital, Copenhagen University Hospital, Faculty of Health Sciences, University of Copenhagen, Denmark; 15) 15The Copenhagen City Heart Study, Bispebjerg Hospital, Copenhagen University Hospital, Faculty of Health Sciences, University of Copenhagen, Denmark; 16) European Union.

Chronic obstructive pulmonary disease (COPD) is characterized by persistent, progressive airway obstruction. COPD is a complex disease which develops due to interplay of environmental factors like tobacco smoking and genetic factors which are still largely unknown. The aim of our study is to identify novel genetic risk factors for COPD using a genome-wide association study (GWAS). Study participants were recruited from the Nelson study, a CT-based lung cancer screening trial in heavy smokers (>20 pack years). DNA samples were genotyped using Illumina Human610-Quad arrays. COPD was defined as obstruction (FEV1/FVC<70%) and controls as FEV1/FVC >70% and FEV1%pred >90. To gain statistical power we added blood bank controls with unknown smoking history which were genotyped using Illumina Human670-Quad arrays. Standard quality checks were performed to remove samples and SNPs performing less well. Ethnic outliers, duplicates and lung cancer cases were excluded from the analysis. Association tests were performed on 1030 COPD cases and 1799 controls. The genomic inflation factor showed no significant deviation indicating no population stratification. Top 312 SNPs were selected for replication in seven independent (population-based) cohorts comprising over 10,000 individuals. Replication set included Vlagtwedde/Vlaardingen, Doetinchem, GRIP, Glucold, BOLD, DCLST and CCHS cohorts of different European descents. Genotyping was performed using Illumina Golden Gate custom panels. All genotype clusters were inspected and adjusted manually if necessary. Each cohort was analyzed separately and results were combined in meta-analysis taking into account heterogeneity between studies. Meta-analysis of half of our replication set revealed several loci approaching genome-wide significance. Currently we are finalizing the analysis of the other half of the replication set and we expect to find more loci with more significant p values.

An Efficient and Powerful Framework for eQTL Analysis. *E. Kostem[1], E. Eskin[1,2].* 1) Computer Sci Dept, UCLA, Los Angeles, CA; 2) Human Gen Dept, UCLA, Los Angeles, CA.

Most expression quantitative trait loci (eQTL) mapping studies collect gene expression data from tens of thousands of genes and genotype data on millions of single nucleotide polymorphisms (SNPs). For a study, this corresponds to computing billions of association statistics and these numbers will only increase as more gene isoforms and SNPs are being discovered by next-generation sequencing studies. However, only a small percentage of the SNPs are expected to be associated and there is a lack of a computationally efficient strategy to identify the associated SNPs without evaluating the association statistic at every gene/SNP pair. We introduce an efficient and powerful eQTL analysis framework that identifies all the associated SNPs with high probability using a two-stage method. In both stages our proposed method identifies a subset of the SNPs and evaluates the association statistic only at these SNPs. Our method uses the correlation structure between all the SNPs and, in the second stage, the observed association statistics from the first stage. In addition, it aims to minimize the total number of SNPs that will be observed such that a given percentage of all the associated SNPs is identified. We conduct simulation studies and use real eQTL data to show that our method can reduce the computational time significantly to identify nearly all of the associated SNPs.

1113/T

Variation in the HGF gene is associated with keratoconus (KC) in the Caucasian population. *Y. Bykhovskaya[1], X. Li[1,2], G. Tang[1], K.D. Taylor[2], E. Mengesha[2], T. Haritunians[2], D. Siscovick[3], J.I. Rotter[2], Y.S. Rabinowitz[1].* 1) Cornea Genetic Eye Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 3) Departments of Medicine and Epidemiology and Cardiovascular Health Research Unit, University of Washington, Seattle, WA.

Keratoconus (KC) is a bilateral non-inflammatory progressive corneal ectasia with an incidence of approximately 1 per 2,000 in the general population. It is a multi-factorial disease influenced by the complex genetic inheritance of multiple nuclear genes. To identify susceptibility loci for KC, we performed a genome-wide screen of 222 Caucasian patients with KC and 3324 Caucasian controls from the Cardiovascular Health Study, using the Illumina Human CNV370-Duo beadchip. Association was evaluated by the allelic test and by logistic regression. Population stratification was tested by EIGENSTRAT program and principal component variables were used as covariates. SNP rs3735520 in the regulatory region upstream of the HGF (Hepatocyte Growth Factor) gene was associated with KC (risk allele T, $p=6.05x10^{-7}$; corrected p_PCA=$4.66x10^{-5}$; corrected multiplicative per-allele odds ratio of 1.5; 95% confidence interval 1.2-1.9). Allele A of the nonsynonymous polymorphism rs5745687 in exon 8 of HGF (E304K) was also associated ($p=4.2x10^{-3}$). Predictive analysis of this amino acid substitution by PMUT software identified this amino acid change as potentially pathological. Population and family based genetic studies have previously identified genomic variants in the HGF gene in patients with refractive abnormalities of the eye. Allele T in the rs3735520 was associated with myopia in Chinese and Caucasian families (Han 2006; Yanovitch 2009), while other HGF gene polymorphisms were found to be significantly associated with hypermetropia (Veerappan 2010). A GWAS study recently presented at the ARVO meeting identified an association between non-coding variants in HGF gene, including the same polymorphism rs3735520, and KC in Caucasian individuals (Burdon 2010). Our study provides further evidence for an association between genomic variation in the HGF gene and various ocular pathologies in the patients of multiple ethnic backgrounds. This suggests that HGF is a potential major genetic determinant of corneal and refractive diseases of the eye. We are currently performing genotyping of the HGF polymorphisms in additional individuals with KC, as well as investigating potential functional consequences of HGF gene variation on the tissue-specific expression and function of the HGF gene.

1114/T

Genome-wide association study of refractive error in 1304 individuals. *S.M. Hosseini[1,2], D. Waggott[3], E. Shen[3], A.P. Boright[4], M.P. Sylvestre[3], W. Sun[5], P.A. Cleary[5], A.J. Canty[6], L. Sun[7], S.B. Bull[3,7], A.D. Paterson[1,2,7], the DCCT/EDIC Research Group.* 1) Genetics & Genome Biology Program, Hosp Sick Children, Toronto, Canada; 2) Inst. of Medical Science, University of Toronto, Toronto, Canada; 3) Prosserman Centre for Health Research, Samuel Lunenfeld Research Inst of Mount Sinai Hosp, Toronto, Canada; 4) Dept of Medicine and University Health Network, University of Toronto, Toronto, Canada; 5) The Biostatistics Center, The George Washington University, Rockville, MD, USA; 6) Dept of Mathematics and Statistics, McMaster University, Hamilton, Ontario, Canada; 7) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada.

Background: Refractive errors, the most common cause of correctable visual impairment, affect one fifth of the population and impose a major economical burden worldwide. Twin and family studies support a genetic basis for refractive errors (estimated heritability 60-85%). Genome-wide linkage studies, mostly focused on myopia as a dichotomous trait, had some success in mapping loci. Quantitative trait linkage analyses have identified loci for the refraction continuum without fine-mapping them. **Purpose:** Identifying common alleles associated with refractive errors in the Diabetes Control and Complications Trial (DCCT) cohort **Methods:** DCCT was a randomized trial to compare the effects of intensive and conventional treatment on the development and progression of diabetes complications. Subjective refraction was measured annually in probands (average of 6 measures). Genotyping was performed using Illumina 1M beadchip. After removing poor performing SNPs and outliers based on population stratification, genotype data was available for ~841K SNPs with a minor allele frequency ≥1% for 1304 white probands. Genotypes for an additional 1.7M SNPs were imputed using HapMap data (CEU, r22). Association between spherical equivalent (after a normal score transformation) and each SNP was tested in linear mixed models assuming additive coding for genotypes. To increase the power, 5 repeated measures of refraction were used. Several sets of analyses were performed with the simplest modeling outcome as a function of SNP genotype alone and more complex models adjusting for important covariates (age, sex, education, near-work, glycemic exposure, etc.). **Results:** Several SNPs showed evidence of association with refractive error without reaching genome-wide significance (7 loci with P-value < 10^{-5}). Of these 5q14 locus (rs1352737, p=4.66E-6) coincides with a linkage peak for ocular axial length (Zhu et al, 2008). rs10260667 (p=2.95E-6) on 7p14 is located within a locus linked to myopia and ocular refraction (Wojciechowski et al, 2009; Stambolian et al, 2006). **Conclusion:** This genome-wide association study of ocular refraction identified a number of interesting loci, some of which within regions linked to myopia or refraction. Efforts are underway to prioritize association results based on linkage, gene-expression and proteomics data and to replicate the observed associations in independent cohorts.

1115/F

Identification of a novel gene influencing total antioxidant status using an integrative genomic approach. *S. Kumar, J.E. Curran, M.A. Carless, E.I. Drigalenko, T.D. Dyer, M.P. Johnson, L. Almasy, E.K. Moses, H.H. Goring, M.C. Mahaney, J. Blangero.* Southwest Foundation for Biomedical Research, San Antonio, TX.

Atherosclerosis, the leading cause of mortality in North America, is predicted to attain a similar distinction on a global scale within the next twenty years. A substantial portion of disease risk has been demonstrated to be due to genetic effects, although attribution of this risk to specific genes involved has been relatively slow. Recently, oxidative stress has been shown to be a significant contributor to atherosclerosis. Plasma total antioxidant status (TAS) is a summary measure of an individual's ability to accommodate oxidative stress that has been inversely related to atherosclerosis risk. While there is strong evidence that genetic factors play a major role in determination of plasma TAS (about 51% of the variation in plasma TAS is due to genes), specific genes for this underlying variation are yet to be identified. We report the comprehensive dissection of a novel candidate gene influencing quantitative variation in plasma TAS, in Mexican American individuals from the San Antonio Family Heart Study (SAFHS). Using genome-wide association data currently available on 1,159 SAFHS samples, we identified two SNPs exhibiting suggestive genome-wide evidence for associations with plasma TAS. One of these SNPs (rs2712104, $p = 1.7\times10^{-7}$) is located near the UBX domain protein 2A (*UBXN2A*) gene. In a separate analysis of whole transcriptome gene expression data from most of these same individuals, we also have determined that this SNP is correlated strongly with *UBXN2A* expression levels in lymphocytes (p-value $=1.0\times10^{-4}$). Further, we find that *UBXN2A* transcript abundance is positively correlated ($p = 4.5\times10^{-6}$) with plasma TAS. The wide distribution of the UBX domain protein families indicates that the UBX domain has a role in basic cellular processes conserved from yeast to man. However specific function for these proteins is not clearly known. Our empirical evidence (coming from two independent sources) strongly supports the hypothesis that *UBXN2A* represents a novel player in the causal pathway for antioxidant status. We are currently employing deep sequencing to identify sequence variants responsible for the variation observed in plasma TAS. Identifying genetic variants directly influencing plasma TAS should greatly advance our understanding of mechanisms of redox homeostasis and facilitate identification of additional contributors to variation in susceptibility to atherosclerosis and other oxidative stress-induced diseases.

Inferring pathogenic mechanisms from genome-wide association studies in autoimmune disease. *C. Cotsapas[1,2,3], BF. Voight[2], K. Lage[1,2,4,5], ER. Rossin[1,2,3], SS. Rich[6], DA. Hafler[7], MJ. Daly[1,2,3], FoCIS Network of Consortia.* 1) Center for Human Genetics Research, Massachusetts General Hospital, Boston, MA, USA; 2) Broad Institute, Cambridge MA, USA; 3) Dept of Medicine, Harvard Medical School, Boston, MA, USA; 4) Pediatric Surgical Research Laboratories, MassGeneral Hospital for Children, Massachusetts General Hospital, Boston, Massachusetts, USA; 5) Center for Biological Sequence Analysis, Department of Systems Biology,Technical University of Denmark, Lyngby, Denmark; 6) Center for Public Health Genomics, University of Virginia, Charlottesville VA, USA; 7) Dept of Neurology, Yale University School of Medicine, New Haven CT, USA.

Recent genome-wide association (GWA) studies have identified approximately 140 replicable genetic associations influencing risk of common autoimmune and inflammatory diseases, with the number still rising. Moreover, several of these loci have been independently shown to influence risk to more than one such disease, suggesting overlap in genetic risk factors for disease.

Here, we show that at least 50% of autoimmune/inflammatory loci influence risk of multiple diseases. These observations allow us to cluster loci into small groups of interacting proteins present in the same tissues. In this way we are able to propose models of pathogenesis from association data. Importantly, we find that our models are often parts of larger pathways; each part appears to influence risk to distinct but overlapping sets of diseases. For example, subsets of proteins involved in the IL23R-mediated signaling pathway appear to predispose to different diseases. This process is thought to initiate activation of pathogenic IL-17 producing T helper cells (Th17) and has been implicated in pathogenesis of several autoimmune and inflammatory diseases including Crohn's disease and multiple sclerosis.

These mechanistic overlaps have prompted us to perform comparisons genome-wide between pairs of diseases to identify the complete sets of loci influencing risk to each pair. We are in the process of replicating some of these observations and will discuss the extent of sharing between diseases.

Our work cumulatively suggests that specific perturbations in cellular pathways may have different intermediate phenotype outcomes. Our mechanistic models will allow us to screen for these phenotypes and shed light on the biology of immune disease.

Making Sense of Small Effects in GWAS: statistics for dealing with diversity by integrating information. *M.A. Reimers[1,2], K.S. Kendler[1,2].* 1) Biostatistics, Virginia Commonwealth University, Richmond, VA; 2) Virginia Institute for Psychiatric and Behavioral Genetics, Richmond, VA.

Recent studies of complex disease genetics have led many researchers to think that complex diseases are different from the Mendelian diseases, which have so far been the model for the development of statistical methodology in genetics. In particular it seems there are many possible causes of a single disorder, including common variants with small effects and rare variants with big effects. I describe several integrated approaches using bioinformatic data within a Bayesian framework. I will describe some novel work on detecting and estimating the size distribution of small effects. I will describe a novel method for tests of small effects organized by functional gene sets. I will describe an approach for selecting most probable pairs of variants to test for epistasis. Then I will review some recent work on tests for rare variants, and present some methods under development. Finally I will propose an empirical Bayesian framework for estimating effect sizes, which may distinguish among rare variants uniquely present in cases.

1118/F

Constructing Endophenotype of complex disease via Nonnegative Matrix Factorization. *H. Wang[1,3], C. Hsu[2], S. Chang[3], C. Fann[1,3].* 1) Division of Biostatistics, Institute of Public Health, National Yang-Ming University, Taiwan; 2) Institute of Information Science, Taipei, Taiwan; 3) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

To effectively identify susceptibility genes of complex disorders, the endophenotype approach has been advocated by many researches. In this study, we hypothesize the existence of molecular dissimilarity across patients, although they may have the same clinical phenotype and belong to the same disease status. We carried out two-stage approach to construct endophenotypes and to investigate the characteristics and biological interpretation of constructed endophenotypes by integrating transcriptional profiles and SNPs data. In the first stage, an unsupervised nonnegative matrix factorization (NMF) was adopted to explore correlations in the high dimensional transcriptional data space and to cluster similar molecular subtypes by cophenetic correlation coefficient criteria. We defined the molecular subtypes derived from transcriptional profiles as endophenotypes. In the second stage, we then used multivariate ANOVA (MANOVA) analysis to detect the significant SNPs among molecular subtypes and to determine the SNP-transcript pairs in which gene expression was correlated with genotype in molecular subtypes. To evaluate the applicability of our approach, we applied our method to a genome-wide late-onset Alzheimer disease (LOAD) case-control data. The results showed that NMF classified a rank-three molecular subtype model for patient group of LOAD. We then performed MANOVA analysis and obtained 88 statistically significant SNPs (. Of the three molecular subtypes, there were 10 and 19 genes which specific expressed in the subtype 1 and the subtype 3 respectively; the subtype 2 was found to have a similar expression pattern with the control group. In conclusion, our approach seems to be able to detect the potential difference in patient group and may further link transcripts of each endophenotype to known functional pathways.

Expression and association analyses implicate genes of the epidermal growth factor family in Behçet's disease (BD) susceptibility. *J.M. Xavier[1,2], T. Krug[1,2], M. Shafiee[3], B.S. Abdollahi[3], B.V. Fonseca[1,2], G. Jesus[4], F. Barcelos[5], J. Vedes[6], M. Salgado[7], J. Vaz Patto[5], F. Davatchi[3], J. Crespo[8], S.A. Oliveira[1,2].* 1) UNIC - Genomics Disease Lab, Instituto de Medicina Molecular, Lisbon, Portugal; 2) Human Genetics Group, Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Rheumatology Research Center, Tehran University of Medical Sciences, Tehran, Iran; 4) Hospital Infante D. Pedro, Aveiro, Portugal; 5) Instituto Português de Reumatologia, Lisbon, Portugal; 6) Hospital de Sousa Martins, Guarda, Portugal; 7) Hospital Pediátrico de Coimbra, Coimbra, Portugal; 8) Hospitais da Universidade de Coimbra, Coimbra, Portugal.

BD is a multisystemic immuno-inflammatory disorder characterized by a generalized vasculitis, particularly at oral and genital mucosa and eye. To better understand the pathogenesis of BD, we applied an integrative approach that combines expression profiling analysis with association studies. We first compared the gene expression profiles in PBMCs of 15 patients and 14 matched controls using Affymetrix microarrays. We identified 508 differentially expressed genes that allow a good separation between cases and controls in hierarchical clustering and principal component analysis. Pathway analysis revealed that several genes in the ErbB signalling pathway were significantly differentially expressed. The ErbB family of receptor tyrosine kinases couples binding of extracellular growth factor ligands to intracellular signalling pathways regulating diverse biologic responses, including proliferation, differentiation, cell motility, cell survival, and vascular permeability. Three differentially expressed genes (EREG, AREG, and NRG1) belonging to the epidermal growth factor family of ligands for ErbBs were tested for association with BD. Genotyping of 43 tagging SNPs was performed in 550 Iranian BD patients and 436 controls. Patients were selected as consecutive patients, according to ICBD criteria. To control for potential confounding due to population stratification, we genotyped 90 ancestry-informative markers in our dataset and assessed population structure using EIGENSOFT. Both principal component analysis and computation of the inflation factor lambda indicated the inexistence of population stratification and of outlier individuals. Association tests (unadjusted and adjusted for gender) were performed using the R software. We found an association ($p<0.05$) in all loci studied: two SNPs in EREG, one SNP in the EREG-AREG intergenic region, and four SNPs in NRG1. Analysis of imputation-based data revealed additional evidence of association with risk of BD for SNPs in the upstream region of EREG, which was confirmed by actual SNP genotyping ($p<0.01$). These association findings support a role for the ErbB signalling pathway in BD pathogenesis that warrants further investigation. This study highlights the importance of combining genetic and genomic approaches to dissect the genetic architecture of complex diseases.

