Background: Genome wide association studies have established a map of loci associated with serum bilirubin levels. Because bilirubin forms one of the major components of gallstones, these variants are likely candidates for gallstone bilirubin content and possibly also for overall gallstone risk. Aim: To investigate loci associated with serum bilirubin levels as predictors of gallstone composition and gallstone risk. Methods: Loci from a recent meta-analysis meeting a genome-wide significance level of p<1.0x10-7 (UGT1A1, SCLO1B1, LST-3TM12, SLCO1A2) were analyzed in over 1000 individuals with known gallstone composition as measured by FTIR spectroscopy. The likely mode of inheritance was extracted for each locus from the meta-analysis. Gallstone risk was analyzed in 2606 German individuals (71% females) with operated gallstone disease and 1121 matched stone-free controls. Results: Using the presence of bilirubin as a phenotype in comparison to gallstones without bilirubin (<=5%), variants rs6742078 (UGT1A1, p=0.003,recessive;OR 1.73), rs4149056 (SLCO1B1, p=0.005,dominant;OR 1.57) and rs4149000 (SLCO1A2, p=0.045,dom.;OR 1.43) yielded significant nominal association with gallstone composition. Only UGT1A1,(rs6742078,p=0.018,rec.;OR 1.3 [1.04-1.64]) was also associated with overall gallstone risk in the total cohort. In a gender-stratified post-hoc analysis the rs6742078 gallstone disease risk was confined to the male sex (males:p=2.1x10-7,rec.;OR 2.34 [1.68-3.26];females:p=0.47, rec.;OR 1.10[0.84-1.45]). Discussion: This study shows how genome wide association data of a laboratory value, i.e. bilirubin levels, can be translated into predictors for stone composition and gallstone risk. We evaluated the four most strongly associated loci for serum bilirubin levels for their relevance to stone composition and tested for disease association. The tested UGT1A1 variant was previously show to be in high LD with a common UGT1A1*28 promoter polymorphism that underlies Gilbert's syndrome and that was reported to increase the susceptibility to gallstone formation in patients with hereditary hemolytic anemias, and recently in a small study of healthy Greek adults. We confirm the association of the UGT1A1 locus with gallstone disease and show that the overall disease association is primarily confined to the male sex. As it is known that the Gilbert syndrome is 4 times more common in men a more complete etiological picture of gallstone pathogenesis is emerging.

Association of *ARMS2* with Exudative Age-related Macular Degeneration. *P.O.S. Tam[1], T.Y.Y. Lai[1], D.T.L. Liu[2], Y.Q. Zheng[1,3], S.W.Y. Chiang[1], X.Y. Liang[1], L.J. Chen[1], C.P. Pang[1].* 1) Department of Ophthalmology & Visual Sciences, The Chinese University of Hong Kong, HKSAR, China; 2) Hong Kong Eye Hospital, HKSAR, China; 3) Joint Shantou International Eye Center of Shantou University and the Chinese University of Hong Kong, Shantou, China.

Purpose: The mapping of 10q26 chromosomal locus in age-related macular degeneration (AMD) had shed light on its genetic etiology, mainly *HTRA1* and *ARMS2*. But the contribution of *ARMS2* remains controversial. We have previously evaluated the contribution of *HTRA1* genetic variations in Chinese exudative AMD patients. In this study, we evaluated the contribution of *ARMS2* in our cohort. **Methods:** We performed whole gene sequencing of *ARMS2* in 156 exudative AMD patients and 248 unrelated normal control subjects aged over 60. **Results:** Thirty sequence variations were found, among which only 3 lead to amino acid change, p.R3H, p.R38X and p.A69S. Strong association was found between p.A69S and AMD (p=9.37x10^{-20}, OR=4.51). p.R38X was found to be predominant in control subjects, which confers a marginally significant protection to AMD under autosomal dominant model (p=0.037, OR=0.61). The reported 54 bp insertion and adjacent 443 bp deletion (indel) in the 3'UTR was also associated with AMD (p=5.78x10^{-18}; OR=4.22), and is in linkage disequilibrium with p.A69S and the *HTRA1* promoter SNP rs11200638. **Conclusions:** Our results indicated association of *ARMS2* with AMD. While further analysis on the functional consequences of the variants, both coding and non-coding, is warranted to substantiate our results.

1178/F

No evidence of association between complement factor I genetic variants and age-related macular degeneration. *V. Cipriani[1,2], B.K. Matharu[3], J.C. Khan[3], H. Shahid[3], C. Hayward[4], A.F. Wright[4], A.M. Armbrecht[5], B. Dhillon[5], S.P. Harding[6], P.N. Bishop[7], C. Bunce[2], D.G. Clayton[3], A.T. Moore[1,2], J.R.W. Yates[1,2,3], Genetic Factors in AMD Study Group.* 1) Institute of Ophthalmology, University College London, UK; 2) Moorfields Eye Hospital, London, UK; 3) Department of Medical Genetics, Cambridge Institute for Medical Research, University of Cambridge, UK; 4) Medical Research Council Human Genetics Unit, Institute of Genetics and Molecular Medicine, Edinburgh, UK; 5) Princess Alexandra Eye Pavilion, Edinburgh, UK; 6) Ophthalmology Research Unit, School of Clinical Sciences, University of Liverpool, UK; 7) Manchester Royal Eye Hospital and University of Manchester, UK.

Introduction Age-related macular degeneration (AMD) is the leading cause of visual impairment and blindness in the developed world. To date, four genetic loci have been confirmed to be associated with susceptibility to AMD, namely CFH, ARMS2/HTRA1, CFB/C2 and C3. Recently, Fagerness et al. reported association with a single nucleotide polymorphism (SNP), rs10033900, near the complement factor I (CFI) gene [1]. We had previously typed 533 AMD cases and 268 controls for four SNPs in and around CFI (including rs10033900) as well as variants at the established AMD loci. These data showed the expected association with CFH, ARMS2, CFB and C3 but no evidence of association with the CFI variants. Following the report by Fagerness et al. [1], we have typed rs10033900 in additional cases and controls to investigate this further. **Methods** A total of 859 cases (55% women, mean age=79 yrs) and 423 examined controls (60% women, mean age=75 yrs) were typed in our English sample. The cases comprised 29 with age-related maculopathy (ARM) and 830 with end-stage AMD of whom 688 had choroidal neovascularization (CNV) and 142 had geographic atrophy (GA). rs10033900 was also typed in an independent Scottish sample of 505 cases (63% women, mean age=78 yrs; 261 ARM, 189 CNV, 55 GA) and 351 examined controls (57% women, mean age=78 yrs). **Results** No evidence of association was found in the English sample (OR=0.94, 95% CI=0.79-1.11, P=0.46) or in the Scottish sample (OR=1.01, 95% CI=0.83-1.23, P=0.94). There was no evidence of association in subgroup analyses confined to cases with end-stage disease only, CNV only, GA only, or ARM only. **Discussion** We have been unable to replicate the association between CFI variants and AMD. Recent studies provide some support for the association with rs10033900 [2] and with variants in and around CFI [3]. Also, genome-wide scans have reported signals of interest in the neighbouring genes CCDC109B [4] and PLA2G12A [5]. Given the variability observed in these results, additional studies would be desirable to clarify the nature of the association between AMD and variants in the CFI region. **References** [1] Fagerness JA et al., *Eur J Hum Genet*, 2009, 17:100-104; [2] Kondo N et al., *Eur J Hum Genet*, 2010, 18:634-635; [3] Ennis S et al., *Eur J Hum Genet*, 2010, 18:15-16; [4] Neale BM et al., *PNAS*, 2010, 107: 7395-7400; [5] Chen W et al., *PNAS*, 2010, 107: 7401-7406.

***SRBD1* gene polymorphism is associated with normal tension and high tension glaucoma.** *F. Mabuchi[1], Y. Sakurada[1], K. Kashiwagi[1], Z. Yamagata[2], H. Iijima[1], S. Tsukahara[1].* 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Health Sciences, Univ Yamanashi, Chuo, Yamanashi, Japan.

Purpose: Primary open angle glaucoma (POAG) is the most common form of glaucoma, and it is clinically classified into high tension glaucoma (HTG), in which an elevated intraocular pressure is a major feature, and normal tension glaucoma (NTG), in which the intraocular pressures are consistently within the statistically normal population range. We reported that the *SRBD1* gene polymorphism was associated with early onset NTG. As a next step, this study was performed to assess whether the *SRBD1* gene polymorphism was associated with HTG. Methods: Four hundred and twenty five Japanese patients with POAG, including NTG (n = 213) and HTG (n = 212) and 191 control subjects without glaucoma were analyzed for the *SRBD1* gene polymorphism (rs3213787). The mean age at the time of blood sampling was 64.0 ± 13.7 years (mean ± SD) in patients with NTG, 62.9 ± 14.8 years in patients with POAG and 65.7 ± 11.4 years in the control subjects. The genotype and allele frequencies were compared between the patients with NTG or HTG and the control subjects. Results: There was a significant difference (P = 0.0071) in the genotype frequencies between the NTG patients (GG: 0.5%, AG: 4.7%, AA: 94.8%) and control subjects, (GG: 0.5%, AG: 13.6%, AA: 85.9%) and the frequency of the A allele was significantly higher (p = 0.0033) in patients with NTG in comparison to the control subjects (97.2% vs. 92.7%). Moreover, a significant difference (P = 0.0018) was also found in the genotype frequencies between the HTG patients (GG: 0.5%, AG: 3.8%, AA: 95.7%) and control subjects, and the frequency of the A allele was significantly higher (p = 0.0013) in patients with HTG in comparison to the control subjects (97.6% vs. 92.7%). Adjusted for age, gender, and intraocular pressure, an almost 2.5 times increased risk of POAG (P = 0.043, odds ratio 2.48, 95% confidence interval 1.03 to 5.99) was found with the A allele. Conclusion: The *SRBD1* gene polymorphism is considered to be a genetic risk factor not only for NTG, but also for HTG.

Rare variants in *BMP2*, *BMP4*, and *TGFB1* associated with otosclerosis in a German population. *M. Ealy[1], J. Cruz Corchado[1], I. Schrauwen[2], N.C. Meyer[1], M. Baur[3], M. Pfister[3], G. Van Camp[2], R.J.H. Smith[1].* 1) Molecular Otolaryngology and Renal Research Laboratory, Department of Otolaryngology, University of Iowa, Iowa City, Iowa; 2) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 3) Department of Otorhinolaryngology, University of Tübingen, Tübingen, Germany.

Otosclerosis is a common form of adult-onset hearing loss. It is caused by abnormal bone remodeling of the otic capsule and can manifest as a conductive hearing loss when the otosclerotic lesion impairs movement of the stapes. While both genetic and environmental factors have been implicated in otosclerotic disease, the pathogenesis remains unclear. To identify genetic contributions to otosclerosis, a number of candidate gene case-control association studies have been successfully performed. Members of the TGFβ superfamily are excellent candidates due to their established role in bone remodeling and expression in the otic capsule. We sought to replicate an association between polymorphisms in genes of the TGFβ superfamily and otosclerosis first made in a Belgian population by studying a smaller German population of cases and controls. While associations with *BMP2*, *BMP4*, and *TGFB1* did not replicate in the German population, rare variants were identified that may contribute to the risk of developing otosclerosis. Most of these rare variants were located in a prodomain common to the three proteins. This regulatory prodomain (referred to as the latency-associated peptide in TGF-β1) is responsible for maintaining all three proteins in an inactive state. However, during the resorptive phase of bone remodeling, enzymes activate BMP2, BMP4, or TGF-β1 dimers by releasing them from the prodomain. Based on this mechanism of action, the rare variants we identified may modulate the ability of the prodomain to regulate protein activity. To test this hypothesis we established an *in vitro* reporter system that is responsive to TGF-β1, BMP2 or BMP4 signaling. Determining how these variants affect function of these TGFβ superfamily members will better our understanding of their role in otosclerosis.

In Silico Genotype Imputation on Large Pedigrees. *C.Y.K. Cheung[1], E.A. Thompson[2], E.M. Wijsman[1,3].* 1) Dept. Biostatistics, University of Washington, Seattle, WA; 2) Dept. Statistics; 3) Div. of Medical Genetics.

Availability of dense SNPs or sequence data is commonplace but expensive. Many pedigree studies contain existing samples with sparse genotypes. In small pedigrees, it is already feasible to impute dense genotypes from the existing sample and a few densely-genotyped individuals. Here we show that “in silico” dense genotyping on large pedigrees is also now computationally practical. Using MORGAN, MCMC-based sampling conditional on genotype data provides realizations of inheritance vectors (IVs) on large pedigrees. We introduce GIGI (Genotype Imputation Given Inheritance), which imputes dense genotypes using sampled IVs and the few observed dense genotypes. GIGI uses probabilistic inference and threshold-based allele calling. Conditional on an IV, genotype probabilities are computed jointly over pedigree members, given population allele frequencies. Overall probability estimates are obtained by averaging over sampled IVs. A threshold is then used to call either a genotype or an allele. Coupled with the IBDgraph program, which identifies equivalent sampled IVs, this provides rapid and efficient imputation.

We used GIGI on a 95-member real pedigree with 5 generations. On a test chromosome, 21 STR genotypes were observed in 64 subjects of the lowest 4 generations, and 323 dense SNPs over a ~50cM region were observed on 60 subjects in the lowest 3 generations. SNPs from 13 individuals were used for imputation, with the SNPs in the remaining subjects used for validation. We explored both the threshold for genotype calling, and the effect of population allele frequency on the fraction of alleles called and the percentage of correct calls. With stringent genotype-calling threshold probabilities of .8 for both alleles and .9 for one of two alleles, 68% of alleles were called in the 47-subject validation sample, of which 97.6% were correct. Reduction of the threshold to .6/.8 for both/one allele(s) increased the call rate to 85%, of which 93% were correct. Allele call rates were inversely related to population allele frequency. These results demonstrate that accurate imputation in large pedigrees is practical, providing a cost-effective sequential approach for both design of further studies and to obtain dense marker genotypes from new platforms such as next-generation sequencing.

Discovery of novel variants in the *SLC30A8* gene in the multiethnic cohort of the Diabetes Prevention Program (DPP) and their impact on diabetes incidence. *L.K. Billings[1,2,3], K.A. Jablonski[4], R.R. Fanelli[1], J.B. McAteer[1,5], A. Taylor[1,5], R. Ackerman[1], C. Guiducci[5], D. Dabelea[6], L.M. Delahanty[2,3], S.E. Kahn[7], P.W. Franks[8], R. Hanson[9], N. Maruthur[10], A. Shuldiner[11], E.J. Meyer-Davis[12], W.C. Knowler[9], J.C. Florez[1,5,2,3], Diabetes Prevention Program Research Group*. 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA; 3) Diabetes Research Center (Diabetes Unit), Department of Medicine, Massachusetts General Hospital, Boston, MA; 4) The Biostatistics Center, George Washington University, Rockville, MD; 5) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 6) Department of Epidemiology, Colorado School of Public Health, University of Colorado, Denver, CO; 7) Division of Metabolism, Endocrinology and Nutrition, VA Puget Sound Health Care System and University of Washington, Seattle, WA; 8) Genetic Epidemiology and Clinical Research Group, Department of Public Health and Clinical Medicine, Division of Medicine, Umea University Hospital, Umea, Sweden; 9) Diabetes Epidemiology and Clinical Research Section, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Phoenix, AZ; 10) Department of Medicine, Division of General Internal Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 11) Department of Medicine, Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD; 12) University of North Carolina, Gillings School of Global Public Health, Department of Nutrition, Chapel Hill, NC.

The common missense single nucleotide polymorphism (SNP) rs13266634 in the *SLC30A8* gene is associated with type 2 diabetes (T2D) with an odds ratio ~1.15 in people of European descent. This SNP encodes a Trp®Arg change at position 325 in the islet-specific Zinc (Zn) transporter ZnT8, whose transport of Zn molecules into insulin granules is essential for insulin storage and processing. In vitro and null mouse models have demonstrated that disruption of *Slc30a8* alters insulin crystallization and secretion, and the T2D risk allele at rs13266634 is associated with impaired β-cell function and high proinsulin levels (adjusted for fasting insulin) in humans. These studies provide supportive evidence that *SLC30A8* contains the causal variant responsible for the association signal; however, in the DPP, the risk variant at rs13266634 was not associated with T2D or glycemic traits. Therefore, to discover additional functional variants in *SLC30A8*, we sequenced 8 exons, 50 base-pairs (bps) around each intron/exon junction, and 1 kb up- and down-stream of *SLC30A8* in 380 DPP participants (76 people in each five different ethnic groups, most of whom developed T2D) on an ABI sequencer. Ten PCR amplicons targeted 5,721 bps with an average of 2X coverage at a rate of 97.8%, for a total of 2.17 Mbp. We discovered 50 novel SNPs and genotyped 73 novel and known SNPs in 3,566 DPP participants on a Sequenom iPlex platform for validation. A total of 60 SNPs, of which 44 are novel, passed stringent quality control criteria. Of the novel SNPs, 11 had a minor allele frequency (MAF) between 1-5% in at least one of the ethnic groups, while the remaining had a MAF of less than 1%. Four SNPs were unique in Caucasians, 9 in African-Americans, 2 in Hispanics, 8 in Asians, and 2 in American Indians. Two novel missense variants, Ala87Thr and Asp295Glu, showed no evidence from bioinformatic analysis that these would be damaging. Among the SNPs with MAF > 1% (24 SNPs), we found no association with T2D incidence adjusted for intervention and no significant interaction between SNP and treatment arm. In stratified analyses by ethnic group, Caucasian participants, carriers of the minor allele at rs2464591, rs2466296 and rs2466297 were nominally less likely to develop diabetes than carriers of the major allele. In conclusion, we identified 44 novel low frequency (MAF < 5%) variants in *SLC30A8*. None of the SNPs with a frequency greater than 1% were significantly associated with T2D incidence.

1183/F

Implication of Next-Generation Sequencing on Association Studies. *H. Siu[1], Y. Zhu[3], M. Bainbridge[2], R. Gibbs[2], F. Yu[2], L. Jin[1], M. Xiong[1,3]*. 1) Dept Genetics, Fudan Univ, Shaghai, China; 2) 3Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas USA; 3) Human Genetics Center, University of Texas School of Public Health, Houston, Texas, U.S.A.

Genome-wide association studies (GWAS) have become the primary approach for identifying genes with common variants influencing complex diseases. Despite considerable progress, the common variations identified by GWAS account for only a small fraction of disease heritability, and are unlikely to explain the majority of phenotypic variations of common diseases. A potential source of the missing heritability is the contribution of rare variants. Next-generation sequencing technologies will detect millions of novel rare variants and open a new way for association studies. In this report, we focus on pilot 3 data of 1000 genome project to investigate the pattern of genetic variations and its implication for association studies. We found that the linkage disequilibrium (LD) between rare and rare alleles, and rare and common alleles are much weaker than the LD between common and common alleles. We estimated the coverage of pilot 3 data by the current commercial arrays. We found that the biggest coverage which Illumina 1M can achieve in the populations ranges from 23% to 38% at $r2 \geq 0.8$. We also estimated coverage of by pilot 1 data. Their coverage varies from 50% to 66% at $r2 \geq 0.8$,depending on populations. To our surprise, further increasing the number of SNPs in arrays may not increase too much coverage. We also investigated power of complete sequencing, and various tag SNP strategies under four disease models by case-control study design. We found that that power of complete sequencing can almost reach 1 with 5000 cases and 5000 controls for the additive model when the risk allele frequency is 0.03 at the significance level of 0.05. However, with the same model, parameters and sample sizes, pilot 1 data, Illumina 1M and Affymetrix 6.0 can only reach the power of 33.7%,15.5% and 4.5%, respectively. These results strongly demonstrated that any strategies based on tag SNPs may be work very well for association studies of common alleles, but will be ill suited for association studies of rare alleles.

1184/F

Efficiently combining single-variant test statistics rather than rare variants is the key to powerful association tests. *D.D. Kinnamon, E.R. Martin.* Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

Methods involving collapsing and summing over rare variants have been proposed to increase power to detect associations in case-control studies. However, these methods have not been compared to efficient combination of single-variant test statistics under realistic scenarios with linkage disequilibrium (LD), potential common risk variants, and missing genotype data. We considered a permutation test based on the maximum Cochran-Armitage test statistic over all variant positions in a locus (CA max) as well as two recently proposed collapsing and summing methods. Analytic power comparisons with varying LD were performed using a simple model of a locus comprising one rare risk and one rare neutral variant with the same minor allele frequency (MAF). Monte Carlo simulations were used to extend the basic conclusions of this simple model to a 100 kb locus with both rare and common risk variants and missing genotype data. Ten populations of 10,000 haplotypes with LD were generated under a standard neutral coalescent model with recombination, and 500 1:1 case-control samples with total sizes 500, 1,000, or 2,000 were drawn with replacement from each population according to a disease model. Each scenario either had complete or 5% randomly missing genotype data and α=0.05 or 0.01. In analytic power calculations with risk MAF=0.01 and minor allele odds ratio (OR)=2, the CA max test dominated collapsing or summing for negative and low-to-moderately positive LD. In simulations, all techniques demonstrated good control of Type I error under a null disease model. However, the multivariate test including both collapsed rare variants and common variants could not be performed with 5% missing genotypes because Hotelling's T^2 requires complete genotype data for common variants in an individual. For disease models with 50 rare risk variants (MAF<0.01, OR=2), the CA max test had power greater than collapsing or summing in two-thirds of scenarios. The CA max test also had power greater than collapsing or summing in >80% of scenarios for a disease model with 50 total risk variants randomly chosen from rare (MAF<0.01, OR=2) and common (0.01£MAF<0.05, OR=1.5; 0.05£MAF<0.1, OR=1.2) variants in the population. Efficient combination of single-variant test statistics with the CA max test offers greater power for detecting associations than collapsing or summing over rare variants under many scenarios likely to occur in actual sequence data.

1185/F

Comparison of methods and sampling designs to test for association between rare variants and quantitative traits. *S. Bacanu[1], M.R. Nelson[1], J.C. Whittaker[2].* 1) GlaxoSmithKline, Res Triangle Park, NC; 2) GlaxoSmithKline, Harlow, UK.

While genome wide association studies of complex traits have been very successful in detecting associations between common genetic variants and disease phenotypes, for most traits such variants explain only a small proportion of the estimated genetic variance. Several studies have demonstrated that some of the currently unexplained variance is due to rare variants. Until recently it was cost-prohibitive to investigate such variants except on a small and targeted scale, but current sequencing technologies are expanding this scale to large fractions of the genome on thousands of individuals. As is often the case, the development of methods for data analysis lags behind the technology for data generation. A commonly used analysis method is a trend statistic which contrasts the aggregate number of rare, putatively functional variants in a gene between subjects in the extreme tails of the trait distribution, assuming that the preponderance of variants have a similar effect on the trait of interest (i.e. effect homogeneity). The assumption of effect homogeneity is likely to be false; moreover, the aggregate trend method does not use the available rank information, nor does it incorporate in-silico predictions of the functional effects of genetic. To account for the possible heterogeneity in effect we propose new methods to test for heterogeneity, trend and heterogeneity and evaluate designs which test the tail and the middle of the distribution when just a fraction of the phenotyped sample is intended to be sequenced. We also propose new trend methods which use the information in ranks and functional prediction from methods such as PolyPhen. All methods and designs are tested via extensive simulation for different gene coding lengths, causal models and levels of heterogeneity for the effects rare variants. Based on this work we have identified four key findings: (1) the best analysis method depends on varying circumstances but a trend test combined with a trend and heterogeneity test appears to be a reasonable combination, (2) simplistic use of functional prediction of rare variants does not necessarily result in a gain of power and it may even result in a loss of power under some circumstances (3) depending on the causal model, incorporation of some subjects within the middle of the distribution can substantially improve power compared to a tail-only design in the presence of effect heterogeneity.

Optimal Study Design for Targeted Re-Sequencing of Pooled DNA for Disease Association Studies. *A. Day-Williams, K. McLay, E. Howard, A.J. Coffey, A. Palotie, E. Zeggini.* Human Genetics, Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

Genome-wide association studies have yielded an unprecedented number of associations between common genetic variants and complex traits. But the loci identified only explain a small proportion of the heritability of the analyzed traits. This has generated a huge interest in re-sequencing large numbers of individuals to find low frequency and rare variants that help account for the missing heritability. Although next-generation sequencing technologies have drastically reduced the costs of sequencing, it is still prohibitively expensive to sequence the whole genomes of thousands of individuals. Therefore targeted resequencing in pooled DNA is currently the preferred study design. But, there are many questions that need investigation in order to optimally design a targeted re-sequencing experiment in pooled DNA including choice of sequence enrichment technology and number of individuals to pool. We evaluate long-range PCR, array based pull down, and in-solution pull down enrichment methods for 6 genomic regions composing 1.6Mb. The enriched regions are sequenced in DNA pools of 1, 2, 10, 20, and 50 individuals with an Illumina GAII. The 50 individuals assayed are composed of 31 HapMap individuals and 19 control individuals from the WTCCC. Additionally, 22 of the individuals were also sequenced in Pilot 1 of the 1000 Genomes project. We have compared the SNPs called and their frequency estimates from our experiments to the SNPs and their known frequency in our pools from HapMap3 r27 and the final SNP call set from the 1000 Genomes Pilot 1, as well as to dbSNP129. In the pool of 10 HapMap individuals the PCR method found 6358 SNPs (60.5% in dbSNP), the array-based pull down method found 5874 SNPs (63.9% in dbSNP), and the in-solution method found 6783 SNPs (62.1% in dbSNP). Of the 6358 SNPs called using PCR enrichment the array-based pull down called 4272 of them, and the in-solution pull down called 4720. Of the SNPs called using array-based and in-solution pull down 5248 SNPs were called by both enrichment methods. Comparing the called SNPs to both the HapMap and 1000 Genomes data, the in-solution pull down method finds the highest proportion of the known variants with array-based pull down in second and PCR in third. We will present the results from the pool of 20 and 50 individuals, as well as a thorough investigation of the accuracy of the allele frequency estimates from all pools.

1187/F

Metabolic effects of common and rare variants in the Glucose Kinase Regulatory Protein. *D. Ng[1], M.G. Rees[2], S.L. Ruppert[1], J.C. Mullikin[3], M.C. Skarulis[4], L.G. Biesecker[1], NISC Comparative Sequencing Program.* 1) Genetic Disease Research Branch, NHGRI, NIH, Bethesda, MD; 2) National Center for Human Genome Research, NHGRI, NIH, Bethesda, MD; 3) Genome Technology Branch, NHGRI, NIH, Bethesda, MD; 4) Clinical Endocrine Section, NIDDK, NIH, Bethesda, MD.

ClinSeq™ is a large-scale medical sequencing (LSMS) project at the National Institutes of Health (NIH). The goal of ClinSeq™ is to study the technical, medical, and genetic counseling issues associated with LSMS and its application to personalized medicine. The research aims are twofold: 1) identify clinically relevant gene variants that impact on health and return these results to study participants to guide medical management; 2) generate hypothesis-driven clinical and molecular research to discover new genetic variants that contribute to disease susceptibility. Glucose Kinase Regulatory Protein (GCKR) was selected as a candidate gene for study in ClinSeq™ because a common coding SNP rs1260326 (p.Pro446Leu) was found to be associated with hypertriglyceridemia in a replication study of quantitative trait loci in type II diabetes mellitus. Rodent studies showed that GCKR regulates glucose kinase (GCK) activity in the liver. GCKR sequesters and stabilizes GCK in the hepatic nucleus in the fasting state. GCKR inhibition of GCK is enhanced by fructose 6-phosphate and reduced by fructose 1-phosphate. We hypothesized that GCKR variants with reduction or loss of GCK inhibition would result in abnormal cellular localization of GCK, altered glucose metabolism, and development of hepatic steatosis. To test this hypothesis, we analyzed over 700 ClinSeq™ participants with Sanger Sequencing to identify GCKR variants. Seventeen rare (n=42 individuals) and one common ((rs1260326), n=355 heterozygotes, n=141 homozygotes) GCKR coding variants were identified. Cellular effects of these genetic variants were studied by co-transfecting CFP-tagged mutant GCKR and YFP-tagged wild-type GCK constructs into Hela cells. Microscopy revealed a spectrum of GCK cellular localization ranging from entirely cytoplasmic (p.Val103Met) indicating a total loss of GCKR inhibition, to preservation of GCK nuclear to cytoplasmic shuttling (p.Arg540Gln). Select ClinSeq™ participants with GCKR variants were invited to the NIH for metabolic phenotyping. Oral glucose tolerance tests with and without fructose showed a spectrum of glucose metabolism ranging from accelerated to delayed glucose clearance. Preliminary data from hepatic MRI scans showed an increased triglyceride content in 3 out of 4 phenotyped individuals. Studies are ongoing to compare individuals who carry the same variant with each other and with wild-type controls to determine if there is a genotype-phenotype correlation.

The ARRA Autism Sequencing Collaboration - Phase 1: Deep Whole Exome Sequencing in 1000 Autism Cases and 1000 Matched Controls. *C. Stevens*[*1], A. Sabo*[*2], B. Neale*[*1], S. Ripke[1], D. Muzny[2], I. Newsham[2], M. Rivas[1], M. Velankar[1], Y.Q. Wu[2], M. Wang[2], J. Reid[2], U. Nagaswamy[2], C. Kovar[2], J. Santibanez[2], H. Dinh[2], S. Gabriel[1], ARRA. Autism Investigators:[1,2,3,4,5,6], M. Daly[1], R. Gibbs[2], J. Buxbaum[3], B. Devlin[4], G. Schellenberg[5], J. Sutcliffe[6], * These authors contributed equally.* 1) The Broad Institute, Cambridge, MA; 2) Baylor College of Medicine, Houston, TX; 3) Mount Sinai School of Medicine, New York, NY; 4) University of Pittsburgh, Pittsburgh, PA; 5) University of Pennsylvania, Philadelphia, PA; 6) Vanderbilt University, Nashville, TN.

Autism (MIM209850) and additional autism spectrum disorders (ASDs) are pervasive developmental disorders defined by social disability and communication impairment as well as repetitive behaviors and/or restricted interests. The onset is generally before the age of 3 years, and the disorder has a prevalence of 0.6% in the population, affecting ~4 times as many more boys as girls. The heritability of autism is estimated at ~90%, making it one of the most heritable complex disorders. Despite the high heritability of autism, linkage and genome-wide association studies have not provided substantial insight into the root causes of idiopathic autism. Thus we have embarked on an ambitious collaboration between experienced large scale sequencing centers at the Baylor College of Medicine (BMC) and the Broad Institute (BI) and experienced autism genetics research groups to take advantage of dramatic advances in sequencing technology to study sequence variation across the entire genome. Phase 1 of this study, described here, aims to assess the entire spectrum of allelic variation using whole exome sequencing in 1000 cases and 1000 matched control samples. Our target parameters for the project are a median sample performance with greater than 80% of target bases covered at 20x per sample. The whole exome target consists of more than 32 Mb of exonic sequence, however, the flanking sequence near each exon also receives extensive coverage for analysis. Here, we present the experimental and analytic strategy of this study, quality control and detailed coverage analysis, as well as initial summaries of the rare and common coding variation found in ASDs. The complete dataset will provide a thorough assessment of variation found in all genes, allowing for a great range of analyses and should, after extension and confirmation of promising results in phase 2, yield discovery of genes and pathways currently not implicated in ASDs. As such it will provide a significant public resource for autism genetics, diagnostics and potential treatment.

Common and rare variants in the PAX7 and VAX1 genes contribute to Orofacial cleft etiology. *A. Butali[1], M.A Mansilla[1], S. Suzuki[1], T.H Beaty[2], M.L Marazita[3], J.C Murray[1].* 1) Department of Pediatrics, University of Iowa 500 Newton Road, Iowa. IA 52242; 2) Johns Hopkins University, School of Public Health, Baltimore, Maryland, USA; 3) Center for Craniofacial and Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh. PA 15260.

Background: Orofacial clefts (OFC) are the most frequent congenital malformations of the head and neck, with birth prevalence approximately 1 in 700. They are commonly divided into cleft lip with or without cleft palate (CL(P)) and cleft palate (CP) groups based on anatomical, genetic and embryological findings. Advances in the knowledge of OFC etiology have shown strong evidence of association with markers in candidate genes including Interferon regulatory factor six (IRF6), Forkhead boxE1 (FOXE1) and Muscle segment homeobox (MSX1). Recently, genome wide association studies (GWAS) of CL(P) have identified genetic associations for non-syndromic CL(P) on chromosome 8q24.21, and in or near the IRF6, ABCA4, and MAFB genes. Signals approaching GWAS significance were also observed in or near the PAX7, VAX1 and NTN1 genes. The present study investigated the presence of common and rare variants in PAX7 and VAX1 genes as a follow up to the GWAS signals (Beaty et al., 2010). Methods: Direct sequencing was used to search for sequence variations in coding regions and conserved non-coding regions in and around the PAX7 and VAX1 genes in 360 individuals (90 Caucasian CL(P) cases and 90 controls, 90 Asian CL(P) cases and 90 controls). The observed variants were compared in cases and controls using the Fishers chi square test. Results: We found a total number of 16 new variants (three missense, two synonymous and eleven non coding variants). Of these, two missense mutations in the PAX7 gene (G411R in Caucasians and G412S in Asians),were observed in 1% 0f the cases and none in the controls. G411R was predicted as possibly damaging of the protein structure by PolyPhen and G412S as probably damaging. Also in the PAX7 gene, a missense mutation P397L predicted as benign by PolyPhen was observed only in 1% of Caucasian controls and none in cases. Common variants in the PAX7 gene showed significant association with CL(P)(rs4920523, p= 0.006 and rs 1416464, p= 0.001 using the Fisher's chi square test) , and new variant in the VAX1 gene were also identified which may contribute to the etiology of CL(P)(Chr10:118,880,130, p= <0.0001 using the Fisher's chi square test). Conclusions: Sequence analysis of chromosomal regions showing GWAS signals can identify both rare and common variants influencing a disease of interest. Grant: The project was supported by the NIH P50 grant DE-016215.

1190/F

Multiple gene and pathway analysis for rare variants in genome-wide associations. *H. Xu, V. George.* Dept Biostatistics, Med Col Georgia, Augusta, GA.

Much efforts have been devoted to genome-wide association studies (GWAS) of complex diseases. However, the genetic basis of most common complex diseases remain unknown. Multiple lines of evidence show that multiple rare alleles at several genes or genes in a pathway may contribute to common complex diseases. Current approach for GWAS has low power in detecting these rare alleles. We propose to an approach to detect multiple rare alleles by combining the alleles in multiple genes or a pathway. The combining strategy effectively increases the frequencies of the "pooled" alleles and hence improves the statistical power. Simulation studies show that it has higher power than the current approach of GWAS for detecting rare allele from multiples genes. This approach is useful in further analysis of the genome-wide data for association of rare alleles from genes in related pathways.

1191/F

Comprehensive Approach to Analyzing Rare Genetic Variants. *T. Hoffmann[1], N. Marini[2], J. Witte[1].* 1) Department of Epidemiology and Biostatistics and Institute of Human Genetics, University of California San Francisco, San Francisco, CA; 2) Department of Molecular and Cellular Biology, California Institute for Quantitative Biosciences, University of California Berkeley, Berkeley, CA.

Recent findings suggest that rare variants play an important role in both monogenic and common diseases. Due to their rarity, however, it remains unclear how to appropriately analyze the association between such variants and disease. A common approach entails combining rare variants together based on a priori information and analyzing them as a single group. Here one must make some strong assumptions about what to combine. Instead, we propose two approaches to empirically determine the most efficient grouping of rare variants. The first considers multiple different possible groupings using existing information. The second is an agnostic "step-up" approach that determines an optimal grouping of rare variants analytically and does not rely on prior information. To evaluate these approaches, we undertook a simulation study using sequence data from genes in the one-carbon folate metabolic pathway. Our results show that using prior information to group rare variants is advantageous only when information is quite accurate, but the agnostic step-up approach works well across a broad range of plausible scenarios. This agnostic approach allows one to efficiently analyze the association between rare variants and disease while avoiding strong assumptions required by other approaches for grouping such variants.

1192/F

Network-based burden test for the analysis of complex phenotypes by exome sequencing. *G.V. Kryukov, D.P. Nusinow, A. Kiezun, S.R. Sunyaev.* Division of Genetics, Brigham & Women's Hospital, Harvard Medical School, Boston, MA.

Identification of the genetic causes of disease through complete resequencing of individual genomes has become a reality. Until now this approach has been successfully applied to detect genes underlying phenotypes with simple Mendelian mode of inheritance. We have previously estimated that identification of genes involved in complex polygenic traits may require large sample sizes. However, combining multiple genes in a single association test can dramatically increase statistical power of the approach. We developed a network-based statistical method that searches for clusters of functionally related genes with a significant difference in rare variant counts between cases and controls. Given that the relevant pathways might not be known a priori, our method is not using any predefined gene sets, but rather searches for sub-networks in the STRING database. The STRING database incorporates heterogeneous information on gene-gene associations. As the internal control we perform an identical type of analysis also for synonymous and intronic variants, that are predominantly neutral and should not show differential burden of rare variants between cases and controls. We applied our method for the analysis of complete exome resequencing data for populations with cardiovascular and psychiatric phenotypes.

1193/F

Amplicon Ligation and Target Resequencing of Pooled DNA Samples for Effective Detection of Rare Variants. *T.S. Niranjan[1], A. Adamczyk[1], H.C. Bravo[4,5], S. Wheelan[3,4], R. Irizarri[4,5], T. Wang[1,2].* 1) The McKusick-Nathans Institute of Genetic Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD; 2) The Department of Pediatrics, The Johns Hopkins University School of Medicine, Baltimore, MD; 3) The Department of Oncology Biostatistics and Bioinformatics, The Johns Hopkins University School of Medicine, Baltimore, MD; 4) The Center for Computational Genomics, The Johns Hopkins University School of Public Health, Baltimore, MD; 5) The Department of Biostatistics, The Johns Hopkins University School of Public Health, Baltimore, MD.

Rare deleterious variants of large effect in multiple genes may confer a substantial genetic risk to common diseases and complex traits. Next-generation sequencing of pooled DNA samples is an efficient way to identify rare variants in large sample sets within targeted genomic regions of interest at a relatively lower cost. We report an optimized sample pooling strategy and base-calling algorithms for reliable detection of rare sequence variants in pooled DNA samples. To sequence 120 exon-containing regions in 480 samples, we have tested different sample pooling strategies and conducted limited PCR amplification for template enrichment of individual exons. Twelve pools of PCR products, each consisting of 120 amplicons normalized at equal molar concentrations were ligated individually using a Quick Blunting Quick Ligation Kit (NEB) and fragmented by nebulization. Twelve indexed libraries were generated using multiplex primer sets and a Genomic DNA Library Preparation Kit for Solexa sequencing (Illumina), pooled at an equal molar ratio, and sequenced using one lane of a flow cell on a Genome Analyzer II to achieve an average depth of coverage at greater than 40-50 for individual bases. To reduce false positive calls contributed by errors accumulated from later sequencing cycles, we utilized *Srfim*, a model-based quality assessment and base-calling algorithm that captures base-cycle and other sequencing effects to create sequence read-specific estimates on the probability for each nucleotide position along individual reads (http://www.rafalab.org). Utilizing *Srfim* in a pilot study, we increased the total mapped reads by 5% reflecting more accurate base-calling and improved quality metrics, and reduced false positive calls by 30%. We confirmed all but one of all coding variants (n=34) identified by Illumina sequencing of 24 exons of a candidate gene using the Sanger method. Using optimized sample-pooling, library-indexing, and base-calling algorithms, we anticipate a reliable detection of rare variants with an allele frequency at 0.1% or higher in large sample sets.