1120/F

Large variation for ROS production among healthy individuals shows strong evidence for genetic control. *H. Attar[1], K. Bedard[2], E. Migliavacca[1], M. Gagnebin[1], Y. Dupré[1], P. Descombes[3], H. Prokisch[4], T. Meitinger[4], D. Mehta[4], E. Wichmann[4], E.T. Dermitzakis[1], KH. Krause[5], S.E. Antonarakis[1,6].* 1) Department of Genetic Medicine, University of Geneva Medical School, Geneva, Switzerland; 2) Pathology Department, Dalhousie University, Halifax NS B3H 4H7, Canada; 3) Genomics Platform, NCCR Frontiers in Genetics, University of Geneva Medical School, Geneva, Switzerland; 4) GSF Research Center, Human Genetics and Epidemiology, Neuherberg, Germany; 5) Department of Pathology and Immunology, University of Geneva Medical School and University Hospitals, Geneva, Switzerland; 6) Department of Genetic Medicine and Development University of Geneva Medical School, and University Hospitals of Geneva.

DNA sequence variation contributes to individual differences in quantitative traits. Several studies have shown the genetic control of gene expression variation, but few cellular traits have been investigated that might be more closely related to clinical phenotypes. Here, we investigate the production of reactive oxygen species (ROS), a complex cellular phenotype that is involved in a number of human disorders. We assessed individual variation of ROS production in EBV-transformed B-lymphoblastoid cell lines (LCL) with a fluorescent AmplexRed assay to identify potential regulatory loci. We found substantial individual variation in ROS production. Heritability estimates using 10 CEPH families were ~45%; linkage analysis using SNP markers identified 2 genome-wide significant and 2 suggestive linkage signals on loci of Hsa12 and Hsa15, and for Hsa1 and Hsa19 respectively. We next performed a genome-wide association analysis (GWA) for the combined cohorts KORA and GenCord (N=279), using enhanced marker resolution through imputation (>1.4 million SNPs). Results indicate significant associations for 53 SNPs with p-values of less than 5e-6, 2 of which mapped in the linked regions on Hsa15 and Hsa19. As a replication sample we used 58 HapMap individuals and > 2.2 million SNPs. A total of 197 SNPs with $p<1e-6$ were identified, and we confirmed hits on Hsa1, Hsa12, Hsa15 and Hsa19. When comparing top association hits among the two GWA analyses, we did not detect replicated SNPs, but only replication within the same region of 1 kb or 1-2 Mb, respectively. A link between Down syndrome and ROS production has been previously made in the literature; we detected a highly significant decrease in ROS production in DS LCLs (N=76; Wilcoxon rank sum test, $p<8.07e-13$). Interestingly, a significant association in HapMap on Hsa21 close to the gene SIK1 ($p=3.12e-8$) has been observed. Taken together, our results show strong evidence of genetic factors at the basis of ROS production variation in cell lines of healthy and in DS individuals. On the other hand cellular phenotypes appear to be more complex than gene expression phenotypes and validation of GWA signals also require considerable sample sizes.

1121/F

Fine mapping of Type 2 Diabetes and Myocardial Infarction associations on chromosome 9p21 by regional sequencing and imputation. *J. Shea[1, 2], A.A. Philipakkis[1, 3, 4], V. Agarwala[1, 3], B. Thompson[1], C. Guiducci[1], N.P. Burtt[1], L. Groop[5], D. Altshuler[1,2,6].* 1) Broad Institute, Cambridge, MA; 2) Harvard Medical School, Boston, MA; 3) Harvard-Massachusetts Institute of Technology Division of Health Sciences and Technology, Harvard Medical School, Boston, MA; 4) Brigham and Women's Hospital, Boston MA; 5) Department of Clinical Sciences, Diabetes and Endocrinology Research Unit, University Hospital Malmö, Lund University, Malmö, Sweden; 6) Massachusetts General Hospital, Boston, MA.

Genome-wide association studies (GWAS) have identified hundreds of loci associated with common diseases, but in only a few cases have specific causal mutations been identified. This is in part because many associations map to poorly annotated non-coding regions that we do not yet know how to interpret, as exemplified by chromosome9p21, a region with associations to Type 2 Diabetes (T2D), Myocardial Infarction (MI), and several cancers. A mouse model in which 70kb of non-coding DNA homologous to the MI-associated region were deleted has provided evidence for regulatory function in the region influencing expression of the nearby tumor suppressor genes CDKN2A and CDKN2B, but specific regulatory elements and variants have not yet been identified. A key step in identifying functional mutations on 9p21 is enumerating the complete set of variants that could explain each association signal. Using the T2D- and MI-associated regions as test cases, we compared several strategies currently available to researchers for assembling such lists, including methods for identifying the full set of variants in associated regions (performing high-coverage re-sequencing versus using emerging data from the 1000 Genomes (1kG) project), and methods for imputing identified variants into case-control samples so they can be tested for association to disease. We found that the 1kG Pilot 1 data contained 78% of all sites detected in high coverage sequencing and 97% of sites with a variant allele frequency greater than 10%. High coverage re-sequencing detected rare variants that were missed by 1kG but, because of heterogeneous coverage, missed some common variants identified by 1kG. We found that imputation directly from both high coverage re-sequencing and 1kG Pilot 1 data into disease samples performed comparably to imputation from a genotyped reference panel. However, in order to capture nearly 100% of common variation in imputation, it was necessary to genotype additional markers in our disease samples. Having tested the majority of common variation on 9p21 for association to T2D and MI, we did not find any evidence for signals stronger than the original GWAS signals. For each disease, we identify a set of potential causal variants with equivalent support for association, which can now be systematically assayed for function.

1122/F

Allelic expression in autism: A novel approach for gene discovery. *E. Ben-David, E. Granot-Hershkovitz, G. Monderer-Rothkoff, E. Lerer, S. Levi, M. Yaari, R. Ebstein, N. Yirmiya, S. Shifman.* The Hebrew University of Jerusalem, Jerusalem, Israel.

Autistic disorder is the most severe end of a group of neurodevelopmental disorders referred to as autism spectrum disorders (ASDs). Autism is a heterogeneous syndrome characterized by social deficits, language impairments and repetitive behaviors. Autism has a strong genetic basis, but despite that, most of the genetic factors that contribute to the disease risk are still unknown. Recent work has led to the identification of several autism susceptibility genes and an increased appreciation of the contribution of de novo and inherited copy number variations (CNVs). Most identified ASD associated mutations and chromosome abnormalities are believed to disrupt the expression of genes from a single parental chromosome. In this study, we present a novel approach for identification of genes implicated in ASD. This method is based on measurement of the relative expression of the two copies of a gene (the paternal and maternal copies) using genotyping arrays. Large allelic expression imbalance (AEI) could arise from a wide range of genetic and epigenetic abnormalities, including rare variants, newly arisen mutations and alteration of the methylation patterns when present in only one copy of a gene. Single nucleotide polymorphism (SNP) arrays provided us with the ability to screen for AEI across the genome, as well as the ability to find structural variations. We screened for genes showing large AEI in lymphoblastoid cell lines derived from an ASD cohort. We first identified around 700 regions in the genome of common AEI - regions showing AEI across multiple samples, including imprinted regions and random monoallelic expression. Additionally, we identified unique regions showing large AEI in specific ASD samples. Validation by quantitative sequencing demonstrated that the genes (or, in some cases, only parts of the genes) are monoallelic expressed. The genes include both known risk factors for ASD and novel candidates, and, in some, the genetic mutation causing the AEI was revealed. Our results demonstrate the ability to identify rare regulatory mutations using genome-wide AEI screens, capabilities which could be expanded to other complex diseases, especially those with suspected involvement of rare mutations.

Genetics of sputum gene expression to identify genes for chronic obstructive pulmonary disease. *C.P. Hersh[1], W. Qiu[1], M.H. Cho[1], J.H. Riley[2], W.H. Anderson[3], D. Singh[4], P. Bakke[5], A. Gulsvik[5], A.A. Litonjua[1], D.A. Lomas[6], J.D. Crapo[7], T.H. Beaty[8], B.R. Celli[1], S. Rennard[9], R. Tal-Singer[10], S.M. Fox[2], E.K. Silverman[1], ECLIPSE Investigators.* 1) Brigham and Women's Hospital, Boston, MA; 2) GlaxoSmithKline, Uxbridge, UK; 3) GlaxoSmithKline, Research Triangle Park, NC; 4) University of Manchester, UK; 5) University of Bergen, Norway; 6) University of Cambridge, UK; 7) National Jewish Health, Denver, CO; 8) Johns Hopkins University, Baltimore, MD; 9) Nebraska Medical Center, Omaha, NE; 10) GlaxoSmithKline, King of Prussia, PA.

Background: Many studies have performed genomewide association studies for gene expression, but most studies have examined blood cells or cell lines from non-diseased individuals. Objective: To examine the genetics of gene expression in a relevant disease tissue from patients with chronic obstructive pulmonary disease (COPD) to find novel disease genes. Methods: The Evaluation of COPD Longitudinally to Identify Predictive Surrogate End-points (ECLIPSE) Study is a multi-center 3-year observational study. Genome-wide SNP genotyping has been performed on all ECLIPSE subjects using the Illumina HumanHap550 BeadChip. Gene expression profiling on induced sputum samples from 131 COPD cases has been performed using the Affymetrix Human U133 Plus2 array. Results: Examining all SNPs within 50kb of a transcript (562,787 tests), we found 4315 SNP-probe associations to be significant at FDR-adjusted $p<0.05$. These 4315 regulatory SNPs (rSNPs) were tested for association with COPD in a GWAS which included subjects from the ECLIPSE, Norway, and NETT-NAS studies (2940 cases, 1380 controls). Adjusted for 4315 tests ($p<1.16x10^{-5}$), the 2 SNPs which were significantly associated with COPD were located in 2 genes on chromosome 15 with known COPD associations: CHRNA5 and IREB2. 70 additional rSNPs which were associated with COPD at $p<0.01$ were genotyped in the International COPD Genetics Network and in the COPDGene Study, finding replicated associations with a SNP in PSORS1C1, in the HLA-C region on chromosome 6 (combined $p=2.2x10^{-4}$). Conclusion: Integrative analysis of GWAS and sputum gene expression data has located potential functional variants in two known COPD genes and has identified a novel COPD susceptibility gene. Funded by: GlaxoSmithKline (SCO104960, NCT00292552) and NIH/NHLBI (R01HL094635).

A Novel Mutation in the Pre-mRNA Splicing Factor PRPF31 causes early-onset Autosomal Dominant Retinitis Pigmentosa. *D. Chung[1,2], E. Place[2,3], M. Falk[3], E. Pierce[1,2].* 1) F. M. Kirby Center for Molecular Ophthalmology, Scheie Eye Institute, Department of Ophthalmology, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) The CHOP Pediatric Center for Inherited Retinal Degeneration, Division of Ophthalmology, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Division of Human Genetics, Department of Pediatrics, The Children's Hospital of Philadelphia and University of Pennsylvania School of Medicine, Philadelphia, PA.

Retinitis pigmentosa (RP) is a clinically and genetically heterogeneous group of inherited retinal dystrophies that are characterized by photoreceptor degeneration with associated visual impairment. It is the most common form of retinal dystrophy, affecting about 1in 3500 individuals world-wide. The autosomal dominant form of RP (adRP) is attributed to mutations in 20 different genes. PRPF31 is one of 4 adRP genes involved with pre-mRNA slicing activity. Here, we report the clinical and genetic characteristics of a large, multi-generational family with adRP caused by a novel nonsense mutation found in the PRPF31 gene. The proband's clinical course began with a 1-2 year history of progressive nyctalopia, and photophobia. Progressive visual field loss was subsequently noted with relatively stable central vision. The clinical diagnosis of RP was made at the age of 6 years. Currently age 14, the proband has had progressively decreased visual acuity (20/60 OD, 20/160 OS). Dilated fundus examination revealed mild optic nerve pallor, attenuated retinal vasculature, and bone-spicules in the mid-periphery. Electroretinogram exhibited decreased rod and cone function. Fundus imaging was performed by spectral domain optical coherence tomography (SD-OCT) illustrated significant photoreceptor loss in the mid-periphery with marked cystoid macular edema, bilaterally. The proband's mother and maternal grandmother were found to have similar clinical features and histories of onset. A 9 year old male sibling also shows early clinical signs of retinal degeneration. Whole blood was collected from the proband and mutational screening was performed on the 20 known adRP genes, SNRNP200, CA4, CRX, FSCN2, GUCA1B, IMPDH1, KLHL7, NRL, NR2E3, PRPF3, PRPF8, PRPF31, RDH12, RDS, RHO, ROM1, RP1, RP9, RP31 and SEMA4A. PCR amplification and direct DNA sequencing was performed in both directions of all coding exons and exon/intron borders. Sequencing revealed a novel nonsense mutation in the PRPF31 gene (p.R354X). This mutation appears to produce an earlier onset of disease (first decade) than typical of other PRPF31 mutations, which cause disease onset in the second to third decades. In conclusion, we identified a novel mutation in the PRPF31 gene as a cause for adRP that exhibits an early onset of nyctalopia and retinal degeneration. Correlation of retinal disease phenotypes with specific genetic mutations may improve insight into disease progression and prognostic outcome.

Novel abdominal adiposity genes and their interactions with dietary factors in association with type 2 diabetes risk: findings from two cohorts. *E. Yeung[1], L. Qi[2], F. Hu[2], C. Zhang[1].* 1) Epidmeiology Branch, DESPR, NICHD, Bethesda, MD; 2) Departments of Nutrition & Epidemiology, Harvard School of Public Health, Boston, MA.

A recent genome-wide association study (GWAS) found three SNPs (LYPLAL1 (rs2605100), MSRA (rs545854), TFAP2B (rs987237)) for central obesity, a strong risk factor for type 2 diabetes (T2D). However, little is known about the role of these SNPs in the development of T2D. We investigated their associations with T2D in two large case control studies from the Nurses' Health Study and Health Professionals Follow-up Study. Self-reported T2D cases were confirmed by validated questionnaire. We examined associations with T2D and interactions with diet among incident cases (1245 women, 828 men) and controls (2149 women, 1326 men) with prospectively collected dietary data by food-frequency questionnaire. We used logistic regression to estimate the odds ratio (OR) and 95% confidence interval (CI). We compared plasma adipokine levels (i.e. total and high molecular weight (HMW) adiponectin, leptin, leptin receptor, and resistin) by genotype among a subgroup of female controls (n=945). The effective allele frequency was 72% for LYPLAL1, 17% for MSRA, and 18% for TFAP2B. LYPLAL1 was associated with T2D after adjustment for BMI in both cohorts (pooled allelic OR 1.12: 1.01-1.24). MSRA was related to slightly increased risk of T2D in men only (age-adjusted allelic OR of 1.24 (95% CI: 1.02-1.51). No significant associations were seen with TFAP2B. We observed significant interactions between B12 intake and LYPLAL1 genotype from both cohorts (p-interaction<0.05). B12 intake was protective of T2D risk only among those homozygous for the effective LYPLAL1 allele. For example, among women with GG, the highest tertile of B12 intake was associated with decreased T2D risk (OR 0.63: 0.47-0.85) compared to the lowest tertile. Similarly for men with GG, OR was 0.62 (p=0.01). However, no benefit of B12 was seen for the other genotypes (p>0.10). Carriers of the MSRA effective allele had higher leptin levels (20.7 vs. 18.8 ng/ml, p= 0.06) and lower percent HMW adiponectin (38.8% vs. 40.9%, p=0.04). The TFAP2B effective allele, however, was associated with lower leptin levels (17.4 vs. 20.1 ng/ml p=0.005). The LYPLAL1 SNP was not related to adipokine levels. Conclusion: These findings suggest potential associations of novel abdominal obesity genes with T2D risk and that LYPLAL1 may synergistically interact with dietary vitamin B in determining risk in both men and women. More research is needed to understand the molecular mechanisms for the interaction.

1126/F

Genetic variation in Mean Platelet Volume and platelet count and metabolic characterization. *R. Rawal[1], K. Suhre[2,7], T. Illig[1], J. Adamski[5,6], H.E. Wichmann[1,3,4], C. Gieger[1].* 1) Institute for Epidemiology, Helmholtz Center, Munich/Neuherberg, Germany; 2) Institute for Bioinformatics and Systems biology Helmholtz Center, Munich/Neuherberg, Germany; 3) Institute for Medical informatics biometry and Epidemiology, Ludwig-Maximilans-Universität, Munich, Germany; 4) Klinikum Grosshadern, Munich, Germany; 5) Institute of Experimental Genetics, Genome analysis Center, Helmholtz Center, Munich/Neuherberg, Germany; 6) Institute of Experimental Genetics, Life and Food Science Center, Weihenstephan, Technische Universität München, Munich, Germany; 7) Faculty of Biology, Ludwig-Maximilans-Universität, Munich, Germany.

Serum metabolite concentrations measured by mass spectrometry and nuclear magnetic resonance provide a direct readout of biological and physiological processes in the human body, and they are associated with disorders such as immunity and cancer. Our recent genome-wide association studies (GWA) have established association between single nucleotide polymorphism (SNP) and blood cell parameters such as Mena platelet volume (MPV) and platelet count. By simultaneously analyzing these phenotypes with genome-wide SNP data and metabolite concentrations (and their ratios), we aim to illustrate the genetic variation that is associated with both blood cell counts and a metabolite concentration, which would provide new information about the underlying etiological processes in disease causing mechanism for the diseases related with platelet counts and platelet volume such as immune responses to infections and cancers of the circulatory system. First we analyzed the association between the phenotype Mean platelet volume (MPV) and platelet count and 151 metabolites in 3044 participants from the KORA population (Germany). 151 metabolites were grouped in to 10 biochemical groups such as amino acids, sugars, acylcarnitines, and phospholipids. In the poster we will try to further elucidate the role of genetic loci from the pre-published genes (3 QTL in the loci near the regions of the gene TAOK1, ARHGEF3 and WDR66) reported for the platelet count and MPV taking in to account the metabolite ratios and associated genes for the enzymes in the metabolism.

PhenX Measures: Enhancing Research Studies of Gene-Environment Interactions. *W. Huggins[1], L.C. Strader[1], D.C. Whitcomb[2], B. Entwisle[3], B. Pescosolido[4], L. Goldman[5], J.A. Hammond[1], T. Hendershot[1], R.K. Kwok[1], H. Junkins[6], E. Ramos[6].* 1) RTI International, Research Triangle Park, NC; 2) Gastroenterology, University of Pittsburgh School of Medicine, Pittsburgh, PA; 3) University of North Carolina at Chapel Hill Carolina Population Center, Chapel Hill, NC; 4) Indiana University at Bloomington, Bloomington, IN; 5) Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; 6) National Human Genome Research Institute, Bethesda, MD.

Few Genome-Wide Association Studies (GWAS) have included robust environmental exposure measures even though gene-environment interactions modulate the severity and presentation of virtually all human disease. The PhenX (consensus measures for Phenotypes and eXposures) Toolkit offers high quality, well-established, standard measures of phenotypes and exposures from 21 domains for use in GWAS and other large-scale genomic research efforts. For each research domain, a Working Group (WG) comprised of academic and clinical researchers from diverse institutions and disciplines is assembled to prioritize a set of low burden, well established measures. Here, we demonstrate a possible scenario to examine gene-environment interactions by highlighting measures from four PhenX Domains: Gastrointestinal, Environmental Exposures, Social Environments, and Psychosocial. The Gastrointestinal WG identified a range of disorders that can be influenced by an individual's environment including abdominal pain, recurrent constipation, and gastrointestinal cancers. These modulating factors can be assessed by other standard measures in the Toolkit. For example, the Environmental Exposures measures include water source, occupation history, and contact with common chemicals and solvents. The Social Environments WG identified a range of relevant exposures that address aspects of work, family, and neighborhood/community. The Psychosocial WG selected measures related to stress, coping, wellbeing, and social connectedness. Researchers can visit the web-based PhenX Toolkit (https://www.phenxtoolkit.org/) to review and select measures. For each measure, the Toolkit provides a description, selection rationale, protocol(s) for collecting the measure, and references. Users can browse, select and download the protocols for measures that are relevant for their research. The Toolkit provides a common currency for investigators who wish to add measures that are outside their primary research focus or to extend their research through the inclusion of salient PhenX measures to go beyond to explore the physical and social environments to determine the etiology of complex diseases. As investigators incorporate PhenX measures into their studies, there will be new opportunities for cross-study analyses to identify loci with small effect sizes and to discover gene-gene and gene-environment associations. Investigation of *FTO* variants and interactions with physical activity among 3,484 Hispanic postmenopausal women in the Women's Health Initiative Study. *E. Rampersaud[1], T. Edwards[2], K. Monda[3], K. North[3], C. Carlson[4], S. Wassertheil-Smoller[5], M. Neuhouser[4], D. Crawford[6], S. Liu[7], M. O'Sullivan[8], DRV. Edwards[2], A. Naj[1].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 2) Vanderbilt Epidemiology Center, Vanderbilt University Medical Center, Nashville, TN, USA; 3) University of North Carolina at Chapel Hill Department of Epidemiology, Chapel Hill, NC; 4) Fred Hutchinson Cancer Research Center; Seattle WA; 5) Yale University, New Haven CT; 6) Center for Human Genetics Research, Vanderbilt, Nashville TN; 7) Program on Genomics and Nutrition Department of Epidemiology, UCLA; 8) Department of Obstetrics and Gynecology, University of Miami, Miami, FL, USA.

The fat mass and obesity associated (FTO) gene has consistently been associated with obesity and other measures of adiposity in multiple cohorts. Genetic interactions with physical activity have also been identified for FTO variants in some studies. In the Women's Health Initiative Observational Study (WHI-OS), associations of rs9939609 and rs8050136 with obesity were validated in an ethnically diverse subset of 3,600 women, which included 415 Hispanics (Song et al. 2008). We performed an expanded analysis of the complete post-QC set of FTO SNPs (n=184) in all 3,484 Hispanic samples genotyped in the WHI SHARe cohort GWAS (Affymetrix Human SNP Array 6.0) and examined their interactions with physical activity (self-reported total MET-hours/week. Linear regression was used to test for main effects of BMI, hip and waist circumference, and waist-hip ratio and logistic regression of obesity, and for interactions with physical activity. Genotype was modeled using an additive term (0, 1, or 2). All analyses were adjusted for smoking, alcohol, dietary energy, and axes of ancestral variation. Both rs9939609 and rs8050136 were significantly associated with all traits (p£0.01) in the complete Hispanic cohort but were not consistently the most highly associated SNPs overall. We did not detect a main effect for physical activity or interaction for either SNP with physical activity in this cohort (p>0.10). However, significant adiposity-physical activity interactions were found for an uncorrelated SNP rs9934504 (p=0.05 for main effect, p= 0.02 for the interaction term) with BMI, waist circumference (p=0.05 for main effect, p=0.008 for interaction term) and obesity (p=0.07 for main effect, p=0.03 for interaction term. Based on our preliminary analysis, we have confirmed the association of several SNPs in FTO with adiposity traits. However our analyses thus far incorporating self-reported physical activity collected at baseline in the WHI-OS study shows limited evidence of FTO x physical activity interactions. Analyses are ongoing in the African American cohort of the WHI-OS.

1129/F

Lifestyle interactions of FTO: Exercise a serious player. *P.J. Wagner[1,2], K. Silander[1,2], S. Männistö[6], S. Ripatti[1,2], T. Mäkinen[11], S. Keinänen-Kiukaanniemi[7,8,9], H. Oksa[10], L. Peltonen[1,2,3,4,5].* 1) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 2) National Institute for Health and Welfare, Unit of Public Health Genomics, Helsinki, Finland; 3) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 4) The Broad Institute, Cambridge, MA; 5) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 6) National Institute for Health and Welfare, Unit of Chronic Disease Epidemiology and Prevention, Helsinki, Finland; 7) University of Oulu, Department of Public Health Science and General Practice, Oulu, Finland; 8) Oulu University Hospital, Unit of General Practice, Oulu, Finland; 9) Oulu Deaconess Institute, Department of Sport Medicine, Oulu, Finland; 10) Tampere University Hospital, Tampere, Finland; 11) National Institute for Health and Welfare, Unit of Health and Welfare Inequalities, Helsinki, FInland.

Variants in and around the FTO gene are consistently strongly associated with BMI and waist circumference. Speculations on the variants' mechanisms causing the physical changes related to obesity include effects on satiety, exercise habits and energy expenditure. We tested the hypotheses behind FTO's effects using the SNP rs8050136 and a study set of 25-65 year-old adults from the Finnish population-based cohorts Health 2000 (H2000) and FINRISK-2007/DILGOM (contributing n=4176 and n=3407, respectively, after exclusions based on missing data and age >65). rs8050136 was associated in additive linear regression models to BMI in both H2000 (p-value 0.013) and DILGOM (p-value $6.49x10^{-10}$). The obesity risk allele (A) is not associated with elevated total energy intake or total dietary fat as a percentage of energy intake in either data set (p-values 0.349-0.994), suggesting that FTO does not affect overall appetite or the preference of a high-fat diet. FTO also did not have an effect on individuals' level of leisure exercise (p-values 0.844-0.998). On the other hand, leisure exercise attenuates FTO's effect on BMI in the DILGOM study (interaction p-value of 6.51e-06). The effect of the FTO risk allele is greater among the inactive group (1.89 kg/m^2 per A allele, standard error of 0.36) compared to the active group (0.26 kg/m^2 per A allele, standard error of 0.11). The interaction was similar among women in the H2000, but was not significant using the same additive model. The women of the H2000 cohort showed a significant interaction under a model comparing AA homozygotes to C-allele carriers (interaction p-value 0.0164). In the inactive group, women homozygous for the risk allele (AA) had average BMI of 28.77 kg/m^2, 1.7 kg/m^2 greater than that among the C-allele group; while in the most active group, AA-homozygotes had a lower average BMI compared to that of C-allele carriers (24.48 vs 24.98 kg/m^2). The interaction among men in the DILGOM study was weaker than that among women, and thus the allele's effect may differ between men and women. We are currently testing the interaction in the following cohorts that have already been genotyped for the same FTO SNP: FinRisk 1992 (n=6000), FinRisk 1997 (n=8000) and FinRisk 2002 (n=8000; approximate sample sizes include people over 65). In conclusion, the effect of FTO at SNP rs8050136 on BMI appears to be dependent on an individual's level of physical activity, and this relationship may differ by gender.

1130/F

Lack of evidence for gene-environment interactions in a population-based sample of isolated CL/P from Norway: A combined case-control and offspring-parent triad study-design. *A. Jugessur[1,2], O. Skare[1], HK. Gjessing[1,3], AJ. Wilcox[4], T. Trung Nguyen[5], RT. Lie[3,5], JC. Murray[6].* 1) Division of Epidemiology, Norwegian Institute of Public Health, N-0403 Oslo, Norway; 2) Craniofacial Research, Musculoskeletal Disorders, Murdoch Childrens Research Institute, Royal Children's Hospital, 3052 Parkville, Australia; 3) Section for Epidemiology and Medical Statistics, Department of Public Health and Primary Health Care, University of Bergen, N-5020 Bergen, Norway; 4) Epidemiology Branch, National Institute of Environmental Health Sciences (NIEHS), Research Triangle Park, NC 27709, USA; 5) Medical Birth Registry of Norway, Norwegian Institute of Public Health, N-5020 Bergen, Norway; 6) Departments of Pediatrics, Epidemiology and Biological Sciences, University of Iowa, Iowa City, IA 52242, USA.

Orofacial clefts are complex birth defects, with strong evidence for both genetic and environmental causal factors. In this study, we looked for evidence of gene-environment (GxE) interactions using data from a nationwide study of orofacial clefts in Norway. Genotypes for 1315 SNPs in 334 autosomal candidate genes were available from a previous analysis of 562 case-parent triads and 592 control-parent triads, in which we looked for the effects of fetal genes on the risk of orofacial clefts. For the current study, data were available for the following exposures during the first trimester of pregnancy: cigarette smoking, alcohol, coffee, folic acid and vitamin A supplementation, and dietary folic acid. We used a combined case-control and offspring-parent triad study-design to look for GxE effects in 311 isolated cleft lip with or without cleft palate (CL/P) triads. Prior to analysis, each exposure was treated as a binary variable (exposed vs. non-exposed). Single-marker and haplotype-based analyses were performed using the statistical software package HAPLIN (http://www.uib.no/smis/gjessing/genetics/software/haplin/). Gene effects were estimated for each stratum of the exposure variable and a Wald test statistic, consisting of a weighted sum of differences of the stratified effect-estimates, was used to screen for evidence of GxE interactions. Finally, separate pathway-wide analyses were done for genes involved in folic acid metabolism and genes involved in the detoxification of xenobiotic compounds such as cigarette smoke and alcohol. To ensure that the Wald test was valid for the sample sizes available for analysis, we generated QQ plots to check whether the distribution of the GxE p-values after permutation of the exposures was consistent with the null hypothesis. Overall, however, none of the p-values were statistically significant in either single-marker or haplotype-based analyses. Furthermore, pathway-wide analyses of genes involved in folic acid metabolism and detoxification of xenobiotics compounds did not reveal any statistically significant interaction. Despite strong evidence for genetic causes of CL/P and previously reported GxE interactions with maternal vitamins and smoking, we found no convincing indication that these exposures influence the risk of isolated CL/P in our data.

1131/F

GENTES, an ensemble approach for feature selection in complex diseases. *M. Pinelli[1,5], D. D'andrea[2,5], R. Amato[2,4,5], R. Tagliaferri[3,5], S. Cocozza[1,5], G. Miele[2,4,5].* 1) Dipartimento di Biologia e Patologia Cellulare e Molecolare "L. Califano", Universitá degli Studi di Napoli "Federico II", Napoli, NA, Italy; 2) Dipartimento di Scienze Fisiche, Universitá degli Studi di Napoli "Federico II", Napoli, NA, Italy; 3) Dipartimento di Matematica e Informatica, Universitá di Salerno, Fisciano, SA, Italy; 4) INFN, Italy; 5) Gruppo Interdipartimentale di Bioinformatica e Biologia Computazionale, Universitá di Napoli ``Federico II'' - Universitá di Salerno, Italy.

Complex diseases are multifactorial phenotypes which are caused by the genetic and environmental factors. As we described in a previous work, genetic and environmental factors can interact in additive or non-additive way (Amato et al, BMC Informatics 2010). The identification of the relevant features among a large number of possible candidates and inside typically small sized datasets hardly challenges any applicable Feature Selection Method (FSM). Especially, if genetic and environmental features interact in a non-additive way. As it is well known, each FSM better performs in particular conditions. In this concern, an ensemble approach combining several FSMs succeeds in adding the positive characteristics of each FSM, diluting at the same time the weakness points. Ensemble application to the features selection task have been explored, however they usually put together several instances of the same methods on permuted datasets. We present new software that implements an ensemble of features selection methods aimed to identify relevant genetic and non-genetic features involved in a given complex disease. The ensemble can be composed by any type of features selection method, as well we present the implementation of four of them, namely the Binary Logistic Regression, the Linear Discriminant Analysis, the Multifactor Dimensionality Reduction and an univariate χ^2 or t-test. We optimized the performances of the ensemble in identifying gene-environment interactions by a large set of simulated datasets as provided by the challenGENS website (http://www.challengens.org/). Once challenged against simulated datasets, the ensemble showed generally better or comparable performances than each one of its components. Moreover it behavior resulted more stable, namely less affected by the reduction of the size of dataset.

1132/F

Cognitive Flexibility is Influenced by N-Methyl-D-Aspartate Receptor Gene Variants and Modulated by Substance Dependence. *H. Zhang[1], H.R. Kranzler[2], N. Li[1], J. Poling[1], J.H. Krystal[1], J. Gelernter[1].* 1) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 2) Department of Psychiatry, University of Connecticut Health Center, Farmington, CT.

The N-methyl-D-aspartate receptors (NMDARs) are glutamate-gated ion channels, mediating excitatory neurotransmission in the brain. They play a critical role in synaptic plasticity, a cellular mechanism for learning and memory. This study investigated whether NMDAR subunit genes and their interaction with substance (alcohol or drug) dependence (SD) influenced cognitive flexibility. Five *GRIN1*, 18 *GRIN2A*, 25 *GRIN2B* and three *GRIN2C* SNPs were genotyped in 391 European Americans [EAs; 337 were affected with SD and 54 were controls] and 519 African Americans [AAs; 443 were affected SD and 76 were controls]. Their cognitive flexibility was assessed by the Wisconsin Card Sorting Test (WCST) and represented by three major indexes [perseverative responses (PR), perseverative errors (PE), and non-perseverative errors (N-PE)]. The main effects of variants and haplotypes and their interaction with SD on cognitive flexibility were examined. Among the four subunit genes, only *GRIN2B* variants exerted a main effect on cognitive flexibility. In EAs, subjects homozygous for the *GRIN2B* rs11055682 minor T-allele made significantly more PRs and PEs than those with the rs11055682 major C-allele [%PRs: 23.75±2.23 *vs*. 14.69±1.08, *P*= 0.003; %PEs: 20.18±1.71 *vs*. 13.01±0.83 , *P*=0.0002]. However, *GRIN2B*-SD interaction improved the cognitive flexibility in EAs with rs11055682 T/T genotype [%PRs: 16.39±1.71 (with SD) vs. 31.11±4.12 (without SD), *P*= 0.0003; PEs: 14.52±1.31 (with SD) vs. 25.84±3.18 (without SD), *P*=0.0002]. Two haplotypes (T-G-T and C-A-T, comprised alleles of three *GRIN2B* SNPs (rs10492141, rs7314376 and rs11055682, in one haplotype block) and both with the rs11055682 minor T-allele, were weakly associated with worse WCST performance, i.e., more PRs (*P*=0.056 and 0.044 for T-G-T and C-A-T, respectively) and PEs (*P*=0.055 and 0.036 for T-G-T and C-A-T, respectively). Similarly, the unfavorable effect of these two haplotypes was reversed by SD, leading to fewer PRs (P=0.094 and 0.071 for T-G-T and C-A-T, respectively) and PEs (P=0.052 and 0.034 for T-G-T and C-A-T, respectively). In AAs, a weak genetic effect of *GRIN2B* rs741327 on cognitive flexibility was observed (PR: P=0.039; PE: P=0.041), but there was no interactive effect of rs741327 with SD on cognitive flexibility. In summary, we found that cognitive flexibility may be influenced by GRIN2B variants and modulated by SD, with a greater genetic effect of GRIN2B on cognitive flexibility in EAs than in AAs.

1133/F

HLA-DRB1*14 allele confers a protective role to Multiple Sclerosis in a Colombian population. *M. Lattig[1], CS. Perea[1], C. Guio[2], A. Porras[4], H. Groot[1], JM. Gonzalez[3], J. Toro[1,2].* 1) Laboratorio de Genetica Humana Biological Sciences, Universidad de los Andes Bogota, Colombia; 2) Grupo Esclerosis Multiple Unidad de Neurologia Hospital Universitario Fundacion Santa Fe de Bogota Bogotá - Colombia; 3) Facultad de Medicina Universidad de los Andes Bogotá - Colombia; 4) Centro de Estudios e Investigación en Salud Hospital Universitario Fundación Santa Fe de Bogotá Bogotá-Colombia.

Multiple Sclerosis (MS [MIM 126200]), the most common demyelinating disease of the central nervous system has a prevalence characterized by geographic variation. According to Kurtzkee the prevalence of MS can be divided into three risk areas based on the disease frequency: low (<5/100.000 inhabitants), medium (5-30/100.000) and high (>30/100.000). In Bogota, an area of defined low risk for the disease, an MS prevalence rate of 4,4/100.000 was previously reported by our group. In this study we evaluated 56 MS patients and 51 controls with a female to male ratio of approximately 4:1 and a mean age of 32.2 years (s.d. 8.3 years) in patients and 35.1 years in controls (s.d. 14.1 years). Clinical evaluations were performed according to McDonald criteria and only those individuals with definite MS were included in the study. Since the HLA -DRB1*15 allele, located within the major histocompatibility complex (MHC) superlocus on chromosome 6p21, is the strongest genetic factor influencing MS susceptibility we performed a molecular analysis of the 16 HLA DRB1 alleles to determine if there was any association with any of these alleles and the disease. We also looked for associations among the alleles and clinical variables such as disease course, mean age of onset, and disability measured by the EDSS. We found no indication of association to the DRB1 alleles and MS or any of the clinical variables, but instead we found association to the HLA -DRB1*14 allele (Fisher 10.7, p=0.001) that suggests a probable protective effect of the allele and the development of MS. Since MS is a multifactorial disease where genes and environment both play important roles in the development of the disease, we propose that in Colombia, specifically in Bogota (a low prevalence zone), the exposure to high UV radiation, due to the high altitude of Bogota (2,600 meters above sea level), could directly influence Vitamin D synthesis which combined with the HLA-DRB1*14 allele may be acting as environmental protective factors of MS.

1134/F

Analysis of nuclear bioavailability of GR in response to glucocorticoid in a pediatric asthma cohort and in the Brown Norway rat model of atopy. *S. Cornejo[1,2], I. Mandeville[2], K. Tantisira[3,4], S. Weiss[3,4], B. Raby[3,4], F. Kaplan[1,2,5].* 1) Human Genetics, McGill University, Montreal, QC, Canada; 2) Montreal Children's Hospital Research Institute, Montreal, QC, Canada; 3) Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, Boston, MA, USA; 4) Harvard Medical School, Boston, MA, USA; 5) Pediatrics and Biology, McGill University, Montreal, QC, Canada.