1194/F

Rare variants in two functionally-related genes (*TREX1* and *PRF1*) and susceptibility to autoimmune diseases. *N. Barizzone[1,2], S. Monti[1], S. Mellone[1], G. Cappellano[1,2], E. Orilieri[1,2], A. Chiocchetti[1,2], M. Marchini[3], R. Scorza[3], M.G. Danieli[4], Y. Carlomagno[1], M.G. Sabbadini[5], G.D. Sebastiani[6], S. Migliaresi[7], M. Galeazzi[8], U. Dianzani[1,2], P. Momigliano-Richiardi[1,2,9], S. D'Alfonso[1,2].* 1) Department of Medical Sciences, University of Eastern Piedmont, Novara, NO, Italy; 2) IRCAD (Interdisciplinary Research Center of Autoimmune Diseases), Novara, NO, Italy; 3) Dipartimento Medicina Interna, IRCCS Ospedale Maggiore di Milano, Milano, MI, Italy; 4) Istituto di Clinica Medica Generale, Ematologia ed Immunologia Clinica, Ancona, AN, Italy; 5) Universita'Vita-Salute San Raffaele, Milano, MI, Italy; 6) Unita'Operativa Complessa di Reumatologia, Azienda Ospedaliera San Camillo Forlanini, Roma, Italy; 7) Unita'Operativa di Reumatologia, II Universita'di Napoli, Napoli, NA, Italy; 8) Struttura Semplice di Diagnosi e Cura delle Malattie Autoimmuni Sistemiche, Divisione di Reumatologia, Universita' Siena, Siena, SI, Italy; 9) Member of American Society of Immunogenetics (ASHG).

We performed a mutational analysis by direct sequencing on the whole coding region of two candidate genes (*PRF1* and *TREX1*), belonging to a common pathway, on three related autoimmune diseases: SLE (Systemic Lupus Erythematosus), SSc (Scleroderma) and SS (Sjögren's Syndrome). Secretory vesicles of CTLs and NK cells contain perforin (PRF1) and granzymes. PRF1 polymerizes on target-cells membrane, forming pores which allow the entry of granzymes, which in turn start the apoptotic response. In particular granzyme A triggers the translocation to the nucleus of the protein complex containing TREX1. Here DNA is digested into small fragments, which become substrates of the exonuclease TREX1 (DNase III). Mutations of *PRF1* gene have been associated with Familial Haemophagocitic Lymphohistiocytosis (FHL2), a rare autosomic recessive disease. Heterozygous *PRF1* variants have been associated with autoimmune diseases. We searched for *PRF1* variants in 2 new diseases: 154 SLE, 131 SSc and 559 controls. We identified 22 variants; 11 were non-synonymous and 4 of them have been observed in patients only. In silico analysis predicts for one of them (H514R) a possible damaging effect. The cumulative frequency of all non-synonymous variants is significantly higher in patients than in controls for both diseases (SLE: p=0.043 OR=1.63; SSc: p=0.0082 OR=1.89). The 2 most frequent non-synonymous variants (A91V and N252S) were further analysed in a larger sample set: (597 SLE, 204 SSc, 1856 controls) and they resulted significantly associated both with SLE (N252S p=0.039 OR= 2.35) and with SSc (A91V p=0.0054 OR=1.70). Heterozygous mutations in *TREX1* had been observed in 10/477 patients with SLE and in 1/169 subjects with SS. Those variations had not been found in 1712 controls (Lee-Kirsh). Furthermore *TREX1* mutations can cause three rare mendelian diseases with autoimmune features: (AGS, FLC, RVCL). We searched for *TREX1* mutations in 210 SLE, 58 SS and 150 cases of SSc. We observed 7 variants; two of them are non synonymous (E198K and M232V) and they are predicted as possibly damaging for protein function. They have been observed in one case of SS and in one case of SSc respectively and in none of the 200 controls typed in our lab or of the 1712 controls sequenced by Lee-Kirsh. E198K has recently been described in one AGS patient, while M232V is novel. In conclusion our work seems to confirm a role for rare variants in susceptibility to common autoimmune diseases.

1195/F

Approaches to Incorporating Uncertainty in Rare Variant Association Studies. *E. Zeggini, J.L. Asimit.* Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, United Kingdom.

In rare variant association studies there is a loss of power due to genotype misspecification. Quality scores are available for genotype and sequence-derived data, but they are not usually put to use in rare variant analyses. Imputation of rare variants is now possible due to the 1000 Genomes reference set, which contains variants with MAF as low as .01. We propose methods for rare variant analyses that incorporate quality scores derived from sequencing and probability distributions resulting from imputation. We consider extensions of two locus-based approaches: (i) collapsing the genotypes across rare variants and testing for an association with accumulations of rare variants; (ii) an allele-matching test based on combining single variant test statistics. The allele-matching test is nonparametric and does not require knowledge of the risk alleles. The SNP-level quality scores are incorporated in extensions of both methods, while the latter method includes genotype-level quality scores, as well. Use of imputation probabilities in the allele-matching test is also explored. In a comparison of the original and quality-weighted collapsing methods, the extension has a consistent, though small, gain in power. The table below provides simulation results for 10000 replications of 5000 individuals generated such that the maximum MAF of a causal SNP is .01, the maximum total MAF of the causal SNPs is .05, and the proportion of phenotypic variation due to rare variants (λ) varies.

Meth-odlambda	0.2%	0.4%	0.6%	0.8%	1.0%
Original	.14	.23	.32	.40	.48
Quality-weighted	.15	.25	.36	.43	.52

In conclusion, methods accounting for inaccuracies arising from sequencing and imputation processes increase power to detect association. We are extending our methods further to achieve greater power.

1196/F

Coding alterations in two adjacent genes at the PSORS2 locus co-segregate with psoriasis in a large human pedigree. *C.T. Jordan, E.D.O. Roberson, L. Cao, C. Helms, S. Duan, A.M Bowcock.* Department of Genetics, Washington University, Saint Louis, MO.

Psoriasis (PS) is a chronic, inflammatory skin disease that affects 2-3% of the European population. Psoriatic arthritis (PsA) is an inflammatory arthritis that occurs in up to 30% of affected individuals. We previously identified a susceptibility locus for PS and PsA at chromosome 17q25 (PSORS2) in a large family segregating a highly penetrant mutation (LOD = 5.84). This region spans ~ 3.5Mb and contains 77 genes. We implemented two sequence capture strategies to search for the causative mutation. First, we used whole-exome capture to obtain coding sequence from 4 affected individuals. Second, we performed genomic capture of the entire 17q25 region using DNA from pools of 8 unaffected and 14 affected individuals. All captured DNAs were sequenced using Illumina Solexa paired-end DNA sequencing technology. Whole-exome capture resulted in 30-fold enrichment of exons in the linkage region, and genomic capture enriched the region by greater than 200-fold. Both approaches identified two unique mutations altering the coding sequences of adjacent genes. Follow-up Sanger DNA sequencing confirmed that these mutations segregate with disease in the large pedigree. One mutation abolishes a splice site in a gene encoding a protein involved in regulation of apoptosis and the NF-κB pathway. The other mutation changes a phylogenetically conserved tyrosine to cysteine in a gene expressed in chondrocytes and high endothelial venule epithelial cells (HEVEC). As PS and PsA are complex diseases, either one or both mutations may contribute to disease pathogenesis. We are resequencing both genes in a larger cohort of unrelated patients and controls and will present an analysis of the frequency of these alterations, their potential functions and their significance in the general disease populations of PS and PsA.

1197/F

Targeted-genomic capture and high-throughput sequencing for genetic testing and new gene discovery in atypical hemolytic uremic syndrome. *T. Maga[1, 2], A. Deluca[3, 4], K. Taylor[3, 4], S. Scherer[5], T. Scheetz[3,4], R.J.H. Smith[1,2,6].* 1) Department of Otolaryngology-Head and Neck Surgery, Carver College of Medicine, University of Iowa, Iowa City , IA; 2) Interdepartmental PhD program in Genetics, University of Iowa, Iowa City, IA; 3) Electrical and Computer Engineering, University of Iowa, Iowa City, IA; 4) Center for Bioinformatics and Computational Biology, University of Iowa, Iowa City, IA; 5) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 6) Department of Internal Medicine, Carver College of Medicine, University of Iowa, Iowa City, IA.

Atypical hemolytic uremic syndrome (aHUS) is characterized by acute renal failure, thrombocytopenia and microangiopathic hemolytic anemia. aHUS is far less common and more severe than typical HUS, which is caused by E. coli infection and manifests as diarrheal illness. The pathogenesis of aHUS is linked to dysregulation of the alternative pathway of the complement cascade. Mutations in the complement regulators factor H (*CFH*), membrane cofactor protein (*MCP*), factor B (*CFB*), factor I (*CFI*), complement component 3 (*C3*) and thrombomodulin (*THBD*) have been implicated in the disease. These loss- or gain-of-function mutations lead to uncontrolled complement activity and immune-mediated host cell damage. Twelve percent of patients who have a mutation in one of these genes have a mutation in a second gene, however in 50 percent of aHUS patients, no mutations are found, suggesting that other genetic causes remain to be discovered. Establishing a genetic etiology is important as it helps to direct treatment during the acute phase of disease and when transplantation is considered. To develop an improved protocol for genetic testing and to discover mutations in novel genes that are causally related to aHUS, we have optimized a platform called CASCADE (Capture and Sequencing of Complement-Associated Disease Exons), which is based on targeted-genome capture and next-generation sequencing of all complement genes. We report here a proof-of-principle study demonstrating the power of CASCADE to detect known and novel mutations involved in the pathogenesis of aHUS in four patients. (Funded in part by the Foundation for Children with Atypical HUS, RJHS).

1198/F

Exon sequencing of α-Actinin-4 for variants associated with non-diabetic end stage renal disease in African Americans. *P.J. Hicks[1], M.A. Bostrom[1,5,6], L. Lu[2], M.C.Y. Ng[4,5,6], C.D. Langefeld[2], B.I. Freedman[3], D.W. Bowden[1,5,6].* 1) Biochemistry, Wake Forest University, Winston-Salem, NC; 2) Biostatistical Sciences, Wake Forest University, Winston-Salem, NC; 3) Internal Medicine/Nephrology, Wake Forest University, Winston-Salem, NC; 4) Pediatrics, Wake Forest University, Winston-Salem, NC; 5) Center for Human Genomics, Wake Forest University, Winston-Salem, NC; 6) Center for Diabetes Research, Wake Forest University, Winston-Salem, NC.

Non-diabetic (non-DM) end stage renal disease (ESRD) disproportionately affects African Americans. Few studies have been done to identify genes responsible for this increased susceptibility. *ACTN4* (α-actinin-4) is an actin binding protein involved in maintaining the cell cytoskeleton. This gene is expressed in podocytes and rare mutations have been identified in familial focal segmental glomerulosclerosis. We sequenced 19 exons and 2800 bases of the promoter of *ACTN4* in 96 non-DM ESRD cases and 96 non-nephropathy controls. Sixty-seven SNPs were identified, including 33 intronic, 21 promoter, 12 exonic (1 non-synonymous), and 1 SNP in the 3' untranslated region. Forty-nine SNPs were novel. Sixty-one SNPs were genotyped in 278 African American non-DM ESRD cases and 327 non-nephropathy controls. A single SNP, rs10404257, located in the promoter region was associated with non-DM ESRD (p = 0.004, odds ratio (OR) = 0.60, confidence interval (CI) = 0.43 - 0.85; dominant model). Forty SNPs had minor allele frequencies less than 5%. These SNPs were collapsed into a single marker, designated by the presence (n=251) or absence (n= 404) of any rare allele. There was no association with having a rare allele at any of these SNPs with non-diabetic ESRD. SNPs were also tested for interaction with *MYH9*, a gene that has been shown to have a significant impact on risk for non-DM ESRD. No interaction with MYH9 was detected, either with single SNPs or with collapsed rare alleles. Twenty-one of the most significantly associated SNPs, including rs10404257, were genotyped in an independent set of 525 non-DM ESRD cases and 267 controls. Rs10404257 was not associated (p = 0.768, OR = 1.05, CI = 0.75 - 1.48; dominant model) however, when the samples were combined rs10404257 was still modestly associated (p = 0.033, OR = 0.78, CI = 0.62 - 0.98; dominant model). We completed a comprehensive analysis of the coding regions *ACTN4* gene and detected limited evidence of association with non-diabetic ESRD in African Americans. This negative finding suggests that the function of *ACTN4* is critical and common to moderately uncommon variants that alter this function may have a catastrophic impact on cellular processes.

1199/F

Resequencing of 10 susceptibility loci in 56 individuals using Next Generation Sequencing based on Long Range PCR enrichment. *S. May[1], M. Schilhabel[1], I. Thomsen[1], M. Forster[1], P. Rosenstiel[1], S. Schreiber[1,2], A. Franke[1].* 1) Institute for Clinical Molecular Biology, CAU Kiel, Kiel, Schleswig- Holstein, Germany; 2) 1st Medical Department, University Clinic Schleswig-Holstein (Campus Kiel), Germany.

One of the key applications of Next Generation Sequencing is to study the genetic variation between healthy individuals and patients using whole - genome or targeted resequencing. The perhaps best-established approach for high throughput population-based sequencing of targeted intervals in the human genome is to amplify the regions of interest using long-range PCR followed by Next Generation sequencing. In our current project we resequenced with the SOLiD platform 10 validated disease susceptibility loci in 56 individuals (30 cases, 20 controls and 6 HapMap control samples). In order to enrich the samples for genetic diversity at the locus of interest, haplotype analyses were carried out using dense genotyping data from available genome-wide association scans. Cases and healthy controls carrying the associated risk haplotypes were preferentially selected and individuals with the remaining haplotypes were used for filling the pools. This means that patient sets that are resequenced vary between targets so we obtained full sequence variation - i.e. in coding and non-coding genomic sequence - and individual haplotypes for these 10 disease-associated genes. For these ten loci, more than 5500 long-range PCR amplicons have been successfully generated. This large number requires a high degree of automation and logistics. On the conference, we will show first results of our sequencing data and we will give a demonstration of the employed workflow.

1200/F

Exploring alternative splicing profiling in autism, a proof of concept study. *Z. Talebizadeh[1], R. Aldenderfer[1], B. Han[2], X. Chen[2].* 1) Pediatrics, Children's Mercy Hosp and University of Missouri-Kansas City School of Medicine, Kansas City, MO; 2) 2Electrical Engineering and Computer Science Department, University of Kansas, Lawrence, KS.

Autism is a complex, heterogeneous neurobehavioral disorder with many causes and varying degrees of severity. To date, the main technique used to screen autism candidate genes has been direct sequencing of exons using genomic DNA. It is surprising that for strong candidate genes such as NLGN3 and NLGN4, few functional mutations have been identified in association with autism. This suggests that implications may be at a higher level than the genomic sequence, including alternative splicing. Previously, we reported novel alternative splicing variants in the NLGN3 and NLGN4 genes using RT-PCR and DNA sequencing. The dysregulation of alternative splicing has been associated with some cancers and neurological diseases such as Parkinson's and Alzheimer's. Despite the growing evidence for the regulatory influence of alternative splicing on gene expression, particularly in brain function, this gene regulatory process has not been previously evaluated in autism spectrum disorders. In order to assess the potential role of alternative splicing, we performed a pilot study to examine global exon expression between autistic subjects (n=5) compared with unrelated controls (n=5) using Affymetrix GeneChip Human Exon 1.0 ST arrays on lymphoblastoid cell line (LCL) derived RNA. Data analyses was limited to the 'core' probe set comprised of 17,800 transcripts. In doing so, 10,072 genes (57%) met the applied filtration criteria and were identified as being "present" above background levels. Within this reliably expressed gene set, ANOVA and multi-test correction were used to identify differential exon expression in autism samples. Applying Bonferroni multiple test correction to the 10,072 genes identified 57 genes that appear to have differential expression between autism and control samples. This list includes genes associated with neurological diseases such as Alzheimer's (SLC30A7). Several genes identified have been linked to nervous system development or autism including CYFIP1, ROBO1, and CDKL5 (ROBO1 and CDKL5 in females only). Our results indicate that changes in mRNA splicing patterns should be considered in the etiology of autism. This pilot study demonstrates that even though LCLs are not neuronal cells, they are a viable cellular model for human neurological diseases and can facilitate understanding the role alternative splicing plays in complex neurodevelopmental disorders such as autism.

1201/F

Multivariate analysis of clinical data for age related hearing impairment diagnosis. *C.H. White, L. Fisher, R. Friedman, J. Ohmen.* Cell Biology and Genetics, House Ear Institute, Los Angeles, CA.

Presbycusis, or Age Related Hearing Impairment (ARHI) results from the complex interaction of genetic susceptibility to aging in the inner ear and unknown environmental components. The identification of the genes underlying this disease requires an accurate phenotypic assessment. The primary tool for doctors to assess presbycusis is the audiogram for pure tone thresholds. Classically, a diagnosis of ARHI is suggested by an audiogram that reflects the loss of ability to hear high frequency tones. Recently, in an effort to convert the qualitative diagnosis of ARHI, into a quantitative measure of disease, geneticists have attempted to apply mathematical tools to audiometric data to derive quantitative phenotypes. Due to the large number of data points present in individual audiograms which results in audiograms with a variety of shapes, one approach to data reduction involves the application of Principle Component Analysis (PCA). We have applied this and other multivariate statistics to our current hearing data, as well as collected additional samples, to derive better a quantitative definition of ARHI.

Population-based survival analysis of children born with orofacial clefts in Texas. *T.G. Barbaro Dieber[1], S.S. Hashmi[1], J.L. Salemi[2], M. Canfield[3], W. Nembhard[2], J.T. Hecht[1].* 1) University of Texas Medical School at Houston, Houston, TX; 2) College of Public Health, University of South Florida, Tampa, FL; 3) Birth Defects Epidemiology and Surveillance Branch, Texas Department of State Health Services, Austin, TX.

Orofacial clefts are the most common craniofacial birth defects in humans and are associated with high morbidity. An increased rate of infant mortality has been reported among children with all types of congenital anomalies. Increased mortality in children with isolated orofacial clefts has been inconsistently reported. Gender, ethnicity and socioeconomic status are known risk factors for infant mortality but have not been systematically evaluated among children with orofacial clefts. Therefore, this study assessed infant mortality in children with all types of orofacial clefts born in Texas between 1996-2003 accounting for these risk factors. All cases were identified through the Texas Birth Defects Registry (TBDR) and were cross-referenced with Texas Vital Statistics through 2005 to ascertain survival and underlying cause of death (COD). Standardized mortality ratios (SMR) were calculated for all cases and separately for isolated and for syndromic/multiple congenital anomalies (MCA) cleft cases. Cox regression analysis was performed to compute hazard ratios (HR) for both isolated and MCA cases of orofacial clefts. A total of 3,713 cases of orofacial clefts were identified, of which 2,543 (68.5%) were isolated cases and 1,170 (31.5%) had MCAs. There were a total of 483 deaths with 343 (71%) in patients with MCA. Overall 10 year survival for all, isolated and MCA cases was 87%, 94% and 71%, with the majority of deaths occurring in the first year of life. The SMRs for all, isolated and MCA cases of clefts were 18.24, 7.62 and 41.34, respectively. There was a two-fold increased risk of death in African-Americans compared to nonHispanic whites (HR=2.096, p=0.007). Higher but nonsignificant risk of death was found for females and Hispanics for both isolated and MCA cases. Low birth weight and gestational age were risk factors for higher mortality among all cases. "Congenital malformations, deformations, and chromosomal abnormalities" were the most common COD (79.0% (n=347) for all cases and 72.7% (n=93) for isolated). In conclusion, this population-based study of orofacial clefts shows that there is a seven-fold increase in death in children with isolated CLP. This information should be used in the treatment and management of these children.

1203/F

The polygenic nature of glaucoma: Dissecting sub-phenotypes to facilitate the characterization of modifier genes. *P. Belleau[1], K. Lebel[1], S. Dubois[1], R. Arseneault[1], J.L. Anctil[2], E. Shink[1], G. Cote[2], M. Amyot[3], V. Raymond[1], The Quebec Glaucoma Network.* 1) Biology of Sensory Systems, Ocular Genetics & Genomics, Laval University Hospital (CHUL) Res Ctr, Québec City, PQ, Canada; 2) Ophthalmology, Laval Univ, Québec City, PQ, Canada; 3) Ophthalmology, Univ of Montréal, Montréal, PQ, Canada.

Open-angle glaucoma (OAG), a major cause of blindness worldwide, is characterized by optic nerve degeneration and visual field impairments. Potential mechanisms leading to OAG involve elevation of intraocular pressures, optic nerve hypersensitivity to stressful events and inflammation. Although OAG is primarily considered a complex genetic disease, families were essential in characterizing 4 disease-genes. We studied the CA family, a huge French-Canadian pedigree showing very wide variability of its autosomal dominant glaucoma phenotype. The myocilin (MYOC) K423E mutation caused OAG in the family. Modifier genes can account for wide variability of ages at onset (AAO). To facilitate the identification of these modifier genes for AAO, we dissected the disorder according to four additional subphenotypes. The records of 155 $MYOC^{K423E}$ heterozygotes were reviewed to extract the values of their respective quantitative variables: 1. maximal intraocular pressures (IOP) in mm Hg, 2. maximal IOP after beginning of treatment, 3. optic nerve degeneration as cup-to-disk (C/D) ratio and, 4. progression of optic nerve degeneration (ΔC/D) as the variation of the C/D ratio divided per the time period between 2 C/D ratios. Ages at onset ranged from 7 to 63 years old with 16 % of the men showing onset < 20 years old as compared to 11 % of the women. IOP sub-phenotypes were classified in 3 categories with 94 heterozygotes classified in the high severity group with maximal IOPs $\geq$ 27, 12 carriers in the moderate group with IOPs between 22 and 27 while 49 heterozygotes were in the low severity group with IOP below 22 mm Hg. Of the 104 heterozygotes who were treated, 84 were categorized in the high severity group with maximal IOP $\geq$ 22 mm Hg following the beginning of the treatment whereas 71 were in the low severity category below this value. When C/D ratios were measured in 142 heterozygotes, 56 were classified as severe with a ratio $\geq$ 0.8, 12 moderate with C/D between 0.7 and 0.8, and 74 in the low category with C/D < 0.7. When ΔC/D was tested in the 142 carriers, 3 groups could be defined with 88 carriers in the low severity group below 0.02, i.e. a variation < 0.2 C/D in 10 years, 13 as moderate: from 0.02 to 0.03 and, 41 as high with a ΔC/D $\geq$ 0.03. In conclusion, we established a novel classification system for severity of glaucoma that should be useful to characterize modifier genes for the disorder. This system can be used to analyze dependency between subphenotypes.

1204/F

Limits in processing speed as a possible endophenotype in dyslexia. *B. Peter[1, 2], M. Matsushita[2], W. Raskind[2, 3].* 1) Speech & Hearing Sci, Univ Washington, Seattle, WA; 2) Medicine; 3) Psychiatry and Behavioral Sciences, University of WA.

This study investigated the hypothesis that limits in processing speed constitute an endophenotype in dyslexia, which, if confirmed, would provide the motivation to identify its genetic origin. Dyslexia is a disability interfering with the acquisition of written language at the word level, characterized by deficits in accurate and/or fluent word recognition, decoding, and spelling. There is strong evidence for a genetic basis. Dyslexia is associated with left-hemisphere white matter abnormalities. Of note, in typical adults, white matter volume and motor speeds decrease with age. Children with dyslexia show slowed speed in various tasks, compared to typical peers, but it is unknown whether slowed processing is a latent dimension in dyslexia. Exploratory factor analysis (FA) was conducted in a sample of 289 multigenerational families, each ascertained through a child with dyslexia. FA was conducted separately in four cohorts (all children, n = 390; children with low reading scores, n = 105; children with typical reading scores, n = 198; and adults with typical reading scores, n = 444) and confirmed in male and female subcohorts. In a first FA model, nine input variables represented verbal and nonverbal processes and alphabet writing; four of these were timed. In a second FA model, two timed motor sequencing tasks involving oral and finger movements were added. Processing speed formed the first factor in all cohorts and models. Leading variables in the first FA model were three timed measures with verbal output, rapid automatic naming with and without category switches and inhibition switch times from a naming task with alternating conditions, followed by a timed measure with motor output, alphabet writing speed. In the extended model, timed oral and hand motor sequencing loaded on the speed factor along with alphabet writing speed, ranking below the speed measures with verbal output. Children with poor reading scores showed lower speed factor scores than typical peers. The speed factor was negatively correlated with age in the adults. Timed measures with verbal output were more closely associated with processing speed than those with motor output. Results are consistent with a unified theory of processing speed as a quadratic function of age in typical development and with slowed processing in poor readers. These findings motivate an investigation of slowed processing speed as an endophenotype in dyslexia.

1205/F

Further investigation of the SNP rs17563 in the *BMP4* gene which was previously associated with in cleft lip and/or palate. *T.K. Araujo, M. Simioni, C.V. Maurer-Morelli, R. Secolin, I. Lopes-Cendes, V.L. Gil-da-Silva-Lopes.* Department of Medical Genetics, Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, SP, BRAZIL.

The pathogenesis of cleft lip and (or) palate (CL/P) involves genetic and environmental factors. The *BMP4* gene has distinct roles in embryonic development, including facial development. Overexpression of *BMP4* has been found in the maxillary prominence. The presence of a CL/P in *BMP4* knockout or null mutant mice indicate the importance of *BMP4* for embryonic facial fusion. The nonsynonymous polymorphism rs17563 (538T®C) of *BMP4* gene changes a valine to an alanine residue at codon 152. This polymorphism was significantly associated to the risk of nonsyndromic CL/P in Chinese population and was also described in patients with microforms of CL/P in a study involving different populations. The aim of our study was to investigate further the evidence for association between the rs17563 SNP and CL/P in a different population than previously reported. To date, we have included in our study 15 CL/P (8 non-syndromic and 7 syndromic) and 100 normal control individuals (50 M: 50F). Patients and controls were ascertained in our University Hospital which is located in the southeastern part of Brazil in Sao Paulo state. Selection criteria for the control group were: negative family history for CL/P in three successive generations, no evidence of any other serious illness and no oriental ancestry. Genotyping was performed using PCR-digestion. The frequencies of the TT, TC, and CC genotypes 538T®C were 40%, 46,7%, and 13,3% in the CL/P group, and 20, 8%, 53,1%, and 26,1% in the controls, respectively. The genotype distribution of the polymorphism is in Hardy-Weinberg equilibrium in both groups. In addition, our preliminary results showed no significant difference in the genotypes and allele frequencies of the *BMP4* 538T®C polymorphism between CL/P and control groups (p=0,119, OR=0,523, 95%CI). Financial Support: FAPESP, CNPQ.

1206/F

Pleiotropic genetic effects contribute to the correlation between bone mineral density and quantitative ultrasound measurements. *S.C. Nguyen[1], N.D. Nguyen[1], J.R. Center[1,3], J.A. Eisman[1,2,3], T.V. Nguyen[1,2].* 1) Osteoporosis and Bone Biology, Garvan Institute of Medical Research, Darlinghurst, NSW, Australia; 2) School of Public Health and Community Medicine, University of New South Wales, Kensington, NSW, Australia; 3) St Vincent's Hospital and St Vincent's Clinical School, Sydney, NSW, Australia.

The heritability of bone mineral density (BMD) has long been established using both twin and familial models. Similarly, various quantitative ultrasound (QUS) parameters of bone have been shown to be under genetic influence. BMD is correlated with QUS, but it is not known whether this is due to genetic or environmental influences. The present study was designed to examine whether BMD and QUS are affected by the same genetic factors. The study involved 622 individuals from 33 multigenerational families who were part of the Dubbo Osteoporosis Genetics Study, all aged 18+ at the time of participation. BMD at the femoral neck (FNBMD), lumbar spine (LSBMD) and total body (TBBMD) was measured by DXA (GE-Lunar Corp, Madison, WI, USA). Speed of sound (SOS) at the distal radius (DRSOS), midshaft of tibia (MTSOS) and proximal phalanges (PPSOS) were measured by Sunlight Omnisense (Sunlight Medical). The indices of heritability (h^2) of BMD and QUS measurements were estimated using the variance components model as implemented in the SOLAR program, taking into account the effects of age, sex, and anthropometric variables. Moreover, the genetic and environmental correlations were estimated by bivariate genetic analysis. The genetic correlation represents a measure of pleiotropic effects of genes influencing both traits concomitantly. Between 42% and 59% of the variation in BMD at different skeletal sites was attributable to genetic factors (h^2 for FNBMD 0.42 (SE: 0.09), LSBMD: 0.59 (0.07), and TBBMD: 0.54 (0.14)). The effect of genetic factors on QUS was slightly lower than for BMD (DRSOS: 0.21 (0.09), MTSOS: 0.39 (0.12), and PPSOS: 0.23 (0.12)). More importantly, there was a strong genetic correlation between the three BMD measurements (FNBMD vs. LSBMD: 0.55 (0.10), FNBMD vs. TBBMD: 0.77 (0.06), and LSBMD vs. TBBMD: 0.81 (0.09)). Moreover, there was a genetic correlation between DRSOS and FNBMD (0.52 (0.22)) and LSBMD (0.40 (0.17)), but the correlation was not statistically significant for other QUS measurements (0.08 to 0.40; $P > 0.05$). Furthermore, a modest genetic correlation was observed between total fat mass and LSBMD: 0.38 (0.17). These results suggest that pleiotropy contributes to the additive genetic variation in BMD measurements, and to a lesser extent, between BMD and QUS measurements. The presence of genetic correlation provides the rationale for multivariate analyses to identify novel genetic loci with pleiotropic effects on these bone traits.

1207/F

Blood group antigens related to transfusions in Italian population. *A. Saluto, O. Camerini, R. Prestinice, F. Rossini, F. Petrazzi, D. Lajolo di Cossano, P. Ottone.* Laboratory of Immunohematology and Transfusion Medicine, Ospedale San Luigi Gonzaga, Orbassano (TO), Italy.

Blood group antigens, present on the cell membrane of Red Blood Cells (RBCs), may be proteins, glycoproteins or glycolipids. Most of them are accommodated in 30 blood group systems; the gene encoding each blood group system has been cloned and sequenced and the molecular bases associated with the vast majority of blood group antigens have been determined (Veldhuisen, 2009). RBCs carrying a particular antigen, if introduced into the circulation of an individual who lacks that antigen (through transfusion or pregnancy) can elicit an immune response. Pretransfusion compatibility tests include ABO grouping and Rh typing of the recipient and donor blood and the detection of clinically relevant RBCs antibodies in the recipient that could potentially cause a severe hemolytic transfusion reactions; the donor blood is not routinely tested for other antigens. To evaluate the frequency of alloimmunization to RBCs antigens in the north-west Italian population we performed a seven years retrospective study (2003-2009) of patients referred to our hospital. 232 new antibody specificities were found in 194 alloimmunized patients; multiple new antibody specificities (2-6) were seen in 38 patients (19.6%). The identified alloantibodies, as a percentage of all alloantibodies observed, were E (19.8%), K (18%), D (9.5%), Jk^a (6.5%), C^w (6%), Lu^a (5.6%), C (5.6%), S (3.9%), e (3.9%), c (3.9%), M (3.5%), Fy^a (3.4%), Kp^a (2.6%), Jk^b (2.2%), Le^a (2.1%), Le^b (1.7%), Fy^b (0.86%), s (0.43%) and P_1 (0.43%). Our results are similar to those previously reported for south-west Dutch population, except for C^w, Lu^a, Kp^a, Le^a and Le^b alloantibodies that were not found (Schonewille, 2006). These findings suggest that relative frequency of C^w, Lu^a, Kp^a, Le^a and Le^b antigens could be different between Italian and Dutch populations. We observed a high frequency of Jk^a alloantibody (6.5%) as in Dutch study (7.9%); this result suggest that, as in Dutch population, there is a significant increase in relative immunogenicity of Jk^a antigen compared to the original result of Giblett, probably reflecting the use of more sensitive antibody screening over the years (Gibblet, 1961). Although RBCs antigen frequencies among whites are known, our work suggest that the relative frequency for the most clinically relevant antigens should be assessed in each European country.

1208/F

Genome-wide linkage scan for QTL influencing physical activity levels of children from the Jirel ethnic group in Eastern Nepal. *K.D. Williams[1], J. Blangero[2], R. Nahhas[3], T.D. Dyer[2], J. Subedi[4], B. Jha[5], J.L. VandeBerg[2], S. Williams-Blangero[2], B. Towne[3].* 1) Temple University, Philadelphia, PA; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Wright State University School of Medicine, Dayton, OH; 4) Miami University, Oxford, OH; 5) Tribuvan University Institute of Medicine, Kathmandu, Nepal.

Familial resemblance for physical activity has been established in several studies, but relatively few genome-wide scans have been conducted on quantitative measures of physical activity, and most of those have been carried out in adults from Western populations. Here we present the results of initial heritability and genome-wide linkage analyses of physical activity levels of healthy children from the Jirel ethnic group of Eastern Nepal who participate in the Jiri Growth Study. A total sample of 383 boys and girls aged 3 to 18 years, most belonging to one very large extended pedigree, each wore an Actical tri-axial accelerometer for one week that collected a data point every 15 seconds during that time period. Data were aggregated into 1 minute epochs and examined over 12-hour daylight periods (6 am to 6 pm). Activity count data in each of four categories (sedentary, light, moderate, and vigorous) were analyzed using a variance components-based method for pedigree data. All measures of physical activity were found to be significantly heritable: (sedentary $h^2 = 0.68 \pm 0.15$, $p < 0.0001$; light $h^2 = 0.85 \pm 0.13$, $p < 0.0001$; moderate $h^2 = 0.53 \pm 0.15$, $p < 0.001$; vigorous $h^2 = 0.33 \pm 0.17$, $p = 0.02$). Genome-wide linkage analyses were conducted in a subset of 220 children typed for ~400 STR markers at an average density of 10 cM. Sedentary activity count was significantly linked to chromosome 1q31-32 (LOD = 3.80). Modestly suggestive linkages at other chromosomal locations were observed for other activity level counts. Despite issues in some study environments regarding the sensitivity of accelerometers to capture variation in physical activity, our study demonstrates that the Actical accelerometer is a useful tool to measure and document variation in intensity of physical activity, especially in a free-living, largely agrarian population such as the Jirels. In sum, these preliminary results demonstrate a significant heritability of physical activity levels in Jirel children, and the feasibility of localizing and eventually identifying genes that influence everyday physical activity. This work was supported NIH grants F32HD053206, R01HD40377, R01AI37091, R01AI44406, and R37MH59490.

1209/F

Application of a genetic risk model of celiac disease to a prospective cohort from the United States. *J. Romanos[1], A. Szperl[1], C.C. van Diemen[1], G. Trynka[1], H.M. Boezen[2], A. Perlman[3], J.M. Norris[4], K. Barriga[3], G. Eisenbarth[3], M.J. Rewers[3], C. Wijmenga[1], E. Liu[3].* 1) Genetics Dept, UMCG, Groningen, Netherlands; 2) Epidemiology Dept, UMCG, Groningen, Netherlands; 3) Barbara Davis Center for Childhood Diabetes, University of Colorado Health Sciences Center, Denver, USA; 4) Epidemiology Dept, Colorado School of Public Health, Aurora, USA.

Celiac disease (CD) is a multi-organ chronic inflammatory disease affecting up to 1% of the general population. Besides the HLA-DQ, several non-HLA genes have been associated with CD in case-control studies, but not yet validated in population-based cohorts. Recently, we have proposed a genetic risk model which classifies individuals into groups of low-, intermediate-, and high-risk for CD, based on their HLA and non-HLA genotypes. Here, we applied this risk model to a large unique population-based cohort of children followed annually from birth to up to 16 yrs of age for development of transglutaminase autoantibodies (TGA) and CD. The phenotype of interest - CD-autoimmunity - was defined as persistent TGA positivity on 2 or more consecutive visits. We have genotyped 6 HLA and 10 non-HLA single nucleotide polymorphisms (SNPs) in 1124 non-Hispanic white independent children, selected from 31,690 newborns from Denver, Colorado, screened at birth for HLA-DR-DQ genotypes. CD-susceptibility HLA genotypes categorized these children into 3 risk groups: low (no-DQ2 or DQ8), intermediate (DQ8 and/or one dose of DQ2) and high (double dose of DQ2). Next, children with intermediate HLA-defined risk who had ≥13 non-HLA risk alleles were reclassified into the high risk group. Finally, CD-autoimmunity status was unmasked. Using non-HLA risk alleles, we were able to reclassify 3.5% CDA cases from the intermediate HLA-defined risk in the high risk group, increasing the number of cases in the high risk group by 39.5%. In Cox regression analysis, individuals with high-HLA risk and £12 non-HLA risk alleles (hazard ratio HR=2.70) and individuals with high-HLA risk and ≥13 non-HLA risk alleles (HR= 6.28) were at a significantly higher risk of CD-autoimmunity than those with intermediate-HLA risk and £12 non-HLA risk alleles. Moreover, persons with a high number of non-HLA loci appeared to develop CD-autoimmunity earlier in life. The risk model based on HLA- and non-HLA risk alleles holds promise of improved risk prediction for TG-based phenotype preceding clinical manifestation of CD.

Specific epithelium sodium channel genotypes are strongly associated with fast decline in lung function among children with cystic fibrosis (CF). *M.J. Emond[1], T. Louie[1], J. Emerson[2], S. Ruuska[2], S. McNamara[2], K.T. Buckingham[2], K. Joubran[2], B.W. Ramsey[2], M. Rosenfeld[2], R.L. Gibson[2], M.J. Bamshad[2], EPIC Observational Study Group.* 1) Biostatistics, University of Washington, Seattle, WA; 2) Dept of Pediatrics.

Background: Patients with CF exhibit high variability in disease severity, even within families, suggesting genetic factors in addition to CFTR mutations contribute to decline in lung function. The epithelial sodium channel (ENaC) is a membrane-bound heterodimer that interacts with CFTR to regulate airway surface liquid volume and composition. Patients with double mutations in ENaC or single mutations in both ENaC and CFTR have been shown to have CF-like disease. Objectives: We sought to determine whether variations in ENaC among children with CF modify severity of CF disease. Methods: Thirty-five ENaC SNPs were genotyped in 617 CF children born between 1992 and 2002 who had lung function measurements from the nation-wide EPIC study. Genotypes were evaluated for association with CF-specific FEV1 percentiles via longitudinal analysis, with modeling for population structure, potential confounders and effect-modifiers such as CFTR mutation class and sex. Results: Homozygous minor genotypes at two unlinked SCNN1B SNPs were strongly associated with faster decline in lung function, regardless of adjustments and sensitivity analyses. Differences in annual change in CF-specific FEV1 percentiles (95% confidence intervals) were -0.019 (-0.013, -0.025) and -0.021 (-0.013, -0.026) compared to other genotypes ($p< 1e-4$ for both after Bonferroni correction); children with these genotypes were more likely to have a negative slope over the study period (OR = 3.0, $p < 0.01$). Sweat test values were significantly higher in subjects with these genotypes compared to those without (105.1 vs. 100.1, $p<0.05$). Conclusions: These results provide strong evidence that variation in SCNN1B is associated with CF lung disease severity, complementing the family-based study of Stanke, et al, 2006. Identifying genetic modifiers can guide early intervention strategies for patients in high risk groups. Supported by the Cystic Fibrosis Foundation.