Rationale: There is considerable variation in therapeutic response to glucocorticoids (GCs) in asthma. This variation is multifactorial, but it is clear that it has a genetic component. Defective nuclear import of the GC receptor (GR) is believed to contribute to GC insensitivity. Importin 13 (IPO13), a nuclear transport receptor cloned by us, mediates nuclear entry of GR in airway epithelial cells. We showed previously that IPO13 variation associates with airway hyperresponsiveness in a pediatric asthma cohort. **Objective:** The objective of the present study was to investigate the effect of GCs on nuclear translocation of GR in lymphoblasts derived from children in the Childhood Asthma Management Program (CAMP) (with a range of GC sensitivity) and in isolated lung cell cultures from the Brown Norway (BN) rat model of atopy. **Methods:** Lymphoblasts from patients at two ends of the spectrum of GC responsiveness and lung fibroblasts or epithelial cells from postnatal BN rats were grown in culture and treated with GC (hydrocortisone 10^{-6}M) for 15, 30, 120, 240 min. and 24 hr. GR and IPO13 mRNA levels were assessed by quantitative real-time PCR. Nuclear localization of GR and IPO13 was assessed by western blot analysis and immunofluorescence. **Results:** GC caused a mild-upregulation of GR mRNA in "good responders" which peaked at 120 min. and was followed by a dramatic down-regulation of GR mRNA expression. By contrast, in lymphoblasts from "poor responders" a very brief stimulation of GR (at 15-30min.) was followed by down-regulation of GR mRNA to baseline levels. Whereas GC addition caused a transient increase in the proportion of GR that localized to the nucleus of "poor responders", in "good responders" the proportion of nuclear GR rapidly increased and reached a plateau that was still maintained at 120 min. following GC treatment. GC had no effect on IPO13 mRNA expression in either group. However, the proportion of IPO13 protein that localized to the nucleus was significantly reduced 15 min. after GC addition and was recovered very quickly in the "good responders" but not in "poor responders". In GC-treated lung fibroblasts isolated from BN rat, nuclear import of GR was significantly greater than that observed in control Lewis rats suggesting that the BN rat modeled a GC responsive phenotype. **Conclusion:** GC insensitivity may be linked to impaired synthesis and/or nuclear translocation of GR and IPO13 in a subset of CAMP patients.

1135/F

Network analysis defines the impact of gene-physical activity interactions. *L. Parnell, C.Q. Lai, Y.C. Lee, J.M. Ordovas.* Nutrition & Genomics, JM-USDA Human Nutrition Research Center on Aging, Boston, MA.

Many genetic variants associating with clinical measures of metabolic diseases have been uncovered by genome-wide association studies. Often, those associations fail to replicate in other populations, thought largely due to genetic and environmental differences. However, a substantial number of gene-environment interactions have been described from approaches examining specific genes where environment equals diet, physical activity (PA), tobacco/alcohol use and sleep. In a gene-environment interaction, the allele-phenotype association is valid only when a lifestyle or dietary factor passes some threshold. Constructing a database of 320 such interactions involving obesity and blood lipids from disparate research reports, we combined those with 318 of our unpublished observations. Placing these triangular interactions (gene/genetic variant, phenotypic measure of obesity or dyslipidemia, and environmental modulator) into a network has revealed some startling connections. For example, extensive relationships exist between genetic factors and both HDL- and LDL-cholesterol levels that are modified by PA to the exclusion of triglycerides. Combining output from bioprocess pathway analysis, using Ingenuity®, g:Profiler and protein-protein interaction (PPI) data, with graph theory on connectivity, we identify in the physical activity-gene network key interacting modules and the nodes that bridge those modules. This network of genes harboring PA-sensitive variants and their PPIs shows an enrichment of functions: transcription, insulin signaling, appetite and response to stress. The derived network allows us to traverse from traditional biochemical pathways to specific variants of genes encoding pathway constituents to disease phenotypes and dietary/environmental factors. This will facilitate management of genetic risk of disease onset and progression by specific intervention.

Glaucoma cell line collection in the NIGMS Human Genetic Cell Repository. *L. Toji[1], B. Frederick[1], G. Spaeth[2], P. Bender[3], T. Bosley[4].* 1) Cell Repositories, Coriell Inst Med Res, Camden, NJ; 2) Wills Eye Institute, Philadelphia, PA; 3) Division of Neuroscience and Basic Behavioral Science (DNBBS), NIH, Bethesda, MD; 4) Department of Opththalmology, College of Medicine, King Saud University, Riyadh, Saudi Arabia.

Glaucoma is one of the leading causes of blindness world-wide, occurring in about 2% of individuals older than 40 years of age. A small percentage of cases have been found to be associated with mutations in the MYOC, OPTN, CYP1B1, WDR36, and OPA1 genes. About half of the individuals diagnosed with the most common type of glaucoma, primary open angle glaucoma (POAG), have a family history of glaucoma. As part of a Wills Eye Institute (WEI) study of molecular genetics of glaucoma risk factors, submission of samples from patients with POAG and age-matched spousal controls to the NIGMS Human Genetic Cell Repository for establishing lymphoblastoid cell lines (LCLs) was incorporated into the informed consent document approved by the WEI Institutional Review Board for the study. Samples were submitted to the NIGMS Repository with only a WEI code on the sample and the medical record associated with it. The medical record included a questionnaire developed at WEI and the results of an ophthalmologic exam and Humphrey visual field assessment administered to both patients and controls by a glaucoma specialist. No identifiers were provided. The Repository assigned a unique reference number for each sample, established and stored LCLs, and put the clinical data elements in the questionnaire into the database. The collection of cell cultures in the NIGMS Repository includes: 51 primary open-angle glaucoma LCLs, one primary closed-angle glaucoma LCL and one exfoliative glaucoma LCL, along with 32 controls. Samples are from African-Americans and Caucasians. Although no significant copy number variation was detected in the glaucoma group compared to the control group (Abu-Amero et al., Molecular Vision, 15:1594-98, 2009), additional molecular studies are continuing at WEI and King Saud University in Riyadh, Saudi Arabia. The NIGMS Repository database will be updated with results from future studies as they become available. This glaucoma collection and accompanying clinical data are available to investigators through the NIGMS Human Genetic Cell Repository: http://ccr@coriell.org.

Identification of Type 2 Diabetes-associated combination of SNPs using Support Vector Machine. *H.J. Ban, J.Y. Heo, K.J. Park, K.J. Park.* Bio-Medical Informatics, Korea Center for Disease Control and Prevention, Seoul, Korea.

Type 2 diabetes mellitus (T2D), a metabolic disorder characterized by insulin resistance and relative insulin deficiency, is a complex disease of major public health importance. Its incidence is rapidly increasing in the developed countries. Complex diseases are caused by interactions between multiple genes and environmental factors. Most association studies aim to identify individual susceptibility single markers using a simple disease model. Recent studies are trying to estimate the effects of multiple genes and multi-locus in genome-wide association. However, estimating the effects of association is very difficult. We aim to assess the rules for classifying diseased and normal subjects by evaluating potential gene-gene interactions in the same or distinct biological pathways. We analyzed the importance of gene-gene interactions in T2D susceptibility by investigating 408 single nucleotide polymorphisms (SNPs) in 87 genes involved in major T2D-related pathways in 462 T2D patients and 456 healthy controls from the Korean cohort studies. We evaluated the support vector machine (SVM) method to differentiate between cases and controls using SNP information in a 10-fold cross-validation test. We achieved a 65.3% prediction rate with a combination of 14 SNPs in 12 genes by using the radial basis function (RBF)-kernel SVM. Similarly, we investigated subpopulation data sets of men and women and identified different SNP combinations with the prediction rates of 70.9% and 70.6%, respectively. As the high-throughput technology for genome-wide SNPs improves, it is likely that a much higher prediction rate with biologically more interesting combination of SNPs can be acquired by using this method. Support Vector Machine based feature selection method in this research found novel association between combinations of SNPs and T2D in a Korean population.

Back to family values: Replacing population based association analysis for mapping menopause genes by a novel family approach. *P.L Pearson, S. Costa, A.M. Vianna-Morgante.* Dept of Genetics and Evolutionary Biology, University of Sao Paulo SP, Brazil.

Introduction: Association studies to detect menopause genes have been singularly unsuccessful on financial cost, number of genes found and low proportion of explained variance. An alternative based on association analyses in pooled data from small families is proposed. This approach, called Intra-Familial Association Analysis, reduces the genetic noise found in population samples by the power of family kinship combined with the simplicity of association analysis. ***Materials and methods:*** The idea emerged from studying normal menopausal age (NMA) in FMR1 pre-mutation carriers. From ~300 Fragile-X families in Sao Paulo 18 families were identified in which both menopausal pre-mutation carriers and menopausal normal sisters were present. NMA comparisons between normal and carrier sisters showed a positive correlation (r=0.63, p= 0.03), and that, while the FMR1 pre-mutation clearly reduced NMA relative to the normal siblings, the familial genetic background (FGB) was a much stronger determinant of NMA variance with relative contributions of respectively 40% and 20%. The true contribution to NMA variance by the FMR1 premutation only emerged when NMA of carriers was compared to that of their normal siblings. The idea was extended to detecting association between SNPs and NMA within families by summing NMA difference between sisters with a SNP difference between them for a given marker and between families. A computer model was developed to compare the population with the family association approach by creating a virtual population and 400 virtual families. ***Results:*** The NMA variance within families was 2-3 times smaller than the population, mainly due to ~66% SNPs becoming monomorphic and there-fore making no contribution to NMA variance within families. Further, it appeared that the family approach required far fewer data points than population analyses to achieve significant association. Arguably the most important advantage of the family approach is that it corrects for huge differences in genetic background between families. ***Conclusions:*** The method permits use of 2 or 3 child families and no parents are required. It exhibits far more power in detecting association than population analyses for mild affect alleles, which will help map genes that currently remain undiscovered using population samples. In principle, the approach can also be adapted for analysis of other quantitative traits such as height and intelligence. ***Support: FAPESP and CNPq***.

Comparison of pooled allelic ratios (CoPAR) analysis: an efficient method for mapping genetic traits in extended pedigrees. *S.B. Bleyl[1,2], N. Matsunami[3], J. Stevens[3], C.B. Arrington[1], N.E. Bowles[1], T. Tuohy[4], M. Jahromi[4], D.W. Neklason[4], R.W. Burt[5], M.F. Leppert[3], J.D. Schiffman[4].* 1) Dept Pediatrics; 2) Dept Neurobiol Anat; 3) Dept Human Genetics; 4) Dept Oncological Sci; 5) Dept Medicine. University of Utah, Salt Lake City, UT.

Among various hurdles to overcome when mapping genes for complex disorders (including many birth defects), one of the most significant is genetic heterogeneity, or the existence of multiple susceptibility loci that contribute to the phenotype in unpredictable combinations. Typical approaches to locate genes for complex disorders, such as genome wide association studies (GWAS), must utilize large cohorts of affected and control individuals to outweigh the negative effects of this problem. An alternative approach takes advantage of large pedigrees in which multiple individuals affected with a complex trait share a common ancestor. Extended kindreds for a wide variety of multifactorial or low penetrance conditions can be ascertained using family history databases like the Utah Population database (UPDB). In such large families, any single occurrence of the disease is likely due to multiple disparate factors. However one of these factors, a genetic susceptibility, can be assumed to segregate to all affected individuals within a block haplotype that is identical by descent (IBD). We describe an efficient and economical method for identifying disease loci in large kindreds segregating susceptibility genes for complex genetic disorders by comparison of pooled allelic ratios (CoPAR) between affected and control groups. This technique is based on the concept that the allele frequencies of SNPs within haplotype blocks inherited from a common ancestor (IBD haplotype blocks) shared among all affected individuals in an extended pedigree (i.e., a 'linked' haplotype) will deviate from allele frequencies in a control population with a similar ethnic background. This excess of linked alleles in the affected group can be identified using either individual genotypes and calculating allele ratios or using pooled DNA in a single sample and directly measuring allele ratios for each SNP. The latter approach offers a dramatic cost-savings in the number of SNP chips needed to perform a genome-wide survey, which could be as few as two: one for the affected pool and one for the control pool. We demonstrate proof of principle for this method in several disorders, highlight its strengths and weaknesses and discuss possible future uses.

Genetic contributions to BMI and related conditions. *J. Derringer[1], R.F. Krueger[1], R.A. Grucza[2].* 1) Psychology, University of Minnesota, Minneapolis, MN; 2) Psychiatry, Washington University, St. Louis, MO.

Obesity, as typically measured by body mass index (BMI), is a major current public health concern. A recent report in the Journal of the American Medical Association shows rates of obesity in the United States to be currently relatively stable in adults, at 32.2% in men and 35.5% in women. In addition, BMI is one of the most robust predictors of increased morbidity and mortality. BMI is itself highly heritable, with approximately 50-70% of its variance accounted for by additive genetic factors. Previous BMI GWAS and meta-analytic efforts have identified several reliable, replicable variants associated with BMI, such as those located in the genes FTO and MC4R. However, these specific variants explain a very small proportion of variance in BMI, and the extent to which BMI-related variants are associated with BMI specifically, or with other commonly co-morbid conditions in general, is currently largely unknown. The goal of our study was to examine the overlap among genetic risk factors for BMI and other related conditions, using a recently described genetic scoring approach (e.g. Purcell et al., 2009, Nature). We split an initial sample of over 9,000 individuals, all of whom had been genotyped on the Affymetrix 6.0 platform, into "discovery" (90% of the sample) and "testing" (10% of the sample) sub-samples. A GWAS was initially run in the discovery sample. Aggregating across SNPs whose GWAS p-value in the discovery sample fell below increasing thresholds created genetic "risk" scores. For each individual in the testing sample, SNPs were weighted according to their discovery sample regression weights and summed into a single summary score (for each p-value threshold). This score was then correlated with BMI within the testing sample, to estimate the proportion of variance explainable by this aggregate genetic risk score. The BMI-derived risk scores in the testing sample were then correlated with BMI-related conditions, including diabetes, hypertension, high cholesterol, and alcohol use, to examine the extent to which this genetic score accounted for BMI-specific variance, or variance common across multiple related phenotypes.

1141/F

Protein tyrosine phosphatase receptor type G (PTPRG) influences the correlated architecture of hepatic steatosis and metabolic phenotypes in the NHLBI Family Heart Study (FamHS). *M.F. Feitosa[1], M.K. Wojczynski[1], K.E. North[2, 3], J. Wu[1], M.A Province[1], J.J. Carr[4], I.B. Borecki[1].* 1) Division of Statistical Genomics, Washington University, Saint Louis, MO; 2) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 3) Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC; 4) University Health Sciences Image Lab, Wake Forest University, Winston Salem, NC.

Non-alcoholic fatty liver disease (NAFLD) is a metabolic disorder characterized by fatty infiltration of the liver in the absence of alcohol consumption, and it presents as a disease spectrum from fatty liver (steatosis), to nonalcoholic steatohepatitis, to fibrosis. Liver attenuation, measured using computed tomography (CT), is a quantitative measure that is inversely related to the amount of fat in the liver and is highly correlated (r^2= 0.92) with the macrovesicular hepatic steatosis in humans. Features of metabolic syndrome, including obesity, insulin resistance, and hypertriglyceridemia are associated with NAFLD; LA is inversely correlated with insulin resistance (HOMA-IR): r^2= -0.38, triglycerides (TG): r^2= -0.25, hypertension (HBP: systolic ≥ 140 mmHg or diastolic ≥ 90 mm Hg blood pressure or taking antihypertensive medication): r^2= -0.14, and percent body fat (PBF): r^2= -0.32, suggesting shared underlying determinants. A search for genetic variants that account for some of the correlated architecture was undertaken by considering LA with each of these risk factor variables using a correlated meta-analysis of 2,679 subjects of European descent in the FamHS. Phenotypes were adjusted by age, sex, clinical centers, and principal components for stratification (EIGENSTRAT); the LA was also adjusted for CT phantom measurements and alcohol consumption. A genomewide (GW) scan of ~2.5 million imputed SNPs was undertaken, correcting for the non-independence of family members and of the paired scans. Variants of PTPRG (3p14-21) were implicated in LA with several phenotypes including HOMA-IR (rs349174: meta-p=4.8E-08), TG (rs1848417: meta-p=4.9E-08), HBP (rs1848417: meta-p=2.0E-08) and PBF (rs6764654: meta-p=8.9E-10), meeting a GW significance criterion. PTPRG encodes a member of the protein tyrosine phosphatase (PTP) family and is known to be signaling molecules that regulate a variety of cellular processes including cell growth, differentiation, mitotic cycle, oncogenic transformation. Some members of PTP have been previously suggested to have a role in insulin and leptin signaling.

Genome-wide meta analysis of gender heterogeneity identifies sexually dimorphic variants associated with human anthropometric traits. *J.C. Randall on behalf of the GIANT (Genetic Investigation of ANthropmetric Traits) Consortium.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Genome-wide association studies (GWAS) of complex traits such as bone density, Schizophrenia, and body shape have previously reported gender-specific variants, but these were typically identified in overall analyses of men and women together, and gender-specific analyses were performed only after replication of the overall signal. Though these studies establish the existence of sexually dimorphic genetic variants affecting complex traits, they were not well-powered to detect variants with the most significant between-gender heterogeneity.

To increase power to detect sexually dimorphic variants influencing human anthropometric traits, we conducted gender-specific meta-analyses of 58 GWAS comprising 133,723 individuals (60,586 men & 73,137 women). Each study stratified by gender and used the additive model to test ~2.8M imputed SNPs for association with 9 anthropometric measures: height, weight, body mass index (BMI), waist circumference (WC), hip circumference (HC), waist-hip ratio (WHR), WC adjusted for BMI (WCadjBMI), HC adjusted for BMI (HCadjBMI), and WHR adjusted for BMI (WHRadjBMI). We performed fixed-effects inverse-variance meta-analyses and pruned the resulting lists of markers using the fine-scale genetic map data from HapMap to define loci (SNPs within 0.2cM are considered part of the same locus).

To maximize power, we pursued two parallel strategies to scan for sexually dimorphic variants of two classes: those with concordant effect direction (CED) and those with opposite effect direction (OED). For CED, we controlled for false discovery rate (FDR) in the association signal of men or women at 5%, filtered out previously reported loci, and took the rest forward into additional samples for replication of the gender-specific association signal. For OED, we performed genome-wide gender heterogeneity testing, comparing the effect estimates in men and women across all 9 traits and controlling for FDR at 20%, taking all loci forward into additional samples for replication of the gender heterogeneity signal.

Work continues on completing our replication effort, but preliminary results from the discovery phase and taken forward into replication include promising candidates, such as those implicated in developmental signaling (*ASXL2*, *DAAM1*, *IGFL2*, & *SOX21*), the control of fat metabolism and insulin sensitivity (*ADIPOQ*), regulation of adipocyte differentiation (*PPARG*), and Bardet-Biedl syndrome (*BBS7*), whose symptoms include short stature and obesity.

1143/F

Molecular reclassification of Crohn's disease by cluster analysis of genetic variants. *I. Cleynen[1], J.M. Mahachie John[2,3], L. Henckaerts[4], W. Van Moerkercke[1], P. Rutgeerts[1], K. Van Steen[2,3], S. Vermeire[1].* 1) Department of Gastroenterology, KU Leuven, Leuven, Belgium; 2) Systems and Modeling Unit, Department of Electrical Engineering and Computer Science, University of Liège, Liège, Belgium; 3) Bioinformatics and Modeling, GIGA-R, University of Liège, Liège, Belgium; 4) Department of Medicine, UZ Leuven, Leuven, Belgium.