Complex chromosomal re-arrangement and imbalances in a family with retinoblastoma and multiple phenotypes. *S.P. Shankar[1,2,3], G.B. Hubbard[2,3], J.R. Wells[2,3], K. Coleman[1,3], E.C. Thorland[4], D. Rushlow[5], B.L. Gallie[5], P.M. Fernhoff[1,3], M.R. Rossi[1].* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Ophthalmology, Emory University, Atlanta GA; 3) Children's Healthcare of Atlanta Pediatric Hospital, Atlanta GA; 4) Department of Lab Med & Pathology, Mayo Clinic, Rochester, MN; 5) Retinoblastoma Solutions, Toronto Western Hospital, Toronto, Canada.

Retinoblastoma (RB) is the most common pediatric intraocular tumor and accounts for 3% of all childhood malignancies. Mutations in the gene *RB1* cause retinoblastoma in the majority of patients and, chromosomal deletions involving chr13q14 accounts for 5-7.5% of retinoblastoma. We report a family with retinoblastoma in proband and her mother having a different underlying etiology. The proband presented at birth with leukocoria and was found to have multifocal unilateral retinoblastoma associated with Hirschsprung disease, bilateral hearing loss, hypotonia, and abnormality of the brain showing unusual cortical folding pattern. Microarray analysis of the proband revealed interstitial deletion on chromosome 13(arr 13q14.11q31.1(40,615,956-84,609,688)X1 [hg18]), a region that includes the *RB1* gene and a number of other genes accounting for the multiple medical issues in her. The proband's mother had bilateral retinoblastoma diagnosed at age 6 months but has no other associated systemic abnormality. Mother's karyotype was reported as apparently balanced insertional translocation, ins(18;13)(18pter->q23::13q14.1::18q23->18qter;13pter->13q14.1::13q32.3->13qter). A genome wide microarray analysis in mother was normal. However, quantitative mutiplex-PCR and long-range PCR of the *RB1* gene showed 2 copies of all *RB1* exons with the exception of exon 12 suggesting disruption of one of the copies of *RB1* gene at exon 12 that resulted in her predisposition to the development of retinoblastoma. The proband has a 5 year old brother with microcephaly, developmental delay and ADHD but no retinoblastoma. His microarray analysis revealed duplication on chromosome 13 (arr 13q14.11q31.1(40,760,629-84,609,688)x3[hg18]), a region that includes *RB1* gene and corresponds to the region of deletion in the proband. Thus, this family demonstrates multiple phenotypes resulting from different molecular and cytogenetic abnormalities. It is not certain which copy of the *RB1* gene has non-amplification of exon 12 although, the most likely possibility is the *RB1* on the translocated copy. Any future children of mother have an overall 50% risk for developing retinoblastoma. The various possibilities of inheritance patterns have to be considered during risk counseling of such families and both molecular testing of *RB1* gene and karyotyping/microarray analysis should be offered to all at risk individuals in the family.

1212/W

Cytogenetics, Fluorescence in situ hybridization (FISH) and Oligo aCGH (OaCGH) techniques applied together in a case of acute myeloid leukemia help in further delineating a concomitant occurrence of the amplified MYC and MLL genes in a ring chromosome and the possible mechanism behind the ring formation. *R. Bajaj[1], A. Dulau[2], J. Gong[2], T. Holdbrook[2], M. Weiss[3], S. Peiper[4], Z. Wang[4].* 1) Molecular Cytogenetics, Thomas Jefferson University Hospital, Philadelphia, PA; 2) Division of Hematopathology, Thomas Jefferson University Hospital, Philadelphia, PA; 3) Department of Medical Oncology, Thomas Jefferson University Hospital, Philadelphia, PA; 4) Department of Pathology, Anatomy and Cell Biology, Thomas Jefferson University Hospital, Philadelphia, PA.

Acute myeloid leukemia (AML) is a heterogeneous disease with several morphologic and genetic subtypes that show recurring and uncharacterized chromosomal aberrations that are of etiologic, diagnostic, prognostic and therapeutic significance. AML may be induced by disruption of the normal structure and function of genes that control the balance of proliferation and differentiation in hematopoietic precursors. Two such genes are the proto-oncogenes MYC and MLL. Abnormalities in MYC expression, which is involved in cell cycle progression, apoptosis and cellular transformation, are often associated with leukemia. AML's with abnormalities of the MYC and MLL genes are associated with a poor prognosis and poor response to chemotherapy. MLL and MYC gene amplification have previously been described occurring together and independently in leukemia cell lines and in some AML patients. We describe the first patient, to our knowledge, with AML to demonstrate both MLL and MYC amplification on a ring chromosome and the possible mechanism for the formation of the ring chromosome identified by cytogenetics, fluorescence in situ hybridization (FISH) and OaCGH techniques. The chromosome analysis revealed a complex karyotype with two cell lines showing loss of both copies of chromosome 11, additional material on chromosome 17p leading to the loss of the TP53 gene, additional material on chromosome 18p, a ring chromosome and double minute chromosomes. FISH performed using MLL and MYC probes showed the presence of both amplified genes in a ring chromosome. In addition, a pattern of deletion of the 5' end and the amplification of the 3' end of the MYC gene in some interphase cells reveals a possible evolutionary mechanism of different cell lines. The OaCGH helped in further characterizing the possible mechanism that might have led to the formation of the ring chromosome.

1213/W

Germinative copy number changes in familial cancer predisposition. *C. Rosenberg[1], A. Gonçalves[2], E.M.M. Santos[2], L. Capelli[2], S. Costa[1], M.I.W. Achatz[2], R.R. Brentani[2], A.C.V. Krepischi[2].* 1) Dept Genetics and Evolutionary Biology, Univ Sao Paulo, Sao Paulo, SP, São Paulo, Brazil; 2) Antonio Prudente Foundation, A.C. Camargo Hospital, São Paulo, Brazil.

Detection of rare CNVs may reveal susceptibility genes in families with cancer predisposition. Such cases have already been reported for neuroblastomas, prostate, breast and pancreas tumors. On the other hand, individuals from such families may also display increased number of CNVs as the result of new mutations. Specifically, the number of CNVs in Li-Fraumeni patients has been reported to be 3 times higher than in normal controls. To ascertain the number and gene content of constitutive copy number changes in patients with cancer predisposition, we have screened germinative CNVs by array-CGH (4x180K Agilent) in 130 unrelated probands from families with clinical diagnosis to cancer predisposition: 60 from families with hereditary breast-ovarian cancer, 70 from Li-Fraumeni and Li-Fraumeni like families, and compared to 80 normal controls. In this study, the probands of breast-ovarian cancer families were prescreened for BRCA1 and BRCA2 gene mutations, and the individuals from Li-Fraumeni families for TP53 mutations; individuals with mutations for either gene were excluded. We subdivided the CNVs into common and rare, the latter being designated by occurring £ 3 times within the Database Genome Variants (DGV), which corresponds to ~15% of CNV detection events. The initial results point to a slight increase in the average number of all CNVs per individual in cancer patients (8.2 for breast-ovarian cancer, and 9.3 for Li-Fraumeni) as compared to the controls (6.8). However, the preliminary data for the category of so-called "rare alterations" indicates that the difference between groups is larger, and occurs approximately twice as frequently in cancer patients (average of 0.96±1.28 per individual) than in controls (average of 0.42±0.67 per individual). Some of the gene changes encompassed by these constitutive CNVs have been previously described in tumors. In conclusion, our results suggest a somewhat higher frequency of constitutive CNVs in cancer patients than controls, with a stronger effect noted for the "rare CNV" category. ***Support: FAPESP and CNPq***.

Interstitial deletion of 8p11.2-p12: clinical report. *J.A. Fahrner, N.L.M Sobreira, C. Dinsmore, A. Hamosh.* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD.

Deletions of the proximal part of 8p (8p11.1 to 8p23.1) have a heterogeneous phenotype characterized by spherocytosis, cardiac anomaly, hypogonadism, ocular abnormality, facial dysmorphism, microcephaly, growth retardation, and psychomotor retardation. Spherocytosis is caused by the deletion of *ANK1* on 8p11.2 and a critical region associated with congenital heart defects has been assigned to 8p23.1. About 20 cases of proximal 8p deletion have been described in the literature and the majority of these cases were characterized by standard karyotyping methods and the sizes of individual deletions were very variable. The delineation of the precise cytogenetic defects in these patients is important to understand their clinical phenotype and implicate novel genes that underlie the pathogenesis. Here we describe a 4-year-old girl with microcephaly, growth retardation, psychomotor retardation, spherocytosis, difficulty feeding, obstructive and central apnea, seizure disorder, mild hearing loss in the high frequencies, ear pits, bilateral retinal detachments and blindness, opaque corneas with band keratopathy in both eyes, deep set eyes with upslanting palpebral fissures, and a sacral dimple. Echocardiogram and abdominal ultrasound were normal. A standard karyotype study and FISH analysis revealed a minimal 5.3 Mb deletion, from 37.3 Mb to 42.6 Mb (8p11.2-p12). This region includes 49 annotated RefSeq genes. Approximately 13 cases of proximal 8p deletion reported in the literature were found to have regions of the deletions that partially overlap with 8p11.2p12 and of these, seven are known to have ocular abnormalities and two do not have ocular abnormalities. The ocular abnormalities usually include strabismus and nystagmus. SNP genotyping of this patient followed by more precise definition of the breakpoints of the deletion will determine what genes are involved in the deletion and comparing this deletion to deletions that overlap may disclose a critical region associated with ocular abnormalities or disclose candidate genes for the features of the deletion.

1215/W

Immunodeficiency-Centromere Instability-Facial Anomalies (ICF) syndrome resulting from a novel homozygous *DNMT3B* mutation. *H. Kearney[1], J. Kearney[1], M. Shook[1], R. Casey[1], J. Tarleton[1], S. Roberts[1], D. Russell[2], E. Boyd[1].* 1) Fullerton Genetics Center, Mission Hospitals, Asheville, NC; 2) Allergy Partners of Western North Carolina, Asheville, NC.

Immunodeficiency-Centromere Instability-Facial Anomalies Syndrome (ICF Syndrome) is a rare autosomal recessive disorder described in fewer than 50 individuals in the medical literature. ICF syndrome is characterized by immunodeficiency (agammaglobulinema or hypogammaglobulinemia resulting in frequent childhood infections and mortality), variable facial dysmorphism, and characteristic non-clonal chromosome abnormalities involving the centromeres of chromosomes 1, 16, and 9. Growth deficiency, failure to thrive and mild mental retardation are also described in a number of patients. The majority of ICF syndrome cases are shown to be caused by mutations in the *DNMT3B* gene, encoding a de novo DNA methyltransferase.

Our patient is a 23 year old male with hypogammaglobulinemia recognized in the first year of life, followed by regular IVIG therapy. Height and weight were below the 3rd centile, and mild dysmorphic features, developmental delays and cognitive disabilities were also noted. Routine cytogenetic analysis of PHA-stimulated lymphocytes showed breaks, isochromosomes, and radial formations involving the centromere of chromosome 1 in approximately half of the cells examined. SNP-based microarray revealed no clinically significant copy number imbalances, but did show multiple large homozygous regions, encompassing approximately 10% of the genome. Review of his family history confirmed that he was the product of a consanguineous union. Given the cytogenetic findings, the *DNMT3B* gene at 20q11.21 was checked for homozygosity, and was found in a homozygous segment. Subsequent sequence analysis revealed a novel homozygous missense mutation (c.1760G>A) that is predicted to result in a deleterious amino acid substitution in the methytransferase domain of the DNMT3B protein (p.G587D). The clinical features of this individual, the hallmark cytogenetic findings, and the predicted pathogenic nature of the missense mutation establish with reasonable confidence that this is a novel case of *DNMT3B*-associated ICF syndrome.

1216/W

Clinical and molecular characterization of chromosome 7p22.1 microduplication detected by array CGH. *J.V. Chui[1], J.D. Weisfeld-Adams[1,2], J. Tepperberg[3], L. Mehta[1].* 1) Department Genetics and Genomic Sciences, Mount Sinai School of Medicine, 1 Gustave L. Levy Place Box 1497, New York, NY 10029; 2) Department of Pediatrics, Mount Sinai School of Medicine, 1 Gustave L. Levy Place Box 1512, New York, NY 10029; 3) LabCorp, Center for Molecular Biology and Pathology, 1912 Alexander Dr., Research Triangle Park, North Carolina 27713.

A 28-month-old Peruvian male presented with speech delay and abnormal facial features including prominent forehead, anteverted nares, and ocular hypertelorism. The patient had a unilateral preauricular pit and a normal hearing evaluation. Closure of the anterior fontanel and bone age were significantly delayed. Motor development and stature were normal. Following normal routine chromosome analysis and subtelomeric FISH, diagnostic considerations included Greig cephalopolysyndactyly, Robinow syndrome or a skeletal dysplasia. However, characteristic features of these conditions were absent. Array CGH revealed a novel 1.7 Mb interstitial 7p22.1 duplication. FISH studies on the proband and his father and mother, who were 47 and 35 years old, respectively, at the time of conception, confirmed that the duplication had occurred de novo. To our knowledge, this finding represents the smallest interstitial 7p duplication reported to date. The Database of Genomic Variants lists 27 genes, 13 of which are OMIM annotated genes, within this region of chromosome 7p. However, none of the known functions of these genes make them obvious candidates for our patient's phenotype. 7p duplications can occur as a result of mis-segregation of unbalanced translocations or as "pure" duplications without any other chromosomal involvement, making genotype-phenotype correlations difficult. Some common phenotypic features of 7p duplication include macrocephaly, hypertelorism, large anterior fontanel, and mental retardation. Based on the findings in our patient, and those in previously reported cases of 7p duplication, we propose a role for genes in the 7p22.1 region in skeletal maturation and intellectual development.

1217/W

A FAMILY BALANCE TRANSLOCATION 46,XX,ins(7;10) (q21;q32q35) RESULTING IN A PARTIAL CHROMOSOME 7 TRISOMY IN THE PROGENY. A CASE REPORT AT THE HOSPITAL PARA EL NINO POBLANO, MEXICO. *J. Aparicio[1,8], M.L. Hurtado-hernandez[2], M. Barrientos-Perez[3], N.C. Gil-Orduna[7,8], W. San Martin-Brieke[7], S.I. Assia-Robles[4], R. Zamudio-Meneses[5], B. Vazquez-Juarez[6], F. Almanza-Flores[4], K. Villarreal-Borrego[4].* 1) Dept Genetics; 2) Cytogentics; 3) Endocrinology; 4) Pediatrics; 5) Cardiology; 6) Neurology; 7) Estomatology, Hosp para el Nino Poblano, Puebla,; 8) Estomatology, Benemerita Universidad Autonma de Puebla, Mexico.

INTRODUCTION. A reciprocal chromosome translocation between 7q and l0q was found in a healthy 44-year-old woman, with no physical or mental alterations was observed. However her unique male progeny, the propositus of this study, had a chromosomal 10q+ translocation. The clinical features of the patient were physical malformations as micrognathia, abnormal ears, and overlapping fingers and toes, cifoescoliosis and mental retardation. MATERIALS AND METHODS. A 7 years old male patient was clinically examined at the departments of Genetics, Neurology and also underwent karyotyping. The latter's karyotype was 46, XY (10q+). Trypsin-Giemsa banding analysis of the consultand's peripheral blood lymphocytes showed a chromosomal translocation. The patient mother was also studied by cytogenetics to find any possible healthy carrier. One translocations and insertion involved a portion of the long arm of a number 7 and number 10 chromosomes in a reciprocal rearrangement was observed in the patient's mother. Brain ventriculomegaly and subcortical atrophy was observed with a cranial tomography. DiSCUSSION. A balanced rearrangement between 7q and 10q was observed in one of the parents in this study, while the progeny had a partial chromosome 7 trisomy. The clinical features in the patient were bone malformations and mental retardation, mainly. Studies on large kindred with three cytogenetic markers were described by Jacobs et al. (1970). The healthy mother, ascertained through a cytogenetic survey, was found to have a balanced translocation and insertion between a number 7 chromosome and a 10 chromosome. There was only one pregnancy, however no miscarriages were reported. The propositus of this study had the chance to inherited 25% (7;10) normal, 25% (7;10q+) like the patient, 25% del(7q-;10), 25% balance translocation like the mother (7q-;10q+). The patient translocation t(7;10q+) leaded to a partial 7 chromosome trisomy. An early cytogenetic diagnosis should be important for an earlier treatment and a better quality of life.

Micronuclei in bone marrow cells of mice exposed to methylparathion, in vivo. *I. Aranha, T. Ornelas.* Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil.

The use of pesticides is still the main strategy to fight plagues in agriculture. Organophosphate esters represent a significant proportion of the world production of pesticides. Methylparathion is an organophosphate pesticide largely used. In order to exert its biological effect it must be biotransformed into its oxon-analogous, methylparaoxon, in the liver. Previous work in our laboratory, using the chromosomal aberrations assay in human lymphocytes exposed to different concentrations of these drugs(0.1, 0.25 and 0.5 ppm)in vitro have shown that while methylparathion had no clastogenic or aneugenic effect on the chromosomes, methylparaoxon in the same concentrations was responsible for the alterations in structure observed. The objective of the present work was to study the effect of methylparathion on chromosomes of mice bone marrow in vivo, using the micronucleus assay. Animals were separated into four groups. In the first group, 6 animals received methylparathion intraperitoneally during five consecutive days in a concentration equivalent to 25% of the LD_{50}. In the 6^{th} day, animals were sacrificed, their femurs removed, the bone marrow collected and smears were made for slides preparation. After 24h cells were stained with Giemsa Gurr (2%) and analyzed under optical microscope. As positive control, 6 animals received cyclophosphamide (50mg/mL) once. Six animals were injected intraperitoneally with the solvent(corn oil) and 6 animals not exposed to any drug served as negative control for the experiment. In the test group, 12000 cells were observed and 199 showed micronuclei. In the group exposed to the solvent, 12000 cells were analyzed, and none had micronucleus. In the positive control group, 12000 cells were observed and 102 had micronuclei and in the negative control group, of 12000 cells observed, none had micronucleus. The chi-square test for independence showed that our results were extremely significant ($P<0.0001$). They suggest that methylparathion is responsible for the micronuclei observed.

Inversions in the genome can both lead to triplications and contribute to rearrangement complexity. *C. Carvalho[1], M. Ramocki[2, 3], D. Pehlivan[1], L.M. Franco[1], L. Seaver[4, 5], L. Friehling[6], S. Lee[4, 5], R. Smith[7], D. del Gaudio[1], M. Withers[1], P. Liu[1], P.J. Hastings[1], S.W. Cheung[1], J.W. Belmont[8], H.Y. Zoghbi[1, 2, 3], J.R. Lupski[1, 2, 3].* 1) Dept Molecular Human Genetics, Baylor Col Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX; 4) Kapiolani Medical Specialists; 5) Departments of Pediatrics, John A. Burns School of Medicine, Honolulu, HI; 6) Children's Medical Associates, Alexandria, VA; 7) Department of Pediatrics, Maine Medical Center, Portland, ME; 8) Division of Cardiology, Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Genomic duplication involving the *MECP2* gene causes a clinically recognizable syndrome that includes infantile hypotonia, global developmental delays, progressive spasticity, recurrent infections, absent speech, and autism or autistic features. We identified complex rearrangements involving *MECP2*, characterized by a triplicated segment embedded within the duplication, in seven subjects. Here we provide detailed molecular characterization of those rearrangements obtained by customized oligonucleotide array CGH (aCGH), southern blot, breakpoint sequence and SNP array (Illumina Human Omni1-Quad). The complex rearrangements vary in size from ~430 kb to ~653 kb, whereas the triplicated regions range in size from ~33 kb to ~537 kb. Remarkably, in all cases one of the duplicated breakpoints and one of the triplicated breakpoints map within a low copy repeat (LCR) or within a small repeat (854 bp) in inverted orientation, suggesting that one of the breakpoint junctions was produced by a Non-Allelic Homologous Recombination (NAHR) mechanism and generated an inversion of the triplicated segment. Sequencing of the second breakpoint showed that the inverted triplicated segment is once more connected to the duplicated segment in opposite orientation (based on the reference genome) suggesting the following genomic organization: DUP-PIRT-DUP. Microhomologies or lack of homology were observed at those breakpoints suggesting the involvement of a second mechanism for formation underlying those rearrangements. All complex rearrangements were inherited from mothers (in one case it was demonstrated to be inherited from the available grandmother) and who display a skewed X-inactivation pattern in DNA isolated from blood. In summary, our data clearly show that inversions can both mediate triplication formation and contribute to the complexity. We also provide further evidence that the presence of LCRs in the *MECP2* vicinity can be associated with genome instability and potentially induce DNA strand lesions, generating complex rearrangements involving *MECP2* and flanking genes.

CLINICAL CHARACTERISTICS AND IDENTIFICATION OF CHROMOSOMAL ABNORMALITIES IN MEXICAN PATIENTS WITH PIGMENTARY MOSAICISM. *D. CERVANTES-BARRAGAN[1], R. CRUZ[1], C. SALAS[1], C. DURAN-MCKINSTER[2], V. DEL CASTILLO-RUIZ[1], P. PEREZ-VERA[1].* 1) DEPARTMENT OF HUMAN GENETICS NATIONAL INSTITUTE OF PEDIATRICS, MEXICO CITY, MEXICO; 2) DEPARTMENT OF DERMATOLOGY, NATIONAL INSTITUTE OF PEDIATRICS, MEXICO CITY, MEXICO.

Introduction: Mosaicism represents a phenomenon which encompasses two or more genetically different cell populations that proceed from the same zygote. Pigmentary mosaicism (PM) is a clinical condition that represents an example of phenotypic expression of genetic mosaicism. PM is a term that refers to hypopigmented and hyperpigmented skin lesions that follows the Blaschko's lines, including patients with Hypomelanosis of Ito and some others with linear and whorled nevoid hypermelanosis. Patients with PM can be associated with abnormal systemic features including central nervous, musculoskeletal and ocular systems (60-90%). Cytogenetic analysis of blood and fibroblasts reveals chromosomal mosaicism with structural or numerical abnormalities (30-60%). The purpose of this study was to determine the clinical systemic involvement and blood/fibroblast cytogenetic analysis of Mexican patients with PM. Methods: We tested 18 patients with PM in a period from 2002-2009, the patients were evaluated by Dermatology, Neurology, Orthopedics, Ophthalmology and Genetics Departments. Cytogenetic analysis of all patients were performed in T-lymphocytes from peripheral blood, and in fibroblasts from dark/light skin biopsies cultures. Fifty metaphases were analyzed by standard GTG bands in at least two cultures. Results: Clinical evaluation of the systemic involvement of the patients showed: mental retardation in 15/18 (83%) seizures 8/18 (15%), musculoskeletal involvement was present in 5/18 (27%), and ophthalmologic changes 4/18 patients (22%). Six out of the 18 PM patients (33%) presented chromosomal mosaicism: a)Three patients with rings: two cases with r(22)(p11.2-q13.3), one with r(7)(p22-q36); b) Two patients with deletions of the same chromosome, del(18)(q21.3) and del(18)(q21.1); and c) One with an apparently balanced translocation t(X;16)(p11.2; p13.3). Conclusions: Cytogenetic analyses in blood and fibroblast from dark and light skin is useful in the etiologic approach for patients with PM.

1221/W

Reciprocal insertion: a rare chromosomal rearrangement in a phenotypically normal mother explaining interstitial deletion and duplication in a patient with developmental delay and dysmorphic features. *S. Chenier, G. Mitchell, G. Mathonnet, E. Lemyre, F. Tihy.* Medical Genetics, CHU Sainte-Justine, Université de Montréal, Montreal, Canada.

Array comparative genomic hybridization (aCGH) is a clinically valuable molecular cytogenetic method for analyzing DNA copy-number variations. Not only aCGH can detect submicroscopic anomalies, but it can also help reveal, in conjunction with fluorescence in situ hybridization (FISH), genomic rearrangements previously thought to be exceedingly rare. We have recently detected by aCGH a 1p31.1p32.1 interstitial deletion and a 13q32.1q32.1 microduplication in a patient with developmental delay and facial dysmorphisms. Interestingly, parental studies using FISH analysis revealed that the mother of the child carried a balanced reciprocal insertion (1;13)(p31p32;q32.1q32.1). Reciprocal insertion is a rare chromosomal rearrangement that requires at least four interstitial breakage events and a reciprocal exchange of DNA fragments. Carriers of reciprocal insertions are at an increased risk of creating gametes with unbalanced chromosomal rearrangements leading to miscarriages or children with abnormalities. To our knowledge, less than five cases of constitutional reciprocal insertions have previously been reported. It can be expected that the increased resolution achieved by aCGH analysis in comparison to karyotype analysis as well as its common use in clinical practice will demonstrate that reciprocal insertion occurs more frequently than previously thought. This case illustrates the need to confirm the location of copy number deletions and duplications detected by aCGH with techniques such as FISH analysis in order to guide genetic counselling.

1222/W

Cytogenetic analysis in fetal blood. *J. Choi[1], M. Woo[1], N. Song[1], H. Ko[1,2], S. Oh[1,2], C. Park[1,2], J. Park[1,2], J. Jun[1,2], S. Kim[1,2], Y. Choi[1,2], S. Moon[1,2].* 1) Institute of Reproductive Medicine and Population, Medical Research Center, Seoul National University, Seoul, Korea; 2) Department of Obstetrics and Gynecology, College of Medicine, Seoul National University, Seoul, Korea.

This study reviewed cytogenetic results in 568 fetal blood samples by cordocentesis from second- and third-trimester pregnancies to identify associated problems with fetus and to confirm abnormal karyotype of cultured amniotic fluid cells. Chromosome abnormality was detected in 80 cases (14.1%) which contained 60 cases (75%) of numerical aberration and 20 cases (25%) of structural aberration. The most frequent abnormalities were sex chromosomal mosaicisms (23 cases, 28.8%) fallowed by autosomal trisomies (22 case, 27.5%) and sex chromosomal trisomies (7 cases, 8.8%). Twenty-two cases (27.5%) were consistent with autosomal trisomies, including eleven cases of trisomy 18, eight cases of trisomy 21 and three cases of trisomy 13. Among structural aberrations, translocations (6 cases, 7.5%), maker chromosomes (4 cases, 0.5%) and additions (4 cases, 0.5%) were prevalent. One of three cases with unbalanced reciprocal translocation and one of two cases with balanced translocation were inherited from male translocation carriers. In order to obtain definitive results, 44 cases with chromosomal aberration in amniotic fluid cells investigated in fetal blood and 25 cases (56.8%) showed the same abnormality in fetal blood. Three of twenty-one cases previously defined as true mosaicism in amniotic fluid cells revealed a normal karyotype in fetal blood. Interestingly, one of three cases with mosaic trisomy 20 confirmed in fetal blood, whereas the others showed a normal karyotype in fetal blood. Cytogenetic analysis in fetal blood by cordocentesis is necessary for prenatal genetic diagnosis in pregnancies that indicated high risk for fetal abnormalities or presented abnormal karyotypes of cultured amniotic fluid cells.

1223/W

Mosaic ring (9) syndrome, report a new case. *M.M. Duenas Roque, G. Campoverde Avila.* Hospital Guillermo Almenara Irigoyen , Lima, Lima, Peru. Resident.

The ring 9 syndrome is a rare genetic disorder observed in the children with variable clinical presentation and phenotype. The syndrome is caracterized by growth and developmental delay, mild hirsutism, dysmorphic face, microcephaly and hipoacusia. We present the case of a nine year old girl, who was born post-term by spontaneous vaginal delivery. Birth weight was 2560g,birth height was 43cm, presenting with microcephaly, prognatism, clynodactyly, short stature, language and learning disabilities, and mild to moderate mental retardation. Auditory evoked potencial was normal. The karyotype was a mosaic of three cell lines: 46, XX/46, XX, r(9)/46, XX, r(dup 9) . The parents karyotypes were normal.

1224/W

Mosaic partial trisomy 19p12-q13.11 in Asperger Syndrome due to a small supernumerary marker chromosome, suspected through array-based comparative genomic hybridization. *F.R. Faucz[1,2], J. Souza[2], A. Bonalumi[2], V.S. Sotomaior[2], E. Frantz[3], S. Antoniuk[4], J. Mokry[5], S. Raskin[2,6].* 1) Section of Endocrinology and Genetics, Program on Developmental Endocrinology & Genetics (PDEGEN), National Institute of Child Health & Human Development (NICHD), National Institutes of Health (NIH), Bethesda, MD, USA; 2) Laboratory of Molecular Genetics, Core for Advanced Molecular Investigation (NIMA), Center for Health and Biological Sciences (CCBS), Pontificia Universidade Católica do Paraná (PUCPR), Curitiba, PR, Brazil; 3) Department of Neurology, Blumenau, SC, Brazil; 4) Departamento de Pediatria UFPR, Curitiba, PR, Brazil; 5) Signature Genomics, Spokane, Washington, USA; 6) Laboratory Genetika, Curitiba, PR, Brazil.

Small supernumerary marker chromosomes (sSMC) are present in 0.075% of unselected prenatal and 0.044% of postnatal cases. In the mentally subnormal population the sSMC rate is 0.288%. The risk of phenotypic abnormalities in de novo prenatally detected cases of sSMC is estimated to be 26%. Here we report the case of a four-year-old boy with Asperger Syndrome. The patient is the first child of a healthy 39-year-old mother and 54-year-old father. Pregnancy was complicated in the last month by oligoamnio. The mother had no history of medication or drug use. There was no family history of any malformation or mental retardation. The weight, height and Apgar score at birth were normal. The neonatal period was complicated by lack of breast suction and mild hypotonia. His developmental milestones were delayed and now, at 4 years and 10 months of age, he is on preschool education and has short attention span and few social interaction with other children. He had long face with high nasal bridge and thin upper lip. No other dysmorphic features were noted. An auditory brain response showed unilateral mild neurosensorial hearing loss. Neurological examination revealed diffuse mild hypotonia with normal deep tendon reflexes and impairment in social interaction, obsessive/compulsive behavior, emotional immaturity, attention deficit, specific interests in certain activities, mood disorder, insecurity and gullibility. The intellect level, eyesight and hearing were normal, fitting with a diagnosis of Asperger Syndrome. Conventional cytogenetic study showed a small supernumerary marker chromosome (sSMC) on around 60% of the cells. To identify the origin of the sSMC a microarray-based comparative genomic hybridization (aCGH) was performed using a 135K-feature whole-genome microarray and a partial trissomy in a pericentromeric region of chromosome 19 was seen. The region spans 18.4Mb, contains at least 55 genes and is located between 19p12 and 19q13.11. To confirm this result and the mosaicism, a FISH was performed using BAC clones to visualize the abnormalities and 43.3% of mosaicism was detected. Based on the size and genic content is expected that the partial trisomy detected to be responsible for the characteristics observed in the patient. In that case it could be an indication of a novel locus associated with Asperger syndrome.

1225/W

Characterization of Chromosomal Aberrations in the NIGMS Human Genetic Cell Repository by the Affymetrix GeneChip SNP 6.0. *N. Gerry, L. Toji, C. Beiswanger, B. Frederick, J. Leonard, D. Berlin.* Coriell Institute for Medical Research, Camden, NJ.

The Affymetrix SNP Array 6.0 was used to define the chromosomal segments gained and lost in more than 700 samples from the NIGMS Human Genetic Cell Repository Chromosomal Aberrations collection. This collection contains a wide variety of copy number variants, including micro or sub-micro deletions and duplications, translocations, aneuploidies, and isodicentric chromosomes. All of the samples had been previously characterized by G-band, FISH and/or PCR. Data were analyzed for copy number changes using Affymetrix Genotyping Console Software. The resolution of the Affymetrix SNP Array 6.0 data allowed characterization of chromosomal copy number changes in the kilobase range. Within the samples studied, the smallest change detected was a 35 kb deletion of an exon in the SNRPN gene in a Prader-Willi sample. This result, along with many other submicroscopic changes detected on the array, agreed with prior molecular mapping experiments. The high resolution of the array also provided the ability to distinguish between chromosome breakpoints in multiple samples of the same disorder that appeared nearly identical by traditional G-band analysis, but in fact were all unique. In addition, the array provided more accurate breakpoints for submicroscopic changes that had previously been identified by FISH using only one, or at most a few, markers in the critical region. Finally, previously unrecognized complexities such as cryptic translocations and duplications adjacent to syndrome-specific deletions were identified by the array.

The copy number segment data and graphic output from Affymetrix Genotyping Console are being used to upgrade the descriptions of these samples on the Coriell Cell Repositories web-site (http://ccr.coriell.org/) to better inform users in their decisions for experimental design and choice of reference samples. Each of the samples is publicly available as a culture and many are available as DNA. In addition, the raw data for all of the samples has been deposited with the database of Genotypes and Phenotypes (dbGaP) and is available for download.

1226/W

A familial 12.7 Mb deletion in the proximal short arm of chromosome 3 with no apparent phenotypic abnormality. *A. Hajianpour, J.C. Wang, A. Khanna, J. Szymanska, R. Habibian.* Dept Cytogenetics, Genzyme, Monrovia, CA.

Amniocentesis was performed on a 43 year old woman G1, P0, SAB1 at a gestational age of 17 weeks due to AMA, abnormal maternal serum screen with increased risk of chromosome abnormality. There were no abnormal ultrasound findings. Cytogenetic analysis revealed an abnormal chromosome 3 with an interstitial deletion in the proximal short arm: 46,XX, del (3)(p11.2p13). The same abnormal chromosome 3 was present in the mother, who apparently does not have any phenotypic abnormality. Array CGH analysis on the mother and the fetus showed a 12.7 Mb deletion in 3p12.3-3p11.1. This deletion contains at least 12 OMIM genes and is expected to be clinically relevant due to size and gene content. However, its clinical significance is less clear in this case since the same chromosome abnormality is present in a phenotypically normal parent,. An apparently normal baby girl was born at 38 weeks. The baby is doing well at age of three months. A follow up examination at age of 8 months is scheduled and will be presented. This case illustrates the many challenges at prenatal diagnosis and the uncertainty in view of abnormal cytogenetic findings with normal follow up of the pregnancy.

1227/W

Genetic, environmental, age, and chromosome-specific influences on acquired aneuploidy frequencies in lymphocytes: A twin study. *C. Jackson-Cook[1,2], K. Jones[1], C. Rehder[1,3], Y-J. Chen[1], T. York[2].* 1) Dept Pathology, VA Commonwealth Univ, Richmond, VA; 2) Dept Human & Molecular Genetics, VA Commonwealth Univ, Richmond, VA; 3) Dept Pathology & Duke University Health Systems Clinical Laboratories, Duke Univ, Durham, NC.

Although acquired chromosomal abnormalities have been associated with several age-related health conditions, little is known about the genetic or environmental factors influencing their frequency in healthy individuals. Therefore, we initiated a twin study to determine the: (1) frequency of acquired aneuploidy in cultured lymphocytes; and (2) variation attributable to genetic versus environmental factors. To date, 191 twins (63 males; 128 females with 88 complete twin pairs) ages 7 to 85 have been studied. Acquired aneuploidy was evaluated using: (1) a micronuclei (MN) assay (n=145) coupled with a SKY analysis (n=79); and (2) an interphase FISH assay (n=191) using probes for each of the 24 chromosomes. For all chromosomes, loss was seen more frequently than gain ($p<0.05$). In both assays significant increases in abnormalities involving the X (female) or Y (male) chromosome were observed, with this effect being positively correlated with age ($p<0.0001$, $p=0.04$). In addition to age, the completion of puberty in either gender ($p=0.036$) and menopause in females ($p=0.024$) was associated with a significant increase in MN frequencies. Interestingly, a significantly increased frequency of aneuploidy "rescue" was observed for the X (females) and Y (males) chromosomes in the MN from younger compared to older twins ($p=0.03$), suggesting that different mechanisms result in the aneuploidy present at different ages. A non-random pattern of autosomal abnormalities was detected ($p<0.0001$ in MN and FISH), with chromosomes 4, 8, & 9 and 1, 18, & 16 having the highest frequencies in the MN and FISH assays, respectively. Thus, 4 of the 6 chromosomes having the highest frequencies are heterochromatin-rich. The lowest frequencies were observed for chromosomes 22 (MN) and 20 (FISH). Genetic model fitting indicated that influences from both additive genetic (46.8%) and unique environmental (53.2%) sources best explained the observed variance in MN data. Specific environmental factors that significantly influenced MN frequencies included dietary [decreases correlated with consuming fruit ($p=0.016$), green, leafy vegetables ($p< 0.001$), and/or folate-enriched bread ($p=0.035$)], and lifestyle [increases in females using tobacco ($p<0.001$)] choices. In conclusion, the frequency of acquired aneuploidy in humans appears to be a complex trait that is influenced by both environmental and additive genetic components, with chromosome-specific and age-related differences being present.

High Resolution Analysis of Human Chromosome 13 Partial Aneuploidies. *V. Jobanputra, A. Burke, A. Muhlhauser, O. Nahum, K. Anyane-Yeboa, W. Chung, B. Levy, D. Warburton.* Columbia University Medical Center, New York, NY.

Partial deletions and duplication of chromosome 13 (Chr13) have been described with widely varying phenotypes. Some cases have major malformations such as oligodactyly, holoprosencephaly, microopthalmia and heart defects: others have only minor developmental delay or dysmorphic features. Although several attempts have been made to establish genotype-phenotype correlations based on banding patterns in patients with Chr13 abnormalities, it is still unclear as to which regions or gene(s) on Chr13 contribute to specific phenotypic features in these patients. The ability to make these correlations is compromised by the limited resolution of standard karyotyping. Oligonucleotide-based genomic microarrays provide an opportunity to re-evaluate these data at an ultra-high resolution. To date we have recruited 16 cases of partial deletions and 4 cases of partial duplications of Chr13. We are collecting detailed clinical information from these patients. We have performed SNP microarray analysis (Affymetrix 6.0) for precise characterization of the chromosome abnormality in 17 cases identified by conventional cytogenetic, array CGH, or targeted clinical microarrays. In addition, cell lines from 3 patients carrying partial trisomy or tetrasomy of distal Chr13 were also analyzed. In preliminary analyses, the deletions (n=16) ranged from 3.28 Mb to 45.23 Mb and the duplications (n=7) ranged from 564 kb to 64.78Mb. To construct a genotype-phenotype map, a smallest region of overlap is identified and the copy number changes from these segmental aneuploidies are compared with the phenotypic features recorded for the patients. As an example of the type of information that can be obtained, we identified 7 cases with duplications that included the ZIC2 gene in 13q32 that leads to holoprosencephaly when deleted or mutated. None had holoprosencephaly, contrary to some experimental data suggesting ZIC2 overexpression would be deleterious. Collection of similar data in other regions will improve our ability to predict phenotype prenatally or in infancy and to establish the genes associated with specific phenotypic abnormalities in these patients.

Chromosomal aberrations delineated by aCGH and RT-PCR in the families with Mental Retardation. *J. Kasnauskiene[1], Z. Ciuladaite[1], A. Alexandrou[2], G. Koumbaris[2], P.C. Patsalis[2], V. Kucinskas[1].* 1) Department of Human and Medical Genetics, Vilnius University, Vilnius, Lithuania; 2) Department of Cytogenetics and Genomics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus.

The purpose of our study was to identify pathogenic chromosomal aberrations for patients with mental retardation. We present the results of analysis in 26 patients with mental retardation, developmental delay and/or congenital malformations with normal karyotype. Oligo aCGH 105K (Agilent Technologies) for identification of copy number changes and submicroscopic deletions/duplications and RT-PCR for confirmation and heritability of rearrangements were used. De novo CNVs were identified in 8 % (del(5)(q14.3q14.1) and dup(16)(p13.3). Del(16)(p11.2) for one patient maternal origin was identified. 16p11.2 microduplication syndrome associated with autism and in published cases arose as de novo rearrangements. We found inherited CNVs (deletions and duplications) not previously described in the normal location in approximately 20% of the cases: dup(1)(p21), dup(3)(p22.2), dup(3)(p26.3), del(4)(q28.3), dup(7)(p21.1), dup(12)(q14.2), dup(12)(q24), and dup(17)(q22q23). Sizes of the variation are from 0.1 to 1.3 Mb. The CNVs can be involved in mental retardation and developmental delay due to altering the expression of the genes in genomic regions. The research is founded by the FP7/2007-2013 under grant agreement No. 223692, CHERISH project.

1230/W

Molecular cytogenetics using array-CGH in three deletion groups of chromosome 6q. *E.M Kwon[1], E.J Seo[1,2,4], S.Y Shin[1,2], K.J Kim[4], M. Hong[4], H.W Yoo[1,3,4], J.Y Lee[1].* 1) Medical Genetics Clinics & Laboratory, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea; 2) Department of Laboratory Medicine, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea; 3) Department of Pediatrics, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea; 4) Genomic Research Center for Birth defects and Genetic disorders, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

Interstitial deletions of chromosome 6q are a relatively rare finding. Deletions have ranged from the loss of a single band to larger deletions spanning multiple bands. The clinical phenotype varies, but some features commonly seen include cardiac anomalies, hypotonia, facial dysmorphism and mental retardation. To further delineate the syndrome, we report a detailed clinical and molecular characterization of three patients with three different deletions, namely, proximal (q12-q14.3), middle (q16.3-q22.31), and terminal (q27) deletion of chromosome 6q. Conventional chromosome analysis revealed an interstitial deletion in the long arm of chromosome 6. The deletion was confirmed and visualized at the molecular level by array comparative genomic hybridization (array CGH). Case 1 was 1-year-old child with a de novo 19.5 Mb deletion in the 6q12-q14.3 ascertained by array CGH. The clinical features of this patient include developmental delay, dolicocephaly, facial asymmetry, dysmorphism such as laterally upslant eye with narrow palpebral fissure, low-set ear, receded chin, flat nasal bridge and bulbous nose, high arched palate, micropenis with both undescended testis, umbilical hernia, slender and pencil-like hands, and hypotonia. Case 2 was a 4-month girl with microcephaly, dysmorphism, and congenital heart defect of VSD. Array CGH showed a 16.2Mb deletion in the 6q16.3-q22.31, demonstrating higher resolution than the conventional cytogenetic findings, del(6)(q16.2q22.2). Case 3 with vetriculomegaly and cerebellar hypoplasia had a prenatally detected to have a de novo 3.8Mb terminal deletion in 6q27. Phenotypes and array CGH results shown in these 3 patients were compatible with clinical features and chromosomal regions described in literatures. Array CGH can provide precise location information linked to physical and genetic maps of the human genome.

1231/W

Copy number gain at Xp22.31: mechanisms and clinical phenotypic consequences. *P. Liu[1], A. Erez[1], S.C. Sreenath Nagamani[1], W. Bi[1], C.M.B. Carvalho[1], A.D. Simmons[1], J. Wiszniewska[1], P. Fang[1], P.A. Eng[1], M.L. Cooper[1], V.R. Sutton[1], E.R. Roeder[4], J.B. Bodensteiner[5], M.R. Delgado[6], S.K. Prakash[1], J.W. Belmont[1], J.S. Berg[7], M. Shinawi[8], A. Patel[1], S.W. Cheung[1], J.R. Lupski[1,2,3].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Dept of Pediatrics, Baylor College of Med, Houston, TX; 3) Texas Children's Hospital, Houston, TX; 4) Dept of Pediatrics, Univ of Texas Health Science Center at San Antonio, San Antonio, TX; 5) Division of Child Neurology, St. Joseph's Hospital and Medical Center, Phoenix, AZ; 6) Dept of Neurology, Univ of Texas Southwestern Medical School, Dallas, TX; 7) Dept of Genetics, Univ of North Carolina, Chapel Hill, NC; 8) Division of Genetics and Genomic Medicine, Dept of Pediatrics, Washington Univ School of Med, St Louis, MO.

Genomic instability is a feature of the human Xp22.31 region wherein deletions are associated with X-linked ichthyosis, mental retardation, and attention deficit hyperactivity disorder. A recombination hotspot motif is enriched within the low copy repeats that mediate recurrent deletion at this locus. To date, few efforts have focused on copy number gain at Xp22.31. Clinical testing has revealed a high incidence of duplication of Xp22.31 in subjects ascertained and referred with neurobehavioral phenotypes. We designed a high-density custom oligonucleotide array comparative genomic hybridization (aCGH) assay to interrogate Xp22.31 and systematically studied sixty-one unrelated subjects with rearrangements revealing gain in copy number. We detected not only the anticipated recurrent and simple nonrecurrent duplications, but also unexpected recurrent triplications and other complex rearrangements. Breakpoint analyses enabled us to surmise the mechanisms for many of these rearrangements; the mechanisms include "hotspot motif" associated NAHR in the majority of the patients, NHEJ (at least 2/61 subjects), and replication based mechanisms. Clinical studies in our subjects with Xp22.31 recurrent duplications and recurrent triplications uncovered potential clinical neurobehavioral consequences of these structural variations. Our findings reveal the spectrum of different mechanisms for genomic duplication rearrangements at a given locus, and provide insights into aspects of strand exchange events between paralogous sequences in humans.

1232/W

Two Cases with Rare Chromosomal Abnormality of Chromosome 12p Presenting Pallister-Killian Syndrome Phenotype. *G. Luleci[1], E. Mihci[2], Z. Cetin[1], S. Yakut[1], I. Keser[1], S. Berker-Karauzum[1].* 1) Medical Biology, Akdeniz University,Faculty of Medicine, Antalya, Turkey; 2) Pediatric Genetics,Akdeniz University,Faculty of Medicine, Antalya, Turkey.

Pallister-Killian Syndome (PKS) is a rare genetic disorder usually characterized by mosaic tetrasomy of isochromosome 12p detected in cultured fibroblast cells. We report here two rare cases with unusual cytogenetic findings including; nonmosaic, pure and complete trisomy of 12p and intrachromosomal triplication of short arm of chromosome 12 which are rare chromosomal abnormalities observed in patients with Pallister-Killian Syndrome phenotype. Case 1; is a unique patient with nonmosaic trisomy 12p which resulted from centric fission of maternal chromosome 12. 12p fission product have observed both in peripheral blood lymphocytes and skin fibroblast cells. Conventional cytogenetic and fluorescence in situ hybridization (FISH) techniques were used to detect proband's karyotype which is 47,XX,+fis(12)(p10)mat, and mother's karyotype is 47,XX,-12,+fis(12)(p10),+fis(12)(q10). Case 2: is a rare case diagnosed as Pallister-Killian Syndrome with a karyotype designated as 46,XX,inv trp(12)(p11.2p13) [34]/ 46,XX[16] de novo in fibroblast cells but not peripheral blood lymphocytes. According to the literature, case 1 is the first case with centric fission of chromosome 12 resulting in formation of telocentric fission product. Also review of the published reports shows that our case 2 is third case with PKS and intrachromosomal triplication of whole short arm of chromosome 12. Our findings show that non-mosaic trisomy 12p and mosaic intrachromosomal triplication of 12p are very rare but possible mechanisms for formation of trisomy 12p syndrome clinical phenotype.

1233/W

Breakpoint determination of X;autosome balanced chromosomal translocations in four patients with premature ovarian failure. *A. Nishimura[1], T. Wada[2], G. Bano[3], T. Kosho[4], N. Ando[5], H. Hamanoue[1,6], H. Sakakibara[6], Y. Tsurusaki[1], H. Doi[1], N. Miyake[1], H. Saitsu[1], Y. Fukushima[4], F. Hirahara[6], N. Matsumoto[1].* 1) Dept Human Gen, Yokohama City Univ Med, Yokohama, Japan; 2) Division of Neurology, Clinical Research Institute, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Cellular and Molecular Medicine, St George's University of London, London, UK; 4) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 5) Division of Obstetrics and Gynecology, Yokohama Municipal Citizens Hospital, Yokohama, Japan; 6) Department of Obstetrics and Gynecology and Reproductive Science, Yokohama City University Graduate School of Medicine, Yokohama, Japan.

Premature ovarian failure (POF) is a disorder characterized by amenorrhea and elevated serum gonadotropins before 40 years of age. The risk of this disorder or natural menopause before 40 years is approximately 1%. Heterogeneous etiology should be involved in POF, such as environmental, autoimmune, and genetic factors. X chromosomal abnormalities [partial monosomies and X;autosome-balanced translocations] are often observed in POF patients. These rearrangements cluster at Xq13-q26 called as the critical region (for POF). The critical region is separated into two, critical region 1 at Xq13-q21 and critical region 2 at Xq23-q26. It may be possible that ovarian development and/or function are hampered by haploinsufficiency of genes in these regions. However, genetic factors of POF are more complex as X;autosome-translocations often disrupt no genes and other factors such as position effects of autosomal genes are proposed. We had an opportunity to analyze four cases of POF each having t(X;autosome). Chromosome analysis revealed 46,X,t(X;4)(q21.3;p15.2) in case 1, 46,X,t(X;2)(q22;p13) in case 2, 46,X,t(X;4)(q22.1;q12) in case 3, and 46,X,t(X;14)(q24;q32.1) in case 4. We hypothesized that precise determination by cloning and sequencing of translocation breakpoints in these patients should bring us direct evidence of POF-related genes. We could successfully clone the junction fragments from all the patients. Data of breakpoint sequences in relation to genes will be presented and discussed.

1234/W

A new case of dup/del8p associated with autism and epilepsy detected by Genome array-CGH. *A. Nucaro[1], T. Pisano[2], I. Chillotti[2], S. Zorco[3], N. Santini[3], C. Montaldo[3], C. Cianchetti[2], D. Pruna[2].* 1) CNR, Inst Neurogen Neurofarmacolog, Monserrato, Italy; 2) Clinica di Neuropsichiatria Infantile, Azienda Ospedaliero- Universitaria, Cagliari, Italy; 3) OBL, Dipartimento Scienze Chirurgiche, Università di Cagliari, Italy.

Autism is a neurodevelopmental disorder with early childhood onset and a prevalence of as much as 5/10,000. Symptoms that may contribute throughout life include qualitative impairments in reciprocal communication and social interaction, as well as repetitive and stereotyped behavior. We report on a case of 8-year-old male with partial trisomy 8p (22;23.1)/partial monosomy 8p(23.2;pter) associated with autism, mild dysmorphic features, epilepsy and moderate learning disability. The cryptic deletion has been detected by Genome array- CGH. Although mental retardation is a common finding in patients with mosaic trisomy 8 or partial trisomy of various regions of chromosome 8, only few cases associated with autism and epilepsy have been reported so far (Glancy et al. 2009). In our case a cryptic deletion is also present. Clinical manifestations were mild compared to other patients with duplication of the same region of chromosome 8. Recently, Chien et al (2010) identified a terminal deletion of about 2.4 Mb at 8p 23.2;pter in a boy with autism and epilepsy. It is known that there is a close relationship between autism and epilepsy as about 30% of autistic individuals also have a history of seizures. Although there has been no strong evidence for linkage on chromosome 8p in any of the genome-wide linkage studies so far, the possibility that this segment includes genes involved in the etiology of both autism and/or epilepsy should be further explored.

1235/W

Prenatal Diagnosis of a Recombinant Chromosome 5 Resulting from a Complex Maternal Chromosome Rearrangement. *V. Potluri[1], J. Smith[1], J. Hoskovec[2], T. Solomon[1], P. Papenhausen[3].* 1) Dynagene/Labcorp, Houston, TX; 2) University of Texas Houston Medical School, Houston, TX; 3) Laboratory Corporation of America, Research Triangle Park, NC.

A 23 year old G2P1 woman was referred for prenatal testing at 30 weeks gestation due to abnormal targeted ultrasound findings including unilateral cleft lip, colpocephaly, possible ventricular septal defect and intrauterine growth restriction. An MRI confirmed the presence of the cleft lip without a cleft palate; no other brain malformations in addition to colpocephaly were detected. She has a previous child from a different partner with developmental delay. Chromosome analysis of amniotic fluid showed additional chromatin of unknown origin on the short arm of chromosome 5. A complex rearrangement involving chromosomes 5 and 9 was observed on the maternal analysis, but the maternal derivative 5 was not the same as the fetal derivative 5. After chromosome painting, the derivative chromosomes were described as follows: der(5)(9pter->9p13::5p15.1->5q13::9p13->9p11::5p15.1->5pter),der(9)(5qter->5q13:: 9p11->9qter). The baby received the normal maternal 9 and a recombinant abnormal 5. A whole arm exchange between the complex maternal der(5) and her normal 5 must have occurred during meiosis to produce the baby's rec(5) which can be described as follows: rec(5)(9pter->9p13::5p15.1->5qter). Therefore, the fetus is trisomic for 9p13 to 9pter and monosomic for 5p15.1 to 5pter. A whole genome microarray analysis was performed on the maternal sample using the Affymetrix 6.0 SNP platform. A 980 kb interstitial deletion was detected in 5p15.1, one of the breakpoints assigned by G banding to her derivative 5. The linear positions of the deletion are 16,338,682 and 17,318,602. Four known OMIM annotated genes are in the deleted region (FAM134B; MYO10; ZNF622; BASP1) with minimal known copy number variant overlap. Additional studies are in progress on her developmentally delayed son and on her mother. The maternal rearrangement appears to represent a translocation with an additional pericentric inversion of the derivative 5 which is likely to predispose to unbalanced recombinants, but which in itself, may not be balanced.

1236/W

Jumping translocation: A conundrum. *K. Reddy.* Cytogenetics department, Kaiser Permanente of Southern California, 4580 Electronics Place, Los Angeles, CA 90039.

Jumping translocations (JTs) are rare constitutional or acquired rearrangements involving a donor and several receiver chromosomes. They may be inherited or de novo. JTs can be found as a cultural artifact, in normal individuals or in pathological conditions. The clinical consequences range from spontaneous abortion, loss of fetus, chromosome syndrome, congenital abnormalities, infertility to malignancy. The breakpoints of JTs, are localized predominantly in repeat regions such as pericentromeric, centromeric, subtelomeric, telomeric and occasionally interstitial regions that may be a low copy repeat(LCR) or variant telomere sequence. Differences between the constitutional and acquired JTs donor breakpoints suggest an independent mechanism in their formation. We describe: a new jumping translocation found during CVS prenatal diagnosis of a twin pregnancy using molecular cytogenetic techniques; discuss two new JTs in hematological malignancy involving rare chromosome donor sites (3q21 and 11q13) and consolidate our knowledge on JTs. This study highlights the diagnostic challenges of JT, recognizes differences in donor sites in constitutional versus hematological malignancies and within different types of hematological disorders.

1237/W

Sporadic Aneuploidy in PHA-Stimulated Lymphocytes of Trisomies 21, 18 and 13. *O. Reish[1,2], M. Regev[1], S. Girafi[1], M. Mashevich[1].* 1) Gen Inst, Assaf Harofeh Med Ctr, Zerifin, Israel; 2) Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel.

Background: In accordance with previous study demonstrating monosomy for one sex X-chromosome is associated with sporadic loss and/or gain of other chromosomes, we studied here whether this instability is a consistent finding in constitutional autosomal trisomies. **Methods:** We used PHA-stimulated lymphocytes derived from 14 patients (10 patients with trisomy 21, 2 with trisomy 18 and 2 with trisomy 13). Fourteen healthy controls were compared. Fluorescence in-situ hybridization (FISH), applied at interphase, was used to evaluate the level of aneuploidy for three, randomly selected chromosomes (autosomes 8, 15 and 16) in each sample. **Results:** For each tested chromosome, our results showed a significantly higher level of aneuploid cells in the samples from the patients than in those from controls (P<0.05 -0.001) with no difference between the patients (P>0.2). The mean level of aneuploid cells (percentage) for all three tested autosomes (8, 15 and 16) was almost twice as high in the patients samples as in the control samples (2.51 vs 1.17, 5.05 vs 2.71, 2.59 vs 1.67 respectively). Aneuploidy level was mainly due to monosomy which was significantly higher in the samples from the patients than in those from controls for each one of the tested chromosomes (P<0.05- 0.001), with no difference between the patients (P>0.53). The mean level of monosomic cells (percentage) for all three tested chromosomes was almost twice as high in the patients samples as in the control samples (2.2 vs 1.03, 3.77 vs 2.14, 2.04 vs 1.46 respectively). **Discussion:** Our study shows that variable constitutional autosomal trisomies are associated with increased frequency of non-chromosome specific aneuploidy. It is possible that primary aneuploid cells destabilize their own genome resulting in variable aneuploidy of other chromosomes. It is also possible that a common factor(s) is involved with both constitutional and sporadic aneuploidy. As cancer is associated with aneuploidy and incidence of cancer is higher in Trisomic patients comparable to controls, our study may uncover a possible mechanism linking this newly detected instability with cancer and may assist in future therapy planning.

1238/W

Monozygotic twins discordant for submicroscopic chromosomal anomalies detected by array CGH. *M. Rio[1], MC. de Blois[1], C. Turleau[1], S. Gobin[1], G. Royer[1], C. Ozilou[1], L. Colleaux[1], A. bernheim[2], M. Vekemans[1], V. Malan[1].* 1) Département de Génétique, Hôpital Necker-Enfants Malades, Paris, France; 2) Laboratoire de genomique cellulaire des cancers (FRE 2939 CNRS) & Département de Pathologie Moleculaire Institut de Cancérologie Gustave Roussy, Paris-Villejuif Cedex, France.

Although discordant phenotypes in monozygotic twins used to be considered as an exception, an increasing number of reports indicate that this phenomenon is not so rare. Most of reported patients have numerical chromosomal anomalies, with only few cases having structural chromosomal anomalies. Here, we report on the clinical and cytogenetic details of 4-year-old female monozygotic twins with discordant phenotypes. Twin 1 exhibited global developmental delay with walk at 35 months, absence of speech, and hyperactivity. Twin 2 had an autistic spectrum disorder without motor delay. Extensive investigations including blood karyotype, metabolic screening and brain MRI were normal in both twins. Molecular karyotyping in twin 1 identified a 2p25.3 deletion, further confirmed by FISH analysis on leukocytes in all cells. Interestingly, array-CGH was normal in twin 2 but FISH analysis performed on leukocytes using the same probes showed mosaicism with 33 % of deleted cells, 33 % of duplicated cells, and 33% of normal cells. Genotyping confirmed the monozygosity of the twins and ruled out uniparental disomy for chromosome 2. We propose that the discordant chromosome imbalance may be due to a mitotic non-allelic recombination occuring during blastomeric divisions of a normal zygote. Such event will result in 3 distinct cell populations whose proportion in each embryo formed after separation from the inner cell mass, may differ, leading to discordant chromosomal anomalies between twins. To our knowledge, this is the first report of monozygotic twins with discordant phenotypes ascribed to a distinct submicroscopic rearrangement detected by array-CGH.

1239/W

Deletions flanked by breakpoints 3 and 4 on 15q13 may contribute to abnormal phenotypes. *J.A. Rosenfeld[1], L.E. Stephens[2], J. Coppinger[1], B.C. Ballif[1], J.J. Hoo[3], B.N. French[3], V.C. Banks[4], W.E. Smith[4], D. Manchester[5], A.C-H. Tsai[5], K. Merrion[5], R. Mendoza-Londono[6], L. Dupuis[6], R. Schultz[1], B.S. Torchia[1], T. Sahoo[1], B.A. Bejjani[1], D.D. Weaver[2], L.G. Shaffer[1].* 1) Signature Genomic Laboratories, Spokane, WA; 2) Department of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 3) Department of Pediatrics, University of Toledo Medical College & NW Ohio Regional Genetics Center, Toledo, OH; 4) Division of Genetics, Maine Medical Center, Portland, ME; 5) Division of Clinical Genetics and Metabolism, Department of Pediatrics, The Children's Hospital, University of Colorado Denver School of Medicine, Aurora, CO; 6) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children and University of Toronto, Toronto, Canada.

Non-allelic homologous recombination (NAHR) between segmental duplications in the proximal chromosome 15q breakpoint (BP) regions can lead to microdeletions and microduplications. Several individuals with deletions flanked by BP3 and BP4 on 15q13, immediately distal to and not including the Prader-Willi/Angelman syndrome (PW/AS) critical region and proximal to the BP4-BP5 15q13.3 microdeletion syndrome region, have been reported, but because the deletion has also been found in normal relatives, the significance of these alterations is unclear. We have identified six individuals with deletions limited to the BP3-BP4 interval and an additional four individuals with deletions of the BP3-BP5 interval from 34,046 samples submitted for clinical testing by microarray-based comparative genomic hybridization (aCGH). Of four individuals with BP3-BP4 deletions for whom parental testing was performed, two were apparently de novo, and two were maternally inherited. A comparison of the clinical features, available for five individuals in our study (four with deletions within BP3-BP4 and one with a BP3-BP5 deletion), to those in the literature shows common features of short stature and/or failure to thrive, microcephaly, hypotonia, and premature breast development in some individuals. Although the BP3-BP4 deletion does not yet demonstrate statistically significant enrichment in abnormal populations compared to control populations, the presence of common clinical features among probands and the presence of genes with roles in development and nervous system function in the deletion region suggest this deletion may play a role in abnormal phenotypes in some individuals.

1240/W

The Genetic Variations that Cause Down Syndrome and Oral Manifestations. *E. Severin[1], A. Stan[2], L. Savu[2], D. Stanciu[1].* 1) Dept Human Genetics, Carol Davila Univ Med Pharm, Bucharest, Romania; 2) Genetic Lab, Bucharest Romania.

Various genetic mechanisms such as, full trisomy 21, mosaic trisomy 21 or translocation trisomy 21, may be contributors to the variability of the Down syndrome (DS) phenotype. The severity of clinical features varies from an individual with DS to another. How trisomy 21 leads to the phenotype of DS is not fully understood. The aims of the study: to evaluate the karyotype pattern in the patients with DS and to find out if there are correlations between the severity of the oro-dental phenotype and chromosomal abnormality mechanism of trisomy 21. A total of 26 individuals with DS ranging from 2 to 30 years of age were chromosomally investigated in order to confirm the clinical diagnosis of DS. All the cases were diagnosed cytogenetically after birth. A karyotype of the parents was required in the case of a child with robertsonian translocation trisomy 21. To characterize the oro-dental phenotypic spectrum of the patients were performed oral, clinical and radiological evaluations. Based on cytogenetically analysis results three groups were identified: patients with full trisomy 21, mosaicism for trisomy 21 and translocation trisomy 21. Most oro-dental features including oral, dental, and periodontal and occlusion anomalies were variable in both frequency and expression. The most common dental anomaly was hypodontia followed by microdontia. Concomitant hypodontia and supernumerary teeth occurred in one patient. Eruption of dentition was delayed in most cases. Taurodontism occurred in few patients. Variation of oro-dental phenotype is not associated with specifically chromosomal mechanisms of trisomy 21.

1241/W

Usefulness of molecular techniques in characterization of sSMC^T. *F. Sheth[1], J. Pani[1], M. Desai[1], J. Andrieux[2], T. Liehr[3], A. Weise[3], S. Mehta[1], H. Patil[1], H. Sheth[4], J. Sheth[1].* 1) Department of Cytogenetics, FRIGE's Institute of Human Genetics,Satellite, Ahmedabad, Gujarat, India; 2) Laboratory of Medical Genetics, Jeanne de Flandre Hospital CHRU de Lille, Lille Cedex France; 3) Jena University Hospital, Institute of Human Genetics and Anthropology, Kollegiengasse 10, D-07743 Jena, Germany; 4) School of Biomedical Sciences, Newcastle University, Framlington Place, Newcastle Upon Tyne, NE2 4HH, UK.

Small supernumerary marker chromosomes [sSMC] are usually observed in addition to numerically normal "essential karyotype". However, they are rarely seen in numerical abnormal karyotypes similar to Turner syndrome [sSMC^T]. Around 565 cases have been identified till date with the frequency of 1 in 100,000 in the general population. In the present study, sSMC^T is documented in three cases where case-1 is a 13-years-old female having clinical presentation of Turner syndrome and cytogenetic finding showed 46,X,+mar. Array-CGH, cenM-FISH, subcenM-FISH mix analysis characterized the sSMC as a del(14)(q11.1) which consisted only of heterochromatic region according to array-CGH and FISH. Case-2 is an 8 month-old child born to consanguineous parents having clinical features of intersex. Karyotypic pattern revealed mosaic cell line with 46,X,mar/45,X of equal number. subcenM-FISH mix for Y-chromosome confirmed marker to be idic(Y)(q11.2) having both euchromatic and hetrochromatic region. Case-3 is a 24 year-old phenotypically male, which was referred due to clinical features of ambiguous genitalia. Chromosomal analysis initially showed 45,X cell line with positive SRY-PCR. Further analysis after the application of subcenM-FISH mix for Y-chromosome analysis and DNA studies for a total of 18 different Y chromosomal loci showed that the rearranged Y was accompanied by SRY region and partial deletion of pseudoautosomal region (PAR1) involving SHOX as a del(Y)(:p11.2->q11.1:) which was missed by routine banding technique. This shows that the sSMC, when associated with a numerical abnormal karyotype, mainly originates from Y chromosome and they are inverted duplicated/isodicentric. sSMC^{T}s of a non gonosomal origin might be easily missed if they are not further characterized by molecular approaches. Overall, this shows the usefulness of oligonucleotide array-CGH is the best initial technique for the characterization of sSMC that can precisely measure the size of the aberration (covering euchromatic region) in a single experiment followed by DNA analysis which together with FISH gives additional information for the structure and the level of mosaicism. This part of the study was supported by DBT-India.

Complex chromosomal rearrangements in males: complexity of rearrangements affects spermatogenesis. *S. Shim[1,2], J. Kim[2], S. Song[4], M. Chin[1], K. Kang[1], T. Yoon[2], D. Cha[1,3].* 1) Genetic Lab, CHA General Hosp, Seoul, Korea; 2) Fertility Center of CHA Gangnam Medical Center; 3) Department of Obstetrics and Gynecology, Kangnam CHA Hospital, CHA University; 4) Department of Urology, CHA University.

Objective: Complex chromosome rearrangements (CCRs) are very rare structural aberrations involving at least three chromosomes or three or more chromosomal breakpoints. Carriers of CCRs have a risk for having a conception with various anomalies and reproductive failure. The most of males with CCRs showed infertility problems resulting from hypospermatogenesis or spermatogenic failure. **Methods**: Ten males with CCRs, who were phenotypically normal, were referred to the Genetic laboratory of CHA Gangnam Medical Center from 2002 to 2009. Seven patients were azoo- or oligozoospermia and the other three were habitual abortions(HA). Sexual development was normal in all patients. The patients were carried out chromosome analysis and histological examination as well as basic laboratory tests such as hormone and sperm assays. Chromosome abnormalities were characterized by FISH and M-FISH as well as routine G-banding. For seven patients with spermatogenetic defects, testicular biopsies were performed and azoospermic factors (AZFs) region defects were also examined. **Results**: Three cases showed OAT and four cases were diagnosed as azoospermia. The level of testosterone was slightly lower in one case. None of the patients with impaired spermatogenesis had a deletion of AZF regions. One azoospermic case was defined as sertoli cell only, and the other three azoospermic cases showed maturation arrest at the early spermatid stage. CCRs identified in ten patients were classified as follow: two cases were group I, three cases were group II and five cases were group III. All three cases with HA and two of three cases with OAT had group III CCRs. On the other hand, CCRs identified in one OAT case and all four azoospermic cases belonged to group I and II. Several breakpoints, located at chromosome 4q, 5q, 7q, 9p, 14q, were frequently reported in HA and breakpoints related to spermatogenetic failure were apt to locate in chromosome 3, 4q, 11q, 12q, 13q. However, the breakpoints randomly distributed, in general. **Discussion**: We understood that not locations of breakpoints but also complexity of chromosomal rearrangement in patients with CCRs could have a role in male infertility and might affect the spermatogenetic process, although more fine characterizations of the chromosomal breakpoints using an advanced technique such as array-based comparative genomic hybridization are necessary.

1243/W

Double and Triple Aneuploidy in Spontaneous miscarriages: A single institution experience. *S. Subramaniyam, LM. Alonso, VR. Pulijaal, S. Mathew.* Pathology and Laboratory Medicine, Cytogenetic laboratory, Weill Cornell Medical College/New York Presbyterian Hospital, New York, NY:10065.

Chromosomal analysis on products of conception (POC) is useful to determine the cause for pregnancy loss and aid in recurrence risk estimates for future pregnancies. More than 50% of first trimester miscarriages are due to chromosomal abnormalities. Double and triple aneuploidy (gain or loss of two or three chromosomes) is rare and is reported in 0.21~ 2.8% of the aborted fetuses with a chromosomal analysis. We present data on double/triple aneuploidy encountered at our institution from January 2006 to December 2009. We retrospectively reviewed 1599 cases of POC. Successful karyotypes were obtained in 94% (1502/1599) of the cases. Of these, 63.2% (949/1502) had an abnormal karyotype and the rest 36.8% (553/1502) showed a normal karyotype. The different abnormalities included loss/monosomy (10%), single trisomy (65%), double aneuploidy (7.4%), triple aneuploidy (0.6%), triploidy (10.8%), tetraploidy (2.3%), and structural abnormalities (3.9%). Among the total 1502 (abnormal and normal) karyotyped cases, 70 cases (4.6%) with double aneuploidy and six cases (0.4%) with triple aneuploidy were observed in this study. Median gestational age for double and triple aneuploidy was 8 weeks (range, 5 ~ 13 weeks), and the median maternal age was 41 years (range, 31 ~ 44 years). Of these 76 cases, 13 women had an abnormal karyotype in the previous pregnancy of which two cases had double aneuploidy, with no recurrence of the same chromosomes. The chromosomes most frequently involved in double/triple aneuploidy were chromosomes 21 (35.5%), 16 (26%), 22 (18.5%), X (17%), 18 (13%), 13 (10.5%) and 15 (10.5%). The most frequent chromosome combinations observed were: X/21 (8 cases, 10.5%), 21/22 (4 cases, 5%), 16/21 (3 cases, 4%), and 7/21 (3 cases, 4%). In conclusion, we have observed a high percentage of double (4.6%) and triple (0.4%) aneuploidy in our series when compared to the previous studies. This abnormal rate is attributed due to the high success rate in obtaining metaphases by both direct and long term cultures at our institution.

1244/W

Complex chromosome 4 rearrangement characterized by array CGH. *J. Szymanska, A. Hajianpour, R. habibian, J.C. Wang.* Cytogenetics, Genzyme Genetics, Monrovia, CA.

A 34 year old woman was referred for prenatal diagnosis due to the abnormal ultrasound findings including IUGR, cardiac anomaly, and clubbed feet. Cytogenetic analysis of G-banded metaphases showed additional genetic material of unknown origin on the short arm of chromosome 4, interpreted as add(4)(p15.3). Parental karyotypes were normal. Array comparative genomic hybridization (aCGH) revealed DNA copy number changes, including: a 2.95 Mb terminal deletion of chromosome 4 at 4p16.3, and a 20.7 Mb gain of chromosome 4 long arm, including 4q32.3-q35.2. FISH analysis using BAC clones from the regions 4p16.3 (RP11-1150B4) and 4q35.2 (RP11-706F1), plus the chromosome 4 centromere probe (D4Z1) identified a derivative chromosome 4 with the 4q35.2 clone inserted into the distal short arm at 4p16.3 with simultaneous loss of 4p16.3 sequences. The rearrangement was described as ish der(4)del(4)(p16.3)ins(4)(p16.3q32.2q35.2)(RP11-1150B4-,RP11-706F1+) The fetus is therefore trisomic for the segment 4q32.3-q35.2 and monosomic for 2.95 Mb DNA sequences within 4p13.6. The deleted region at 4p16.3 contains at least 30 genes, including the Wolf-Hirschhorn syndrome critical region (WHSC1/WHSC2). The 4q32.3-q35.2 duplication region contains at least 36 currently known OMIM genes. This case illustrates the importance of comprehensive testing in prenatal diagnosis, combining conventional cytogenetics, aCGH, and FISH analyses. It also demonstrates how all three techniques are necessary for an accurate interpretation.

1245/W

A familial complex chromosome rearrangement (CCR), der(8)t(8;21)(q24.3;q22.1)idic(21)(q22.1), resulting in a 18.6 Mb duplication of proximal long arm of chromosome 21 with minimal dysmorphic features. *G.V.N. Velagaleti[1], E.R Roeder[2], V.S. Tonk[3], D.M. Farley[4], R.W Huff[4].* 1) Dept Pathology, Univ Texas Hlth Sci Ctr, San Antonio, TX; 2) Dept Pediatrics, Univ Texas Hlth Sci Ctr, San Antonio, TX; 3) Dept Pediatrics, Texas Tech Univ, Lubbock, TX; 4) Dept. Obstetrics and Gynecology, Univ Texas Hlth Sci Ctr, San Antonio, TX.

The widespread use of comparative genomic microarrays (CGH) has resulted in identification of many genomic imbalances including large genomic duplications. The phenotypic variability associated with these duplications precludes identification of carriers of these duplications based on phenotypic evaluation. Here we report on a family where a CCR is identified in a mother and her children with variable phenotype. A 24-year- old, Hispanic woman was referred for prenatal counseling due to a maternal translocation. She has had 5 first trimester miscarriages and one preterm male that died at 3 months. He had congenital heart disease and clubbed feet. She underwent amniocentesis at 16 weeks gestation. Her height is 60 inches (152 cm) and weight 184 lb (83.5 kg). She had mild dysmorphic features including bilateral ptosis, mild cubitus valgus and short 4th metatarsals bilaterally and 4th toes overlap 5th toes, mild 2-3 toe syndactyly and mildly short great toes with a gap between 1st and 2nd toes. She does not have Down syndrome facies. She is mildly retarded and has a seizure disorder. An echocardiogram obtained recently because of her son's history was normal. Her fetus showed no anomalies on ultrasound at 28 weeks gestation with normal growth. Chromosome analysis from peripheral blood lymphocytes showed a CCR with karyotype, 46,XX,der(8)t(8;21)(q24.3;q22.1)idic(21)(q22.1), idic(21)(q22.1). Array CGH studies showed an 18.6 Mb duplication involving the 21q11.2-q22.11 region with no imbalance on the chromosome 8. Subtelomeric FISH studies showed both the 8q and 21q subtelomeres present on the der(8). Amniotic fluid chromosome analysis showed two cell lines on her fetus with the karyotype 46,XY,der(8)t(8;21)(q24.3;q22.1)idic(21)(q22.1), idic(21)(q22.1)[16]/ 46,XY,idic(21)(q22.1)[3]. Chromosome analysis on her son that expired at 3 months showed partial monosomy with 45,XY,der(8)t(8;21)(q24.3;q22.1). Chromosome studies from the grandparents showed that the mother of our proband is the carrier of 5 different cell lines and transmitted the CCR to her daughter who in turn transmitted it to her children. This is the first case to our knowledge of a CCR with large duplication segregating in several members of the family with minimal phenotypic manifestations and normal fertility.

1246/W

8p23.1 duplication and 15q25-26 duplication due to an (11;15)(p13;q25q26) insertion characterized by high resolution array in a patient with aniridia. *T.P. Vieira[1], M. Simioni[1], I.C. Sgardioli[1], C.V. Maurer-Morelli[1], I. Lopes-Cendes[1], A.C. Fett-Conte[2], V.L. Gil-da-Silva-Lopes[1].* 1) Department of Medical Genetics, Faculty of Medical Sciences,-University of Campinas, Campinas, SP, Brazil; 2) Molecular Biology Department, Medicine School in São José do Rio Preto, São José do Rio Preto , SP, BRAZIL.

High resolution array technology has provided a better understanding and insight into the delineation of chromosomal abnormalities. Here we report on a two years old male patient referred to us for investigation of velocardiofacial syndrome. He presented cardiac anomaly (ventriculoseptal defect), submucous cleft palate, dysmorphic facies, developmental delay, renal anomaly (hydronephrosis) and aniridia. Multiplex ligation-dependent probe amplification analysis with the SALSA P250 kit, was normal for the 22q11 region, but it showed a duplication in 8p23.1. Subsequent studies with a high resolution array (Genome-Wide Human SNP Array 6.0, Affymetrix®), confirmed an 8p duplication of 3.8 Mb at p23.1 region (8.129.435-11.934.586 [hg18]), and revealed an additional interstitial duplication of 17.09 Mb at 15q25-26 region (81.869.248-98.962.477 [hg18]). In order, to confirm the large duplicated segment detected, we performed chromosome (chr) analysis that revealed an insertion of chr 15 on chr 11 [46,XY,der(11)-ins(11;15)(p13;q25q26)]. Both cytogenetic and array analyses of parents were normal. Since our patient has aniridia, a more detailed analysis of the array results was performed for chr 11p13, and a small deletion of approximately 49 kb was also detected. This deletion is 12 kb downstream of the PAX6 gene and includes the ELP4 gene. The 8p and 15q duplications such as these identified in our patient are well characterized in the literature, and interestingly our patient presents typical clinical features of both: i) cardiac anomaly as described in patients presenting 8p duplication, and ii) renal anomaly as described in individuals with 15q25-26 duplication. Additionally, the (11;15) insertion probably altered the normal expression of the PAX6 gene by a position effect or deletion of a regulatory element, which explains the aniridia phenotype that is not described in association with 8p23.1 nor 15q25-26 duplications. This case report shows that array analyses together with classical cytogenetic techniques are making an extraordinary impact in our way of seen chromosome abnormalities and their phenotypic correlates. Cytogenetic abnormalities in amniotic fluid cells. *M. Woo[1], J. Choi[1], N. Song[1], H. Ko[1,2], S. Oh[1,2], C. Park[2], K. Park[2,3], J. Park[2], J. Jun[2], B. Yoon[2], Y. Choi[1,2], S. Moon[1,2].* 1) Institute of Reproductive Medicine and Population, Medical Research Center, Seoul National University, Seoul, Korea; 2) Department of Obstetrics and Gynecology, College of Medicine, Seoul National University; 3) Seoul National University Bundang Hospital, Bundang, Korea.