Crohn's Disease (CD) has a heterogeneous presentation, and is typically being classified according to extent and location of disease. The genetic susceptibility to CD is well known and genome-wide association scans (GWAS) and meta-analysis thereof have identified over 30 susceptibility loci. Except for the correlation between ileal CD and NOD2 mutations, efforts in trying to link CD genetics to clinical subphenotypes have not been very successful. We hypothesized that the large number of confirmed genetic variants enables (better) classification of CD patients. Patient and control genotypes of 46 SNPs identified from CD GWAS were analyzed separately by Latent Class Analysis (LCA) to look for molecular subgroups. Six molecular subgroups were identified in CD patients, which were significantly different from the five subgroups found in healthy controls. The identified CD clusters are therefore likely to contribute to disease pathogenesis. The SNPs determining the molecular subgroups do not cluster in specific pathways, pointing to the existence of disease susceptibility pathways leading to CD overall (autophagy, IL23/Th17), as opposed to single disease modifying genes that define the specific disease subtype. Although differences in prevalence of disease location and behavior could be observed among the CD clusters, Random Forest analysis showed that patients could not be allocated to one of the 6 molecular subgroups, based on the typically used clinical parameters alone. This suggests that the currently used clinical subphenotypes are imperfect, and need to be supplemented or amended. This approach serves as a first step to reclassify Crohn's disease. The used technique can be applied to other common complex diseases as well, and will help to complete patient characterization, in order to evolve towards personalized medicine.

1144/F

Genome scan for spelling deficits: effects of verbal IQ on models of transmission and trait gene localization. *W.H. Raskind[1,2], K. Rubenstein[3], M. Matsushita[1], V.W. Berninger[4], E.M. Wijsman[1,3].* 1) Departments of Medicine; 2) Psychiatry and Behavioral Sciences; 3) Biostatistics; 4) and Educational Psychology, Univ of Washington, Seattle, WA.

Dyslexia is a complex learning disability with strong evidence for a genetic basis. Deficits in fluent oral reading and spelling persist into adulthood for many individuals with a childhood diagnosis, even after other manifestations have been corrected. Thus spelling deficits are a key aspect of dyslexia and are useful as phenotypes in both children and adults. Strategies that may be useful for dissecting the genetic basis of dyslexia include study of component phenotypes, which may simplify the underlying genetic complexity, and use of an analytic approach that accounts for the multilocus nature of the trait to guide the investigation and increase power to detect individual loci. Here we present results of a genetic analysis of spelling disability as a component phenotype on a sample of 260 2-4 generation pedigrees (2040 individuals) selected through a dyslexic proband. Total spelling scores from the WIAT and WRAT3 spelling tests were used, after adjustment for age, cohort, and gender. We also evaluated scores with and without adjustment for verbal IQ (VIQ). We used an MCMC-based oligogenic trait model for both an initial segregation analysis, and a subsequent joint segregation and linkage analysis in a marker-based genome scan. Bayes' factors (BF) for linkage and marker-simulation under the hypothesis of no linkage were used for evaluation of evidence for linkage. Oligogenic segregation analysis identified a small number of quantitative trait locus models (QTLs) that are sufficient to explain the inheritance of the VIQ-adjusted and unadjusted traits in our sample, with one prominent QTL for the VIQ-unadjusted, and two prominent QTLs for the VIQ-adjusted trait. Each of these QTLs was recessive for low spelling scores. In the genome scans, each of these QTLs mapped to one of four genomic regions: the VIQ-unadjusted trait to chromosome (chr) 6 (max BF=35, p<0.005, 167 cM), and the VIQ-adjusted trait to chr 2, 9, and 15 (max BF=22, 19, and 25, at 145, 155, and 23 cM, respectively). For the VIQ-adjusted trait, each of the 2 QTLs from the segregation analyses mapped separately to each of chr 9 and 15, and both QTLs mapped to the region on chr 2. Because the genomic locations of the mapped QTLs vary as a function of whether a VIQ adjustment is included, these results suggest mediation of a genetic basis for spelling deficits through both VIQ-related and unrelated pathways.

miRNA biomarkers for detecting lung diseases. *A.C. Keller[1], P. Leidinger[2], E. Meese[2].* 1) Biomarker Discovery Center Heidelberg, Heidelberg, Germany; 2) Deparmtne of Human Genetics, Saarland University, Homburg, Germany.

Purpose Perturbed expression of non-coding RNAs is associated with various pathological cellular processes. The miRNome of both, tissues and body fluids promises to contribute to better diagnosis and prognosis of diseases. Aim of this study is to evaluate blood and serum as source of specific biomarkers for detecting lung diseases including lung cancer and chronic obsessive pulmonary diseases (COPD). Methods We profiled the miRNome, containing about 900 miRNAs, from blood and serum samples of individuals using a microarray platform and validated the results using qRT-PCR. Altogether, the cohort contains over 800 samples including a variety of cancer and non-cancer diseases as well as unaffected controls. Results The detected profiles in lung cancer and COPD could be separated from healthy controls and non-lung diseased samples with high accuracy. It was even possible to separate lung cancer from COPD as a non-cancerous lung disease with an accuracy, specificity and sensitivity of 90.4%, 89.2%, and 91.7%, respectively. By using a restricted subset of six highly relevant markers, accuracy still was as high as 86.3%. Moreover, the comparison of serum profiles to autologous blood profiles revealed significantly different profiles. Serum of lung cancer patients, collected in a retrospective study indicated a pre-symptomatic profile of lung cancer. Conclusion Taken together, our comprehensive results on miRNome wide profiling of serum and blood samples impressively outlines the potential of these small and stable molecules for non-invasive detection of lung cancer samples from unaffected controls and COPD patients and furthermore indicates pre-symptomatic serum profiles in lung cancer patients.

Finding the Missing Heritability of a Common Disease: Multi-Allelic Copy-Number Variation of Complement C4A, and HLA-DRB1 alleles DR3 and DR2 Are Common, Medium-to-High, and Additive Risk Factors for Human Systemic Lupus Erythematosus (SLE) of European Ancestry. *Y.L. Wu[1], E. Lundström[2], C.C. Liu[3], Y. Yang[1], B.P. Tsao[4], E.K. Chung[1], B. Zhou[1], K.N. Jones[1], H.N. Nagaraja[5], G.C. Higgins[1], C.H. Spencer[1], H.I. Brunner[6], D.J. Birmingham[7], B.H. Rovin[7], I. Gunnarsson[2], E. Svenungsson[2], J.M. Ahearn[3], L.A. Hebert[7], L. Padyukov[2], C.Y. Yu[1].* 1) The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) Department of Medicine, Karolinska Institutet, Karolinska Hospital, SE-171 76, Stockholm, Sweden; 3) Lupus Center of Excellence, University of Pittsburgh School of the Health Sciences, Pittsburgh, PA; 4) Division of Rheumatology, Department of Medicine, University of California, Los Angeles, CA; 5) Department of Statistics, The Ohio State University, Columbus, OH; 6) Division of Rheumatology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 7) Division of Nephrology, Department of Internal Medicine, The Ohio State University, Columbus, OH.

The MHC at chromosome 6p21.3 has the strongest association with human SLE. Because of complex polymorphisms, multi-allelic copy-number variations (CNV) and strong linkage disequilibrium, identifying SLE disease causal variant(s) in the MHC has been difficult. This study aims to dissect the roles of HLA-DRB1 polymorphisms and complement C4 CNVs, separated by 544 kb in the MHC, in genetic risks of SLE. The study population included 744 SLE patients and 760 unrelated healthy controls of European ancestry, recruited mainly from mid-western US (patients/controls: 476/461) and Sweden (268/299). Copy-numbers of total C4, C4A and C4B were determined by genomic Southern blot analyses and real-time qPCR with double standard-curve calibrations. Two-digit genotypings for HLA-DRB1 were performed by 20 independent SSP-PCRs for each sample. χ^2 analyses, 2-tailed t-tests, and multiple logistic regression analyses (MLRA) were performed to calculate p-values, odds ratios (OR) and identify independent risk factors for SLE. The gene copy-number (GCN) of C4A in a diploid genome varies from 0 to 6, with the norm at 2 copies. Low C4A GCN (0 or 1 copy), the presence of HLA-DRB1 alleles DR3 and DR2 together occurred in 71.2% of SLE patients, compared to 53.2% of controls ($p=7.1x10^{-13}$). MLRA revealed that each of these three parameters can be independent risk factors for SLE in the US and Swedish study cohorts, separately and combined. Using subjects with non-low C4A, non-DR3 and non-DR2 as the reference group, the OR for SLE with low C4A only was 2.22 (p=0.031), DR3+ only was 1.81 (p=0.004), and DR2+ only was 1.65 (p=0.0002). Notably, the ORs increased to 4.16 ($p=2.5x10^{-8}$) for subjects with all three parameters, 2.80 ($p=3.6x10^{-12}$) with low C4A and DR3, and 2.71 (p=0.037) with low C4A and DR2. In the US cohort, a clear gene-dosage effect was present for association of C4A-CNV with SLE from high to moderate risk, to neutrality and then protection when copy-numbers increased from 0 to 1, 2, and 3, respectively (OR: 6.07®0.41). In the Swedish cohort, an autosomal dominant effect was observable: subjects with 0 and 1 copy were at risk (OR: 2.3-2.4), and with 2 and 3 copies were protected (OR: 0.61-0.66). In conclusion, C4A-CNV, HLA-DR3 and HLA-DR2 are common variants with medium to high effects for SLE, which fills in part of the missing link of heritability between common variants with low effects and rare variants with high effects for a common disease.

1147/F

Overlap between loci influencing risk of type 2 diabetes and fasting glucose through large-scale replication using "Metabochip": preliminary results. *I. Prokopenko[1,2], A. Mahajan[1,3], V. Lagou[1], A. Kumar[1,4], N. Robertson[1], N.W. Rayner[1], R. Mägi[1], C. Groves[2], A.J. Bennett[2], S. Wiltshire[1], J. Trakalo[1], S.E. Hunt[7], K. Stirrups[7], G. Mirza[1], D. Buck[1], K. Zhou[5], C.N.A. Palmer[5], A.D. Morris[5], T. Frayling[6], A. Hattersley[6], M. Weedon[6], J. Perry[6], C. Langford[7], S. Potter[7], P. Deloukas[7], P.J. Donnelly[1], A.P. Morris[1], C.M. Lindgren[1,2], M.I. McCarthy[1,2], Wellcome Trust Case Control Consortium, the DIAGRAM consortium, MAGIC.* 1) WTCHG, Univ Oxford, Oxford, United Kingdom; 2) OCDEM, Univ Oxford, Oxford, United Kingdom; 3) Institute of Genomics and Integrative Biology, CSIR, Delhi, India; 4) Swiss Tropical and Public Health Institute, University of Basel, Switzerland; 5) Biomedical Research Institute, University of Dundee, Ninewells Hospital & Medical School, Dundee, United Kingdom; 6) Institute of Biomedical and Clinical Science, Penninsular Medical School, Exeter, United Kingdom; 7) Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

Complex relationships exist between disease traits and related continuous endophenotypes. Among 16 loci influencing fasting glucose (FG) identified in healthy non-diabetic individuals by the MAGIC meta-analysis, eight were shown to be associated with type 2 diabetes (T2D) at genome wide significance levels ($P<5x10^{-8}$). However, the extent to which other common variants with a putative role on FG levels have an impact on T2D risk has not been determined. The "Metabochip", a custom-made iSELECT array (~195,000 SNPs), supports large-scale follow-up of putative associations for metabolic (including FG), cardiovascular traits and T2D. This analysis is based on genotype data, called using GenCallv1.1, from 4,434 T2D cases and 7,932 controls from the UK T2D Genetics Consortium, the Warren 2 collection and 1958 British Birth Cohort. Additional T2D *in silico* GWA results were available from the DIAGRAM consortium (12,057 cases, 56,071 controls of European-descent). After excluding known T2D loci, we analysed 4,621 high-quality, top-ranked ($10^{-75}<P<0.02$) independent SNPs selected for the Metabochip from the stage 1 discovery meta-analysis for FG performed by MAGIC investigators. Association analyses to determine the effects of these variants on T2D-risk were performed within each sample under an additive model assuming allelic effects and combined using fixed effects meta-analysis in up to 16,491 T2D cases and 64,003 controls. Overall 2,657 of 4,621 SNPs (57.5%) showed directional consistency of association between increased FG levels and higher T2D risk (binomial $p<10^{-24}$). Of these 2,657, 308 showed nominal association with T2D ($p<0.05$, same effect direction) whereas only 90 of the total of 4,621 SNPs showed $p<0.05$ in the opposite direction (binomial $p<10^{-43}$). Only 2 Metabochip loci prioritised for FG showed suggestive association with T2D: at *CCDC88C* (rs17803791, $P=4x10^{-7}$, MAGIC FG $P=8x10^{-3}$) and near *TOP1* (rs6072299, $P=1x10^{-6}$, MAGIC FG $P=3x10^{-4}$). For both, the glucose raising allele contributed to an increased risk of T2D. In this study, we examined SNPs showing putative associations with FG in healthy non-diabetic individuals and tested them for their impact on T2D risk, demonstrating a substantial degree of concordant evidence for association. Joint modelling of FG and T2D may help to uncover novel loci contributing common effects to both traits.

Explaining the "missing heritability" of osteoporosis: contributions of ESR1 and LRP4 polymorphisms to fracture susceptibity in families. *B.N.H. Tran[1], S.C. Nguyen[1], N.D. Nguyen[1], J.R. Center[1,2], J.A. Eisman[1,3], T.V. Nguyen[1,2,3].* 1) Osteoporosis and Bone Biology, Garvan Institute of Medical Research, Darlinghurst, NSW, Australia; 2) School of Public Health and Community Medicine, University of New South Wales, Kensington, NSW, Australia; 3) St Vincent's Hospital and St Vincent's Clinical School, Sydney, NSW, Australia.

Genetic factors could account for up to 50% of fracture liability, but single nucleotide polymorphisms (SNPs) identified by genomewide association studies (GWAS) have explained less than 5% of the genetic variance in fracture, which raises the question of "missing heritability". We hypothesize that the part of the "missing heritability" can be explained by considering the effects of these SNPs within families. This study was designed to test the hypothesis by examining the contribution of SNPs to fracture susceptibility in within families.

The study was undertaken as part of the on-going Dubbo Osteoporosis Genetics Study (DOGS), which involved 53 families, with 147 individuals aged 18 and 80 years. Seventy-four SNPs in 34 genes were genotyped. Bone mineral density (BMD, GE-Lunar Corp, WI, USA) at the femoral neck and lumbar spine was measured prior to the fracture event. Fracture was ascertained by X ray report during 1990 and 2009. The association between fracture risk and SNPs was analysed by the Genomewide Association Analyses with Family (GWAF) program.

Four genes, including SPTBN1, PRDM12, RPS6K5, and CHD20 genes, were found to be associated with variation in femoral neck BMD. The 4 genes explained 6% variance in femoral neck BMD. During the follow-up period, 13 individuals (9.7%) had sustained fracture. Two SNPs in the ESR1 gene (rs4870044, rs712219) and 3 SNPs in the LRP4 gene (rs10838635, rs7935346, and rs7121418) were independently associated with fracture risk under the dominant genetic model. The relative risk of fracture associated with these variants ranged between 1.73 and 1.87 ($P < 0.001$). The association was independent of age, BMD, and gender. The area under the receiver operating characteristic curve (AUC) was 0.77 for a model with age, BMD and gender as predictors; incorporation of the 4 variants into the model increased the AUC value to 0.93 ($P < 0.001$).

The results are consistent with the hypothesis that a large part of "missing heritability" can be explained by analysing the effect of genes within families rather than in unrelated individuals. These results also indicate that genetic factors can enhance the prognosis of fracture over and above traditional clinical risk factors.

The missing genetic variation: beyond the additive model. *L. Atwood, M. Phillips, N. Heard-Costa.* Framingham Heart Study, Boston Univ Sch Med, Boston, MA.

The additive model is ubiquitous in genome wide association analysis (GWAS) of quantitative traits. Here we compare the additive model to a more general model which assumes the entire trait sample is distributed as a mixture of normal distributions (a distribution for each genotype). We compare the performance of these two models on body mass index (BMI) measured in 1114 participants in the Framingham Heart Study by performing a GWAS using 547,554 SNPs. To remove any concern about inflation of the genetic signal we computed the null distribution empirically (an empirical null distribution is considered the gold standard of statistical testing). The null distribution (1000 replicates) showed that the genome wide p=0.05 significance level was at a nominal p=0.000000126 (-log(p)=6.9). In order to insure stable parameter estimates, we only analyzed those SNPs with at least 30 genotypes in each genotypic group.

The largest -log(p) from the additive model was 5.5. The mixture model found 207 SNPs with -log(p) > 6.9, representing 122 independent loci. The largest -log(p) was 12.7 and 65 SNPs showed -log(p) > 8.0. The additive model did find an average -log(p) of 1.6 for these 207 SNPs, thus showing a small degree of robustness. Parameter estimates for all significant SNPs showed a large degree of non-additive effects with 69% (142/207) being either dominant or recessive.

A major difference between the mixture approach and additive approach is that the mixture approach models residual variation in a genotype specific manner whereas the additive approach models it as a single error variance. Theoretically, modeling genotype specific variation allows the effect of the SNP to show some dependence on its genetic and environmental context (the additive approach can only model independence). To explore this difference, we repeated the mixture GWAS with the genotype specific variation removed. The genetic signal was greatly reduced; the largest -log(p) was 6.2. We infer that the apparent added power comes from modeling the genotype specific variation, i.e. relaxing the independence assumption.

1150/F

An uncommon SNP strongly associated with adiponectin levels in Filipinos is indirectly associated with a GWA signal 800 kb away at the ADIPOQ gene. *D.C. Croteau-Chonka[1], Y. Wu[1], Y. Li[1,2], L.A. Lange[1], C.W. Kuzawa[3,4], T.W. McDade[3,4], M. Laakso[5], J.B. Borja[6], L.S. Adair[7], E.M. Lange[1,2], K.L. Mohlke[1].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 3) Department of Anthropology, Northwestern University, Evanston, IL; 4) Cells 2 Society: The Center for Social Disparities and Health at the Institute for Policy Research, Northwestern University, Evanston, IL; 5) Department of Medicine, University of Eastern Finland, Kuopio, Finland; 6) Office of Population Studies, Inc., University of San Carlos, Cebu City, Philippines; 7) Department of Nutrition, University of North Carolina, Chapel Hill, NC.

Adiponectin is a protein hormone responsible for regulating glucose and fat metabolism. Multiple common genetic variants in the *ADIPOQ* gene region have been associated with adiponectin, but few causal variants have been suggested. In a cohort of 1,776 Filipino mothers from the Cebu Longitudinal Health and Nutrition Survey (CLHNS), we found a common SNP in *ADIPOQ* (rs864265, minor allele frequency [MAF] = 0.12) to be associated with adiponectin levels in genome-wide analysis ($P = 3.7 \times 10^{-9}$). Further analysis identified evidence for an uncommon haplotype at rs11924390-rs864265 (C-T frequency = 0.05) that showed markedly stronger evidence of association with lower adiponectin ($P < 1 \times 10^{-24}$). We now detect that a single uncommon SNP (MAF = 0.03) located nearly 800 kb from rs864265, downstream of the body mass index-associated *ETV5* gene, was strongly associated with adiponectin in the 1,725 young adult offspring of the CLHNS mothers ($P = 2.9 \times 10^{-15}$) and in a combined analysis of mothers and offspring accounting for relatedness ($P = 1.1 \times 10^{-15}$). This *ETV5* SNP is in low linkage disequilibrium with rs864265 ($D' = 0.37$) in the CLHNS offspring and was monomorphic in >2,000 samples of northern European ancestry. Conditional analyses using phased haplotypes indicated that neither the rs11924390-rs864265 haplotype nor the *ETV5* variant fully explained the observed association between adiponectin and this locus. Comprehensive imputation of >2,800 SNPs in a 2 Mb region encompassing *ADIPOQ* using 1000 Genomes Project reference haplotypes from CHB, JPT, and CEU revealed no variants that were more strongly associated with adiponectin in the mothers, suggesting that known variants do not completely explain the observed association. Ongoing sequencing of the *ADIPOQ* gene region may detect additional candidate functional variants. These data suggest that the *ETV5* SNP is present on a long haplotype (>800 kb) that contains one or more unknown rare SNPs that may be responsible for some of the observed evidence of association at the *ADIPOQ* locus.