This study reviewed cytogenetic results in amniotic fluid cells and analyzed chromosomal abnormalities according to patient's indications. The 2438 cases obtained by amniocentesis were performed using traditional cytogenetic methods at the Institute of Reproductive Medicine and Population, Seoul National University between January 2005 and December 2009. The cytogenetic results of 2438 cases on cultured amniotic fluid samples were observed normal chromosomes (2283 cases, 93.6%), chromosome heteromorphisms (77 cases, 3.2%), and chromosomal abnormalities (78 cases, 3.2%). A total of 78 cases of abnormal fetal karyotypes were identified including 54 cases (2.2%) of numerical aberrations, 14 cases (0.6%) of structural aberrations, and 10 cases (0.4%) of mosaicism. Numerical abnormalities consisted of autosomal aneuploidies with trisomy 9 (1 case), 13 (3 cases), 18 (12 cases), and 21 (29 cases), sex chromosome abnormalities (7 cases), and polyploidy (1 case). Structural abnormalities showed balanced reciprocal translocations (10 cases), deletion (1 case), addition (1 case), and marker chromosome (2 cases). The 10 fetuses with balanced reciprocal translocations were inherited from three maternal carriers, five paternal carriers and two de novo, respectively. The rate of indication with chromosome aberrations was most frequently detected in advanced maternal age (35.9%), followed by abnormal ultrasonographic findings and abnormal maternal serum marker positive. Of fetuses with an abnormal karyotype, the abnormal ultrasonographic findings in the cases observed trisomy 21 could be considered a predictive marker. These data provides a comprehensive review of the prenatal diagnosis and helpful information in genetic counseling for patients with the high-risk pregnancy.

1248/W

Clinical and Molecular-Cytogenetic Characterization of Partial Monosomy 13 (13q33-13qter) in Adults with Ring Chromosome 13. *R. Badilla-Porras[1], D.J. Stavropoulos[2], L. Dupuis[1], R. Mendoza-Londono[1].* 1) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children and University of Toronto,Toronto, Canada; 2) Department of Paediatric Laboratory Medicine, The Hospital for Sick Children and University of Toronto, Toronto, Canada.

Partial monosomy of chromosome 13q is a rare condition. Ring chromosomes result from the breakage of a portion of both arms of a chromosome with fusion of the points of fracture. Loss of the distal fragments result in a partial monosomy and are commonly associated with congenital malformations and mental retardation. We present the clinical characterization of two adult patients with ring chromosome 13 with overlapping deletions of 13q33-13q34. We define the cytogenetic abnormality by array comparative genome hybridization (Array CGH), and compare their features with other cases of partial monosomy 13q. Patient 1 is an 18 year-old male born after pregnancy complicated by IUGR. His birth parameters at 36 weeks of gestation were below the third centile. He developed self-resolving early chylothorax and PDA. Urogenital malformations included hydronephrosis and posterior ureteral valves. Additional findings included microcephaly ataxia, short stature, strabismus and constipation. He has severe developmental delay and lack of verbal language. He completed life-skills training. Karyotype analysis revealed a ring chromosome 13. Array CGH identified a deletion of chromosome region 13q33.1 to 13qter with an estimated size of 13.528 Mb. Patient 2 is a 33 year-old female born at 38 weeks of gestation with birth parameters below the third centile. She developed early feeding difficulties. She developed diabetes mellitus type 2 at age 20 and hyperlipidemia at age 28. She has mild to moderate developmental delay with speech delay but was able to complete school to grade 10 and is now able to hold a job and live with supervised independence. Additional findings include short stature and myopia. Karyotype analysis revealed a ring chromosome 13. Array CGH identified a deletion of chromosome region 13q34 to 13qter with an estimated size of 1.957 Mb. The cases presented herein highlight the clinical variability in the phenotype of patients with partial monosomy 13q due to ring chromosome and allow a better genotype-phenotype correlation. Common features in patients with monosomy of distal 13q include short stature, developmental delay and dysmorphic features. Our findings also demonstrate that patients with this cytogenetic abnormality survive into adulthood without major complications, which is distinctive from patients with more proximal breakpoints involving band 13q32.

1249/W

Deletion 12Q: A first patient with 12q14 microdeletion syndrome Delineated by Whole Genomic Array Comparative Genome Hybridization. *C. Chong Kun.* Pediatrics, Pusan National Univ Chld Hosp, Geungsang Nam Do, Korea.

The 12q14 microdeletion syndrome is a rare chromosomal abnormality. Characteristic features of the 12q14 microdeletion syndrome include low birth weight, failure to thrive, short stature, learning disabilities and Buschke-Ollendorff lesions in bone and skin.We report a 12(q14.3q14.3) deletion identified by array-CGH analyses in a boy resenting with growth retardation, developmental delay, and dysmorphic features. We utilized whole genomic array comparative genome hybridization (CGH)with 4,000 selected bacterial artificial chromosomes (BACs) to define the chromosomal breakpoints and to delineate the extent of the microdeletion in more detail. To our knowledge, this is the novel microdeletion, rarely reported to-date, defined by whole genomic array CGH.

1250/W

Further delineation of the 17p13.3 microdeletion involving *YWHAE* but distal to *PAFAH1B1*: four additional patients. *A. Delahaye[1], M. Schiff[2,3], J. Andrieux[4], D. Sanlaville[5,6], S. Passemard[2,3,7], A. Labalme[5], L. Perrin[7], S. Bouquillon[4], M. Elmaleh-Berges[3,8], A. Aboura[7], S. Drunat[7], S. Manouvrier-Hanu[9], B. Benzacken[1,3,7], P. Edery[5,6], A. Verloes[3,7], C. Vincent-Delorme[9].* 1) Histology-Embryology & Cytogenetics Department, AP-HP - Jean Verdier Hospital, Bondy, France; Paris 13 University, UFR SMBH, Bobigny, France; 2) Department of Pediatric Neurology , APHP - Robert DEBRE University Hospital, Paris, France; 3) Inserm, U676, Paris, France; 4) Laboratoire de Génétique Médicale, Centre Hospitalier Régional Universitaire, 59000 Lille, France; 5) Service de Génétique, Hospices Civils de Lyon, Hôpital de l'Hotel Dieu, 69288 Lyon, France; 6) EA 4171, Université Claude Bernard, 69622 Lyon, France; 7) Department of Genetics, APHP - Robert DEBRE University Hospital, Paris, France; 8) Pediatric Imaging Department, AP-HP - Robert DEBRE University Hospital, Paris, France; 9) Service de Génétique Clinique, Hôpital Jeanne de Flandre, Centre Hospitalier Universitaire de Lille, 59000 Lille, France.

BACKGROUND: The 17p13.3 deletion syndrome (or Miller Dieker syndrome, MDS, MIM 247200) is characterized by lissencephaly, mental retardation and facial dysmorphism. The phenotype is attributed to haploinsufficiency of two genes present in the minimal critical region of MDS: *PAFAH1B1* and *YWHAE*. Whereas isolated *PAFAH1B1* deletion causes lissencephaly, *YWHAE* is a candidate for the dysmorphic phenotype associated with MDS.

OBJECTIVE: We describe clinical, neuroradiological and molecular data in four patients with a 17p13.3 deletion distal to *PAFAH1B1* involving *YWHAE*.

RESULTS: All patients presented with mild or moderate developmental delay and pre and/or post-natal growth retardation. Patients A, B and C had leucoencephalopathy with macrocephaly (patients A and C), Chiari type 1 malformation (patient A) and paraventricular cysts (patient C). Patient B had patent ductus arteriosus and pulmonary arterial hypertension. Patient C had unilateral club foot. Patient D had enlarged Virchow Robin spaces, microcornea and chorioretinal and lens coloboma. Array-CGH revealed *de novo* terminal 17p13.3 deletions for patient A and B, and showed interstitial 17p13.3 deletions of 1.4 Mb for patient C and of 0.5 Mb for patient D.

CONCLUSION: Our patients confirm that 17p deletion distal to *PAFAH1B1* have a distinctive phenotype : mild mental retardation, moderate to severe growth restriction, white matter abnormalities and developmental defects including Chiari type 1 malformation and coloboma. Our patients contribute to the delineation and clinical characterization of 17p13.3 deletion distal to *PAFAH1B1* and highlight the role of the region containing *YWHAE* in brain and eye development and in somatic growth.

1251/W

WAGR Syndrome associated with unbalanced segregants of a balanced insertion. *I. Gadi[1], j. Tepperberg[1], V. Jaswaney[1], S. Schwartz[1], R. Burnside[1], B. Williford[1], H. Risheg[1], P. Papenhausen[1], D. Day-Salvatore[2], M. Horner[2].* 1) Dept Cytogenetics, Lab Corp America, Res Triangle Park, NC; 2) St. Peters Medical Center New Brunswick, N.J.

In this study we report cytogenetics , FISH and SNP array analyses in a family in which some individuals presented with Wilms tumor, abnormal genitalia and mental retardation while others presented with Beckwith Wiedemann syndrome. Our initial cytogenetic analysis of a normal adult, who has two sons, a sister and a niece with WAGR, revealed an apparent deletion of the proximal short arm of chromosome 11. A previous cytogenetic analysis had described the deletion break points p13->p15.1 region of chromosome 11. However no loss of chromosome 11 DNA was apparent from the whole genome SNP array analysis (Affymetrix 6.0 version) in this apparently normal individual. Subsequent FISH using a whole chromosome 11 paint probe (Abbott Molecular Inc.) showed partial hybridization in the proximal short arm of chromosome 6. A cytogenetic analysis of both children showed a deletion in the proximal short arm of chromosome 11. Both children presented with hypospdias and aniridia consistent with a deletion of 11p. The whole genome SNP array analysis on his children confirmed the cytogenetic studies and revealed a 12.381 Mb deletion of the chromosome 11 short arm p14.3->p13 segment (linear position 22,392,777-34,774,080). This study is important as it illustrates the importance of combining SNP analysis along with FISH and cytogenetic studies to determine chromosome structure and recurrence risk. The array has delineated the precise identity of the material deleted (leading to WAGR) or duplicated (leading to Beckwith-Weidemann Syndrome), while FISH and cytogenetic studies were instrumental in illustrating a high risk family.

1252/W

Complex rearrangements in monosomy 1p36. *M. Gajecka[1], J. Karolak[1], J. Shen[2], C. Glotzbach[3], L.G. Shaffer[3].* 1) Institute of Human Genetics, Polish Academy of Sciences, Poznan , Poland; 2) Children's Hospital Central California, Madera, CA, USA; 3) Signature Genomic Laboratories, LLC, Spokane, WA, USA.

Deletions of 1p36 occur in approximately 1 in 5,000 newborns. To date, we have ascertained 150 cases with monosomy 1p36, representing four possible classes of rearrangements: pure terminal deletions, interstitial deletions, unbalanced translocations, and complex rearrangements. Here we present five complex rearrangements involving duplications in monosomy 1p36. For each individual, deletion and duplication sizes, and parental origin of the rearrangements were determined using array CGH and genotyping. To further understand the mechanisms for concurrent deletions and duplications, we narrowed the breakpoints and investigated the junctions using molecular cytogenetics and molecular biology methods. Our results show high complexity at the breakpoint junctions and indicate involvement of multiple mechanisms in the DNA breakage and repair process during rearrangement formation.

1253/W

Clinical features in two patients with de novo overlapping interstitial deletions of chromosome 1q21.2. *J. Goldstein[1], A. McConkie-Rosell[1], E. Cordoba[2], P. Jayakar[3], S. Schwartz[4], I. Gadi[4], Y.H. Jiang[1].* 1) Pediatrics, Duke University Medical Center, Durham, NC; 2) St. Mary's Hospital, West Palm Beach, FL; 3) Miami Children's Hospital, Miami, FL; 4) Laboratory Corporation of America, Research Triangle Park, NC.

We report the clinical features of two children with de novo overlapping interstitial deletions of chromosome 1q21.2, one of which extends into chromosome 1q21.3. Patients with deletion of this chromosomal region have not been previously reported; the deleted region in both patients is distinct from the 1q21.1 microdeletion that has been associated with autism spectrum disorder (ASD) and schizophrenia. Patient 1 is a 12 year-old Caucasian old male with classic ASD, seizure disorder, cognitive impairment, amblyopia, astigmatism, and mild dysmorphic features including small chin and flat nasal bridge. His karyotype was normal (46, XY) but chromosome SNP array analysis revealed a 210 kb deletion of chromosome 1q21.2 (position 149,100,105 - 149,309,823). Fluorescence in situ hybridization (FISH) analysis, using a BAC probe from the deleted area, was normal for the patient's parents and sister, all of who are healthy and developmentally normal, suggesting that the deletion is de novo. Patient 2 is a 3 year-old Filipino male born at 34 weeks gestation and conceived by in vitro fertilization. He is the product of a twin pregnancy that was complicated by twin-twin transfusion. He has global developmental delay, hypotonia, history of febrile seizure, microcephaly, failure to thrive, cleft palate, and mild-to-moderate bilateral hearing loss. He has had a normal EEG and brain MRI. Chromosome SNP array revealed a 1.68 Mb deletion of chromosome 1q21.2-q21.3 (position 148,224,484 - 149,900,535). This deletion encompasses the deletion identified in Patient 1. FISH analysis, using a BAC probe from the deleted area, was normal for both parents, suggesting that the deletion is de novo. Results of FISH analysis for the twin of Patient 2 are pending. Further genetic and biochemical analysis of these two patients, as well as documentation of clinical features in other patients with deletions of chromosome 1q21.2, may lead to hypotheses regarding the pathogenesis of their clinical features, and whether altered expression of a particular gene(s) in this region may be associated with ASD.

1254/W

Isolation and characterization of cis-regulatory elements at the deletion junction for 9p- syndrome. *X. Hauge, P. Hord, J. Ezcurra, K. Traver.* Dept Biol & Physics, Kennesaw State Univ, Kennesaw, GA.

Deletions of the terminal region of the short arm of chromosome 9 (9p-) are associated with trigonocephaly, dysmorphic facial features, and mental retardation. The deletion of cerberus 1 (CER1) gene located at 14.7 Mb from the 9p terminus has been postulated as the cause of trigonocephaly. However, two independent studies showed that patients whose phenotype is consistent with 9p- syndrome possess smaller than 12.4 Mb deletions. Therefore, these patients have two, intact copies of CER1 gene. It raises the possibility that cis-regulatory elements for CER1 gene could be located in the first 12.4 Mb of 9p. Previously, we identified ~270 highly conserved sequences (CNSs) between 10 and 12.4 Mb from the 9p terminus. We report here cloning of 5 CNSs located at the deletion junction region (12.4 Mb) and characterization of their potential regulatory functions by using a dual luciferase reporter assay. The genomic DNA sequences corresponding to these 5 CNSs were amplified and cloned into a pGL4 vector at the 5' of the luciferase gene, which is controlled by a minimal promoter. A co-transfection of the CNSs-luciferase gene construct and a renilla gene, an internal control gene, was performed. To evaluate the tissue specificity of CNSs enhancer/silencer activity, two human cell lines were transfected. Of the 4 CNSs-luciferase constructs tested, one dramatically increased the luciferase expression in 2 types of cells, neuroblastoma and embryonic kidney cells. The second clone significantly reduced the luciferase expression in both types of cells, while the third clone showed tissue specific regulatory functions, acting as an enhancer in one cell type but a silencer in the other cell type. The last clone suppressed expression of luciferase in neuroblastoma cells but did not alter the expression level in the embryonic kidney cells.

Chromosome 10p terminal deletion in a fetus with novel congenital type2 cystic adenomatoid malformation and renal agenesis. *V. Hucthagowder, TC. Liu, F. White, S. Kulkarni.* Cytogenomics and Molecular Pathology, Pathology and Immunology, Washington University School of Medicine, St Louis, MO 63110.

The terminal deletion on the short arm of chromosome 10 is a rare chromosomal abnormality and in some case is associated with DiGeorge syndrome/ Velocardiofacial, syndrome (DGS/VCFS; OMIM#601362 and 192430) like phenotypes and the hypoparathyroidism, sensorineural deafness, and renal disease (HDR) syndrome (OMIM#146255). Congenital cystic adenomatoid malformation (CCAM) is a rare developmental symptom of the lung with unclear pathogenesis, unknown incidence and unpredictable prognosis. We report here an affected 27-week male fetus with multiple anomalies and a previously undocumented CCAM who carried a terminal deletion on the short arm of chromosome 10. Overall, the gross anatomy, general measurements and organizations were appropriate for the gestational age of the fetus. The face was mildly abnormal with slight receding of the chin and features often associated with oligohydramnios. The autopsy revealed the right and left lung had three and two lobes respectively and were hypoplastic with the missing pulmonary veins. Microscopic findings indicated congestion, hemorrhage, and early cannalicular alveolar pattern of the lung. In addition, type II- CCAM was identified in the right lower lobe. The kidney and bladder were not present which is concordant with the characteristic involvement of chromosome 10p deletion (HRD syndrome). High resolution chromosomal analysis was conducted using cultured skin fibroblast and the metaphase spreads showed a deletion in the terminal region on the short arm of the chromosome 10. Fluorescence in situ hybridization (FISH) analysis further confirmed the presence of the identified deletion in this proband. While compared to fifty prviously reported individuals with 10p deletion, our proband showed some overlapping clinical presentations but stood out unique with the involvement of type II-CCAM. In conclusion, 10p deletion syndrome is rare and the underlying mechanism is complex; however, the identification of type-II CCAM in our proband with 10p deletion suggests that any suspected CCAM patient early in the development are warranted for chromosome and molecular cytogenetic studies to rule out 10p deletion. On the contrary, some affected individuals may manifest atypical symptoms with absence of the classic features of 10p syndrome.

A recurrent interstitial microdeletion at Xp22.13 transmitted in a family presenting Nance-Horan syndrome. *H. Liao[1,8], Y. Chen[2,3], J. Fang[4], D. Niu[5,6], S. Chen[7], C. Chen[8,9].* 1) Institute of Biotechnology, National Tsing Hua University, Hsinchu,, Taiwan; 2) Department of Life Sciences and Institute of Genome Sciences, National Yang-Ming University, Taipei, Taiwan; 3) Department of Teaching and Research, Taipei City Hospital, Taipei, Taiwan; 4) Institute of Molecular Biology and Human Genetics, Tzu-Chi University, Hualien, Taiwan; 5) Institute of Clinical Medicine, School of Medicine; National Yang-Ming University, Taipei, Taiwan; 6) Department of Pediatrics, Veterans General Hospital-Taipei, Taiwan; 7) Department of Ophthalmology, Taipei Veterans General Hospital-Taipei, Taiwan; 8) Division of Mental Health and Addiction Medicine, Institute of Population Health Sciences, National Health Research Institutes, Miaoli, Taiwan; 9) Department of Psychiatry, Chang Gung Memorial Hospital at Linkou and Chang Gung University School of Medicine, Taoyuan, Taiwan.

Nance-Horan syndrome (NHS) is a rare X-linked disorder characterized by congenital cataracts, dental anomalies, and mental insufficiency. The disease has been linked to a novel gene NHS located at Xp22.13. The majority of pathogenic mutations of the disease are nonsense mutations that lead to truncation of the NHS protein, while some small deletions and insertions at the coding sequences of the NHS gene also contribute to the frame shift of open reading frame and premature stop codon of the NHS gene. Recently, several patients with NHS or X-linked congenital cataracts were found to be associated with copy number variations (CNVs) of the NHS locus, suggesting genomic rearrangement also plays a role in the pathogenesis of NHS. Here we describe the genetic analysis of a novel interstitial microdeletion of ~0.92 Mb at Xp22.13 detected by array-based comparative genomic hybridization (array CGH) in two brothers presenting congenital cataract, dental anomalies, facial dysmorphisms, and mental insufficiency. This microdeletion was transmitted from their carrier mother who presented only mild ophthalmological symptoms. The deleted region encompasses the REPS2, NHS, SCML1, and RAI2 genes, and is similar to a microdeletion of ~ 0.9 Mb encompassing the NHS, SCML1 and RAI2 genes reported recently in a NHS patient. Thus, the interstitial microdeletion found in our subjects might be a recurrent microdeletion associated with NHS, and that the deletion of NHS, SCLM1 and RAI2 genes in this family contributes to the genotype-phenotype correlations of patients with NHS and X-linked congenital cataracts.

1257/W

Phenotypic consequences - deletion 8pter vs duplication 15qter. *J. Pani[1], F. Sheth[1], J. Andrieux[2], S. Mehta[1], M. Desai[1], H. Patil[1], J. Sheth[1].* 1) Department of Cytogenetics, FRIGE's Institute of Human Genetics, Ahmedabad, Gujarat, India; 2) Laboratory of Medical Genetics, Jeanne de Flandre Hospital CHRU de Lille, Lille Cedex, France.

Subtelomeric rearrangements have been identified as a major cause of mental retardation and/or malformation syndromes and are observed in ~2-5% of the cases. Deletions involving these regions can lead to severe phenotypic consequences. We here report a 4-year-old girl born to a non-consanguineous parent having multiple congenital anomalies such as microcephaly, convergent strabismus, micropthalmia, dolichocephaly, congenital heart defects in form of atrio-ventricular septal defects, seizures, chronic anemia and mental retardation. Cytogenetic study revealed 46,XX,add(8)(p23). On further analysis by array-CGH using 44K oligonucleotide probe and BAC FISH confirmed deletion on 8p23.3p23.1 of 7.3 Mb and duplication involving 15q23q26.3 of 30.2 Mb. Phenotypic presentation in our case may have resulted from a balancing effect due to trisomy 15q23qter and *IGF1R* overgrowth on one hand and monosomy 8p23.1pter and loss of one copy of microcephalin on the other hand resulting in a borderline microcephaly, which suggests that deletion of 8p distal segment has shown more powerful phenotypic expression than trisomy of 15q distal segment.

1258/W

Mitigative Role of Melatonin on Mercury induced Cytogenetic Alterations *In Vitro*. *M.V. Rao, T.A. Patel, A.R. Purohit.* Human Genetics Centre, Department of Zoology, University School of Sciences, Gujarat University, Ahmedabad-380009, India.

INTRODUCTION: Mercury present in the environment is a potent toxicant to human health. Environmental contamination is the main cause of primary exposures which results due to mining, smelting, extensive industrial and agricultural usage including inhalation and ingestion via the food chain. It is also very well known genotoxic heavy metal. Melatonin is a hormonal product of the pineal gland and is also produced by certain plants. It is an antioxidant as it has a capacity to act as an electron donor and reduces the oxidative stress. METHODOLOGY: An *In Vitro* study was made in peripheral blood lymphocyte cultures (PBLC) to evaluate the protective effect of melatonin on mercury induced genotoxic potential at various dose levels. The cultures were exposed to four different doses of mercury for 24 hours. Melatonin alone and in combination with mercury were added to the cultures. EMS was used as a positive control. The genotoxic indices evaluated were sister chromatid exchanges (SCEs), cell cycle proliferative index/replicative index (CCPI/RI), average generation time (AGT), population doubling time (PDT) and total chromosomal aberrations (CAs) using suitable statistical analysis. RESULTS: A dose dependent increase in the SCEs, total aberrations, AGT and PDT, with a concomitant reduction in CCPI values. Melatonin supplementation to treated cultures reduced the genotoxicity exerted by mercury. CONCLUSION: Melatonin had a protective effect due to its antioxidant properties as observed by percent amelioration in this study. The importance of these findings is discussed.

Identification of a recurrent microdeletion of 3q13.2q13.31 associated with hypotonia and developmental delay. *J.B. Ravnan[1], J.A. Rosenfeld[1], N.J. Neill[1], M.G. Bialer[2], C. Moore[2], P. Wheeler[3], S.E. Wallace[4], M.C. Hannibal[4], M.F. Murray[5], M.A. Giovanni[5], R.A. Schultz[1], B.C. Ballif[1], L.G. Shaffer[1].* 1) Signature Genomic Laboratories, Spokane, WA; 2) Cohen Children's Medical Center of NY, Manhasset, NY; 3) Nemours Children's Clinic, Orlando, FL; 4) Seattle Children's Hospital, Seattle, WA; 5) Brigham and Women's Hospital, Boston, MA.

The use of microarray technology in clinical diagnosis has greatly increased the detection of copy number alterations and allowed correlation between the gene content of the alteration and the clinical phenotype of the affected individuals. Here we describe the clinical and molecular characterization of four individuals with a recurrent 3.4 Mb deletion of the proximal long arm of chromosome 3 at 3q13.2-3q13.31 detected by array-based comparative genomic hybridization (aCGH). These individuals ranged from 16 months to 38 years old at age of diagnosis. All four individuals have hypotonia and motor delays; three have mild to moderate cognitive delays. Common facial features include ptosis, downslanting palpebral fissures with epicanthal folds, a slightly bulbous nose, and a large head (greater than 75th centile). Additional anomalies include abnormalities of the brain (Chiari malformation, agenesis of the corpus callosum, cerebellar agenesis), and vision (myopia, strabismus, nystagmus). The deletions were apparently de novo in the three individuals for whom parental samples were available. At least 25 genes have been mapped to the deleted region, including four genes, *DRD3*, *ZBTB20*, *GAP43*, and *BOC*, that have been implicated in neuronal growth or brain development. The *DRD3* protein product (dopamine receptor D3) is localized to the limbic areas of the brain, and the *ZBTB20* protein (zinc finger- and BTB domain-containing protein 20) appears to be involved in the development of the hippocampus. The protein product of *GAP43* (growth-associated protein 43) regulates the growth of axons, modulates the formation of new connections and appears to be involved in neuronal growth across the midline. Of particular interest is *BOC* (brother of *CDON*), a member of the cell surface Ig/fibronectin superfamily. *BOC* appears to play a role in axon guidance across the midline through the sonic hedgehog signaling pathway as well as in muscle development by promoting the differentiation of myogenic cells. Analysis of the shared deletion breakpoints revealed no segmental duplications; however, long terminal repeats (LTRs) were identified at both breakpoints in direct orientation. These repeats contain a shared 4.3 kb region of approximately 95% homology which could mediate non-allelic homologous recombination (NAHR) at this location and create the observed recurrent breakpoints.

High resolution prenatal array CGH improves detection rate of clinically significant copy number abnormalities in the clinical laboratory. *A. Breman[1], I. Van den Veyver[1,2], P. Eng[1], W. Bi[1], S. Darilek[1], A. Pursley[1], P. Ward[1], A. Patel[1], L. White[1], J. Lupski[1], A. Beaudet[1], S. Cheung[1].* 1) Dept of Molec & Human Genetics, Baylor College of Med, Houston, TX; 2) Dept of Ob-Gyn, Baylor College of Med, Houston, TX.

Objectives: Current Array Comparative Genomic Hybridization (aCGH) performed at Baylor College of Medicine utilizes the latest microarray technology to detect unbalanced chromosome abnormalities associated with over 210 clinical disorders. Inclusive of our reported experience with 300 prenatal cases (PMID 19012303), we now have aCGH results on 682 clinical prenatal samples. Notably, 250 were analyzed on our custom high-resolution clinical BCMV7 array having 105,000 oligonucleotides to interrogate regions of the human genome at an average resolution of 30 kb, with increased coverage at known disease loci. Coverage also includes all the known microdeletion/duplication syndromes, 41 unique subtelomeric regions and all 43 unique pericentromeric regions. Methods: Analysis by aCGH was performed on DNA extracted directly from amniotic fluid (AF) for 352 (52%) samples, directly from chorionic villus sampling (CVS) for 87 (13%) samples and from cultured cells (amniocytes/CVS) for 234 (34%) samples. For the remaining 9 samples, the sources of fetal DNA were tissues, fibroblasts, or fetal blood. Results: Copy number changes were detected in 131 (19.2%) of the total 682 cases. Of these, 72 (10.6%) were CNVs that were interpreted as likely benign either because they were inherited from a phenotypically normal parent (66) or they were de novo (6) but had been previously observed in our aCGH database of over 28,000 clinical cases and phenotypically normal individuals. Of the 57/682 (8.4%) cases in which clinically significant genomic imbalances were detected, 26/432 were detected on our 44K clinical BCMV6 or BAC arrays (6% detection frequency) and 31/250 were detected on our higher-resolution 105K BCMV7 array (12.4% detection frequency). A subset of 88 cases with an indication of abnormal ultrasound was studied using our BCMV7 array, with a resulting detection rate of 21.6%. Conclusion: aCGH testing yields highly accurate results on both direct CVS/AF samples and cultured cells, with a rapid turn around time averaging 6 days. aCGH maximizes the possibility of detecting unbalanced genomic rearrangements, including submicroscopic copy number changes below the resolution of standard karyotype. Since the introduction of our higher-resolution BCMV7 clinical prenatal array, we have observed an approximately 2-fold increase in our detection rate for clinically significant unbalanced genomic rearrangements.

1261/W

A novel *de novo* deletion of the chromosome 12q23.1q23.2 in a patient with short stature, dysphagia, severe microcephaly and developmental delay. *W. Burdo-Hartman[1], H. Toriello[1], J. Koops[1], M. Gorre[2], S. Gunn[2], K. Hovanes[2].* 1) Spectrum Health, Grand Rapids, MI; 2) CombiMatrix Diagnostics, Irvine, CA.

The patient is a four-year-old girl who was first evaluated for significant hypotonia, global developmental delay and microcephaly at the age of nine months. She was born at 34 weeks of gestation via cesarean section due to breech presentation and was 3 pounds and 2 ounces at delivery. She was kept in the NICU for 5 weeks. Her mother smoked during pregnancy and was on insulin due to insulin-dependent diabetes. At the age of 12 months, her weight was below 3rd percentile. She received a Nissen fundoplication and a gastrostomy tube. She has been fed mainly with her G-tube since then. She was able to sit by herself at the age of 16 months and walked at the age of 21 months. At 30 months, she had cognitive and language score within the normal limits but her expressive language was at 25 months. She had fine and gross motor delays which suggested the diagnosis of developmental coordination disorder. She is a poor sleeper and has breathing concerns including snoring. She also coughs and gags when she runs. At the last visit, she was 4 years 4 months of age. Her weight, height, and head circumference were in 25th to 50th, 10th and less than 2nd percentile respectively. Oligonucleotide array comparative genomic hybridization analysis revealed an approximately 4.9 Mb deletion of the 12q23.1-q23.2 region. FISH analysis confirmed the deletion in the proband and parental analysis suggested a *de novo* event. The 12q deletion encompasses 33 annotated genes including a number of disorder-related genes such as *PAH, SLC17A8, SLC25A3, IGF1, TMPO, SYCP3, ASCL1* and *GNPTAB*. This patient's short stature and microcephaly is likely due to haploinsufficiency of *IGF1* gene as reported previously in patients with *IGF1* mutations. The *ASCL1* deletion is likely the cause of the patient's breathing problems since intragenic deletion of this gene is associated with congenital central hypoventilation syndrome. Haploinsufficieny of *PMCH* may be related to her dysphagia based on the recent studies of *PMCH* (-/-) rats. Missense mutation of *SLC17A8* gene is associated with autosomal dominant deafness, however, no hearing problems were reported in our patient. Haploinsufficiencies of the other disorder-related genes have not been correlated with a specific phenotype. This report summarizes a novel deletion encompassing a number of disorder-related genes and the genotype/phenotype correlation.

1262/W

Detection and quantification of mosaic isodisomy in Beckwith-Wiedemann patients in the Clinical CytoGenomics Laboratory. *L.K. Conlin[1], B.D. Thiel[1], S. Mulchandani[1], J.M. Kalish[2], K.E. Nichols[3], J.A. Biegel[1,2], C.A. Stanley[4], L.M. Ernst[5], N.B. Spinner[1], M.A. Deardorff[2].* 1) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Division of Oncology, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Division of Endocrinology, The Children's Hospital of Philadelphia, Philadelphia, PA; 5) Department of Pathology, Northwestern University, Chicago, IL.

Historically, cytogenetic abnormalities, such as inversions and duplications involving 11p, have been reported in a small percentage (1-2%) of patients with Beckwith-Wiedemann syndrome (BWS). The majority of BWS patients present with methylation abnormalities, detectable by molecular methods. With the advent of SNP array analysis in the cytogenetics laboratory, we have been able to expand our detection of pathogenic findings in BWS patients to include paternal uniparental isodisomy. To date, we have identified mosaic loss of heterozygosity (LOH) of 11p in 9 of 43 patients (21%) referred for BWS, hemihypertrophy, hypoglycemia, and/or congenital hyperinsulism. Mosaic LOH was detected by identification of abnormal genotype frequencies in combination with normal probe intensities, and was quantified using a mathematical model developed in our laboratory. Samples from multiple tissues were tested in 4 patients, with LOH detected in all but one sample. Our testing was more sensitive than methylation testing, as SNP array analysis allowed for quantification of the level of mosaicism down to 5%. In addition, the extent of the LOH along the chromosome was determined for each patient. All patients had LOH involving the IGF2, H19, and CDKN1C loci at 11p15.5, while 3 patients had LOH of the Wilms tumor loci at 11p13. In total, 7 patients presented with LOH involving only 11p, suggesting mitotic recombination as a mechanism of formation. One patient presented with whole chromosome LOH, suggesting a mechanism of mitotic nondisjunction. A final patient was found to have mosaic genome-wide LOH and a 46,XX karyotype, indicating a subset of cells with complete uniparental isodisomy. Using SNP genotyping data, we were able to verify that this cell line showed isodisomy of the paternal genome, consistent with a fertilization error resulting in androgenetic chimerism. The use of array technology in the cytogenetics laboratory has enormously enhanced our ability to detect small genomic deletions and duplications, and additionally, to identify isodisomy. In BWS, this technology is useful for finding low levels of mosaicism for loss of heterozygosity, and in determining parent-of-origin. The high resolution allows for identification of breakpoints and precise gene involvement in the isodisomy. In summary, the robustness of the genome-wide SNP assay provides the ability to diagnose unexpected etiologies and characterize uniparental disomy in BWS.

1263/W

Pathogenic copy number variants detected by array-based comparative genomic hybridization (aCGH) in fetuses with malformations and a normal karyotype. *G. D'Amours[1,3,6], G. Mathonnet[1], R. Fetni[2,3,4], F. Tihy[1,3,5,6], S. Nizard[1,5,6], J. Michaud[1,3,5,6], E. Lemyre[1,3,5,6].* 1) Service de génétique, CHU Sainte-Justine, Montréal, Canada; 2) Pathologie, CHU Sainte-Justine, Montréal, Canada; 3) Centre de recherche, CHU Sainte-Justine, Montréal, Canada; 4) Pathologie et biologie cellulaire, Université de Montréal, Montréal, Canada; 5) Pédiatrie, Université de Montréal, Montréal, Canada; 6) Faculté de médecine, Université de Montréal, Montréal, Canada.

Array-based comparative genomic hybridization (aCGH) has been increasingly used in the clinical setting, and has even replaced conventional karyotyping as the first-tier test in patients with mental retardation and/or multiple congenital malformations. Only a few studies have investigated its use in the prenatal setting, and even fewer have focused on fetuses with malformations. We report copy number variants (CNV) detected by aCGH in a cohort of 50 fetuses with major malformations diagnosed by ultrasound. Most cases were tested after termination of pregnancy. Pathogenic CNVs were identified in 7 fetuses (14%), and CNVs of uncertain clinical significance in 3 (6%). The proportion of CNVs of uncertain clinical significance reported here is comparable to what has been reported in similar cohorts (0-12%), while the proportion of clinically significant results is slightly higher (2-10%). This difference might be explained by the lower resolution and the more targeted coverage of the arrays used for those studies. Cerebral, cardiac and renal abnormalities were the malformations most often found in fetuses with a pathogenic CNV.

Our results confirm the relevance of aCGH as a useful prenatal diagnostic tool, as it allowed a larger proportion of fetal malformations to be explained, thus improving the associated genetic counseling. However, clinical interpretation difficulties, linked with CNVs of uncertain clinical significance, prompt for caution when ordering aCGH in the prenatal setting, especially during ongoing pregnancies.

1264/W

Non-contiguous de novo chromosome 1q43 and 1q44 segmental losses detected in a patient with developmental delay by array CGH and FISH techniques. *G. Ghaffari[1], B. Gray[1], A. Bent-Williams[1], S. Link[1], R. Zori[1,2].* 1) University of Florida, Department of pathology Cytogenetics Laboratory, 4800 SW 35th Dr, Gainesville, FL; 2) University of Florida, Department of Pediatric, Box 100296, Gainesville, FL.

Microarray analysis is now the preferred method for clarification of chromosome deletions and duplications in situations where routine cytogenetic study is inconclusive. Here we report a 3 year and 7 month old boy with developmental delay and muscular hypotonia. He was visually attentive, with significant motor delays, he was not able to sit up independently and was not saying any words at 3 years 7 months of age. He was a normal-appearing child without obvious facial dysmorphism. His height was 85.8 cm, weight 12.6 kg, and head circumference 47.5cm, which was in 3rd percentile. He had no minor or major anomalies of the extremities. Chest, abdomen, and genitalia were normal. His muscle mass felt fairly good but he clearly was hypotonic both in upper and lower extremities. Chromosomal studies revealed a normal karyotype. Comprehensive genetic analyses using microarray-based comparative genomic hybridization (aCGH) analysis on patient DNA revealed two non-contiguous distinct deletions in 1q43 and 1q44 of 1.6 and 1.0 Mb in size respectively and 2.5 Mb apart. aCGH results were confirmed by conducting metaphase FISH using BAC probes RP11-80B9 from 1q43 for 1.6 Mb deletion, RP11-212E221 from 1q43 for 2.5 Mb undeleted , and RP11-156E8 from 1q44 for 1.0 Mb deleted region. Parental FISH studies using the above BAC probes confirmed a de novo origin of deletions. Further investigations are needed to determine the mechanism of formation for the above changes. Within the deleted regions based upon our finding 18 refseq gene are located, including FMN2, GREMLIN2, OPN3, KMO, FH, and ADSS, those genes play important roles in G-protein signaling , hydroxylation of L-tryptophan, krebs cycle, cytoskeletal organization, and purine nucleotide biosynthesis. This is a novel Non-contiguous de novo change not reported to-date. The 1.0 Mb deletion at 1q44 has an overlap with the smallest common region of 360kb, in which has been reported by Van Bone et al (2007) in nine out of the 10 patient with corpus callosum.

Clinical Dilemma in Interpretation of CGH Microarray Results: Illustration of a case with a copy number gain and loss inherited from each parent. *A. Pandya, V. Kirkland, K. Withrow, J. Hiemenga.* Dept. of Human & Molecular Genetics, Med Col Virginia, VCU, Richmond, VA.

Microarray-based comparative genomic hybridization (array CGH) is a powerful molecular cytogenetic tool increasingly utilized in clinical practice to detect genomic imbalances which help to explain the clinical presentation in a child with multiple anomaly syndromes and/or cognitive delay. Current standard practice includes performing parental studies in follow up when a variant of unknown significance is identified in the proband. Although this practice is helpful in interpreting the pathogenic nature of a genomic imbalance, it often poses a dilemma in certain situations as illustrated by our case. We present a 20 month old Caucasian infant who presented with hypotonia, moderate cognitive delay, minimal coarse facial features and large body size, with subsequent failure to thrive. He developed a seizures after his initial evaluation. Routine cytogenetic studies, LIT1 and SNRPN methylation testing were negative. CGH microarray studies through Athena Diagnostics (105K Panel) revealed 1) loss of 20q13.33 region with a 1000Kb deletion which is paternal in origin and 2) gain of material at 22q13.31, about 490Kb in size which is maternally inherited. Both the parents are asymptomatic and hence these changes of unknown clinical significance are thought to represent a benign polymorphism. However the proband has several features which overlap with the clinical presentation in a few cases reported with 20q13.33 subtelomeric deletion. Additional clinical details of the case with genes of interest in the affected chromosomal regions and its comparison to the few reported cases in the literature will be presented. This case illustrates the uncertainty posed with regard to ascribing genotype-phenoytpe correlation and pathogenic significance to a laboratory finding in light of parental studies. Additional reports of unusual cases and publicly available databases with clinical copy number variants will help resolve such dilemmas and enhance clinical care.

1266/W

Frequency of aneuploidy in sperm cells of smoking males. *C. Pereira[1], M.S. Juchniuk de Vozzi[1], S.A. Santos[1], M.A.C. Vasconcelos[2], C.C.P. Paz[1], L. Martelli[1].* 1) Department of Genetics, FMRP- University of Sao Paulo, Ribeirão Preto, SP, Brazil; 2) Department of Gynecology and Obstetrics, FMRP- University of São Paulo, Ribeirão Preto, SP, Brazil.

The chromosomal aneuploidies in sperm are directly related to infertility, increasing the risk of birth defects and fetal losses. Although advanced maternal age still remains as one of the few well established risks, other factors have been identified as potential contributors to the increase of aneuploidy, including alcoholism, smoking and occupational exposure to pesticides. In this study, using interphase FISH analysis, we have evaluated the frequency of disomy of chromosomes 3, 13, 21, 22, X and Y sperm in ten male smokers compared with a control group of seven fertile men, nonsmokers. We analyzed aneusomies of these chromosomes by dividing in two hybridization sets; 13/21/22 and 3/X/Y. All the members of both groups presented a normal karyotype. The overall frequency of disomies showed a significant increase in the smoking group when compared to the control group, ($p<0.0001$) in both hybridization sets. When the analysis was made for each chromosome individually, the error in meiosis I to sex chromosome complement (disomy XY) and disomies involving chromosome 3 (disomy 33) showed a significant increase in smokers ($p<0.0001$ and $p<0.01$ respectively). The frequency of diploidy arising from an error in meiosis I (diploidy XY33) increased in the smoking group ($p<0.0002$). When the error was in meiosis II, only diploid YY33 complement was increased in smoker subset ($p<0.0167$). Our results suggest an association between cigarette smoking and incomplete reduction in meiosis I. Comparison of semen characteristics between the two groups found higher frequency of abnormal morphology in the smoking group ($p<0.0365$), showing that these factors may also be affected by the habit of smoking.There was no statistically significant difference between the frequency of disomies, when smokers were divided into those who smoked less and more than 20 cigarettes per day. Molecular cytogenetic investigation of germ cells is an essential tool for the elucidation of the meiotic segregation mechanisms, allowing the identification of possible factors responsible for infertility.

Submicroscopic Interstitial Deletion 3q22.3-q23 in a Patient with Blepharophimosis-Ptosis-Epicanthus Inversus Syndrome (BPES) and Microcephaly, Development Delay and Growth Retardation: Further Characterized by SNP Array Analysis. *C.A. VENEGAS[1,2], L.M ZEPEDA[1,2], F. FERNANDEZ[2], J. BERUMEN[3], S.E KOFMAN[1,2].* 1) Servicio de Genética, Hospital General de México, Mexico City, DF, Mexico; 2) Facultad de Medicina, UNAM; 3) Servicio de Medicina Genómica, Hospital General de México.

Blepharophimosis, ptosis and epicanthus inversus syndrome [BPES; OMIM# 110100] is a rare autosomal dominant disorder caused by mutations in the FOXL2 gene, located in 3q23. Haploinsufficiency of FOXL2 gene in typical BPES patients can occur by intragenic mutations (~72%), microdeletion (6kb to <1.9Mb) (14%) and cytogenetic rearrangement (2%). To our knowledge only five cases with a submicroscopic interstitial deletion (2.7Mb to <4Mb) of 3q23 have been described (Beysen D et al., Am. J Hum Genet.77:205-218, 2005) and a defined clinical phenotype has not been established yet. We report the clinical and molecular findings in a 5-year-old male with de novo interstitial deletion on 3q22.3-q23. Our patient has typically BPES with additionally facial anomalies, microcephaly, psychomotor and growth retardation. Conventional cytogenetic analysis performed in the child and parents did not reveal abnormalities. 500K SNP array analysis showed an interstitial deletion in 3q. Physical position of the deletion was from [139,017,148 to 142,106,194] and the size of the deletion was ~3.09 Mb. We compare the clinical and molecular findings in our patient with previously reported cases and hypothesize that our case has a contiguous deletion gene syndrome and that the non-BPES-associated anomalies (microcephaly, psychomotor and growth retardation) result from the deletion of FOXL2 and the genes telomeric to it. Additional studies on patients carrying microdeletions are required to shed light on genotype-phenotype correlations for these deletions encompassing FOXL2. Chromosomal Microarray Analysis (CMA) is a widely available method for the detection of genomic gains and losses, and a useful tool to help establish a clinical diagnosis. High density single nucleotide polymorphism (SNP) arrays have been recently implemented for clinical diagnostics and allow for the detection of copy neutral changes such as contiguous regions of absence of heterozygosity (AOH) in addition to copy number variation. AOH limited to single chromosomes may indicate uniparental disomy (UPD) that can cause clinically recognizable phenotypes if an AOH block contains imprinted genes or mutated autosomal recessive alleles. The detection of multiple contiguous regions of copy neutral AOH that occurs through identity by descent may help to elucidate genetic syndromes due to recessive conditions in consanguineous families. Baylor Medical Genetics Laboratories has provided clinical testing for over 300 cases using the Illumina Human610-Quad SNP array. We have detected clinically significant CNVs in ~10% of cases, and CNVs of uncertain clinical significance in 11% of cases. Notably, at least one contiguous region of AOH greater than 5Mb was detected in 27.5% of samples. Five patients evidenced UPD. Two had UPD of chromosome 15, the others had UPD of either chromosome 1,11, or 22. Several cases from consanguineous families for whom pedigree information was available had an extent of AOH that was consistent with the estimated coefficient of inbreeding, including seven cases where the proportion of AOH was consistent with mating between first degree relatives. In six patients, the block of AOH was present in a region containing autosomal recessive genes or loci related to the indicated clinical findings. Our experience shows that the CMA - SNP array is a comprehensive clinical tool that can detect common microdeletion/microduplication syndromes, novel copy number variants, and UPD. Interestingly, this method is also being applied as a tool to narrow down the regions of interest in patients from consanguineous families as a "positional" approach to locate potential disease-causing genes.

Pure trisomy of distal long arm of chromosome 15(q24-qter) detected by SKY. *K. Abe, I.M.P.O. Rizzo, L.M. Formigli, M. Schneider, C.E. Speck-Martins.* Pat Molecular, Lab de Citogenetica, Rede SARAH-Hosp de Reabil, Brasilia DF, Brazil.

Introduction. There are only few reports of distal 15q duplications with no concomitant monosomy for another chromosome segment. In order to contribute to the clinical characterization of 15q24-qter trisomy/duplication phenotype, we report some additional clinical findings on the patient with pure trisomy 15q24-qter. Cytogenetic analysis showed additional material on 21p. Spectral karyotyping (SKY) showed an extra copy of the chromosome 15q transposed to chromosome 21p. Clinical report. The patient, female, first twin of three amnion, was born at 34 weeks because was affected by oligohydramnion. The two others were normal. At birth, she had respiratory distress, jaundice, arterial channel persistence and atrial septal defect, development delay, hypotonia, abnormal head shape, increase in OFC, dysfagia, chronic respiratory distress with choanal atresia, and pubic hair. MRI and CT-scan of the brain revealed supratentorial hydrocephalus and sagittal synostosis. Imaging analyses showed stomach malrotation and ovarian cysts. Clinical evaluation at 9 months showed normal growth, synophrys, short palpebral fissures, telecanthus, high nasal bridge, defined philtrum, thin upper lip, flat occiput, prominent forehead, camptodactyly of the third finger, deep crease on feet, heart murmur, and hypotonia with development delay. At 2 years and 3 months, she had an extremely delay in cognitive, motor, and behavioral development. Results and Discussion. After SKY, reevaluating G band analysis we could conclude that the patient had a duplication of 15q24-qter with no assotiated monosomy. In previously reported cases, unusual prenatal overgrowth, tall stature, macrocephaly, and craniosynostosis have been described as distal 15q trisomy syndrome, although they also had monosomic components. By contrast, similar trisomy without concomitant monossomy has been reported to patients with ptosis, small size, developmental delay, and no craniosynostosis or overgrouth. In addition, case of a child with autistic disorder, seizure, posnatal overgrowth, and a minor brain malformation has been described to 15q25.2-qter. Based on the cases reported to date, some of features as above quoted are controversial. Further studies could help to delineate a pattern of abnormalities to patients with trisomy of terminal segment of chromosome 15. Since the patient reported here had no concomitant monosomy, we can reasonably assume that her abnormal phenotype results from those duplicated segment.

1270/W

Marker chromosome 13 with an apparent neocentromere detected by array CGH in a fetus with MCA. *r. habibian, a. hajianpour, j. Szymznska, f. wang, q.q. huang, j.c. wang.* cytogenetics laboratory, genzyme, monrovia, CA.

Amniocentesis was performed on a 31 years old woman at gestational age of 19 weeks due to abnormal fetal ultrasound findings, including enlarged stomach, postaxial polydactily of upper extremities, and nuchal fold thickening. Cytogenetic analysis revealed a de novo supernumerary medium size marker chromosome. FISH analysis using alpha satellite centromeric probes specific for chromosomes X, Y, 18 and acrocentric chromosomes excluded these chromosomes as the origin of the marker. Array CGH analysis revealed two copy gain of 24.2 Mb from terminal long arm of chromosome 13 segment 13q31.3-qter. FISH confirmed the marker to be an inverted duplication of the 13q31.3-q34 region in 30 out of 30 cells examined (100%). As the marker was stable and did not show hybridization with D13Z1/D21Z1 probe specific for the centromere of chromosomes 13 and 21, formation of a neocentromere is speculated. The pregnancy was terminated. This case illustrates the importance of aCGH as an adjunct test to conventional cytogenetics for the characterization of marker chromosomes in abnormal pregnancies and to help parents make informed decision.

Cytogenetic biomonitoring of residents of a distillery unit. *K. Kaur, G. Kaur, G. Gandhi.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, India.

Alcohol distilleries discharge highly coloured effluents which tend to be highly noxious in terms of odour, causing water and soil pollution and may alter the pH of the soil and thereby affect agricultural crops. Rather treatment of effluents by standard practices may potentiate the outcomes and hence requires the continuous evaluation of environmental health and the environmental contribution to the burden of human disease. Human Biomonitoring studies have gained significance with genetic biomarkers as useful tools for the early assessment of exposure to occupational/environmental pollution. The objective of the present study was to investigate the genomic integrity of some people residing near and/or working in a distillery unit at Hamira, Punjab. Samples of peripheral blood were evaluated using the single cell gel electrophoresis assay (comet assay) and the micronucleus (MN) assay. The exposed group (n = 50; 25males, 25 females; 20-40 y) was compared to a reference group (n = 50) of subjects located far from industrial units and matched for age, sex and socio-economic status. The standard Cytokinesis block MN assay revealed significant increase for aneugenicity/clastogenicity. DNA damaging effect as functions of DNA migration length, per cent tail DNA, tail moment and Olive tail moment was also significant. Statistical analysis (Student's t-test) revealed high significance ($p<0.001$) for tail length and micronuclei frequency values compared for the exposed (12.87+0.29μm, 0.62±0.06%) and control (5.13+0.21 μm, 0.13±0.15%) groups. Thus, indicating that individuals residing near/working in distillery have more chromosomal and DNA damage as compared to controls. The statistical comparison for both parameters on exposed males (14.00±0.47 μm, 1.07±0.65 %) and females (11.67±0.16 μm, 0.31±0.10%) revealed greater genetic damage in males than in females. Keywords: Cytokinesis block micronucleus assay, Comet assay, Peripheral blood lymphocytes, Binucleated cells, DNA migration.

Clinically relevant microdeletions encompassing long-range gene expression regulatory elements as a cause of human genetic disease. *F.M. Mikhail, N.H. Robin, J.C. Henegan, K.D. Rutledge, E.J. Lose, A.J. Carroll.* Department of Genetics, University of Alabama at Birmingham, Birmingham, AL.

The routine use of array CGH has enabled the detection of numerous clinically relevant submicroscopic copy number variations (CNVs) throughout the human genome. However, determining the significance of a CNV in an extragenic region close to clinically significant gene(s) has proven to be difficult. The expression pattern of developmental and tissue-specific genes is regulated not only by the core promoter but also by multiple *cis*-acting distant genomic elements that are crucial for spatiotemporally correct gene expression. These regulatory elements can be as distant as 1.0 Mb in either direction from the gene transcription unit. Here we report three cases that illustrate this problem. In each case, array CGH (ISCA 4x44k and 2x105k Agilent oligo-arrays) revealed a microdeletion thought to encompass long-range gene regulatory/enhancer elements for proximal clinically significant gene(s) relevant to these patients' phenotypes. Patient 1 presented with neonatal respiratory distress, congenital hypothyroidism, and abnormal frequent movements. He was shown to carry a *de novo* ~280 kb deletion at 14q13.3 located ~80 kb downstream of the *NKX2-1* gene, which encodes the thyroid transcription factor 1 (TTF1). Haplonsufficiency of *NKX2-1* has been reported to cause the same phenotype seen in our patient. Patient 2 presented with bilateral sensorineural hearing loss. He was shown to carry an ~1.3 Mb extragenic deletion at 13q31.1q31.2 flanked by the *SLITRK5* and *SLITRK6* genes, which encode integral membrane proteins that are expressed predominantly in neural tissues. *SLITRK6* deficient mice have been shown to have disorganized innervation and neural loss in the inner ear. Patient 3 presented with autistic features and language delay. He was shown to carry an ~1.0 Mb extragenic deletion at 2q14.3 located ~450 kb upstream of the *CNTNAP5* gene, which encodes a member of the Neurexin family. *CNTNAP5* has been linked to autism and language delays. No benign CNVs spanning these regions have been reported in the DGVs. A comparative sequence analysis of these deleted regions using the UCSC Multiz Alignment and Conservation track showed multiple highly conserved elements between the human sequence and other species. In conclusion, this report supports the notion that some CNVs can cause human genetic disease by transcriptional misregulation of nearby genes, and underscores the need for careful interpretation of CNVs in extragenic regions.

1273/W

Utilization of high density oligonucleotide array to analyze patients with developmental delay and congential anomalies. *M. Nimmakayalu[1], H. Major[1], Q. Qian[1], O.A. Shchelochkov[1], B. Darbro[3], R. Van Rheeden[1], D. Hulseberg[1], V.C. Sheffield[1], P.L. Nagy[2], S.R. Patil[1].* 1) Med Genetics, Pediatrics, Univ Iowa, Iowa City, IA 52242; 2) Department of Pathology, Columbia University Medical Center, New York City, NY 10032; 3) Department of Pathology University of Iowa, Iowa City IA 52242.

Array comparative genomic hybridization (aCGH) is a powerful tool that provides high resolution whole genome analysis of copy number variations and can reveal submicroscopic deletions and duplications. We present aCGH data on 937 patients referred for developmental delay/mental retardation (DD/MR) and/or congenital anomalies using a high-density 385K oligonucleotide array (Roche NimbleGen). We found genomic copy number variations (CNVs) in approximately 22% (214/937) of the examined cases. Of these 214 patients, 49% (104/214) were referred for evaluation of DD/MR, 31% (67/214) for congenital anomalies, and 19% (40/214) for other diagnoses. Of the genomic alterations detected, 25% (53/214) represented known clinical syndromes, for example del(22)(q11.2) which was present in 6% (12/214) of the cases. The remaining 75% (161/214) consisted of the recently described CNVs including del(16)(p11.2) which was present in 3% (7/161) of the cases, as well as CNVs of uncertain clinical significance. Parental aCGH analyses of 58 probands with CNVs (200 kb - 1.5 Mb) showed that the majority of them were inherited (37% maternal vs. 63% paternal). Our cohort also includes patients with cytogenetically balanced rearrangements in which aCGH detected subtle imbalances at the breakpoints in ~30 % of the cases. We used FISH and higher density array to further characterize clinical significance of the de novo cases and cases with interchromosomal and intrachromosomal rearrangements. We provide frequency estimates of the common and newly identified CNVs in the samples submitted to the diagnostic lab.

Mechanism of XXY/XXXY: Maternal MII/Post Zygotic X Chromosome Non-Disjunction and Homozygosity Identified SNP Microarray Analysis. *J.H. Tepperberg[1], S. Schwartz[1], P.R Papenhausen[1], A.N. Injac[2], I.K. Gadi[1], V. Jaswaney[1], J. Neely[1], H. Risheg[3], E. Keitges[3], R. Pasion[1], J. Smith[4], R. Potluri[4], R. Burnside[1].* 1) Dept Cytogenetics, Lab Corp America, Res Triangle Pk, NC; 2) Baylor College of Medicine, Dept Pediatrics. One Baylor Plaza, MS BCM 320 Houston, TX 77030; 3) Dept Cytogenetics, Dynagene/LabCorp America, Seattle WA; 4) Dept Cytogenetics, Dynagene/LabCorp America, Houston, TX.

The frequency of 47,XXY Klinefelter syndrome (KS), is reported to be ~1:1000 male births with ~50% involving the maternal X chromosome [MI non-disjunction (47.0%), MII (29.0%) or post zygotic mitotic (PZM) nondisjunction (15.7%)], and ~50% due to paternal MI nondisjunction. The 48,XXXY KS is much less common than XXY KS with an estimated frequency of 1:8500. XXY/XXXY mosaicism is even rarer, requiring two independent nondisjunction events. We report a 12.1 year old male referred for microarray testing due to DD, hypotonia, and inattentiveness in which XXY/XXXY chromosome mosaicism was detected. Formation of this particular mosaicism is difficult to elucidate and could result from various complex maternal or paternal meiotic and mitotic nondisjunction pathways. SNP genotyping microarray analysis offers an easier, more informative alternative method of assessing the origin of extra X chromosomes than the traditional method using DNA polymorphic markers in which samples from parents and proband are needed. Microarray analysis showed a copy number gain of ~2.8 consistent with poly X mosaicism. FISH was performed using alpha satellite X and Y probes and confirmed 80% of the metaphases XXXY and 20% XXY, while interphase analysis showed 56/100 nuclei with XXXY hybridization signals and 44% with an XXY hybridization pattern. No XY cell line was observed. The SNP genotyping array also showed complete homozygosity for all three X chromosomes indicating that all were genetically identical. Therefore, the X aneusomy must have originated from an MII error followed by a PZM nondisjunction error. Paternal origin is less probable, requiring meiotic MI and MII nondisjunction errors to produce an XXY gamete, with subsequent PZM nondisjunction error following fertilization with a nullisomic X egg. A more plausible supposition is maternal MII nondisjunction error producing an XXY fetus with subsequent PZM error producing three theoretical cell lines, XY/XXY/XXXY, although no XY cell line was observed. This result demonstrates a sophisticated utility for SNP based copy number/genotyping microarray testing in patients with X chromosome aneuploidy (and autosomal aneuploidy and UPD), as well as providing easier insight into the meiotic and post zygotic mechanistic origin of X chromosome nondisjunction. Although no XY cell line was observed in the blood sample, it is conceivable that an XY cell exists in another tissue. Buccal smear FISH would address this hypothesis.

1275/W

Recombinant chromosome 7 in a mosaic triple X/Turner patient. *E.K. Torgbe[1], F. Valdez[1], S. Iyer[1], R. Garcia[1], P. Pichurin[2], M. Suterwala[3], P. Koduru[1], S. Dallaire[4], T. Appleberry[4], C. Tirado[1].* 1) Pathology, University of Texas Southwestern, Dallas, Te; 2) Genetics, The University of Texas Southwestern Medical Center at Dallas, Dallas, TX; 3) Pediatrics, Baylor College of medicine, Department of Pediatrics; 4) Perkin Elmer Laboratories, Waltham, Massachusetss.

Trisomy X syndrome occurs at a rate of 1/1000 and presents with no obvious physical features. Individuals with this syndrome may be at an increased risk for mild speech and motor delay as well as learning disabilities. However, they have normal secondary sexual development with minimal impairment in their reproductive abilities. They may also have an increased risk for psychologic problems during their lifetime. A small proportion of patients with Turner syndrome (3-4%) are mosaic for a triple X (47,XXX) cell line. In general, patients with a lower proportion of the 45,X cell line show fewer Turner syndrome features. Terminal 7q deletions present with variable phenotype depending on the size of the deletion. These includes cleft palate, microcephaly, syndactily of fingers and toes, cardiac malformations and hyperplasia of Lagerhans' cells. Herein, we present a newborn with pedal edema, microcephaly, micrognathia, slightly down slanting palpebral fissures, ventricular septal defect, patent ductus arteriosus, and a unilateral dysplastic kidney. Conventional cytogenetics and FISH revealed a mosaic karyotype: 47,XXX,add(7)(q32)[18]/45,X,add(7)(q32)[2]. Chromosome analysis of the mother showed a normal female karyotype. Chromosome analysis of the father showed an abnormal but apparently balanced karyotype due to two overlapping paracentric inversions in the long arm of chromosome 7. His karyotype was described as 46,XY,der(7)inv(7)(q22.1-q34)inv(7)(q32q36). This result was confirmed by FISH and array CGH with BACs specific for 7q36.1, 7q36.2 and 7q36.3 bands (RP11-728K20, RP11-80J22 and RP11-58F7). FISH using the same BACS on the proband showed deletion from 7q36.1 to 7q36.3 in the rec(7) chromosome, therefore her karyotype was described as: 47,XXX,rec(7)del(q35q36.3)inv(7)(q22.1q34)inv(7)(q32q36)[18]/ 45,X,rec(7)del(q35q36.3)inv(7)(q22.1q34)inv(7)(q32q36)[2]. Genetic counseling was recommended for this patient and her parents regarding planned future pregnancies.

1276/W

Coexistence of different genomic mutations in three mentally retarded subjects: further evidence that a genetic double trouble can explain atypical phenotypes. *M. Zollino[1], G. Marangi[1], D. Orteschi[1], M. Murdolo[1], M.C. Stefanini[2,3], G. Vento[4], M.G. Pomponi[1], S. Lattante[1], G. Neri[1].* 1) Dept Medical Genetics, Univ Catt Sacro Cuore, Rome, Italy; 2) Dept Child Neuropsychiatry, Univ Catt Sacro Cuore, Rome, Italy; 3) Don Carlo Gnocchi Foundation, Rome, Italy; 4) Dept Pediatrics, Univ Catt Sacro Cuore, Rome, Italy.

During routinary genetic diagnosis for mental retardation or neuromuscolar disorders we observed:1) a DMD gene mutation causing Duchenne muscolar distrophy in a 8-year-old boy who also had severe mental retardation;2) a 47,XXY chromosome constitution in a newborn who was referred for hypotonia and minor facial anomalies and 3) a full mutation of the FMR1 gene in an 18-year-old male who was severely mental retarded and also had minor physical anomalies. Since the clinical manifestations in each of these patients exceeded those typical of their diagnosed conditions, we decided to perform a further study of the cases by array-CGH (Agilent 4x44k, NCBI 36 hg18 probes alignment). We found the following CNVs not reported in the Database of Genomic Variants: 1) a 220 kb deletion of chromosome region 11q14.3 (89508377...89730095) in association with the DMD gene mutation (parents are under investigation); 2) a dn deletion of 2 Mb in 2q37.3, (240561565...242690037) in association with the 47,XXY chromosome constitution (a-CGH revealed the additional copy of the X chromosome as well); 3) a deletion of 500 kb in 2p25.3 (1135059...1649356), in association with the full FMR1 mutation. Genotype-phenotype correlations are discussed. These cases represent further examples of genetic double troubles resulting in complex phenotypes. Overall, they stress the importance of considering additional DNA testing in patients with known mutations who have unusual phenotypes.

1277/W

Validations of array-CGH results and definition of CNVs categories in mental retardation. *D. Orteschi[1], G. Marangi[1], M. Murdolo[1], S. Lattante[1], S. Ricciardi[1], V. Romanelli[2], O. Gabrielli[3], D. Battaglia[4], E. Mercuri[4], M.C. Stefanini[4,5], G. Zampino[6], C. Leoni[6], F. Gurrieri[1], P. Chiurazzi[1], R. Lecce[1], M.E. Grimaldi[1], G. Neri[1], M. Zollino[1].* 1) Dept Medical Genetics, Univ Catt Sacro Cuore, Rome, Rome, Italy; 2) INGEMM, Instituto de Genética Médica y Molecular, IdiPAZ-Hospital Universitario La Paz, Universidad Autónoma de Madrid, Madrid, Spain; 3) Institute of Maternal-Infantile Sciences, Polytechnic University of Marche, Ancona, Italy; 4) Dept Child Neuropsychiatry, Univ Catt Sacro Cuore, Roma, Italy; 5) Don Carlo Gnocchi Foundation, Rome, Italy; 6) Dept Pediatrics, Univ Catt Sacro Cuore, Rome, Italy.

Array-CGH is proving to be a powerful tool enabling the detection of submicroscopic chromosomal imbalances associated with mental retardation and physical anomalies. However the pathogenic relevance of several CNVs can be uncertain, thus a validation of the a-CGH results is needed for proper genetic diagnosis and counseling. We performed a-CGH (Agilent 4x44k or 244K) in a total of 550 subjects with mental retardation and minor physical anomalies, who mostly had apparently normal chromosomes on conventional cytogenetics. A total of 186 CNVs were detected, that were grouped in the following categories: 1) pathogenic (total 96/550, 17.5 %). This category was defined by the following criteria: de novo occurrence; association with known syndromic conditions or sized > 2 Mb; gene content analysis consistent with the clinical features. Of them, 6 were susceptibility factors, that were usually associated with mental retardation of variable degree; 2) polymorphic CNVs, that were all inherited from a healthy parent (total 75/550, 14%). Of them, 57 were common polymorphisms, as reported in the Database of Genomic Variants, 18 were rare, not reported in the Database.; 3) CNVs of uncertain significance (total 15/550, 3%). Based on genotype-phenotype correlation analysis of pathogenic CNVs, we found that predictive of a causative role were also: deletion event, disproportion of growth parameters, peculiar facial characteristics, hands and feet abnormalities, hypotonia, subtle brain abnormalities, major malformations and cryptorchidism. A checklist of the most consistent clinical signs is suggested, as useful tool in validating a-CGH results of uncertain significance, along with gene content analysis. With respect to familial data, in some instances we found that a carrier parent, first referred as healthy, actually had a variable expressivity of the child genetic condition. A detailed clinical analysis of parents is suggested in assessing the pathogenic role of inherited CNVs. Finally, rare polymorphic CNVs are considered to act as cofactors in causing complex phenotypes, as inferred from their occurrence in association with different genomic mutations in several occasions. This last observation seems to confirm the recently suggested two-hit model for severe developmental delay.

1278/W

Xp22.31 duplication: the role of recombination and secondary CNVs. *E. Rajcan-Separovic[1], R. Wildin[2], J. Eichmeyer[2], R. Jiang[3], B. DuPont[4], L. Arbour[5], B. Kamien[6], S. Martell[1], E. Strong[1], C. Harvard[1], Y. Qiao[1], J. Holden[7], S. Lewis[3], W. Robinson[3].* 1) Dept Pathology, Child & Family Res Inst, Vancouver, BC, Canada; 2) St. Luke's Regional Medical Center, Boise, USA; 3) Dept. Medical Genetics, UBC, Vancouver, BC, Canada; 4) Greenwood Genetic Center, Greenwood, USA; 5) Medical Genetics Dept, Victoria General Hospital, Victoria, Canada; 6) Royal Brisbane and Women's Hospital Health Service District, Herston, Australia; 7) Depts Psychiatry & Physiology, Queen's University, Kingston, Ontario, Canada.

Recent studies show that Xp22.31 duplication occurs in ~ 0.4% subjects with intellectual disability (ID) and 0.15% of controls, suggesting the possibility of its role as a risk factor in ID (Li et al., 2010). In our cohort of 435 subjects with ID, the Xp22.31 duplication (Xpdup) was detected in 3 males (0.7% of cases) either by qPCR or whole genome array screening. We performed skewed X inactivation and chromosome X allele transmission analysis using a panel of 8 microsatellite probes in two multigenerational families from this cohort and in one family recruited subsequently. In all three families the male proband had a maternally transmitted Xp22.31 duplication. The duplications ranged from ~0.5 to 1.5 Mb. In 2/3 male probands with Xpdup an additional chromosome change was noted upon whole genome array analysis-de novo gain of 19p13.3 and de novo loss of 11p15.1. All normal female Xpdup carriers (8) showed skewed X inactivation with values >80%(>90% in 7/8 cases). However, the Xpdup chromosome was the preferentially inactive chromosome in only 4 of these cases, based on the AR allele transmission analysis and haplotype segregation. The Xpdup in the male probands was always a recombinant chromosome, with recombination occurring between the Xpdup carrying and non-carrying X chromosomes in their mothers or grandmothers or both. We therefore propose that the inconsistent pattern of inactivation of Xpdup carrying chromosome, may suggest that in some instances skewing is due to the presence of a deleterious chromosome X mutation that is unrelated to the Xp duplication. In support of this hypothesis, two affected male cousins of one of the probands with Xp22.31 duplication, neither of which had the Xp dup, showed an Xq21.1 duplication (Xqdup) in the X-linked ID gene MAGT1 detected by a chromosome X specific array. The Xqdup was subsequently also detected in the proband with Xpdup using the chromosome X array. Further haplotype and chromosome X specific array analysis showed that the Xqdup chromosome was inherited from the great-grandmother and was preferentially inactive in all Xqdup female carriers, regardless of whether they had the Xpdup or not. Investigations of the presence of deleterious CNVs/mutations on chromosome X in affected subjects from families with Xpdup, as well as the search for secondary CNVs at the whole genome level in carriers of Xpdup, may shed more light on the clinical and biological variability associated with this duplication.

1279/W

ASSESSING THE PHENOTYPIC EFFECTS OF IMMP2L AND DOCK4 DETECTED BY WHOLE GENOME SNP ARRAY. *H. Risheg[1], E. Keitges[1], R.D. Burnside[2], I. Gadi[2], V. Jaswaney[2], R. Pasion[2], S. Schwartz[2], J. Tepperberg[2], P. Papenhausen[2].* 1) LabCorp/Dynacare, Seattle, Washington; 2) LabCorp, Research Triangle Park, North Carolina.

Several copy number variants within putative autism genes have been implicated in autism susceptibility. Recently, copy number variations of the *IMMP2L* gene and the adjacent *DOCK4* gene have been identified as possible risk factors for autism spectrum disorder (ASD), speech and language disorder, Tourette syndrome, and dyslexia. To investigate this phenomenon, we performed a retrospective analysis on a population of ~15,000 patients referred for SNP microarray analysis for the detection of duplications or deletions of *IMMP2L* and/or *DOCK4*. We identified 169 patients with >50kb deletions or duplications of *IMMP2L* and *DOCK4*. Of these, 164 had intragenic deletions of *IMMP2L* only , one had a 174 kb partial deletion of both *IMMP2L* and *DOCK4* , three had intragenic *DOCK4* deletions only, and one had a *DOCK4* duplication. No duplications of the *IMMP2L* gene were identified within our cohort. Detailed clinical information was obtained and assessed on a subgroup of 32 *IMMP2L* deletion patients and 5 *DOCK4* deletion/duplication patients. Of the 32 *IMMP2L* microdeletions, 13 deletions were localized within intron 3, and 19 deletions involved exons 1, 2 or 3. Furthermore, secondary changes were seen in 4/32 individuals (2 patients with structural chromosome abnormalities of other chromosomes; and 2 patients with a duplication or deletions of other chromosomes of varying size). Of eight cases with available parental follow-up, all were determined to be inherited (3 maternally inherited; 5 paternally inherited). The most common phenotypic features in this cohort were developmental delay, speech delay, and autism. The three individuals with deletions of *DOCK4* had multiple congenital anomalies and mental retardation. Parental follow-up was available on two of the three patients(1 maternally inherited; 1 paternally inherited). The single *DOCK4* duplication was paternally inherited, and was associated with a complex de novo rearrangement. The findings in our initial 37 *IMMP2L* and *DOCK4* cohort suggest a possible involvement of this region with developmental delay. Since all of the deletions or duplications of IMMP2L or DOCK4 were inherited, additional research is warranted focusing on secondary changes within the genome that might include possible modifier regions.

1280/W

Intragenic ANCO-1 duplication in two brothers affected by complex malformation syndrome. *D. Rusconi[1], C. Castronovo[1], M. Crippa[1], S. Russo[1], C. Gervasini[2], A. Cereda[3], A. Selicorni[3], L. Larizza[1,2], P. Finelli[1,4].* 1) Laboratorio di Citogenetica Medica e Genetica Molecolare, Istituto Auxologico Italiano, Milano, Italy; 2) Divisione di Genetica Medica, Dipartimento di Medicina, Chirurgia e Odontoiatria, Facoltà di Medicina e Chirurgia, Ospedale San Paolo, Università degli Studi di Milano, Milano, Italy; 3) Ambulatorio di Genetica Clinica Pediatrica, Clinica Pediatrica, Ospedale San Gerardo, Monza, Italy; 4) Dipartimento di Biologia e Genetica per le Scienze Mediche, Università degli Studi di Milano, Milano, Italy.

Genome-wide analysis in large cohorts of patients with mental retardation and/or multiple congenital anomalies (MR/MCA), showing a not recognizable phenotype, has led to identify a number of novel microdeletion/microduplication syndromes. We present two brothers sharing facial dysmorphisms, nasal voice, growth retardation, microcephaly and moderate mental retardation. In both patients a congenital atrioventricular canal defect was diagnosed and surgically corrected. The male patient also displayed a third degree vesicoureteral reflux whereas in the female proband a left ureterocele in double calico pielico district was diagnosed. The mother showed a milder phenotype characterized only by slight dysmorphisms and a nasal voice. High resolution array-CGH analysis identified in the two siblings a ~60 kb microduplication in 16q24.3, involving the ANCO-1 gene, also known as ANKRD11, which was not found in the parents by the same technique. The microduplication, confirmed by BAC i-FISH experiments, interrupts ANCO-1, likely resulting in its haploinsufficiency. On the basis of the mother's mild phenotype a low-level mosaic condition of the duplication was suspected. In order to verify this hypothesis, i -FISH was also carried out on the parents' peripheral blood lymphocytes. Indeed, a mosaicism of about 5% was identified in the mother and excluded in the father. Microsatellite analysis confirmed the maternal origin of the duplication. Recently, microdeletions at 16q24.3, varying in size but with a common overlapping region involving ANCO-1 and ZNF778 genes, have been described. It has been proposed that the haploinsufficiency of ANCO-1 and ZNF778 may be responsible for a distinctive syndrome mainly characterized by autism spectrum disorder, cognitive impairment, facial dysmorphisms and brain abnormalities. We suggest that our patients' phenotype, milder than those reported, is likely due to the only involvement of ANCO-1, resulting in distinctive craniofacial dysmorphisms, growth retardation and cognitive impairment but not autistic traits. Further investigations of patients with ANCO-1 anomalies are needed to correlate the presence of major malformations in organs derived from the same embryonic leaflet, such as cardiac and renal anomalies, to the single ANCO-1 haploinsufficiency.

Targeted Array for Autism Spectrum Disorders. *G.A. Toruner, D. Streck, R. Kurvathi.* Institute of Genomic Medicine, UMDNJ-NJ Medical School, Newark, NJ.

Aim: Clinical validation of a targeted array called AutChip 1.0 **Background:** There is an ongoing debate about the use targeted or genome wide arrays in diagnostic genetic testing. Our hypothesis was an array targeting recurrent cytogenetic aberrations in autism spectrum disorders would have a good diagnostic yield and low rate detection of copy number variants of unknown significance. **Materials and Methods:** We designed a custom array on Agilent 44K platform targeting 33 loci. Using that array, fifty-one independent banked DNA samples obtained from Autism Genetics Resource Exchange and Simons Simplex Collections were analyzed. When a copy number variation was detected, the clinical significance of that finding was ascertained using a portal provided by International Standard Cytogenomic Array Consortium. **Results:** No copy number variants were detected in twenty-seven (53%) of the samples. Nine samples (17%) have pathogenic copy number variants. Fourteen samples (%) have benign copy number and one sample (2%) have a copy number variation of unknown significance. **Conclusion:** AutChip 1.0 has a reasonable diagnostic yield and low rate of equivocal results. Targeted array designs should be considered during array-CGH testing for autism spectrum disorders.

Analysis workflow for array-based CNV genotyping. *A. Tsalenko[1], N. Sampas[1], A. Ben-Dor[2], Z. Yakhini[2], R. Navon[2], P. Sudmant[3], C.D. Campbell[3], E. Eichler[3,4], L. Bruhn[1].* 1) Agilent Laboratories, 5301 Stevens Creek Blvd., Santa Clara, CA; 2) Agilent Laboratories, 94 Em Hamoshavot Road, Petach-Tikva, Israel; 3) Department of Genome Sciences, University of Washington, Seattle, WA; 4) Howard Hughes Medical Institute, University of Washington, Seattle, WA.

Copy Number Variation (CNV) is now recognized as a prevalent form of structural variation in the genome contributing to human genetic variability. Methods for genotyping samples over known CNV regions (CNVRs) provide a basis for exploring CNV association to Mendelian and complex diseases. We present a data analysis pipeline that starts with raw two-color hybridization data and a list of CNVRs, and ends with the assigning of absolute discrete copy numbers or copy number estimates for all samples for each CNVR. The workflow includes sample clustering and copy number assignment utilizing both the measured signal intensities and their ratios. We then evaluate population specificity of each CNVR using minimum hyper geometric statistics (Eden et.al., PLOS Comp Bio, 2007) in both low and high copy number regions. We apply the pipeline to a recently published array CGH dataset for 447 distinct HapMap samples (Conrad et. al., Nature 2009) hybridized to an Agilent Human CNV array with 105K probes targeting ~11,000 loci against a common pooled reference. For each CNVR, we first compared the variability of the single channel signal intensities in the cohort to the variability of single channel signal intensities of the reference. Based on this comparison, we estimate that only 44% of the regions are polymorphic, and 56% are non-polymorphic. For each polymorphic CNVR, we applied a t-test based clustering approach to distributions of median log2ratio values as measured across the cohort, followed by a discrete copy number fitting procedure applied to these log2ratios and to corresponding median single channel intensities. We observe that 55% of these regions could be fitted robustly to discrete copy numbers. Regions that do not robustly cluster are typically associated with high sample signals, corresponding to high-copy number states. A significant fraction of polymorphic regions are population specific with more than 30% of them having more than four copies on average among HapMap samples. We compare our results with Conrad et.al., and to copy number estimates for a subset of these samples from 1000 genomes sequencing data. In more than 77% of regions absolute discrete array-based copy number assignments agree with sequencing-based copy numbers in more than 80% of the samples. This analysis demonstrates the utility of combining single intensity and ratio measurements for array-based copy number profiling in the context of various association studies.

Infertile sperm cells exemplify telomeres dysfunction and genetic instability parameters. *T. Biron-Shental[1,4], A. Shulman[1,4], M. Yonish[2,3], L. Goldberg-Bittman[2,3], M.D. Fejgin[1,2,4], A. Amiel[2,3].* 1) Obstetrics and gynecology, Meir Medical Center, Kfar Saba, Israel; 2) Genetic Institute, Meir Medical Center, Kfar Saba, Israel; 3) Faculty of Life Sciences, Bar Ilan University, Ramat Gan, Israel; 4) Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel.