1151/F

Predicting Progression to Advanced Age-Related Macular Degeneration Using a Polygenic Score. *V. Gateva[1], T. Bhangale[2], X. Sun[1], W. Ortmann[1], L.A. Damico-Beyer[3], E. Strauss[3], M. Friesenhahn[4], T.W. Behrens[1], R.R. Graham[1].* 1) Department of Human Genetics, Genentech, Inc, San Francisco, CA; 2) Department of Bioinformatics, Genentech, Inc, San Francisco, CA; 3) Early Development, Genentech, Inc, San Francisco, CA; 4) Department of Biostatistics, Genentech, Inc, San Francisco, CA.

Age-Related Macular Degeneration (AMD) is a slowly progressive degenerative disease that culminates in loss of central vision. Only 18% of patients with intermediate AMD (Category 3) will progress to advanced AMD over 5 years. Identifying individuals at higher risk of rapid progression would enable clinical trials to test novel AMD therapies, identify a patient population amenable to treatment with intravitreal therapeutics, and provide insight into pathogenic pathways. We first confirmed the ability of 7 known AMD genes to enrich for progression to advanced AMD in 764 individuals with Intermediate AMD (category 3) from the Age-Related Eye Disease natural history study. Using a composite score of the 7 known AMD risk alleles, we identified a population (14% of the intermediate AMD population) with a progression rate of 31% at 5 yrs, a 1.6 fold increase over the unselected population. We next tested the hypothesis that a polygenic score computed using thousands of common variants could be predictive of progression to advanced AMD. We conducted a genome-wide association study on 925 advanced AMD cases and 7,863 healthy controls of European descent. We created a polygenic score composed of 10,616 independent loci with p-value < 0.10 from the genome-wide association scan. Using 10,616 independent SNPs with p-value <0.1 from this study we computed polygenic score for each of 764 individuals with Intermediate AMD (category 3) as the average sum of the number of risk alleles (0, 1 or 2) at the SNP weighted by the log odds ratio for that SNP. Individuals with high polygenic score (14% of the intermediate AMD population) have a 47% risk of progression at 5 yrs compared to only 13 % risk for the rest of the intermediate AMD population. This represents a 2.6 fold increase over the unselected population, and a significant improvement in predictive power to a score calculayed using 7 confirmed AMD loci. Our results demonstrate that thousands of common variants can be predictive of AMD progression, and suggests that hundreds of AMD risk loci of modest individual effects contribute to the heritability of AMD.

1152/F

Validity of the "missing heritability" concept. *F. Clerget-Darpoux.* INSERM UMRS 669, Univ Paris-Sud, Villejuif, France.

Over the last three years Genome Wide Association Studies (GWAS) identified many SNPs associated with multifactorial diseases. The information provided by these SNPs was quantified as a proportion of explained heritability and, in line with this terminology, the information yet to be identified was termed "missing heritability". These measurements presuppose that the genetic factors are numerous, each with minor, independent effects, and that no interaction with environmental factors is involved. In order to correctly estimate missing heritability these assumptions must be correct. However, interaction between genes involved in disease susceptibility is very likely and, in our view, demonstrating its existence statistically is complicated due to the fact that the SNPs identified through GWAS poorly represent the gene effects in terms of differential risks. This is illustrated in Multiple Sclerosis where the joint information from two SNPs of IL2RA corresponds to an almost 4-fold differential risk between the least and most at-risk genotypes, whereas it is less than 1.6 for the SNP reported in the literature as the most associated. Similarly for Rheumatoid Arthritis, the differential risk between the least and most at-risk genotype is 2.7 for the PTPN22 SNP most strongly associated, but reached 4.7 for a combination of 3 SNPs in this gene. In both cases, the linkage information provided by the Identity By Descent allele shared between affected sibs within the family is compatible with our gene model but not with the risk hierarchy corresponding to the single SNPs reported in the literature. A good hierarchy of risk for a gene must be established to test the potential interaction between two genes and to reconstruct the entire physio-pathological pathway. In addition, in contrast to monogenic diseases or monogenic sub-entities of a disease, the primary cause(s) of a multifactorial disease may be non-genetic. This is clear for some diseases for which the environmental factor is well known. Thus, for leprosy, the genetic differences described for a predisposition to develop this disease only come into play when the Hansen bacterium is encountered. For most multifactorial diseases, although the environmental factors are unknown, exposure to them may be essential in disease initiation. Thus, the missing information is not generally measurable although it may be the key to disease etiology.

1153/F

Sequencing and fine-mapping within known loci identify new associated variants, implicates causal genes, and increases the explained heritable variation in fetal hemoglobin levels. *G. Galarneau[1], C. Palmer[2,3], V. Sankaran[4,5], S. Orkin[4,5], J. Hirschhorn[2,3], G. Lettre[1,6].* 1) Montreal Heart Institute, Montréal, Québec, Canada; 2) Divisions of Genetics and Endocrinology and Program in Genomics, Children's Hospital Boston, Boston, MA, USA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA; 4) Division of Hematology/Oncology, Children's Hospital Boston, Boston, MA, USA; 5) Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA, USA; 6) Département de Médecine, Université de Montréal, Montréal, Québec, Canada.

Fetal hemoglobin (HbF) is a strong and heritable modifier of disease severity for patients with sickle cell disease (SCD) and β-thalassemia: patients with high HbF levels have less severe complications and a longer life expectancy. Three loci - BCL11A on chromosome 2, HBS1L-MYB on chromosome 6, and the β-globin locus on chromosome 11 - carry common DNA sequence variants that modulate HbF levels in population of European and African ancestry. To identify additional variants, fine-map association signals, and potentially pinpoint causal genes at these loci, we re-sequenced 175.2 kb from these three loci in 190 individuals, including 70 African-American SCD patients. We discovered 1,489 DNA sequence variants, of which 910 were previously unreported. We genotyped 88 common SNPs and nine rare missense mutations in 1,100 African-American SCD patients from the Cooperative Study of Sickle Cell Disease (CSSCD). We identified one additional independent HbF signal at BCL11A, refined the HbF signals at HBS1L-MYB and the β-globin locus, and ruled out the previously proposed rs7482144-XmnI polymorphism upstream of HBG2 as causal for HbF regulation. We also found rare missense mutations in MYB that strongly influence HbF levels, suggesting that MYB, rather than the neighboring HBS1L gene, plays a causal role in influencing HbF levels in SCD patients. Our results provide important insights into the regulation of a clinically important trait for diseases that affect millions of individuals worldwide. Moreover, they provide a proof-of-principle of the utility of fine-mapping known associated loci to address the "missing heritability" question: our results increase the HbF phenotypic variance explained in African-American SCD patients from 21.8% to 27.8%, with heritable variation explained increasing from 24.5-36.3% to 31.2-46.3%.

1154/F

Epidemiologic Architecture for Genes Linked to Environment (EAGLE): Association of ABCG2 Q141K with Uric Acid Concentration and Gout in the National Health and Nutrition Examination Surveys. *K.L. Spencer, K. Glenn, K. Brown-Gentry, D. Murdock, J.L. Haines, M.D. Ritchie, D.C. Crawford.* Ctr Human Genetics Res, Vanderbilt Univ, Nashville, TN.

Uric acid levels are highly heritable, and increased levels are strongly associated with gout, a common form of arthritis affecting nearly 3 million Americans. A recent meta-analysis of more than 28,000 people has firmly established that the Q141K rs2231142 polymorphism in the urate transporter ABCG2 is associated with increased uric acid levels and increased risk of gout in individuals of European descent. However, to our knowledge, only 1 study has examined this variant in African Americans and there have been no studies in Mexican-Americans. We, as part of the Population Architecture using Genomics and Epidemiology (PAGE) Study, are genotyping DNA samples collected for the National Health and Nutrition Examination Surveys (NHANES), a cross-sectional survey of Americans representing 3 major groups: non-Hispanic Whites (n=6605), non-Hispanic Blacks (n=3442), and Mexican-Americans (n=3949). We tested Q141K for association with serum uric acid levels and self-reported gout in unadjusted regression models and in models adjusted for age, sex, body mass index, glomerular filtration rate, systolic blood pressure, and type II diabetes status. Based on previous positive reports, we also investigated the potential for gene*sex interaction on uric acid level. The frequency of the T allele (encoding 141K) varied across the 3 groups: 0.20 in W, 0.03 in B, and 0.11 in MA, though the mean uric acid levels were similar (5.4 mg/dL W, 5.4 B, 5.2 MA). However, in all 3 groups, the T allele was strongly associated with increasing uric acid level (in adjusted models β=0.32, p<10-10 in W, β=0.28, p=0.003 in B, β=0.25, p<10-10 in MA). Self-report of gout was available in only a subset of samples from NHANES III (n=87 W cases, 2315 W controls, 36 B cases, 1718 B controls, 16 MA cases, 1754 controls). Despite being underpowered, ABCG2 Q141K was significantly associated with gout in MA (odds ratio (OR)=2.22, 95% confidence interval (CI)=1.08 to 4.52, p=0.03), though not in W (OR= 1.22, 95% CI=0.78 to 1.89, p=0.38) or B (OR=2.22, 95% CI=0.90 to 5.46, p=0.08). We did not detect evidence for a gene*sex interaction on uric acid level (p>0.09 in all groups), despite being adequately powered. In conclusion, the association of ABCG2 Q141K with uric acid level was common to all 3 groups, though the frequency of this polymorphism varied widely across race-ethnicities. Thus, this association first observed in European-descent populations can be generalized to other race-ethnicities.

1155/F

Fine mapping of the NRG1 Hirschsprung's-associated gene. *M. Garcia-Barcelo[1], C. Tang[1,2], W.K. Tang[1], M.T. So[1], P.C Sham[2], S.S. Cherny[2], P.H. Tam[1].* 1) Dept Surgery, Univ Hong Kong, Hong Kong, NA, Hong Kong; 2) Dept Psychiatry, Univ Hong Kong, Hong Kong.

Hirschsprung's disease (HSCR, aganglionic megacolon), is a congenital disorder characterized by the absence of enteric ganglia in variable portions of the distal intestine. HSCR has a complex pattern of inheritance and presents mainly sporadically. Besides the major HSCR gene, RET, there is evidence that other loci contribute to HSCR. Through a genome-wide association study (GWAS) on Chinese individuals we identified the association of a 350kb genomic region encompassing the NRG1 gene with HSCR. Within the region, the strongest associations were found for two physically close SNPs, rs16879552 and rs7835688 with association values of p= 1.80x10-8 and p=1.12x10-9, respectively. These NRG1 HSCR-associated SNPs are not predicted to functionally affect the gene. Thus, we hypothesized that a common causative/functional variant must lie within the 350kb region and was not revealed by the 500K Affymetrix chips used in the GWAS. To identify the functional variant/s, we resorted to increase the marker density within the region by genotyping 325 SNPs in 380 HSCR Chinese HSCR patients and 380 Chinese controls and test for association. Genotype imputation was also used to increase the SNPs density. We identified a SNPs (rs10088313T/G) highly associated with HSCR, with an EIGENSTRAT corrected p-association value of 6.71x10-5, which is lower than those obtained for the NRG1 intron 1 SNPs identified through the GWAS after correction. Importantly, rs10088313 maps »20kb upstream the NRG1 transcription start site. Since rs10088313 could be either functional or/and be in perfect LD with other functionally relevant markers, we focused on the region encompassed by Chinese Han from Beijing (CHB) HapMap markers whose r2 with rs10088313 equals 1 (rs7830563; rs10113578; rs10107065; rs10113593; rs10094655). This delineated a 10.2 kb region. As a) further genotyping of these 5 SNPs in an expanded sample would not help discern among these SNPs in perfect LD and, b) the finding of association across an intron implies involvement in regulation, we used comparative genomics to investigate the 10.2kb region. rs7830563, rs10088313 and rs10113593 create/disrupt binding sites of transcription factors with a prominent in the development of the enteric nervous system. The predicted changes caused by the SNP HSCR-associated alleles are bound to alter the regulation of NRG1 transcription and could possibly affect the NRG1 signalling during ENS development.

1156/F

Association of endothelin receptor type A and migraine without aura in a group of Portuguese patients. *C. Lemos[1], J.L. Neto[1,2], J. Pereira-Monteiro[2,3], D. Mendonça[2,4], J. Barros[2,3], J. Sequeiros[1,2], I. Alonso[1], A. Sousa[1,2].* 1) UnIGENe, IBMC, Porto, Portugal; 2) ICBAS, Univ. Porto, Portugal; 3) Serv. Neurologia,CHP- HSA, Porto, Portugal; 4) Instituto de Saúde Pública, Univ. Porto, Porto, Portugal.

Migraine is a highly prevalent disorder, affecting about 15% of the general population. Different mechanisms have been proposed as contributing for migraine. However, some results are contradictory and replication is needed to confirm the observed association in other populations. Anomalies of vascular function, with dilatation of cerebral blood vessels and release of vasoactive neuropeptides have also been implied in migraine pathophysiology. Endothelin type A receptor (EDNRA) mediates the biological effects of endothelin-1 (ET-1), leading to vasoconstriction. Some authors described an association between a polymorphism of the ENDRA gene and migraine. All these findings point to a possible role of EDNRA in migraine. Our aim was to assess the involvement EDNRA in susceptibility to migraine in a sample of Portuguese migraineurs, by a case-control study. Three tagging SNPs (rs702757, rs5333 and rs5335) were analyzed in 188 cases - 111 without (MO) and 77 with aura (MA) - and 287 controls. A multivariable logistic regression included the three SNPs, adjusted for gender. Allelic and haplotypic frequencies were compared between cases and controls. We found a borderline increased risk for the rs702757 T-allele (OR=1.44, 95% CI: 1.05-1.99) and for the TT genotype (OR=2.34, 95% CI: 1.12-4.90) for MO. A trend towards an increased risk for MA regarding the C-allele of rs5333 was also found. The T-C-G haplotype was found to be significantly overrepresented in the MO subgroup. Our results reinforce EDNRA as a susceptibility factor for MO, although we cannot exclude the involvement of this gene in MA susceptibility in our population. Dissecting migraine genetic susceptibility will be crucial to develop better therapeutic strategies, as the risk variants implied and their effects may vary in different populations.

1157/F

Genetic variants of the FAS gene are associated with vitiligo in a brazilian, family-based population sample. *L.M. Nascimento[1], C.C.S. Castro[1,2], R.I. Werneck[1], M. Olandoski[1], M.T. Mira[1].* 1) Graduate Program in Health Sciences, Pontifical Catholic University of Paraná, Curitiba, Parana, Brazil; 2) Department of Dermatology, Santa Casa de Misericordia Hospital, Pontifical Catholic University of Parana, Curitiba, Brazil.

Vitiligo is an acquired systemic, chronic disease characterized by macules devoid of melanic pigment and identifiable melanocytes. Previous findings have suggested that polymorphisms of the FAS gene are associated with an increased risk of autoimmune diseases, including vitiligo. Moreover, an abnormal expression of FAS has been observed in biopsy samples from vitiligo-affected skin. We hypothesized that genetic variants of FAS might be risk factors for vilitigo in a family-based population sample from south of Brazil. To test this hypothesis, we genotyped 5 tag SNPs capturing the information of the entire FAS gene in 600 individuals distributed in 212 trios composed by an affected child and both parents. Markers were genotyped using the SEQUENOM MassARRAY platform, which uses the iPLEX assay to incorporate mass-modified terminal nucleotides that are then detected by matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) mass spectrometry. Family-based association analysis was performed as implemented in the software FBAT. Association analyses identified at least two variants that contribute independently to increased risk of disease in our population sample: the allele "A" of synonymous tag SNP rs2234978 and allele "A" of intronic tag SNP rs4406738 (P = 0.001, OR = 1.65, 95% IC = 1.20-2.29; P=0.01, OR = 2.02, 95% IC = 1.14 - 3.58, respectively). These results are the first independent replication of association between vitiligo and variants of the FAS gene of the apoptosis regulatory pathway.

1158/F

Analysis of polymorphisms in 4 complement related genes, *CFH*, *C2*, *CFB* and *C3*, and in *ARMS2* in Mexican Mestizo patients with advanced age-related macular degeneration. *A. Ramos-Perez[1], J.C. Canseco-Mendez[1], U. Rodríguez-Corona[1], F. Morales-Mandujano[1], L. Sebastian-Medina[1], J.C. Zenteno-Ruiz[2], D. Ochoa Contreras[3], S. March[1], E. Graue[2,4], A.V. Contreras[1], G. Jimenez-Sanchez[1], I. Silva-Zolezzi[1].* 1) National Institute of Genomic Medicine, Mexico DF, Mexico; 2) Conde de Valenciana Hospital, IAP, Mexico DF, Mexico; 3) School of Medicine, UNAM. Mexico DF, Mexico; 4) Asociacion para Evitar la Ceguera en Mexico, AC.

Age-related macular degeneration (AMD) is the most common cause of central blindness in the elderly population. This disease is characterized by poor vision in the central field due to a progressive destruction of the macular area. Recently, several studies in different populations have clearly identified five genes associated to the disease with independent contributions: Complement Factor H (*CFH*), complement component 2 and 3 (*C2* and *C3*), complement factor B (*CFB*) and age-related maculopathy susceptibility (*ARMS2*). To evaluate the participation of these five loci in the Mexican Mestizo population we genotyped six SNPs in these genes previously associated with AMD in 278 unrelated Mexican patients with the two forms of advanced AMD and 204 healthy controls and 300 population controls from the Mexican Genome Diversity Project. We confirmed a significant association to AMD in Mestizo patients from Mexico City of *ARMS2* rs10490924 (OR=3.09, 95%CI [2.47-3.85], p-value=5.7E-24), *CFH* rs1061170(C) (OR 1.85, 95%CI [1.30-2.65], p-value=7.4E-04, *C2* rs547154(A) (OR=0.177, 95%CI [0.06-0.53], p-value=5.2E-4), *CFB* rs4152667(A) (OR=0.503, 95%CI [0.29-0.89], p-value=1.6E-2) and *C3* rs1047286(A) (OR=2.16, 95%CI [1.42-3.27], p-value=2.2E-4), and rs2230199(C) (OR=2.15, 95%CI [1.48-3.12], p-value=4E-5). Our results show that *ARMS2* and *C3* are major contributors to advanced AMD in Mexicans as previously found in other populations. Interestingly, the contributions of *CFH*, *C2* and *CFB* in Mexicans are minor to those of other populations due to the low frequency of the associated variants in Mexican Mestizos: 15% for *CFH* rs1061170(C), 6% *C2* for rs547154(A) and 4% for *CFB* rs4152667(A). Currently, we are analyzing these data together with other variables such as smoker status in a multivariate model.