Objective: Telomeres are nucleoprotein complexes that maintain the stability of chromosomal ends. They are shortened with aging and by environmental injury and may form aggregates. Telomere capture can stabilize chromosome breakage. Some parameters of genetic instability include aneuploidy and telomeres dysfunction. Aim: In this study, we evaluated aneuploidy, telomeres length, aggregates and capture, as genetic instability markers, in human sperm of fertile and subfertile men. Materials & Methods: Sperm cells retrieved from 16 men with sub-fertility that required in-vitro fertilization and from 10 fertile men. 200-500 cells were assessed from each participant. Using FISH techniques, the following parameters of genetic instability were evaluated in both groups: random aneuploidy, telomeres length, telomeres aggregates and telomere capture. Results: We found significantly higher rates of spontaneous aneuploidy among sub-fertile compared to fertile sperm cells, in somatic chromosomes (P=0.006) and in the sex chromosomes (P= 0.04). Although telomeres length was not different between the groups, the amount of telomeres aggregates was significantly higher in the sub-fertile group (P<0.001). The rates of telomere capture were also higher among the sub-fertile sperm cells (P=0.007). Conclusions: Sub-fertile sperm cells may have shortened telomeres that are elongated by the alternative pathway of telomere capture. The genetic instability parameters of increased aneuploidy and dysfunctional telomeres may imply on sperm fertilization ability.

Characterization of inversion polymorphisms in genomic disorders. *O. Migita[1], M.A. Joseph-George[1], R. Wong[1], Y. He[1], A.W. Pang[1], J.R. MacDonald[1], D. Pinto[1], C.R. Marshall[1], R. Weksberg[2], S.W. Scherer[1,2].* 1) The Centre for Applied Genomics, the Hospital for Sick Children, Toronto, ON, Canada; 2) Genetics & Genome Biology, the Hospital for Sick Children, Toronto, ON, Canada.

Structural variants such as copy number variants (CNVs) and copy neutral variants (i.e. inversions and translocations) are recognized as important contributors to underlying mechanisms of human disease. It has been reported that structural variants encompass more nucleotides than SNPs in the human genome, and it has been suggested that segmental duplications and/or low copy repeats (LCRs) are favored sites mediating chromosomal rearrangements. Our understanding of sub-microscopic copy neutral structural variants is however, rather limited in terms of contribution to genomic instability in CNV biogenesis.

Williams-Beuren Syndrome and Sotos syndrome are genomic disorders associated with deletion variants, which are flanked by LCRs. Intriguingly, with Sotos syndrome half of Japanese patients have 1.9Mb deletion at 5q35, but only 10% of non-Japanese have the same deletions. Osborne et al. (2001) reported that ~30% of parents of Williams-Beuren Syndrome individuals carry an inversion polymorphism on chromosome 7q11.23. Visser et al. (2005) found an inversion polymorphism at the NSD1 gene on chromosome 5q35 in all parents of Sotos syndrome patients. Building on these and other studies, we hypothesize that inversions can cause higher CNV formation rates.

To further determine the genomic architecture in Sotos syndrome we tested for the presence of inversions in 8 non-Japanese families (European, African and Asian populations from HapMap). In our preliminary data, we have found no inversion polymorphisms at the NSD1 locus, which is consistent with the fact that non-Japanese Sotos syndrome cases have less deletions involving NSD1. We are further characterizing this region and others, which will provide new insights about the population genetics of inversions and allow evaluating their contribution to chromosomal disorders.

1285/W

Visualizing sister chromatid segregation during metaphase by nanoscale imaging. *P.K. Rogan[1], W. Khan[1], J.H.M. Knoll[1], S.M. Tadayyon[2], P.R. Norton[2], R. Chisholm[3], L.J. Johnston[3].* 1) Schulich Sch Med & Dentistry, University of Western Ontario, London, ON, Canada; 2) Department of Chemistry, University of Western Ontario; 3) Steacie Institute, National Research Council of Canada, Ottawa.

At metaphase, chromosome segregation initiates processes that reorganize DNA sequences that have previously replicated and form kinetichore structures attached to the spindle through a microtubule network. This network is disintegrated by colchicine treatment; however these structures remain essentially unaltered. We have investigated formation of these structures and sister chromatid segregation at nanometer scale resolution. We have developed protocols to relate fluorescent images of FISH probes on the topography of human metaphase chromosomes. Correlated fluorescence in situ hybridization (FISH) with atomic force and near field scanning microscopy (AFM, NSOM) can demonstrate the spatial relationships between centromeric DNA and epigenetic structures associated with these sequences on the surface of chromosome 17. Optical and topographic images of multicopy centromeric probes hybridized to chromosomes have been obtained independently in the UWO and NRC facilities. Generally, probe signals of similar fluorescence intensities correspond to the highest features at the centromeric locations of sister chromatids. Image processing procedures quantify probe context, relative to neighboring 30 nm chromatin fiber bundles imaged by AFM. Kinetochore structures are the highest prominences (typically 100 nm above background) found at the centromere and are present on all metaphase chromosomes. These peaks are formed early in metaphase, and are usually present as pair (or sometimes triplet) structures, and correspond to kinetichore attachment sites. Interestingly, segregation of sister chromatids is not coordinated with the formation of these structures within individual homologous chromosomes, occurring after the formation of these structures. By the end of metaphase, the locations of the segregated sister chromatids are coincident with the locations of these structural features. The integrated area and intensities of FISH probes on different homologs can differ by up to ~20% in the same cell, as expected for length polymorphisms in alphoid heterochromatin. The timing of epigenetic mark formation and DNA segregation are not synchronized between homologs, or between cells. We propose that asynchronous segregation of previously replicated sister chromosomes may account for differences in the hybridization patterns for multicopy and single copy probes in different cells from the same individual.

1286/W

Identification of a new gene involved in IHH by positional cloning of an IHH patient with t(8;10)(q13;p13). *H. Kim[1], R. Ullmann[2], H. Ropers[2], V. Kalscheuer[2], L. Layman[1].* 1) Dept OB/GYN, Medical College of Georgia, Augusta, GA. USA; 2) Dept of Human Molecular Genetics, Max Planck Institute for Molecular Genetics, Berlin, Germany.

Patients with idiopathic hypogonadotropic hypogonadism (IHH) present with absent puberty due to a hypothalamic-pituitary defect, and may be either normosmic (nIHH) or anosmic (Kallmann syndrome/KS). Although mutations in genes such as FGFR1, KAL1, CHD7, and PROKR2 constitute the most commonly encountered etiology in IHH/KS, the molecular basis for most patients remains unknown. Approximately 1/2,000 liveborns possess a de novo balanced translocation, and about 6% of these patients manifest the phenotype of a significant, developmental disorder. These rare, but exceedingly informative patients provide the unique opportunity to identify new genes causing birth defects. We were able to ascertain a male patient with adult onset of IHH who has an apparent balanced chromosome translocation 46, XY,t(8;10)(q13;p13), which affords the opportunity to identify a gene important in pubertal development. Array Comparative Genome Hybridization (CGH) analysis of patient DNA was consistent with a balanced translocation and excluded Copy Number Variation (CNV) as the cause of the IHH phenotype. We hypothesize that a new IHH gene is disrupted or dysregulated by one breakpoint. By performing FISH we revised the real chromosome 10 translocation breakpoint as 10p11.23-10p12.1, narrowing the breakpoint to 3.6 Mb containing 29 known genes between RP11-990I14 and RP11-747L3. The breakpoint of 8q13 was revised to 8q12.1-12.3 and was refined to 6.3 Mb region containing 33 genes between RP11- 826G18 and RP11-59E4. Thus further refining of both breakpoint regions in our balanced translocation patient by array painting is warranted to identify a new causative gene for IHH/KS.

1287/W

Deletions of Xp Provide Evidence for the Role of *HCCS* in Congenital Diaphragmatic Hernia. *D.M. Pearson[1], K. Qidwai[1], G. Simpson Patel[2], B.R. Pober[3,4], L.L. Immken[2], S.W. Cheung[1], D.A. Scott[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Specially for Children, Austin, TX; 3) Department of Pediatrics, Mass General Hospital for Children, Boston, MA; 4) Department of Surgery, Children's Hospital, Boston, MA.

Microphthalmia with linear skin defects (MLS) is a rare, congenital, X-linked dominant syndrome most commonly caused by terminal deletions of Xp. The Holocytochrome C-Type Synthase gene (*HCCS*) is located on Xp22.2 and inactivation of this gene has been implicated as the cause of many of the characteristic findings in MLS including linear skin defects, microphthalmia and other ocular anomalies, cardiac anomalies, and mild to severe mental retardation. Inactivation of *HCCS* is usually lethal in 46,XY males but several MLS males with Xp;Yp translocations involving the SRY gene have been reported. We report a male infant, prenatally diagnosed with congenital diaphragmatic hernia (CDH), who carried a de novo unbalanced translocation between Xp and Yp—46,X,der(X)t(X;Y)(p22.2;p11.2). After birth he was found to have additional anomalies consistent with MLS including microphthalmia, linear skin defects, bilateral ventriculomegaly, agenesis of the corpus callosum, a small phallus, and right cryptorchidism. Array comparative genome hybridization (aCGH) analysis confirmed that the deleted portion of Xp included the *HCCS* gene. Review of data from this case, and of all other Xp deletions associated with CDH, suggest that disruption of *HCCS* may be sufficient to cause CDH and that another gene(s) located distal to the STS may also contribute to the development of CDH in these patients.

1288/W

Identification of cryptic genomics aberrations in patients with idiopathic mental retardation using MLPA and array-CGH methods. *S. Berker Karauzum[1], D. Yasar Sirin[1], M. Ozcan Caliskan[2], E. Mihci[3], S. Tacoy[3], G. Luleci[1].* 1) Akdeniz University, Medical Faculty, Department of Medical Biology & Genetics; 2) Department of Pathology; 3) Department of Pediatric Genetics, Antalya, Turkey.

The cryptic subtelomeric chromosomal rearrangements are found 5 to 7% of cases with moderate-severe Idiopathic Mental Retardation(IMR) and %1 of cases with mild IMR. The Fluorescence In Situ Hybridization (FISH) using chromosome-specific subtelomeric probes is commonly used for detection of the subtelomeric chromosomal rearrangements. Because the FISH technique is very expensive and time consuming, alternative methods are being used for detection of these rearrangements. One of the these methods is MLPA (multiplex ligation dependent probe amplification) which is a semi-quantitative method that aims to detect copy number chances at genomic levels in a test DNA compared a control DNA. In this study, we aimed to compare the diagnostic capacity of MLPA and subtelomeric FISH methods for cryptic subtelomeric rearrangements and detection an addition rearrangements by array-CGH. In 100 patients with dismorphic features and IMR who had normal karyotype by conventional cytogenetic analysis and subtelomeric FISH analysis, MLPA were used. Although no subtelomeric rearrangements were observed using either MLPA or FISH techniques, the deletions and/or duplications were found in 38(67 %) of 56 patients using array-CGH methods. We propose that the use of array-CGH can be a reliable whole genome screening method to detect of the copy number changes as shown in this study.

1289/W

MRNET TP7 - Summary of high resolution molecular karyotyping of patients with mental retardation -identification of regions containing candidate genes. *K. Hackmann, N. Tyshchenko, T.N. Neuhann, E.M. Gerlach, S. Tinschert, E. Schrock.* Inst. fuer Klinische Genetik, TU Dresden Medizinische Fakultät Carl Gustav Carus, Dresden, Germany.

The German Mental Retardation Network (MRNET) is a nationwide consortium that aims for elucidation of genetic causes of intellectual disability (ID). Currently, ten centers (TP="Teilprojekt") are involved. Participating patients are carefully examined in the Clinical Genetics departments of each center. Eligible causes like Fragile X syndrome or RETT syndrome as well as other phenotypically noticeable conditions are excluded by standard diagnostics before chromosome analysis is performed. If this examination does not reveal any major genomic rearrangements array CGH is carried out. We started off with Agilent's array CGH platform utilizing the standard 244k chip and subsequently upgraded to the 1M technology employing standard 2x400k arrays. Every suspicious copy number variation (CNV) is validated by FISH analysis, customized array CGH, quantitative PCR, or quantitative genotyping in patients as well as in parents to see if a certain variation is of familial origin or arose de novo. All obtained data sets are fed into a database that is accessible for every participating center to carry out comparisons to distinguish between unpublished common CNVs and CNVs that may contain candidate genes. Disease causing mutations that have been confirmed as plausible reason of a patient's phenotype will be further investigated for functional analysis for example in animal models. Out of 117 patients we found 16 de novo mutations of which five have not been described to date and 27 patients without any suspicious CNVs. All remaining patients carry common and/or familial rearrangements of unclear impact. Candidate loci we are currently investigating include one locus with four genes for frontotemporoparietal polymycrogyria and one gene for perisylvian polymicrogyria, one candidate gene for Shprintzen-Goldberg syndrome/ Loeys Dietz syndrome type 1, one gene for microcephaly as well as several other genes for non-syndromal intellectual disability. One family with autosomal dominant presentation of ID and unremarkable array CGH will be put to exome sequencing on a next generation sequencing device.

1290/W

CNV-WebStore: Online CNV Analysis, Storage and Interpretation. *F. Kooy, G. Vandeweyer, E. Reyniers, N. Van der Aa, L. Rooms.* Dept Medical Genetics, Univiversity and University Hospital , Antwerp, Belgium.

Microarray technology allows the analysis of genomic aberrations at an ever increasing resolution, making functional interpretation of these vast amounts of data the main bottleneck in rou-tine usage of high resolution platforms such as the Illumina BeadArray platform, and emphasising the need of a centralised and easy to use CNV data management system. We present an online platform to streamline the processing and downstream analysis of microarray data, tailored towards but not limited to the Illumina BeadArray platform. Provided tools include data analysis, data visualisation, gene prioritisation, automated qPCR primer design and linking data to several genome browsers and databases. To gain insight in the practical resolution of the BeadArray platform, we validated and integrated into the platform an approach to reliably detect rare Copy Number Variations (CNVs) covered by 3 consecutive probes. The presented approach combines three published Hidden Markov Method based algorithms. Up to one third of the small CNVs detected by the presented platform disrupted known coding sequence, stressing the importance of centralised, easy to use functional interpretation tools. The website is freely available for non-commercial use at http://medgen.ua.ac.be/cnv. It is implemented in PHP and Apache with support for all major browser types.

1291/W

A small duplication of 9q22.3-p23 in a patient with 9p-duplication syndrome suggests critical region and a candidate gene for mental retardation and digital anomalies. *X. Li[1], M. Sifry-Platt[2], A. Grix[2].* 1) Dept Genetics, Kaiser Permanente San Jose Medical Ctr, San Jose, CA; 2) Dept Genetics, Kaiser Permanente Sacramento Medical Ctr, Sacramento, CA.

The 9p-duplication syndrome is a clinically recognizable genomic disorder with growth and mental retardation, short fingers and toes with hypoplastic nails, and characteristic craniofacial appearances including microbrachcephaly, deep and wide-set eyes, bulbous nose, and low-set ears. Most of the reported 150 cases with partial or complete 9p duplications were derived from unbalanced translocations and had a concurrent deletion of another chromosome. Isolated tandem duplications of 9p are uncommon. The critical region of the 9p duplication syndrome has recently been delineated to approximately 2.6 Mb (12.8-15.4 Mb) at 9p22.3-9p23 (Zou et al 2009). We report here that a patient with the 9p-duplication syndrome has the smallest de novo isolated duplication of 9p22.3-p23. The patient is a 10 years old male with mental retardation but a normal stature, microcephaly, broad nasal root, conductive or mixed hearing loss, superiorly protruding and mildly posteriorly rotated ears, bifid uvula, and digital anomalies including hypoplastic middle and distal phalanges on the 5th fingers with radial clinodactyly, hypoplastic distal phalanges on the 2nd digits, thumbs mildly hypoplastic with good thenar muscle mass, left foot with cavo-varus position with hypoplastic toenail, left 2nd toe distal phalange mildly bulbous with small nail, right hallux with creased nail, and mild 2/3 toe syndactyly. Array comparative genomic hybridization using the Agilent 8x60K human whole genome microarray designed by the International Standard Cytogenomic Array (ISCA) Consortium revealed an interstitial genomic copy gain of 2.21Mb from 9p22.3-p23 at genomic nucleotide position 12,377,640 - 14,586,920. The affected region of 9p contains 3 OMIM genes, TYRP1, MPDZ, and NFIB, and 2 transcripts, C9orf150 and AK123194 (UCSC HG Build 19). The Nuclear Factor I/B (NFIB) gene belongs to a transcriptional factor family also composed of NFIX and NFIC. Brain malformation (including neocortical callosal dysgenesis) and skeletal defects have been observed in Nfi-deficient mice (Driller et al, 2007, Piper et al, 2009, Pérez-Casellas et al, 2009). Therefore, we proposed here that the NFIB is a candidate gene and its haploinsufficiency is associated with mental retardation and digital anomalies in 9p-duplication syndrome.

1292/W

A 16q24.3 Microdeletion Involving Only the ANKRD11 Gene in a Male with Autism. *M.G. Butler, E.L. Youngs, J.A. Hellings.* Departments of Psychiatry & Behavioral Sciences and Pediatrics, University of Kansas Medical Center, Kansas City, KS 66160.

The 16q24.3 microdeletion syndrome has been recognized only recently with one previous report involving four patients with autism and variable cognitive impairment and each having interstitial deletions of this cytogenetic region (Willemsen et al., 2010). We report another example of a subject involving a microdeletion of the 16q24.3 band with atypical autism and mental retardation. He was the product of a full term gestation following a difficult delivery and a calcified placenta. During infancy and early childhood, developmental delays, recurrent infections, self-injury and anxiety were noted. He was nonverbal, but did use several basic signs. Because of his developmental delays and behavior problems, he had undergone two brain MRIs which were normal and a normal chromosome analysis. On physical exam at 17 years of age, his height, weight and head circumference were < 3rd centile. He had two disorganized hair whorls, bilaterally attached ear lobes, long eye lashes, and a high-arched palate with dental crowding. Plantar creases were noted bilaterally. He had cutis marmorata of his feet and Raynaud's phenomenon (mother with same finding) noted on his hands (right greater than left). Chromosomal microarray analysis performed on our subject identified a small 180 kb deletion of chromosome 16q24.3 band (located at 87.92 to 88.10 Mb from pter) containing the ankyrin repeat domain-containing protein 11 (ANKRD11) gene, a proposed candidate gene for autism (Marshall et al., 2008). ANKRD11 is a member of the ankyrin repeat-containing cofactors that interacts with p160 nuclear receptor coactivators and inhibits ligand-dependent transcriptional activation. The four previously reported subjects with 16q24.3 deletions had deletions of varying size, but had an approximate 90 kb region of overlap (located at about 87.80 to 87.90 from pter) involving ANKRD11 and zinc finger 778 (ZNF778) genes with characteristics including autism spectrum disorder, variable cognitive impairment, facial dysmorphisms and brain anomalies. These two genes were reported as candidates for the autism phenotype in their subjects. The 16q24.3 microdeletion in our subject was more distally positioned compared with the smallest region of overlap in the four previously reported subjects and involved only the ANKRD11 gene further supporting a role for this gene in the clinical presentation of autism.

1293/W

A novel 4p16.3 microduplication characterized by aCGH with new phenotypic features. *A.B. Cyr, M. Nimmakayalu, H. Major, S.R. Patil, K. Keppler-Noreuil, O.A. Shchelochkov.* Division of Medical Genetics, Department of Pediatrics, University of Iowa Hospitals and Clinics, Iowa City, IA.

Trisomy 4p syndrome is a heterogeneous disorder defined by large duplications of the short arm of chromosome 4. The syndrome presents clinically with growth retardation, delayed psychomotor development, and an array of craniofacial and skeletal malformations including microcephaly, prominent glabella, short neck, and low set ears. The majority of the cases reported to date have large duplications of several megabases making precise genotype-phenotype correlations difficult. Reports of smaller microduplications in this region have been rare. We present a 16-month old boy diagnosed with microduplication of chromosome 4p16.3, who, while having some characteristic findings of trisomy 4p syndrome, presents with unique features of macrocephaly, normal growth parameters and irregular iris pigmentation/heterochromia. Chromosome studies conducted on the patient were normal. The array CGH showed a 506kb duplication at 4p16.3. The parental aCGH studies were normal, indicating a de novo microduplication. The purposes of this study are to: 1) report a case with the smallest duplication of chromosome 4p; 2) compare this case to other similar cases in the literature; 3) provide a more specific template for genotype-phenotype comparisons; and 4) to discuss involvement of dosage dependent genes accounting for the clinical phenotype.

1294/W

Clinical Report of a 4q35.2 Microdeletion Involving the MTNR1A, FAT1 and F11 Genes. *R.S. Henkhaus, E.L. Youngs, J.A. Hellings, M.G. Butler.* Departments of Psychiatry & Behavioral Sciences and Pediatrics, University of Kansas Medical Center, Kansas City, KS 66160.

Our subject was diagnosed in early childhood with a variety of conditions, including autism, ADHD, OCD, mild mental retardation, PTSD, self-injury, pica, aggression, easy bruisability and irregular sleep patterns. High resolution chromosome and fragile X DNA analyses were reportedly normal. He was born following a 33 week gestation complicated by maternal diabetes, alcohol used during the first trimester and premature rupture of membranes. He has been successfully treated medically to control his behavior, but other symptoms such as easy bruisability and irregular sleep patterns have persisted. Genetics evaluation at 12 years, 9 months showed normal height, weight and head circumference with flattening of the right occiput, coarse hair and a disorganized single posterior hair whorl. He had malar hypoplasia, relative hypertelorism, a short nose with anteverted nares, a smooth and flat philtrum, a thin upper lip, a broad mouth and a high-arched palate. He had 5th finger clinodactyly, hyperflexible fingers and shallow nail beds. He had short 5th toes bilaterally with malalignment. There was a large ecchymotic area (6 X 8 cm) on right lateral knee area not related to recognized trauma. A chromosome microarray analysis revealed a 1.2 Mb deletion of chromosome band 4q35.2 (located at 187.47 to 188.66 Mb from pter). This deletion contains three genes: Melatonin receptor 1A (MTNR1A); Fat tumor suppressor, Drosophila, homolog of 1 (FAT1); and the blood coagulation factor XI (F11). MTNR1A is a G-protein coupled receptor that plays a role in the regulation of sleep patterns and the circadian clock. The FAT1 gene is a trans-membrane protein that regulates cell-cell adhesion and is expressed in embryonic stem cells and neuronal tissues. Mutations and deletions in the FAT1 gene have been linked to developmental delay and autism. The F11 gene was partially deleted (at the 3' end), likely contributing to his easy bruisability. Several prior reports of chromosome 4q deletions have shown facial and digital dysmorphism, congenital heart defects (e.g., VSD), cleft palate, and mental retardation and one recent report of an autistic individual with a 4q35.1-35.2 deletion, including the area deleted in our subject. Further investigations of this chromosomal region and the expression of genes contained therein may give insights into new causes and therapies for autism and other developmental disorders.

Challenges in establishing the clinical implications of microarray findings of uncertain clinical significance. *D.L. Pickering, B.J. Dave, D.M. Golden, J. Stevens, E. Griess, W.G. Sanger.* Munroe Meyer Institute, University of Nebraska Medical Center, Omaha, NE.

Chromosomal microarray has a significantly higher diagnostic yield than conventional cytogenetics among patients with unexplained developmental delay and/or multiple congenital anomalies and has become the first tier testing for this patient cohort. A substantial number of investigations, however, result in novel copy number changes of uncertain clinical significance presenting a formidable challenge in establishing the clinical implications of these findings. For most cases, the standard testing algorithm involves parental studies to determine inheritance patterns. Customarily, the copy number change is interpreted as 'benign' if the aberration is inherited from an 'apparently' normal parent. Our report focuses on cases with initial microarray findings of uncertain clinical significance and subsequent classification of these cases after parental studies. In the past 2 years, our laboratory has performed 2540 post-natal microarray investigations utilizing a customized 44,000 oligonucleotide array. We detected a significant copy number change in 551/2540 (21.6%) cases and 400/2540 (15.7%) were reported as causative for the patient's phenotype. In 151/2540 (5.9%) cases, the copy number change was associated with uncertain clinical significance. The majority of these aberrations were in regions of genome previously not associated with a known syndrome, contained one or more genes and showed little or no overlap with the public and internal databases. All cases had a normal karyotype and harbored cryptic deletions or duplications ranging in size from 94Kb - 2.27Mb. Parental studies were accomplished in 54 of these 151 cases; 3 were *de novo* aberrations and in 51 cases, the abnormality was inherited. Of the 51 familial studies, 38 (74.6%) had alterations that were classified benign in the proband following parental studies, 6 studies (11.7%) remained uncertain and 7 (13.7%) familial aberrations were subsequently determined to be of probable clinical relevance in the proband because the "carrier" parent and/or other family member(s) had a clinical history of a condition similar to the child. A total of 25.4% of our cases were classified as either uncertain or abnormal after parental studies. Thus, our report underscores the importance of collecting precise family history and accurate clinical information in addition to detailed communication with the provider when interpreting inherited copy number changes of uncertain clinical significance.

Characterization of previously identified chromosomal abnormalities by high-resolution SNP array analysis. *S. Zimmerman, K. Sund, S. Rudnik, L. Bao, T. Smolarek.* Human Gen, Cincinnati Children's Hosp Med, Cincinnati, OH.

Genome-wide single nucleotide polymorphism (SNP) microarrays provide high resolution copy number information. SNP microarray was used to further characterize previously identified cytogenetic abnormalities to determine whether any significant additional information would be gained. Of approximately 1,667 individuals analyzed by SNP microarray, approximately 56 (3.4%) had a previously identified cytogenetic abnormality detected by karyotype and/or FISH analysis. A chromosomal imbalance was identified in 50 cases, of which clinically significant genetic results were identified in 26 (52%).The chromosomal breakpoints were refined or identified potential pathogenic genes within the imbalance in 24 cases (48%). Two patients had an apparently balanced translocation with an imbalance at the breakpoints and one balanced translocation was identified with an additional clinically significant abnormality. Additional material of unknown origin identified the chromosomes involved in four patients, and the breakpoints were refined in five patients with duplications and 20 patients with. Breakpoints were defined in seven patients with an unbalanced translocations and marker chromosomes (material of unknown origin) were identified in two patients.. Further characterization of complex abnormalities were completed in nine patients. No imbalances were detected in the remaining six patients, which included two patients with an apparently balanced tranlocation inversion, and two inversions. The remaining two patients were phenotypic male or female. These results emphasize the value of combining conventional cytogenetic methods with SNP microarray analysis to better define previously known cytogenetic abnormalities.

1297/W

TULIP1 (RALGAPA1) haploinsufficiency with brain development delay. *K. Shimojima[1], Y. Komoike[2], J. Tohyama[3], S. Takahashi[2], M. Paez[1], E. Nakagawa[4], Y. Goto[4], K. Ohno[5], M. Ohtsu[6], H. Oguni[7], M. Osawa[7], T. Higashinakagawa[2], T. Yamamoto[1].* 1) Institute for Integrated Medical Sciences, Tokyo Women's Med Univ, Shinjuku Ward, Japan; 2) Department of Biology, School of Education, Waseda University, Tokyo, Japan; 3) Department of Pediatrics, Nishi-Niigata Chuo National Hospital, Niigata, Japan; 4) Department of Mental Retardation and Birth Defect Research, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Tokyo, Japan; 5) Division of Child Neurology, Institute of Neurological Sciences, Faculty of Medicine, Tottori University, Yonago, Japan; 6) Department of Pediatrics, Saiseikai Yokohamashi Nanbu Hospital, Yokohama, Japan; 7) Department of Pediatrics, Tokyo Women's Medical University, Tokyo, Japan.

A novel microdeletion of 14q13.1q13.3 was identified in a patient with developmental delay and intractable epilepsy. The 2.2-Mb deletion included 15 genes, of which TULIP1 (approved gene symbol: RALGAPA1)was the only gene highly expressed in the brain. Western blotting revealed reduced amount of TULIP1 in cell lysates derived from immortalized lymphocytes of the patient, suggesting the association between TULIP1 haploinsufficiency and the patient's phenotype, then 140 patients were screened for TULIP1 mutations and four missense mutations were identified. Although all four missense mutations were common with parents, reduced TULIP1 was observed in the cell lysates with a P297T mutation identified in a conserved region among species. A full-length homolog of human TULIP1 was identified in zebrafish with 72% identity to human. Tulip1 was highly expressed in zebrafish brain, and knockdown of which resulted in brain developmental delay. Therefore, we suggest that TULIP1 is a candidate gene for developmental delay.

1298/W

A functional analysis of GABARAP on 17p13.1 by knockdown zebrafish. *T. Yamamoto[1], Y. Komoike[2], K. Shimojima[1], J-S. Liang[1], Y. Fujii[3], Y. Maegaki[3], M. Osawa[4], S. Fujii[5], T. Higashinakagawa[5].* 1) Institute for Integrated Medic, Tokyo Women's Med Univ, Tokyo, Japan; 2) Department of Hygiene and Public Health I, Tokyo Women's Med Univ, Tokyo, Japan; 3) Division of Child Neurology, Institute of Neurological Sciences, Faculty of Medicine, Tottori University, Yonago, Japan; 4) Department of Pediatrics, Tokyo Women's Medical University, Tokyo, Japan; 5) Department of Biology, School of Education, Waseda University, Tokyo, Japan.

Array-based comparative genomic hybridization identified a 2.3-Mb microdeletion of 17p13.2p13.1 in a boy presenting with moderate mental retardation, intractable epilepsy and dysmorphic features. This deletion region was overlapped with the previously proposed shortest region overlapped for microdeletion of 17p13.1 in patients with mental retardation, microcephaly, microretrognathia and abnormal magnetic resonance imaging (MRI) findings of cerebral white matter, in which at least 17 known genes are included. Among them, DLG4/PSD95, GPS2, GABARAP and KCTD11 have a function in neuronal development. Because of the functional importance, we paid attention to DLG4/PSD95 and GABARAP, and analyzed zebrafish in which the zebrafish homolog of human DLG4/PSD95 and GABARAP was knocked down and found that gabarap knockdown resulted in small head and hypoplastic mandible. This finding would be similar to the common findings of the patients with 17p13.1 deletions. Although there were no pathogenic mutations in DLG4/PSD95 or GABARAP in a cohort study with 142 patients with idiopathic developmental delay with/without epilepsy, further studies would be required for genes included in this region.

1299/W

CGH+SNP microarrays for simultaneous detection of copy number and copy-neutral variations. *P. Costa, B. Curry, B. Peter, P. Anderson, N. Sampas, S. Giles, A. Ashutosh, J. Ghosh, D. Roberts, A. De Witte.* Agilent Technologies, Santa Clara , CA.

Microarray-based comparative genomic hybridization (aCGH) is a powerful tool used in the detection of DNA copy number variations. The analysis of single nucleotide polymorphisms (SNPs) can complement DNA copy number (CN) measurements to enable identification of copy-neutral changes such as loss/absence of heterozygosity (LOH/AOH) and uniparental disomy (UPD). A set of SNP probes was included in the Agilent SurePrint G3 Human CGH platform, in addition to CGH probes, to enable simultaneous copy number and LOH detection. Using a standard enzymatic labeling workflow, copy number and copy-neutral variations were assessed in a cohort of cytogenetic samples with previously established conditions. Prior to labeling, the genomic DNA was restriction digested with AluI and RsaI, to allow the identification of the SNPs located in the enzymes' recognition sites. After hybridization to CGH+SNP microarrays, the data were analyzed using a novel algorithm implemented in Agilent's Genomic Workbench software. Several LOH regions were identified, from 3 Mb to entire chromosome arms. In two cases, the detected UPDs were found associated with samples known to have Prader Willi and Angelman syndromes. In an additional case, numerous copy-neutral LOH regions were observed throughout the genome, associated with parental consanguinity. SNPs were also accurately determined in genomes bearing amplified and deleted regions in one of the chromosomal copies. Genomic variations including allelic gains and losses, LOH and UPD aberrations were confidently determined by the CGH+SNP platform.

SNP MICROARRAY ALLELE DIFFERENTIATION IN 4-COPY NUMBER INTERVALS. *P. Papenhausen, S. Schwartz, R. Burnside, I. Gadi, V. Jaswaney, C. Kelly, R. Pasion, J. Tepperberg.* Dept Cytogenetics, Labcorp America, Res Triangle Park, NC.

Over the past several years the utility of array technology in delineating copy number change has become well established. Genotyping microarrays have major advantages for the detection of UPD, parent of origin and consanguinity, while providing high resolution copy number analysis. However, what is not often highlighted is that the allele designation also permits the elucidation of the mechanism of genomic errors. Segmental triplications have presented G-band diagnostic problems, as well as in microarrays and often FISH. Allele ratios in 31 cases of confirmed four copy intervals offer insight into the underlying etiology. These cases may be divided into five groups with all but group four showing three copies in one homologue: 1) twelve cases that yielded an allele pattern of homozygous (HZ) alleles mixed with 3:1 ratio heterozygotes , 2) eleven cases with homozygosity and both 3:1 and 2:2 ratio heterozygotes, 3) two cases which showed only HZ alleles, 4) two cases with duplications of both homologues and 5) four cases with exclusive 2:2 ratio heterozygosity. Metaphase/interphase FISH analysis revealed that the largest 12 case subset with 3:1 allele heterozygotes represents a triplication of a single parental homologue. Two of the 11 cases in group 2 shared the same distal base pair site adjacent to a large LCR at 5q13.2 and two others were PWS and VCF region triplications, suggesting a NHR correlation and involvement of both parental homologues in this group. In one of two cases in group 4, FISH showed two copies of the 16p11.2 microduplication on each homolog and the SNP array further showed that the interval was within one of many long runs of homozygosity in the proband, consistent with first degree consanguinity and inheritance from both parents. Group 5 has the most intriguing pattern, consisting of four cases with the restricted AABB heterozygosity pattern that is consistent with duplication of both homologues. However, bicolor FISH confirmed a single homolog triplication with the middle copy inverted all four which also demonstrated unbroken allele homozygosity from the distal end of the triplication to the telomere, the hallmark of mitotic recombination. These 4 cases offer compelling evidence for a mitotic recombination mechanism that adds a third copy to the duplication from the other homologue, creating the unique AABB triplication pattern while generating homozygosity from the distal end of the triplication through to the telomere.

Increased Telomere Shortening as a Potential Biomarker for Mild Cognitive Impairment and Dementia in Down syndrome. *E. Jenkins[1], L. Ye[1], M. Velinov[1], D. Pang[2], S. Krinsky-McHale[2], W. Zigman[2], N. Schupf[3,4], W. Silverman[5,6].* 1) Dept Hum Genetics, NYS Inst Basic Res Dev Disab, Staten Island, NY; 2) Dept Psychol, NYS Inst Basic Res Dev Disab, Staten Island, NY; 3) Taub Inst Res Alzheim Dis and Aging Brain, Columbia Univ, New York, NY; 4) Depts Epidem and Psychol, Columbia University, New York, NY; 5) Dept Behav Psychol, Kennedy-Krieger Inst, Baltimore, MD; 6) Dept Psychiatry Behav Med, Johns Hopkins Univ Sch Med, Baltimore, MD.

Using quantitative telomere protein nucleic acid FISH analysis, we have shown that people with Down syndrome and dementia (N=15) or mild cognitive impairment (MCI)(N=6) had consistently shorter telomeres (chromosome ends consisting of highly conserved TTAGGG repeats) than age and sex-matched peers (total N = 42; Jenkins et al., 2006, 2008a). “Manual counts” of total fluorescence telomere signals showed increased signal loss for 9 of 9 individuals with DS and dementia as well as 4 of 4 with MCI. Including age- and sex-matched controls, 26 individuals were analyzed for “total telomere loss” (Jenkins et al., 2008b). Employing centromere 2 fluorescence as a “standard,” we calculated the ratio of telomere/centromere 2 fluorescence in telomeres from 9 more individuals (5 females and 4 males and controls) with MCI using PNA probes for both the telomere and the chromosome 2 centromere. This measure generally resulted in greater statistically significant differences between cases and controls versus the PNA telomere light intensities method alone. In addition, it was possible to analyze one of the 9 age- and sex-matched pairs, where one woman of the pair developed MCI over the course of follow-up and one remained cognitively healthy. For the woman with MCI, the light intensity was significantly higher in the earlier sample (p<.005) while the telomere length remained relatively constant from one time to the next for control samples (ps<.23, .33) but were strikingly longer than the telomeres in samples from the woman with MCI (p<.000000). Mean duration of follow-up was 5.4 years. The rate of change was 5.7 light intensity units/year in the woman who developed MCI, while the rate of change was 3.4 light intensity units/year in the woman who remained cognitively healthy. Until now, our analyses of individuals with and without dementia/MCI have been cross-sectional. This is the first longitudinal demonstration of increased telomere shortening “pre-clinically.” Only additional longitudinal research will confirm these exciting results so that telomere shortening may be established as a biomarker indicating increased risk for MCI/dementia. Early detection is especially important because it would allow more timely initiation of future treatments and interventions to minimize central nervous system damage. Supported in part by NYS-OMRDD, Alzh. Assoc. grants IIRG-07-60558, IIRG-99-1598, IIRG-96-077; by NIH grants P01HD35897, R01HD37425, R01AG014673, and R01AG14771.

Correlation between interstitial telomeres, chromosomal instability and mosaicism. *M. Roy-Tourangeau[1,2], W. Dridi[3], N. Lemieux[1,2], R. Fetni[1,2].* 1) Pathology and cell biology, University of Montreal, 2900 boul. Édouard-Montpetit, Montreal (Quebec), Canada, H3T 1J4; 2) Pathology and research center, CHU Sainte-Justine, 3175 Côte Sainte-Catherine, Montreal (Quebec), Canada, H3T 1C5; 3) Faculty of Medical Applied sciences, Jazan University, Po Box 114, Royaume de l’Arabie Saoudite.

Telomeres are nucleoprotein complexes localized at chromosomes extremities to maintain the genomic integrity and stability. We propose that the aberrant presence of interstitial telomeres in break points of chromosomal translocations could induce a fragile site like chromosomal instability. To verify our hypothesis, we used Fluorescent In Situ Hybridization (FISH) to look for the presence of interstitial telomeres in patients bearing chromosomal translocations with breakpoints within the terminal bands. We used probes targeting telomeric and sub telomeric sequences of two chromosomal translocations: t(3;3)(p26;q27) and t(14;21)(q24.3;q22.3). Breakpoints and gaps are co-localized with translocation breakpoints and interstitial telomeres. Comparison of the frequency of normal cells and gaps was carried out on cells cultured in RPM-I 1640 with and without BrdU and in 199 media. Our results confirm our proposed hypothesis that the interstitial telomeres confer a chromosomal instability of derivative chromosomes, leading to mosaicism especially in cultures after exposure to BrdU. The role of telomeric sequences as a cause of the observed chromosomal mosaicism is discussed.

1303/W

A normal appearing child with developmental delay and uniparental maternal disomy for all of chromosome 21 including a region of isodisomy. *J.I. Estrada Veras, T.C. Markello, C.J. Tifft.* National Institutes of Health, National Human Genome Research Institute, Bethesda, MD.