1159/F

Resequencing analysis of the complement Factor H gene (*CFH*) in Mexican Mestizo patients with advanced age-related macular degeneration. *U. Rodriguez-Corona[1], J.C. Canseco-Mendez[1], A. Ramos-Perez[1], F. Morales-Mandujano[1], L. Sebastian-Medina[1], J.C. Zenteno-Ruiz[2], D. Ochoa-Contreras[3], S. March[1], E. Graue[2,4], A.V. Contreras[1], G. Jimenez-Sanchez[1], I. Silva-Zolezzi[1].* 1) National Institute of Genomic Medicine, Mexico DF, Mexico; 2) Conde de Valenciana, Hospital, IAP, Mexico DF, Mexico; 3) School of Medicine, UNAM, Mexico DF, Mexico; 4) Asociación para evitar la Ceguera en México, AC.

Age-related macular degeneration (AMD) is the most common cause of central blindness in the elderly population. This disease is characterized by poor vision in the central field due to a progressive destruction of the macular area. Recently, several studies in different populations have clearly identified five genes associated to the disease with independent contributions: Complement Factor H (*CFH*), complement component 2 and 3 (*C2* and *C3*), complement factor B (*CFB*) and age-related maculopathy susceptibility (*ARMS2*). We have confirmed the association of 6 different SNPs in these five loci in the Mexican Mestizo population: *ARMS2* rs10490924 (p-value= 5.7E-24), *C3* rs2230199 and rs1047286 (p-value=4.0E-5 and 2.2E-4 repectively), *CFH* rs1061170 (p-value=7.4E-4), *C2* (p-value=5.2E-04) and *CFB* (1.6E-2). Due to its low frequency (frequency in Mestizos), the contribution of *CFH*(rs1061170) in Mexicans is minor to that in Caucasian groups. An important proportion (57%) of our advanced AMD patients do not have this mutation. Considering these data and due to the relevance of *CFH* in the genetic contribution to AMD in other population groups, we have define it as a candidate gene for medical resequencing to search for additional variants associated to this disease in Mexicans. To characterize genetic variants of potential functional relevance we have designed a resequencing strategy using amplification primers with M13 adaptor sequences at the 5' end for the 23 exons of the *CFH* gene. Our approach is based in resequencing DNA samples of 48 advanced AMD patients (CARMS grade 4 and 5) and 48 healthy controls to have >85% power to detect variants with allele frequencies above 1%, and >99% power for those above 5%. To date we have successfully amplified the 23 exons and are in the process of analyzing the resequencing data. We have identified an insertion/deletion tetranucleotide variant in exon 23 in our cases group. In addition to the generation of variants potentially associated to AMD, in this study, we will generate the first catalog in the Mexican population of genetic variants with potential functional relevance in *CFH*, a highly relevant gene in different medical conditions (AMD and renal diseases).

A 3' UTR polymorphism in *ANXA11* is associated with pulmonary tuberculosis in the South African Coloured Population. *M. Salie[1], M. Möller[1], P.D. van Helden[1], S. Schreiber[2], E.G. Hoal[1], A. Nebel[2], S. Hofmann[2].* 1) Division of Molecular Biology and Human Genetics, MRC Centre for Molecular and Cellular Biology and the DST/NRF Centre of Excellence for Biomedical TB Research, Faculty of Health Sciences, Stellenbosch University, Tygerberg 7505, South Africa; 2) Institute of Clinical Molecular Biology, Christian-Albrechts-University, Schittenhelmstraβe 12, 24105 Kiel, Germany.

Tuberculosis (TB) remains one of the leading causes of death by an infectious agent. Annexin A11 (ANXA11) has recently been shown to be associated with sarcoidosis, a disease with clinical and pathophysiological similarities to TB. ANXA11 belongs to the annexin superfamily of calcium/phospholipid binding proteins and is involved in apoptosis, calcium signalling, cell division and vessicle trafficking. A population-based case-control study with 417 cases and 410 controls from the South African Coloured population was done to investigate the role of polymorphisms in the *ANXA11* gene and susceptibility to TB using the TaqMan® genotyping system. Of the six polymorphisms investigated, we observed a nominal association with the intronic polymorphism, rs2784773 (P_{gen}=0.048 and P_{allele}=0.03; OR[95%CI]=0.80[0.66-0.98]) and a strong association with the 3' UTR polymorphism, rs7071579 (P_{gen}=0.01 and P_{allele}=0.0017; OR[95%CI]= 1.38[1.13-1.68]). Three estimated haplotypes were also associated with TB, where two haplotypes carrying the A-allele of rs7071579 were found more frequently in cases (*P*=0.047 and *P*=0.00037) and the remaining haplotype carrying the G-allele of rs7071579 was found more frequently in controls (*P*=0.01). Haplotype analysis between the South African and German populations show differences in their linkage disequilibrium structure, which indicated that the variants identified in the German population as susceptibility variants may not hold true for the South African population. Alternatively, the susceptibility variant for sarcoidosis may not be the susceptibility variant for TB. This study suggests a possible role of *ANXA11* polymorphisms in the outcome of developing TB in the South African Coloured population. This could be due to the apoptotic and vessicle trafficking properties of the ANXA11 protein or its potential role in the endocytic-autophagic pathway.

Replication study of genetic variants affecting glucose and insulin levels in the Chinese. *C. Hu, R. Zhang, C. Wang, W. Yu, J. Lu, F. Jiang, K. Xiang, W. Jia.* Shanghai Diabetes Inst, Shanghai, Shanghai, China.

Recent studies reported 19 loci influencing glucose and insulin related traits including G6PC2, GCK, GCKR, MTNR1B, DGKB, ADCY5, MADD, ADRA2A, CRY2, FADS1, GLIS3, SLC2A2, PROX1, C2CD4B, GIPR, VPS13C, IGF1, SLC30A8 and TCF7L2. To test for the association of SNPs from these loci and traits related to glucose metabolism and type 2 diabetes, we genotyped 22 SNPs from these loci in 6822 Shanghai Chinese Hans comprising 3410 cases and 3412 controls. We found SNPs from GCK, G6PC2, MTNR1B, DGKB, MADD and SLC30A8 showed association to fasting plasma glucose; SNPs from GCKR, TCF7L2, PROX1 showed association to OGTT 2h plasma glucose; SNPs from GCKR, GIPR, GLIS3 and SCL30A8 showed association to type 2 diabetes risk; IGF1 rs35767 showed association to fasting insulin levels and index of insulin resistance; and SNPs from DGKB and PROX1 showed association to index of insulin secretion.

1162/F

Association study of common type 2 diabetes risk gene polymorphisms with disease in Latvian population. *J. Klovins[1], I. Kalnina[1], L. Tarasova[1], K. Geltnere[2], V. Pirags[2].* 1) Latvian Genome Ctr, Latvian Biomedical Research and Study Ctr, Riga, Latvia; 2) University of Latvia and Department of Endocrinology, Pauls Stradins Clinical University Hospital , Riga, Latvia.

A number of new common genetic variants associated with type 2 diabetes (T2D) have been recently discovered on the basis of genome-wide screening and confirmed in different populations. The present study was conducted to confirm the possible association between 11 candidate genes in T2D patients selected from the Genome Data Base of Latvian Population, the population based biobank. A total of 16 previously reported single- nucleotide polymorphisms (SNPs) from the KCNJ11, SLC2A2, ABCC8, HHEX, PPARG, IGF2BP2, CDKAL1, TCF7L2, FTO, CDKN2A&CDKN2B AND SLC30A8 were analyzed. Candidate SNPs were genotyped in 645 T2D patients and 900 control subjects. In our case-control group the association of four SNPs, rs4402960 (IGF2BP2), rs10811662 (CDKN2A&CDKN2B), rs8050136 and rs9939609 (FTO), were replicated with statistical significance (adjusted p value <0.05). The odds ratio (OR) was significantly increased in patients with a higher total number of risk alleles ranging from OR 1.08 to OR 2.02 for 2 risk alleles versus 6 risk alleles, respectively. The presence of risk alleles was significantly associated with age of disease onset in the group of T2D patients for SNP located in the FTO gene locus. rs4402960 located in IGF2BP2 gene showed strong interaction with BMI being associated with increased risk of T2D only in obese individuals. Interestingly, the SNP rs7903146 located in the TCF7L2 gene whose association with T2D has been replicated in almost all populations studed was not associated with T2D in our cohort (p=0.923). Three additional SNPs in TCF7L2 gene were selected to study LD architecture of this locus in Latvian population. It should be noted that this is the first replication study of T2D candidate genes in the Baltic countries and further studies in these populations are required to confirm our findings. In conclusion, T2D susceptibility of three candidate genes was confirmed in Latvians.

1163/F

The search for early-onset type 2 diabetes loci using Metabochip. *A. Mahajan[1,2], A. Kumar[1], N.W. Rayner[1], N. Robertson[1], V. Lagou[1], S. Wiltshire[1], R. Magi[1], I. Prokopenko[1], C.M. Lindgren[1], C. Groves[3], J. Trakalo[1], G. Mirza[1], D. Buck[1], K. Stirrups[4], C. Langford[4], S.E. Hunt[4], S. Potter[4], P. Deloukas[4], A. Doney[5], C.N.A. Palmer[6], A.D. Morris[6], J. Perry[7], T.M. Frayling[7], A.T. Hattersley[7], M.I. McCarthy[1,3], A.P. Morris[1], The Wellcome Trust Case Control Consortium, The DIAGRAM Consortium.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Institute of Genomics and Integrative Biology, CSIR, Delhi, India; 3) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 4) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 5) Department of Medicine and Therapeutics, Ninewells Hospital and Medical School, Dundee, United Kingdom; 6) Biomedical Research Institute, University of Dundee, Ninewells Hospital and Medical School, Dundee, United Kingdom; 7) Institute of Biomedical and Clinical Science, Penninsular Medical School, Exeter, United Kingdom.

Despite the success of genome-wide association studies (GWAS) of type 2 diabetes (T2D), the more than 30 established loci account for only ~10% of the genetic component of the disease. One approach that may aid the identification of novel T2D loci is to focus on early-onset cases, defined here to have age of diagnosis <45 years, who are less likely to be affected by exposure to environmental risk factors, and thus may have greater genetic loading.

The Metabochip is a custom iSELECT array, designed to support follow-up of putative associations for metabolic and cardiovascular traits, including 1040 SNPs for early-onset T2D. These SNPs were chosen from the strongest signals of early-onset T2D association from a meta-analysis of 1317 cases and 29078 controls from five GWAS undertaken by the DIAGRAM consortium. We have analysed these Metabochip SNPs for association with early-onset T2D under an additive model in an additional 886 cases and 7915 controls from the UK T2D Genetics Consortium, the Warren 2 Collection and the 1958 British Birth Cohort.

We compared patterns of replication between the “Stage 1” DIAGRAM and “Stage 2” Metabochip data at 947 independent SNPs passing quality control protocols. We observed directional consistency (i.e. the same allele at high risk in both stages) at 557 of these SNPs (binomial test p=3.2x10^{-8}). After removal of SNPs within established T2D loci, the evidence for directional consistency between stages was diminished, but still highly significant (507 of 889 SNPs, binomial test p=1.6x10^{-5}). These preliminary results are consistent with a long tail of common, modest effect variants contributing to early-onset T2D.

In an attempt to discover novel loci contributing effects to early-onset T2D, we performed meta-analysis of the two stages of our study. No novel loci achieved a genome-wide level of significance (p<5x10^{-8}). However, after removal of SNPs within established T2D loci, there is still a strong enrichment of nominal associations (p<10^{-5}) with early-onset disease (13 of 889 independent SNPs, binomial test p<10^{-16}). The strongest novel signal of association is in *ANXA11* (p=8.8x10^{-7}, allelic OR 1.25 [1.14-1.37]). This locus has previously failed in DIAGRAM replication efforts for overall T2D, but has not been tested for early-onset disease.

1164/F

The association analysis of susceptibility loci for ulcerative colitis in Japanese Crohn's disease. *K. Yamazaki[1], M. Takazoe[2], Y. Nakamura[3], N. Kamatani[4], M. Kubo[1].* 1) Laboratory for Genotyping Development, Center for Genomic Medicine, RIKEN, Kanagawa, Japan; 2) Department of Medicine, Division of Gastroenterology, Social Insurance Chuo General Hospital, Tokyo, Japan; 3) Laboratory of Molecular Medicine, Institute of Medical Science, The University of Tokyo, Japan; 4) Laboratory for Statistical Analysis, Center for Genomic Medicine, RIKEN, Kanagawa, Japan.

Inflammatory bowel disease (IBD) represents the two common types of chronic intestinal disorders, Crohn's disease (CD) and ulcerative colitis (UC). Genetic epidemiological studies suggest UC and CD share many common genetic factors and resulted in the similarity of mechanistic features. Recent genome-wide association studies (GWAS) of CD and UC supported this hypothesis and it have been uncovering some shared factors in Caucasian population. To investigate the common susceptible loci between CD and UC across populations, we have examined 32 SNPs which identified by GWAS of UC. These markers were including 5 SNPs identified in Japanese UC patients and others were in Europeans. We genotyped them in a total of 484 CD patients and 992 controls and detected 5 SNPs with positive association. Two SNPs in MHC region showed strong association; rs9263739 in *CCHCR1* reported in Japanese population (p=5.79x10-5, OR= 1.67 (1.29-2.19)) and rs660895 in *HLA-DRB1* (p=4.57x10-10, OR=1.69 (1.43-1.99)). Other three SNPs showed marginal association; rs9268858 in *HLA-DRA* (p=0.0020,OR=1.28 (1.09-1.50)), rs2395185 on 6p21 (p=0.0026, OR=1.28 (1.09-1.50)) and rs1558744 near *IFNG* (p=0.045, OR=1.29 (1.00-1.66)). Among five variants with association in this study, the *IFNG* gene was reported that are secreted by abundant lamina propria lymphocytes in the mucosa of patients with CD. Other associated SNPs with Japanese CD patients were located in MHC region. These results indicate that the MHC region and IFNG will be common genetic factors for CD and UC in populations from various ethnics. Identifying shared and disease-specific susceptibility loci for CD and UC would help define the biologic relationship of IBD. However, our study is small to detect modest genetic effect. Further studies with larger sample sizes are necessary to clarify the common susceptibility loci between CD and UC in various populations.

Interaction analysis for the *HLA-DRB1* shared epitope alleles and the MHC class II transactivator *CIITA* gene variant in the risk of rheumatoid arthritis. *M. Ronninger[1], M. Seddighzadeh[1], D. Plant[3], N.A. Daha[4], R.E.M. Toes[4], J. Worthington[3], L. Alfredsson[2], L. Padyukov[1].* 1) Dept Medicine, Karolinska Inst & Hosp, Stockholm, Sweden; 2) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 3) 1arc-Epidemiology Unit, University of Manchester, Manchester, UK; 4) Department of Rheumatology, Leiden University Medical Center, Leiden, The Netherlands.

Several risk factors for rheumatoid arthritis (RA) have been found to interact with *HLA-DRB1* shared epitope (SE) alleles. Recently we found a variant of the MHC class II transactivator (*CIITA*) gene, which associates with inflammatory diseases. This association was not consistently replicated in different populations. *CIITA* is known to be the key regulator of MHC2 expression and may be involved in development of RA in relation with SE alleles. We hypothesize that the risk variant rs3087456 in the *CIITA* gene may interact with the *HLA-DRB1* SE in development of rheumatoid arthritis. Interaction between *HLA-DRB1* SE alleles and rs3087456 in *CIITA* was first investigated in a cohort of 2519 RA cases and 1347 matched controls from Swedish EIRA study and later repeated in two cohorts from UK (1916 cases and 1270 controls) and The Netherlands (486 cases and 283 controls). Genotyping was performed by Taqman genotyping assay (*CIITA*) and by SSP-PCR (HLA). The ACPA (anti-citrullinated protein antibody) status was identified for all RA patients by anti-CCP ELISA. We have used departure from additivity of effects as a measure of interaction between rs3087456 (homozygous for G allele) and *HLA-DRB1* shared epitope alleles defined as any of *DRB1*01*, *DRB1*04* or *DRB1*10*. This measurement gives the proportion of risk among those carrying both genetic risk factors that is attributed only to the interaction (attributable proportion due to interaction, AP). In the analysis of the 3866 individuals from Swedish population for interaction between rs3087456 and SE we found no significant interaction (AP=0.15, 95%CI: -0.24-0.53). Since SE is primarily a risk factor for ACPA positive disease we stratified data according to positive (AP=0.27, 95%CI: -0.05-0.59) and negative (AP=-0.19, 95%CI: -1.0- 0.62) autoantibody status. We further found no significant interaction between the subgroups of SE (*DRB1*01*, *DRB1*04* or *DRB1*10*) and *CIITA*. Similar analysis of two independent RA cohorts from two European populations confirmed an absence of interaction between genetic marker in *CIITA* and SE alleles in development of RA. We did not observe a significant interaction between rs3087456 and SE alleles with regard to risk of RA. Since a biological link between products of these genes is evident, this finding may point towards a more complex relation between *CIITA* and class 2 antigens in the autoimmune process.

1166/F

Replication study of leprosy susceptibility genes PARK2/PACRG and LTA. *A.S. Francio[1], R.I. Werneck[1], C.C. Mackert[1], F.P. Lazaro[1], F.C.G Fernandes[1], M.B. Xavier[2], A. Alter[4], A. Alcais[3], E. Schurr[4], M.T. Mira[1].* 1) Graduate Program in Health Sciences, Pontifical Catholic University of Paraná, Curitiba, Paraná, Brazil; 2) Department of Tropical Medicine, Federal University of Pará, Belém, Brazil; 3) Laboratory of Human Genetics of Infectious Diseases, University of Paris René Descartes, Paris, France; 4) McGill University and Genome Quebec Innovation Centre, Montreal, Canadá.

Leprosy is a chronic infectious disease caused by Mycobacterium leprae that affects mainly the skin and the peripheral nerves. Previous studies have shown a major contribution of genetic variants controlling host susceptibility to leprosy. For example, positional cloning has led to the identification of variants of the regulatory region shared by PARK2 and PACRG as common risk factors for leprosy. The same strategy, followed by stepwise replication, revealed the low-producing LTA+80 allele as a risk factor for early-onset disease. In order to independently replicate the association signals observed between leprosy and both PARK2/PACRG and LTA, we enrolled a study population of families composed of leprosy patients and their parents recruited at the former leprosy colony of Santo Antonio do Prata, located at the amazonic state of Pará, north of Brazil. The colony has been geographically and socially isolated for almost a century, with the population being continuously exposed to high prevalence and incidence rates of the disease. We genotyped 20 tag SNPs capturing the information of the PARK2/PACRG regulatory region and the LTA gene in 154 individuals distributed in 48 trios composed by an affected child and both parents. Genotyping was performed using the SEQUENOM platform. Family-based association analysis was performed as implemented in the software FBAT. Linkage disequilibrium estimations were carried out using the Haploview software. Association analyses identified at least six variants of PARK2/PACRG that contribute to increased risk of disease in our population sample: the allele "C" of tag SNP rs1040079 (P = 0.01), allele "T" of tag SNP rs10945859 (P = 0.006), allele "G" of tag SNP rs2276201 (P = 0.005), allele "T" of tag SNP rs2803073 (P = 0.04), "C" of tag SNP rs6930532 (P = 0.01). Of note, the risk allele of marker rs1040079 is the same as observed previously. Allele "T" of LTA tag SNP rs2239704, also known as LTA+80, was borderline associated with leprosy in our population sample (P = 0.09). Here we present results of a perfect replication of association between leprosy and variants of the PARK2/PACRG genes in a hyper-endemic leprosy population sample.

1167/F

Replication of a GWAS for Behçet's disease confirms the association of the KIAA1529 gene. *S.A. Oliveira[1,2], N.M. Shafiee[3], J.M. Xavier[1,2], F. Ghaderi[3], B.S. Abdollahi[3], F. Shahram[3], F. Davatchi[3].* 1) Instituto de Medicina Molecular, Lisbon, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Rheumatology Research Center, Tehran University of Medical Sciences, Tehran, Iran.

A recent genomewide association study for Behçet's disease (BD) demonstrated an association of KIAA1529, LOC100129342, CPVL and BASH3B genes with BD (Fei et al. 2009). Since replication in independent samples remains the gold-standard in association findings, we investigated the reported associations with BD of single nucleotide polymorphisms (SNPs) in LOC100129342, CPVL and BASH3B, and of all tagging SNPs in KIAA1529. A total of nine SNPs were genotyped in 550 Iranian BD patients and 436 controls. Patients were selected as consecutive patients, according to ICBD criteria. We tested the association of alleles, genotypes and haplotypes with BD, unadjusted and adjusted for sex and ethnicity. SNP rs7038496 in KIAA1529 showed a significant association with BD (p=0.040). This SNP belongs to a 20kb haplotype block (from rs7038496 to rs725229) that also shows a significant association (p=5.6x1E-3). We found a different polymorphism in KIAA1529 associated to BD that the one previously described (rs2061634). This finding further supports the involvement of KIAA1529 in BD susceptibility, but the exact marker within this genes remains to be pinpointed.

1168/F

Study of systemic lupus erythematosus susceptibility genes in a Hispanic population: Identification of six new candidate susceptibility loci. *E. Sanchez-Rodriguez[1], K.M. Kaufman[1, 2], J.A. Kelly[1], A.H. Williams[3], P.S. Ramos[3], A. Rasmussen[1], C.O. Jacob[4], P.M. Gaffney[1], K.L. Moser[1], B.P. Tsao[5], L.A. Criswell[6], R.P. Kimberly[7], T.J. Vyse[8], C.D. Langefeld[3], J.B. Harley[2,9], B. Pons-Estel[10], M.E. Alarcon-Riquelme[1,11], SLEGEN.* 1) Arthritis and Immunology, Oklahoma Medical Research Foundation, Oklahoma City, OK, USA; 2) US Department of Veterans Affairs Medical Center, Oklahoma City, Oklahoma, USA; 3) Wake Forest University Health Sciences, North Carolina, USA; 4) University of Southern California, Los Angeles, California, USA; 5) University of California, Los Angeles, California, USA; 6) University of California, San Francisco, California, USA; 7) University of Alabama, Birmingham, Alabama, USA; 8) Imperial College London, Hammersmith Hospital, London, UK; 9) University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma, USA; 10) Sanatorio Parque, Rosario, Argentina; 11) Center for Genomics and Oncological Research (GENyO), Granada, Spain.

Background: Genome-wide association studies (GWAS) have proven highly effective for identifying hundreds of associations across numerous complex diseases. Four GWAS for systemic lupus erythematosus (SLE) in European populations and two in Asian populations have identified more than 20 robustly associated susceptibility genes. Differences in the prevalence and severity of SLE between various ethnicities are well documented, showing the need for further genetics studies in non-European populations. Objective: The aim of this study was to evaluate and replicate all genes previously associated with SLE with p values <0.05 in the SLEGEN(1) study through fine mapping in Hispanic SLE cases and controls. Material and methods: Here we evaluated 7069 single nucleotide polymorphisms (SNPs) in a set of 1510 Hispanic SLE patients and 825 Hispanic healthy controls. Tests of association were under a logistic regression model (SNPGWA), adjusting for ancestry proportions (ADMIXMAP) as covariates. Results: We confirmed 17 previously reported loci in European and Asian populations (BLK, IRF5, TNPO3, STAT4, ITGAM, ITGAX, 1q25, TNIP1, MSH5, HLA-DRA, XKR6, CFB, C2, MICB, PRDM1, ATG5 and LYN). In addition, we identified six new susceptibility loci in Hispanic SLE with a P< 0.0001 (C6orf10, MSRA, SLC44A4, ZBTB12, EHMT2 and CLIC1,). Conclusion: While we replicated the majority of the previous GWAS genes, new candidate genes have been discovered. These findings support the need to perform GWAS and additional fine mapping in Hispanics to locate additional susceptibility loci. (1)Harley JB, Alarcon-Riquelme ME, Criswell LA, et al. Genome-wide association scan in women with systemic lupus erythematosus identifies susceptibility variants in ITGAM, PXK, KIAA1542 and other loci. Nat Genet 2008;40:204-10.

Electronic Medical Records for genetic research in a multi-ethnic Rheumatoid Arthritis cohort. *F.A.S. Kurreeman[1,2], K.P. Liao[1], T. Cai[1], V. Gainer[1], B. Thomson[2], K. Ardlie[2], S. Mahan[2], S. Raychaudhuri[1,2], E. Stahl[1,2], L.B. Chibnik[1,2], L. Bry[1], G. Li[1], P. Szolovits[1], S. Churchill[1], S. Murphy[1], I. Kohane[1], E.W. Karlson[1], R.M. Plenge[1,2].* 1) Brigham and Women's Hospital, Boston, MA; 2) Broad Institute, Cambridge, MA.

Introduction Electronic medical records (EMR) represent a rich source of clinical data, but are often considered inaccurate for research purposes. Linking EMR with biospecimens (DNA and plasma) can also be challenging, partially due to the cost of enrolling patients in traditional registries. Here, we demonstrate proof of concept that we can link EMR data and discarded blood samples to establish a case-control cohort with highly accurate clinical data for genomic research of rheumatoid arthritis (RA). **Methods** We used clinical data from the EMR to define a case-control cohort of 4,500 RA cases and 13,500 matched controls. We collected discarded blood samples on a subset of 1500 RA cases and 1500 controls that presented to the clinic for routine laboratory testing. We measured RA disease-specific autoantibodies against citrullinated peptide antigens (ACPA). We compared the odds ratios (ORs) of 29 SNPs genotyped in our EMR cohort to the ORs from a GWAS of >25,000 case-control samples collected as part of traditional registries. We calculated a cumulative genetic risk score (GRS) using a weighted log-additive model of all SNPs, and used area under the ROC curve (AUC) to estimate the effect size of the GRS. All analyses were subset by ACPA status and genetically assigned ethnicity [defined using a panel of 190 ancestry informative markers (AIMs)]. **Results** After controlling for population ancestry with AIMs, a panel of 29 RA risk variants demonstrated ORs largely consistent with studies using traditional patient cohorts. A GRS derived from these variants differentiates RA cases from controls with high statistical significance across all RA cases vs controls, ACPA+ (n=1051) vs controls, and ACPA- (n=446) vs controls ($P_{ALL}=10^{-43}$, $P_{ACPA}+=10^{-58}$, and $P_{ACPA-}=10^{-4}$). Analyses restricted to the ACPA+ subgroup across the three major continental populations of European, African and Asian descent showed similar results (AUC = 0.70, 0.61 and 0.67, respectively), implying that despite some non-overlapping loci, a common effect exists across these continental populations. **Conclusion** The approach outlined here has broad implications in diseases that seek to use vast amount of clinical data available in EMRs in a largescale manner that matches the capacity to generate genetic and genomic data. For diseases with complex phenotypic diversity, this method allows the interrogation of specific disease subsets and ethnic groups in an unbiased fashion.

1170/F

Exploration of molecular mechanisms for tuberculosis susceptibility by genetic association study. *HQ. Qu[1], Q. Li[2], B.I. Restrepo[1], S.P. Fisher-Hoch[1], J.B. McCormick[1].* 1) University of Texas Health Science Center at Houst, School of Public Health, Brownsville campus, Brownsville, TX; 2) Endocrine Genetics Lab, The McGill University Health Center (Montreal Children's Hospital), Montréal, Québec, Canada.

Genome-wide association studies (GWAS) are a unique approach to understand the molecular mechanism of many human complex diseases. The Wellcome Trust Case-Control Consortium (WTCCC) genome-wide case-control association study for tuberculosis in a population from The Gambia is one of the largest case-control cohorts and is the only GWAS on tuberculosis to date (WTCCC, 2007). However, in contrast to studies of other human complex diseases, particularly non-infectious diseases, the GWAS on tuberculosis is more complicated. The Gambia has multiple ethnic populations. The population structure in The Gambia and the nongenetic confounding factors, e.g. the intensity of contact with infectious tuberculosis patients, AIDS, diabetes, aging, and socioeconomic condition increase the difficulty of identifying genetic loci of tuberculosis susceptibility. For our analysis we removed 341 ethnic outliers, and we used the Eigenstrat algorithm (Price et al. 2006) with the application of genomic control (Devlin and Roeder, 1999) for the association test in 2,653 individuals. Genetic associations were suggested by both the Q-Q plot and the individual tests corrected for multiple comparisons. A number of candidate genes that may be involved in tuberculosis susceptibility, i.e. *SLC30A2*, *TNFRSF1B*, and *FAM19A1*, were highly statistically associated with TB (cleared the strict Bonferroni correction). We screened the tuberculosis-associated SNPs that cleared false discovery rate (FDR) corrections for association with gene expression levels (GENEVAR data, Stranger et al. 2005; 2007). The TB-associated SNP, rs4875958, was identified in association with the CLN8 gene expression in all three HapMap Phase 2 population samples, i.e. African, European, and East Asian. Higher *CLN8* expression is associated with increased tuberculosis susceptibility. This SNP could affect altered oxidative stress reaction, host cholesterol metabolism, or lysosome function. Validation of the tuberculosis associations in an independent case-control cohort is warranted. To address this issue, we are actively recruiting a case-control cohort of Pakistan population, including 600 cases and 1200 controls. Acknowledgments. This study makes use of data generated by the Wellcome Trust Case-Control Consortium. A full list of the investigators who contributed to the generation of the data is available from www.wtccc.org.uk. Funding for the project was provided by the Wellcome Trust under award 076113 and 085475.

Polymorphisms in *MSX1*, *IRF6* and *MTHFR* genes are associated with isolated cleft lip with or without cleft palate in a Mexican population. *J.A. Velazquez[1,3], M.A. Alcantara[1], B. Estandia[1], C. Cruz[2], S. Villagomez[1], M. Diaz[1], A. Gonzalez[1].* 1) Genetics, Instituto Nacional de Pediatria, Mexico, Distrito Federal, Mexico; 2) Genetics, Instituto Nacional de Psiquiatria, Mexico, Distrito Federal, Mexico; 3) Posgrado Ciencias Biologicas, Universidad Nacional Autonoma de Mexico, Distrito Federal, Mexico.

Introduction. Isolated cleft lip with or without cleft palate (CL/P) is a common birth defect, prevalence vary between 0.5-1.7/1000(Mexico 1/1000).Several genes have been associated with CL/P but results are contradictory.The aim of our work was to identify association between 12 polymorphisms in *TGFA*, *TGFB3*, *MSX1*, *PVRL1*, *MTHFR*,*IRF6* candidate genes and isolated CL/P.Methods. A Case control study was carried out. Genotyping was performed by PCR-Restriction assay or allelic discrimination RT-PCR. Chi square test was performed to identify differences in allelic frequencies.Results. From 12 variants analyzed 4 showed association. On the other eigth polymorphisms no significant differences on allelic frequencies were observed.

Polymorphism	Controls/ Cases	Alelle freq Control	Allele freq Cases	Odds Ratio
MTHFR 677 C>T	342/122	0.38/0.62	0.50/0.50	0.61 C.I.= 0.45-0.82
IRF6 V274I	255/122	0.64/0.36	0.75/0.25	0.57 C.I.= 0.41-0.81
MSX1 1170A>G	179/85	0.40/0.60	0.31/0.69	1.52 C.I.= 1.03-2.25
MSX1 X1.3	269/127	0.84/0.16	0.63/0.37	3.14 C.I.= 2.22-4.42

Discussion. In variant *MTHFR* 677C>T we observed an elevated proportion of the allele T in controls compared with Europeans (0.62 vs 0.25 HapMap-CEU), allele T has been associated with CL/P but in our population seems to be the opposite, it may be explained if it does not have functional effect on protein.*IRF6* V274I showed association with CL/P. Two variants in *MSX1* were associated with CL/P, since Mexican population is heterogeneous we expected differences in polymorphisms associated with CL/P.

Large population risk of a common variant on chromosome 11q13 (rs7927894) on eczema, asthma, and hay fever. *Y.A. Lee[1,2], A. Bauerfeind[1], J. Esparza-Gordillo[1], T. Kerscher[1,2], R. Granell[3], J. Henderson[3], I. Marenholz[1,2].* 1) Max-Delbruck-Centrum for Molecular Medicine, Berlin, Germany; 2) Pediatric Pneumology and Immunology, Charité Universitätsmedizin Berlin, Berlin, Germany; 3) University of Bristol, Department of Community-based Medicine, Bristol, United Kingdom.

Eczema (atopic dermatitis) is a chronic inflammatory skin disorder and a major manifestation of allergic disease. In a genome-wide association study for eczema, a common variant on chromosome 11q13.5 (rs7927894) has been identified as a novel susceptibility locus in four European study populations. The aim of this study was to evaluate the effect of this risk variant on eczema and on other allergic phenotypes such as asthma, hay fever, and elevated specific IgE on the population level. To this end, we performed an association study of rs7927894 in more than 9300 individuals from the Avon Longitudinal Study of Parents and Children (ALSPAC) cohort, a large, well-characterized, population-based cohort of children born in 1991 and 1992 in the Avon area, UK.

Beyond replicating the association with eczema (OR 1.19; 95% CI 1.09-1.30; P =$4.9x10^{-5}$), we found that the effect of this risk variant was restricted to individuals with the atopic subtype of eczema (OR 1.21; 95% CI 1.04-1.40; P =0.013). In contrast, no association of rs7927894 with non-atopic eczema was observed. Moreover, we detected an association of rs7927894 with concomitant allergic asthma and hay fever, yielding the strongest effects on the combined phenotypes allergic asthma and eczema (OR 1.48; 95% CI 1.19-1.85; P =$4.0x10^{-4}$) and on hay fever and eczema (OR 1.40; 95% CI 1.19-1.65; P =$7.56x10^{-5}$). Finally, the ALSPAC cohort enabled us to estimate the population attributable risk fraction which indicates the proportion of cases in the population attributable to the rs7927894 risk allele. The population attributable risk fractions for eczema, concomitant asthma, and concomitant hay fever were estimated to be 9.3%, 24.9%, and 23.5% respectively.

We conclude that rs7927894 is a common variant that confers moderate individual risk for allergic disease, but carries a substantial risk at the population level. We demonstrate that rs7927894 is not only a susceptibility factor for eczema, but also for concomitant asthma and hay fever. The association of this variant with allergic skin and airways disease may point to a shared molecular mechanism underlying different allergic disorders.

Celiac disease (CD) is a complex, chronic inflammatory disorder of the intestine affecting as much as 1% of the Caucasian population. The disease is caused by a strong immune reaction towards gluten in genetically predisposed individuals. All CD patients carry HLA DQ2 and/or DQ8 risk variants which accounts for around 35% of the heritability. Two genome-wide association studies (GWAS) in CD and their follow-up have identified 39 non-HLA loci that contribute to CD risk. The highest prevalence of CD in the world (5.6%) has been described in the Saharawi, an African population of Arab-Berber origin living in the Western Sahara. Our aim was to investigate the association of previously described CD loci in this exotic population. We have conducted a genome-wide scan in a total of 384 individuals from 143 Saharawi families with CD (168 affected and 216 non-affected family members). For this study, we tested 1.601 SNPs from the 39 previously identified risk loci for association using family based association tests (FASTA; GenABLE). After correcting for multiple testing per locus, we replicated association with CD for the ETS1 locus on 11q23.3 (P corrected= 0.0007), but due to the small sample size we did not observe significant association for the other loci. This is supported by a separate analysis on the different Caucasian populations from the original GWAS (British, Dutch, Italian and Finnish) where we observed that for only two out of the four populations there was at least one SNP among the 1.601 SNPs that was significant. To increase statistical power, we therefore conducted a meta-analysis of the Caucasian and Saharawi cohorts. In this analysis we observed 24 loci for which association signal did not decrease, indicating that by increasing the sample size for the Saharawi population we will likely to identify more non-HLA CD risk loci in this population.

Efficient Replication of Genetic Associations with Medical Phenotypes Using Self-Reported Data. *J.Y. Tung, N. Eriksson, C.B. Do, B.T. Naughton, J.M. Macpherson, A.K. Kiefer, J.L. Mountain.* 23andMe, Inc, Mountain View, CA.

While the pace of advances in genetics has increased in recent years, the high cost of collecting phenotype data in large cohorts of patients still hampers genomic research. This can make the replication of associations difficult, leaving many initial discoveries in a limbo of uncertain validity. Here we sought to determine whether collecting self-reported information via the web is an effective phenotyping method for large genome-wide association studies on medical conditions by assessing our ability to replicate genetic associations with health-related phenotypes in our genotyped customer database. We gathered self-report data using web-based questionnaires on approximately 65 medical phenotypes in a generally unselected cohort of over 12,000 individuals and replicated over 100 previously reported associations, including many in type 2 diabetes, prostate cancer, and multiple sclerosis. Of a list of genome-wide association hits curated by the National Human Genome Research Institute's Office of Population Genomics, we successfully replicated ~70% that we expected to detect. There was significant variation across conditions in the percentage of expected associations that we observed, which may reflect differences between our population and the initial study populations, or differences across diseases in the difficulty of diagnosis or communication to patients. These data demonstrate that collecting self-reported information can be a very efficient method for medical phenotyping in large genome-wide studies and can significantly reduce the overall resources required to validate an association.

Coding Variant R32W in Complement Factor B and Risk of Age-Related Macular Degeneration. *A. Hughes, G. Mullan, D. Bradley.* Centre for Public Health, Queen's Univ Belfast, Belfast, United Kingdom.

We investigated the association between rs12614 (R32W) in the complement factor B (*CFB*) gene and risk of age-related macular degeneration (AMD) in a case-control association study of 224 patients with neovascular AMD and 181 disease-free controls. The minor allele of the *CFB* rs12614 (R32W) polymorphism was associated with protection from AMD on simple allele count (odds ratio 0.56 (95%CI 0.32-0.97); p=0.028) and in a logistic regression model (odds ratio 0.39 (95%CI 0.20-0.75); p=0.005). Complement factor B has an important role in amplification of the alternative complement pathway. We report that the minor alleles of rs12614 (R32W) and rs641153 (R32Q) are associated with protection from AMD. The size of each effect is consistent with previously reported functional effects of these polymorphisms on alternative complement pathway activation in vitro.