Uniparental disomy for chromosome 21 is an uncommon finding rarely reported in the literature. There is no published evidence for imprinting of Chromosome 21. Previous reports of these individuals describe a phenotype that includes the normal range. We investigated the observation of a region of anomalous continuous homozygosity reported from a commercial micro array laboratory. This array was ordered by a local pediatrician for a 4 year old boy with language and neuro-cognitive delays. This individual was the product of an uncomplicated pregnancy with no evidence of a prenatal aneuploidy. He was born full term via vaginal delivery at 3.5kg and had no perinatal complications or dysmophic features noted in the newborn nursery exam. His first year of life was without documentation of delays in early developmental milestones. Cognitive and speech delays were first recognized at the 15 month well child evaluation. His progression has been delayed but continuous and currently he is enrolled on a special education program where he receives speech and occupational therapy. The parents are bilingual and non-consanguineous. To further investigate this case we reanalyzed the child and both parents on a high density genotyping array (Illumina Ominiquad IM). The results revealed 736 SNPs that were consistent with Maternal disomy on chromosome 21 only. The fluorescent intensity at all SNPs showed two alleles at each locus. For a region on chromosome 21 from 20,995,444 to 35,526,209 (bands 21q21.1 to 21q22.12) there is a region of uniparental isodisomy which is 14.53Mb long and contains 53 genes from C21orf131 to RUNX1. We recently reported a patient with Chediak Higashi Syndrome due to Paternal UPD on chromosome 1. That syndrome was due to uniparental isodisomy of a paternal LYST gene that had a single point mutation(Manoli et. al. AJMG(2010) part A,152A: 1474). We are currently in the process of performing whole exome sequencing though the entire region of uniparental isodisomy on Chromosome 21 for both the mother and child. We will identify and further characterize any homozygous mutations in this region that may be involved in this child’s neurodevelopmental delay.

1304/W

Exploration of genes related to X-linked mental retardation (XLMR) by BAC-based X-tiling array. *S. Honda[1], S. Hayashi[1], J. Kobayashi[1], I. Imoto[1], E. Nakagawa[2], Y. Goto[2], J. Inazawa[1].* 1) Dept Molec Cytogenetics, Medical Research Inst, Tokyo, Japan; 2) Dept. of Mental Retardation and Birth Defect Research, Natl. Inst. of Neurosci., Natl. Center of Neurol. and Psychiat.

An estimated 10-12% of mental retardation (MR) is caused by mutation on the chromosome X. Although >90 X-linked mental retardation (XLMR) genes have been identified so far, many other XLMR genes have not been identified. Here, we examined copy number variations (CNVs) by array CGH using BAC-based X-tiling array in patients with MR from 171 families with at least one affected male. CNVs have been considered candidate pathogenic CNVs (pCNVs) when CNVs containing known XLMR genes or not registered in Database of Genomic Variants (http://projects.tcag.ca/variation/) were segregated with MR in the family. This results showed that pCNVs were detected in 13 families (7.6%) and inherited from mothers in 12 families other than unavailable one family. Among them, 8 families had pCNVs involved in known XLMR genes: dup(X)(q28) including *MECP2* detected in 5 families, dup(X)(p11.23) including *FTSJ1* and *PQBP1*, del(X)(p11.23) including *SHROOM4* and del(X)(q24) including *UBE2A* detected in one family respectively. In one family having dup(X)(q28), dup(X)(q21.1) containing *ATRX* was detected simultaneously. On the other hand, pCNVs detected in other 5 families were novel: dup(X)(p22.2) including *MSL3* and part of *FRMPD4*, dup(X)(q21.1) including *HDX*, del(X)(q24) at non-coding region detected in one family respectively, and identical complicated genomic rearrangement involved in Xp22.2 and Xp21.3 containing *NHS*, *REPS2* and *IL1RAPL1* detected in non-consanguineous two families. We identified these breakpoint sequences and performed screening in the general population from ethnic group. As a result, the genomic rearrangement was detected in Japanese (male3; female4/1000), Mongolia (female1/435) and Chinese Korean (male1/200), suggesting that the genomic rearrangement was occurred in a founder in Mongol and introduced into Japan.

1305/T

Examining the role of Rere in inner ear development and hearing loss. *H. Zaveri[1], B. Kim[1], M. Justice[1], B. Lee[1], J. Oghalai[2], D. Scott[1].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Otolaryngology-Head & Neck Surgery, Baylor college of Medicine, Houston, TX.

The most common telomeric deletion in humans is monosomy 1p36 which affects 1 in 5000 newborns. This deletion has a spectrum of phenotypes which includes mental retardation, developmental delay, and hearing loss. One of the key regulatory genes that reside in the proximal region of chromosome 1p is Atrophin 2 which is also known as RERE due to the presence of Arg-Glu repeat motifs. RERE acts as a nuclear receptor coregulator and is required for normal embryogenesis. In zebrafish, reductions in Rerea expression lead to inner ear anomalies—including fused otoliths and abnormal semicircular canals—and diminished microphonic potentials. Since Rere is conserved from fly to human, RERE may play a similar role in the development of the inner ear in mammals. Mice that are homozygous for the Rere null allele openmind (Rereom/om) are not a useful model for hearing loss because they die at E9.5 with open neural tube and cardiac failure. To overcome this, we have generated an allelic series of Rere deficient mouse bearing different combinations of the om allele and a hypomorphic allele, eye3. In contrast to Rereom/om mice, a portion of Rereom/eye3 mice live into adulthood. Rere om/eye3 mice have an inappropriate startle response to a 108 dB burst at 19.9 kHz emitted from a click box—a common preliminary test for severe hearing loss. Rereom/eye3 mice also fared poorly in tests requiring normal balance and coordination. We are presently confirming and characterizing these phenotypes using distortion product otoacoustic emissions (DPOAE), auditory brainstem evoked response (ABER) testing, and micro CT analysis. We are also making a conditional Rere knock out mouse which will be used to identify the molecular mechanisms by which Rere contributes to normal inner ear development. This will also allow us to bypass the high mortality rate caused by the wide spectrum of phenotypes.

1306/T

Determining the expression pattern of NPAS3 during human brain development. *P. Gould[1], K. So[2], C. Hawkins[3], D. Kamnasaran[4].* 1) CHAUQ Hôpital de l'Enfant-Jésus, Québec, PQ, Canada; 2) PRP laboratory, Laboratory Medicine Program, University Health Network, Toronto, ON, Canada; 3) Division of Neuropathology, Hospital for Sick Children, Toronto, ON,Canada; 4) Department of Pediatrics, Laval University, Québec, PQ, Canada.

The NPAS3 gene belongs to the neuronal PAS transcription factor gene family: basic helix-loop-helix Period-aryl hydrocarbon receptor-single minded (bHLH-PAS); genes which have diverse roles including cancer, development and neuro-behavior. We previously cloned the human NPAS3 gene, mapping to human chromosome 14 and is among one of the largest genes in the human genome. Unfortunately to date, the function of NPAS3 in humans is still relatively unknown. Prior work by us and others had discovered some precursory findings on the developmental expression pattern of NPAS3 in mice. We now determined the expression of NPAS3 in the developing human nervous system from first trimester human fetuses towards adulthood, using immunohistochemistry. During the first trimester, we identified very confined expression of NPAS3 in the developing nervous system, but with some evidence of expression also noted in the developing gut, lungs and oro-pharyngeal cavity. Expression is very strong at this developmental stage especially in the eppendymal cells of the ventricular zones in the developing cerebrum. However, the expression continues to progressively emanate into the outer cortex of the developing fetal brain as the brain matures. In this manner, expression expands into many cell types including choroid plexus epithelial cells, astrocytes, oligodendrocytes and neurons. In fact, no expression was noted in endothelial cells of blood vessels and in smooth muscle cells in the developing brain. Interestingly in early childhood and even in adult brains, NPAS3 expression co-localizes with calretinin expressing neurons. Furthermore, in the brains of the fetuses, children and adults, NPAS3 expression is very strong in the neurogenesis centres, including in the dentate gyrus of the hippocampus, the subventricular zone and in the external granular layer of the cerebellum. Overall, the expression pattern in developing human nervous system appeared to be similarly conserved with the developing murine brain. In summary, findings from this study will assist in better understanding the role of the NPAS3 gene in human nervous system diseases.

1307/T

VANGL2 gene mutations in human Neural Tube Defects. *Z. Kibar[1], P. De Marco[2], S. Salem[3], C. Bosoi[1], E. Pauwels[3], E. Merello[2], A. Bassuk[4], P. Gros[3], V. Capra[2].* 1) Obstetrics & Gynecology, Univ Montreal, Montreal, QC, Canada; 2) U.O. Neurochirurgia, Instituto G. Gaslini, Genova, Italy; 3) Department of Biochemistry, McGill University, Montreal, QC, Canada; 4) Department of Pediatrics, University of Iowa, Iowa City, Iowa, USA.

Neural tube defects (NTDs) are congenital malformations resulting from failure of neurulation. Recent years have witnessed a breakthrough in elucidating the role of planar cell polarity (PCP) pathway in neurulation and how molecular lesions in this pathway lead to NTDs in animal models and humans. PCP is controlled by the non canonical Frizzled/Dishevelled signalling pathway that involves a number of additional core genes, including Stbm/Vang, Flamingo, Prickle, and Diego. The Loop-tail (Lp) mouse that develops a severe form of NTDs called craniorachischisis provided the first line of evidence for involvement of the PCP pathway in NTDs in mammals .Two independent alleles of Lp carry two missense mutations in the Vangl2 gene that is the mammalian homolog of the Drosophila Stbm/Vang gene. .Vangl2 has another homologue Vangl1 that shares similar structures and biochemical activities. We previously identified 8 missense mutations in VANGL1 in human NTDs that were most likely pathogenic based on genetic and functional data. In this study, we screened the human VANGL2 gene in a cohort of 673 patients and we identified 6 novel missense in 7 patients affected with open and closed forms of isolated NTDs. All these mutations were missense heterozygous and were not present in 1362 analyzed controls.The VANGL2 variants, p.Arg135Trp, p.Arg177His, p.Arg270His, affect absolutely conserved aa residues while the three VANGL2 variants, p.Leu242Val, p.Thr247Met and p.Arg482His, affect highly conserved residues across evolution. Four of these mutations were predicted to be deleterious to protein function using bioinformatics tools. The frequency of VANGL2 mutations predicted to be pathogenic in this study (7 in 673 or 1%) is comparable to what we detected in its homologue VANGL1 (0.9%) These results support a role for VANGL2 as a genetic risk factor in a fraction of NTD patients.

1308/T

A transcriptional atlas of human brain development. *E. Lein[1], A. Bernard[1], A. Bongaarts[1], T. Chen[2], G. Coppola[3], C. Dang[1], E. Deelman[4], O. Evgrafov[2], B. Fischl[5], M. Gerstein[6], D. Geschwind[3], J. Hohmann[1], S. Horvath[3], T. Hyde[7], A. Jones[1], H. Kang[6], Y. Kawasawa[6], J. Kleinman[7], P. Levitt[2], S. Mane[6], J. Noonan[6], G. Sedmak[8], E. Shen[1], K. Smith[1], A. Stevens[5], S. Sunkin[1], P. Wohnoutka[1], M. Hawrylycz[1], J. Knowles[2], N. Sestan[6].* 1) Allen Institute for Brain Science, Seattle, WA; 2) USC, Los Angeles, CA; 3) UCLA, Los Angeles, CA; 4) Information Sciences Institute, USC, Los Angeles, CA; 5) Massachusetts General Hospital, Harvard Medical School, Boston, MA; 6) Yale University, New Haven, CT; 7) NIMH, Bethesda, MD; 8) Croatian Institute for Brain Research, Zagreb, Croatia.

Although the human genome sequence has been available for over a decade, similar systematic efforts to map detailed gene expression patterns in human brain development have been lacking. To fill this void, we describe here an ARRA-funded, consortium-based project aimed at creating a unique multimodal transcriptional atlas of the pre- and postnatal developing human brain as a publicly accessible online resource for the neuroscience, genome and medical research communities. This resource will integrate transcriptomic, cellular resolution histology and imaging data in the context of human brain development through an online portal for viewing, searching and mining of spatiotemporal gene expression patterns. Specifically, the project aims to profile the transcriptome of a series of cortical and subcortical brain regions in males and females across eleven pre- and postnatal developmental stages from very early neocortical development (4-7 post-conceptual weeks) through adulthood (n=6/stage, 8-16 structures/stage, ~960 samples total). Transcriptome analysis is performed using Illumina RNA-seq methodology to allow a highly quantitative analysis of gene, exon and splice junction usage in specific brain regions. To complement these moderate resolution transcriptome data, a large scale in situ hybridization (ISH) data set is being generated to analyze cellular distributions using an industrial scale histology platform. ISH gene selection was biased towards genes associated with human neurological and neuropsychiatric disorders, as well as a portion matching the NIH Blueprint NHP Atlas (www.blueprintnhpatlas.org) to allow a direct comparison of gene expression patterns between human and non-human primate expression model systems across postnatal brain development. Finally de novo MRI, DTI and histology reference atlases spanning human brain development are being created to provide a neuroanatomical and neurodevelopmental context for understanding spatiotemporally regulated transcriptional programs. The final product, integrating these large-scale data sets with tools for data visualization and analysis, aims to create a lasting resource for relating specific transcriptional programs to processes of human brain development and a normative data set for understanding the genetic basis of neuropsychiatric disease. The transcriptional atlas of human brain development will be publicly accessible through the Allen Institute for Brain Science portal (www.brain-map.org).

Tubulinopathies are associated to neuroblasts migration deficit and axonal guidance disturbances in human brains. *K. Poirier[1], J. Martinovic[2], M. Bonnieres[2], M. Ossondo[3], V. Cayol[4], T. Attie-Bitach[2], A. Benachi[5], J. Chelly[1], M. Vekemans[2], F. Encha-Razavi[2].* 1) Institut Cochin - INSERM Unité 1016, CHU Cochin, Paris, France; 2) Unité de Génétique du Développement Embryo-F=9Ctal, Groupe Hospitalier Necker-IPP. Université Paris Descartes. INSERM U781; 3) CHU de Fort de France; 4) Service Gynécologie-Obstétrique, Groupe Hospitalier Necker-IPP Paris; 5) Service Gynécologie-Obstétrique, Hôpital A. Béclère, Clamart.

Microtubules are important components of the eukaryote cytoskeleton. They are crucial for many cell functions, including axon formation, cell shape, motility, intracellular trafficking and mitosis. The main components of microtubules are different isoforms of alpha and beta tubulins, which are often cell-type specific. The recent identification of numerous mutations in genes that encode different alpha- and beta-tubulin isoforms in relation to congenital neurological disorders has raised the question of the impact of microtubules deficit on brain development. Here we report a de novo heterozygous mutation in the TUBA1A (p.K326N) gene observed in a 23 weeks-gestation fetus. The fetus presented on neuropathological examination, a microlissencephalic brain with unusual cytoarchitectonic anomalies, dominated by an arrest of neuroblasts migration and major axonal guidance disturbances. The cerebellum was hypoplastic poorly cellular and devoid of lamination. The present study supports the hypothesis that tubulin genes are required for normal brain development.

1310/T

Mutations in centrosomal protein CEP152 in primary microcephaly families linked to MCPH4. *M. Samuels[1, 2, 3], D. Guernsey[3], H. Jiang[3], J. Hussin[1], M. Arnold[5], K. Bouyakdan[1], S. Perry[3], T. Babineau-Sturk[6], J. Beis[6], N. Dumas[3], S. Evans[3], M. Ferghuson[6], M. Matsuoka[3], C. Macgillivray[3, 4], M. Nightingale[3], L. Patry[1], A. Rideout[6], A. Thomas[6], A. Orr[4], I. Hoffman[5], J. Michaud[1], P. Awadalla[1], D. Meek[7], M. Ludman[6, 8].* 1) Centre de Recherche du CHU Ste-Justine, Montreal, PQ, Canada; 2) Deparment of Medicine, University of Montreal, Montreal, PQ, Canada; 3) Department of Pathology, Dalhousie University, Halifax, NS, Canada; 4) Department of Ophthalmology and Visual Sciences, Dalhousie University, Halifax, NS, Canada; 5) German Cancer Research Center, Heidelberg, Germany; 6) IWK Health Sciences Centre, Halifax, NS, Canada; 7) Dalhousie University, Halifax, NS, Canada; 8) Department of Pediatrics, Dalhousie University, Halifax, NS, Canada.

Primary microcephaly is a rare condition in which brain size is substantially diminished without other syndromic abnormalities. Seven autosomal loci have been genetically mapped, and the underlying causal genes have been identified for five of these. The known genes play roles in mitosis and/or cell division. We ascertained three families from a Maritime Canadian subpopulation, each with one microcephalic child having head circumference between five and seven standard deviations below the mean (two girls, one boy). There were no other dysmorphic signs and height and weight were normal. One girl showed cognitive impairment with both verbal and performance scores below 1st percentile, but with visual motor skills up to 4th percentile. The other girl excelled at reading and kept up to her peers academically until age 11 years. MRI scan was performed for one girl, showing markedly reduced brain size with mild enlargement of the posterior horns of the lateral ventricles. The gyral pattern was simplified in keeping with the small brain size but the cortex appeared of normal thickness. Homozygosity analysis in two families using genome-wide dense SNP genotyping supported linkage to the published MCPH4 locus on chromosome 15q21.1. Sequencing of coding exons of candidate genes in the interval identified a non-conservative amino acid change in a highly conserved residue of the centrosomal protein CEP152. The affected children in these two families were both homozygous for this missense variant. The third affected child was compound heterozygous for the missense mutation plus a second, premature termination mutation, truncating a third of the protein and preventing its localization to centrosomes in transfected cells. CEP152 is the putative mammalian ortholog of Drosphila asterless, mutations in which affect mitosis in the fly. Published data from zebrafish are also consistent with a role of CEP152 in centrosome function. By RT-PCR, CEP152 is expressed in embryonic mouse brain, similar to other MCPH genes. Like some other MCPH genes, CEP152 shows signatures of positive selection in the human lineage. CEP152 is a strong candidate for the causal gene underlying MCPH4, and may be an important gene in the evolution of human brain size. This represents the sixth novel gene discovered as part of the Genome Canada/Genome Atlantic project, the Atlantic Medical Genetics and Genomics Initiative (AMGGI).

1311/T

The Role of *Semaphorin 3D* in Hirschsprung disease (HSCR): From GWAS to Functional Analyses in Model Systems. *S.M. Arnold[1], T.A. Heanue[2], S.L. Bessling[1], G.M. Burzynski[1], V. Pachnis[2], A.S. McCallion[1], A. Chakravarti[1].* 1) Inst Gen Med, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Div Mol Neurobiol, Natl Inst Med Res, London, UK.

Hirschsprung disease (HSCR) is a multifactorial neurocristopathy of the enteric nervous system. The receptor tyrosine kinase *RET* plays a key role in all forms of HSCR and interacts with other genes to produce a range of phenotypes. By genome-wide association studies in 220 affected trios and a replication set of 430 trios, we identified, beyond a known enhancer polymorphism in *RET*, a polymorphism (rs12707682) at 7q21.11 with significant association with HSCR ($p=1.03x10^{-7}$). This marker resides in the vicinity of several Semaphorin Family 3 members (downstream of *SEMA3D*; upstream of *SEMA3A*, *SEMA3E*, and *SEMA3C*). To identify the culprit gene, we sought functional insight through model systems. Morpholino knock down of orthologous genes in zebrafish identified *sema3d* and *sema3c* as the prime candidates, with increasing concentrations of each morpholino producing a proportional loss of innervation along the digestive tract at days 4-6 post-fertilization. In addition, the morpholino for *sema3d*, at a concentration too weak to generate a gut phenotype, worked synergistically with a *ret* morpholino (also at a sub-phenotypic concentration) to eliminate intestinal innervation. This effect was also seen when the *sema3c* morpholino was coinjected with the *ret* morpholino but required higher, modest phenotype-producing input concentrations for both. These results support the hypothesis that additional HSCR genes exist to modify the effect of *RET* and mirrors our previous work in mice showing a synergistic relationship of *Ret* and *Ednrb* on HSCR. *In situ* hybridization in mice similarly supports these data. Of the four candidates, temporal and spatial expression of *Sema3d* most closely resembled that of *Ret*: both were present in the enteric neural crest-derived cells (ENCCs) at E11.5 and in the myenteric plexus at E15.5 and P3. *Sema3c* was the only other message evident in the developing ENS (confined to E15.5) while *Sema3e* was detected in the ENS only at P3, and *Sema3a* showed no ENS expression at any stage. In addition, analysis of $Ret^{k-/k-}$ mice at E15.5 showed an absence of *Sema3d* and *Sema3c* expression in the myenteric plexus of aganglionic intestines and severe reduction of both in the partially ganglionated stomach, but no change in *Sema3a* or *Sema3e* expression in these tissues, confirming an ENS role for the former and no role for the latter. Taken in concert, these data suggest that *SEMA3D* is the most likely *RET* modifier and HSCR candidate at 7q21.11.

1312/T

CRISPLD2 and Neural Crest Cell Migration. *B.T. Chiquet[1,2], E. Swindell[1], R. Henry[1], L. DeVault[1], A. Burt[3], J.B. Mulliken[4], S. Stal[5], M. Warman[4,6], S.H. Blanton[3], J.T. Hecht[1].* 1) Dept Pediatrics, Univ Texas Med Sch, Houston, Houston, TX; 2) Univ Texas Dental Branch, Houston, TX; 3) Univ Miami Miller School of Medicine, Miami, FL; 4) Children's Hospital, Boston, MA; 5) Texas Children's Hospital, Houston, TX; 6) Howard Hughes Medical Institute, Boston, MA.

Craniofacial development is a tightly regulated process that involves the complex orchestration of genetic and environmental factors, including interaction of cell growth, growth factors and receptors, the convergence and fusion of the facial and palatal processes, apoptosis, and adequate nutrient supply. The tissues that form the craniofacies are derived from cells that migrate from the neural tube and direct craniofacial patterning. Perturbation of neural crest cell (NCC) migration can cause abnormal craniofacial development, such as nonsyndromic cleft lip with or without cleft palate (NSCLP). NSCLP is a common, complex birth defect that is caused by genetic and environmental factors. We have previously identified association between NSCLP and variants in the CRISPLD2 (cysteine rich secretory protein LCCL domain containing 2) gene and genes in the folate gene pathway. The CRISPLD2 protein contains more cysteine residues than comparably sized proteins and the folate gene pathway produces endogenous cysteines. In this study, we tested for gene interactions between the CRISPLD2 gene and genes in the folate gene pathway and identified 19 interactions in our nonHispanic white dataset (0.0005£p£0.01) and 11 interactions in our Hispanic dataset (0.002£p£0.01). Of these findings, the most significant interactions were with genes in the methionine arm of the folate gene pathway, which is responsible for producing homocysteine and cysteine. Homocysteine has previously been shown to regulate neural crest cell (NCC) derived tissues. Interestingly, our recent zebrafish studies have shown that knockdown of CRISPLD2 during embryogenesis alters Dlx2 staining of NCCs and the zebrafish have altered cartilage structures of the craniofacies. Taken together, these studies suggest a potential function of CRISPLD2 in NCC migration that alteration of normal CRISPLD2 during development can contribute to clefting etiology.

1313/T

Gene expression profiling of developing human hearts. *L. Larsen[1], K.D. Ajbro[1], M. Bak[1], M.L. Vestergaard[1], K. Møllgård[2], K. Lage[3], C.A. Clement[4], S.T. Christensen[4], E. Bendsen[5], N. Tommerup[1].* 1) Wilhelm Johannsen Centre for Functional Genome Research, Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark; 2) Department of Cellular and Molecular Medicine, University of Copenhagen, Blegdamsvej 3, DK-2200 Copenhagen, Denmark; 3) NNF Center for Protein Research, Faculty of Health Sciences, University of Copenhagen, Copenhagen, Denmark; 4) Department of Biology, University of Copenhagen, Universitetsparken 13, DK-2100 Copenhagen, Denmark; 5) Fertility Clinic, Department of Obstetrics and Gynaecology, University Hospital of Odense, Odense, Denmark.

Development of the human heart starts approximately two weeks post fertilization (PF) with formation of the cardiac crescent and the subsequent formation and looping of the primitive heart tube in week 3-4. These events are followed by extensive tissue remodeling which takes place in week 5-9 and includes septation of the atrium and ventricles, development of trabeculae within the ventricles, valve development and separation of the outflow tract. Development of the heart involves spatial and temporal regulation of an unknown number of genes. In order to identify genes which are temporally regulated during heart development, we used deep-sequencing based expression analysis to study the gene expression profile in human developing hearts. Using Illumina's digital gene expression assay we analyzed total RNA extracted from twelve different hearts (four groups of three hearts at ages around day 41, 48, 59 and 67 PF). Differentially expressed genes were identified using student's T-test. The set of differentially expressed genes are enriched for genes encoding sarcomeric proteins and genes known to cause heart defects when deleted in mice. Data quality was validated by real-time quantitative RT-PCR analysis of randomly selected differentially expressed genes. For 79% of the genes the gene expression profiles were replicated by this independent method. We conclude that expression profiling based on deep-sequencing analysis is useful for identification of temporal differentially expressed genes within the developing human heart.

1314/T

Shox2 mediates Tbx5 activity by regulating Bmp4 in the pacemaker region of the developing heart. *S. Puskaric[1], S. Schmitteckert[1], A.D. Mori[2], A. Glaser[1], K.U. Schneider[1], B.G. Bruneau[2], R.J. Blaschke[1], H. Steinbeisser[1], G. Rappold[1].* 1) Institute of Human Genetics, Heidelberg, Germany; 2) Gladstone Institute for Cardiovascular Disease, San Francisco, US.

Heart formation requires a highly balanced network of transcriptional activation of genes. The homeodomain transcription factor Shox2 is essential for the formation of the sinoatrial valves and for the development of the pacemaking system. The elucidation of molecular mechanisms underlying the development of pacemaker tissue has gained clinical interest as defects in its patterning can be related to atrial arrhythmias. We have analysed putative targets of Shox2 and identified the *Bmp4* gene as a direct target. Shox2 interacts directly with the *Bmp4* promoter in ChIP assays and activates transcription in luciferase reporter assays. In addition, ectopic expression of *Shox2* in *Xenopus* embryos stimulates transcription of the *Bmp4* gene and silencing of *Shox2* in cardiomyocytes leads to a reduction in *Bmp4* expression. In *Tbx5*$^{del/+}$ mice, a model for Holt-Oram syndrome, and *Shox2*$^{-/-}$ mice we show that the T-box transcription factor Tbx5 is a regulator for *Shox2* expression in the inflow tract and that *Bmp4* is regulated by Shox2 in this compartment of the embryonic heart. In addition, we could show that Tbx5 acts cooperatively with Nkx2.5 to regulate *Shox2* and *Bmp4* expression. This work establishes a link between Tbx5, Shox2 and Bmp4 in the pacemaker region of the developing heart and thus contributes to the unravelling of the intricate interplay between the heart-specific transcriptional machinery and developmental signalling pathways.

1315/T

CRELD1 is Required for Vascular Maturation and Craniofacial Development. *J.K. Redig[1], D. Babcock[2], B. Reshey[2], C.L. Maslen[1, 2].* 1) Molecular and Medical Genetics; 2) Cardiovascular Medicine, Oregon Health & Science University, Portland OR.

CRELD1, a member of the TGFβ superfamily, is a cell surface protein of unknown function. We previously demonstrated that heterozygous missense mutations in *CRELD1* are associated with cardiac atrioventricular septal defects (AVSD), establishing *CRELD1* as a genetic risk factor for AVSD. Creation and characterization of a constitutive Creld1-knockout mouse model has provided insight into the role of CRELD1 during development. Lack of Creld1 results in embryonic lethality with *Creld1*$^{-/-}$ embryos dying before embryonic day 11.5 (E11.5). One striking feature is that there is a failure of vascular maturation. Although a primitive vascular plexus forms, the vascular system does not continue on with higher-order branching morphogenesis. This lack of a mature vasculature is apparent in the *Creld1*$^{-/-}$ embryos and their yolk sacs by approximately E10.0. Branching morphogenesis is a VEGF-dependent process, and we had previously demonstrated that Creld1-deficient cells are hyper-responsive to VEGF, which may provide a mechanism to explain why vascular development is arrested in the absence of Creld1. Until approximately E10.5 the *Creld1*$^{-/-}$ embryos are morphologically indistinguishable from their wild type and heterozygous littermates. At that point they begin to lag in development and exhibit gross morphological defects. There is considerable apoptosis in the null embryos, particularly in the head and branchial arches and some regions of the heart. Accordingly, the null embryos have significant developmental defects that appear to be a result of programmed cell death as opposed to necrosis due to vascular insufficiency. This includes a failure of development of the forebrain and abnormal facial development. In addition, the tissue along the dorsal midline fissure appears to be grossly disorganized which might disrupt midline fusion if development continued. Consequently, in some respects the cranial phenotype is reminiscent of holoprosencephaly. The heart, which is still beating, has a thin myocardium with decreased trabeculation of the single common ventricle. Significantly, the atrioventricular endocardial cushions show considerable cell loss due to apoptosis, which is consistent with the proposed role of CRELD1 in the cause of AVSD. Overall, the phenotype suggests that CRELD1 is involved in the development of neural crest derived structures as well as a playing a specific role in cardiovascular development, which is likely linked to an interaction with VEGF.

1316/T

Fibulin-4 is required for the development of the notochord and the cardiovascular system. *Z. Urban[1,2], A.B. Maxfield[2], S.M. Khatri[1], R.P. Mecham[3], E.M. Joseph[4].* 1) Department of Human Genetics, University of Pittsburgh, Graduate School of Public Health, Pittsburgh, PA; 2) Department of Pediatrics, Washington University School of Medicine, St. Louis, MO; 3) Department of Cell Biology and Physiology, Washington University School of Medicine, St. Louis, MO; 4) Massachusetts General Hospital, Charlestown, MA.

Homozygous mutation in fibulin-4 (*FBLN4*, *EFEMP2*) cause a recessive cutis laxa syndrome associated with vascular tortuosity and aortic aneurysms. To elucidate the molecular mechanisms of this novel disease, a zebrafish model was chosen for study. In silico analysis of the zebrafish genome demonstrated that human *EFEMP2* has two paralogues in the zebrafish genome, *efemp2a* and *efemp2b*. Whole mount in situ hybrization analysis of zebrafish *efemp2a* and *efemp2b* displays a dynamic expression pattern during embryogenesis associated with the segmentation of the lateral mesoderm and neural crest migration. Expression of *efemp2a* is then detectable in the bulbus arteriosus (outflow tract) of the developing heart around 101 hours post fertilization. Zebrafish embryos injected with morpholinos designed to knock down the expression *efemp2a* and *efemp2b* where shorter than controls, displayed delayed development of segmental vasculature and circulation, developed thinner notochords as well as disorganized ventral mesenchyme at 24 hours post fertilization. At 2 days post fertilization, embryos injected with *efemp2a* specific morpholinos did not develop a swim bladder and showed enlargement of the heart associated with valvular insufficiency. Knockdown of *efemp2b* resulted in circulation failure with pooling of the blood in the caudal region suggesting obstructive vascular disease. Immunoblot analysis showed progressive proteolytic degradation of both efemp2a and efemp2b during the course of segmentation. This degradative process coincided with a peak in pSMAD2 levels. Losartan treatment rescued vascular abnormalities in both *efemp2a* and *efemp2b* knockdown animals. Our results suggest that efemp2 inhibits the release of transforming growth factor-beta from the extracellular matrix, but allows developmentally regulated release through proteolysis.

1317/T

Change in Visual Acuity in Albinism in the Early School Years. *J.M. Dijkstal, A.M. Holleschau, S.S. Cooley, R.A. King, C.G. Summers.* University of Minnesota, Department of Ophthalmology, Minneapolis, MN.

Introduction and Purpose: Albinism is a genetic disorder in which biosynthesis of melanin pigment is absent or reduced. Affected persons typically have reduced vision, nystagmus, iris transillumination, and foveal hypoplasia. We sought to determine if binocular best-corrected visual acuity (BCVA) improves in the early school years, and if this is related to type of albinism, ocular pigment, and/or appearance of the macula.

Methods: This retrospective chart review was conducted at the University of Minnesota with IRB approval and included persons with albinism seen from 1984-2010. Diagnosis was made by a geneticist and a pediatric ophthalmologist based on clinical phenotype and detection of a gene mutation known to cause albinism, and was supported by misrouting with VEP, a normal ERG, and the absence of platelet dense bodies in Hermansky Pudlak syndrome. We included patients with ophthalmologic visits at ages 5.5 to <9 years (Visit A) and 9.5 to <14 years (Visit B), with Visit A and B being separated by ≥2.5 years. Patients who had surgery for nystagmus were excluded. We recorded type of albinism, binocular BCVA, glasses wear, grades of iris pigment and macular transparency, and presence or absence of an annular reflex and melanin in the macula.

Results: Mean age of 65 subjects was 6.9 years at Visit A and 11.8 years at Visit B ($p<0.001$). Mean BCVA was 20/84 at Visit A and 20/61 at Visit B ($p<0.001$). Subgroup analysis for OCA1B and OCA2 also found BCVA improvement from 20/68 to 20/51 ($p=0.003$) and 20/79 to 20/63 ($p=0.018$), respectively. Iris grade correlated moderately with change in BCVA ($r=0.329$, $p<0.001$). Weak correlations were found between improvement in BCVA and glasses wear, macular grade, and macular melanin and/or an annular reflex. A moderate correlation was found between BCVA and iris grade ($r=0.559$, $p<0.001$) and the presence of macular melanin ($r=0.402$, $p<0.001$) at Visit A. BCVA also moderately correlated with iris grade at Visit B ($r=0.499$, $p<0.001$).

Conclusions: BCVA often improves in albinism in the early school years and this should be included in counseling. The etiology is unknown but may be related to change in nystagmus, use of precise null point, developmental maturation, and/or some of the ocular characteristics evaluated in this study.

1318/T

Deciphering the connection between cilia and cell signaling in the dorsal neural tube using the mouse mutant, *Arl13b^{hnn}*. *V. Horner, T. Caspary.* Department of Human Genetics, Emory University, Atlanta, GA.

Human disease states that disrupt cilia have long supported the importance of this ubiquitous cellular organelle; however, renewed interest in cilia-related genes was sparked by the discovery that cilia are essential for cellular signaling during development. Joubert syndrome is the most commonly inherited cerebellar malformation syndrome with a prevalence of approximately 1:100,000 and is known to be due to defects in cilia. To better understand the relationship between cilia, cell signaling, and disease, we study a small GTPase implicated in all three. In humans, hypomorphic mutations in *Arl13b* lead to the classical form of Joubert syndrome. In mice, lack of Arl13b disrupts the structure of the ciliary axoneme, resulting in abnormally short cilia. The ciliary defect in *Arl13b^{hnn}* mutants disrupts the gradient of Sonic Hedgehog (Shh) activity during development, leading to ventral neural tube patterning defects. Here we show that the *Arl13b^{hnn}* mutation also disrupts dorsal neural tube patterning. In the dorsal neural tube, transforming growth factor-β (TGFβ) and Wnt signaling pathways specify dorsal cell types. The dorsal phenotype in *Arl13b^{hnn}* raises the possibility that the signaling pathways involved in dorsal cell specification are disrupted in *Arl13b^{hnn}* mutants. Here, we show that Wnt signaling is normal in the *Arl13b^{hnn}* dorsal neural tube, but BMP signaling is disrupted. Further, we demonstrate that Arl13b is not directly required in the dorsal neural tube for BMP signaling; instead aberrant Shh signaling in the ventral neural tube prevents cells in the dorsal neural tube from responding to BMP signals. However, unlike other mutants where abnormal Shh signaling disrupts dorsal neural tube patterning, BMP ligand expression is normal in the *Arl13b^{hnn}* roof plate. Therefore, our results propose a novel role of Shh signaling in modulating the BMP pathway downstream of BMP ligands.

1319/T

BBS8 interacts with a component of the Wnt/planar cell polarity (PCP) pathway to establish left-right asymmetry in zebrafish. *H.L. May-Simera[1], M. Kai[4], V. Hernandez[2], D.P.S. Osborn[2], M. Tada[3], M. Kelley[1], P. Beales[2].* 1) NIDCD, National Section on Developmental Neuroscience, National Institute on Deafness and other Communication Disorders, National Institutes of Health, Bethesda, Maryland, USA of Health, Bethesda, MD; 2) Molecular Medicine Unit, Institute of Child Health, University College London, WC1N 1EH, UK; 3) Department of Anatomy and Developmental Biology, University College London, WC1E 6BT, UK; 4) National Institute for Basic Biology, Okazaki, 444-8585, Japan.

Laterality defects such as situs inversus are not uncommonly encountered in humans either in isolation or as part of another syndrome, but can have devastating developmental consequences. The events that break symmetry during early embryogenesis are highly conserved amongst vertebrates and involve the establishment of unidirectional flow by cilia within an organising centre such as the node in mammals or Kupffer's vesicle (KV) in teleosts. Disruption of this flow can lead to failure to successfully establish left-right asymmetry. The correct apical-posterior cellular position of each node/KV cilium is critical for its optimal radial movement which serves to sweep fluid (and morphogens) in the same direction as its neighbours. Planar cell polarity (PCP) is an important conserved process that governs ciliary position and posterior tilt; however the underlying mechanism by which this occurs remains unclear. Here we show that Bbs8, a ciliary/basal body protein important for intraciliary/flagellar transport and the core PCP protein Vangl2 are required for establishment and maintenance of left-right asymmetry during early embryogenesis in zebrafish. We discovered that loss of bbs8 and vangl2 results in laterality defects due to cilia disruption at the KV. We discovered that perturbation of cell polarity following abrogation of vangl2 causes nuclear mislocalisation, defective centrosome/basal body migration and apical docking. These data suggest that bbs8 and vangl2 act synergistically on cell polarization to establish and maintain the appropriate length and number of cilia in the KV and thereby facilitate correct LR asymmetry.

1320/T

N-Ethyl-N-Nitrosurea mutagenesis identifies a hypomorphic allele at the *Looptail* locus. *M. Guyot[1], F. Kharfallah[1], M.J. Justice[2], Z. Kibar[1].* 1) CHU Sainte Justine and Department of Obstetrics and Gynecology, University of Montreal, Montreal, Quebec, Canada; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas.

The *Looptail* (*Lp*) mouse represents a well-established model for the study of neural tube defects (NTDs), the most common and severe malformations of the central nervous system in humans. *Lp* heterozygous mice are characterized by a looped-tail appearance while homozygous embryos suffer from a severe form of NTDs called craniorachischisis where the neural tube remains open throughout the hindbrain and spinal cord region. *Lp* homozygous embryos also display severe inner ear polarity defects manifested by disorganization of the stereociliary bundles of hair cells of the organ of Corti. In two previously described *Lp* alleles, *Lp* and *Lp^{m1Jus}*, the gene mutated was identified as *Vangl2* that forms part of the non-canonical Frizzled-Dishevelled or planar cell polarity pathway. In this study, we describe a novel *Lp* allele called *Ska^{m17Jus}* that was generated by N-Ethyl-N-Nitrosurea (ENU) mutagenesis at the Mouse Mutagenesis and Phenotyping Center for Developmental Defects in Texas Medical Center in Houston. Sequence analysis of *Vangl2* in *Ska^{m17Jus}* identified one disease-specific mutation, p.Arg259Leu, that was absent in parental strains, C57BL/6J Tyr-/Tyr- Brd (albino) and 129SvEv, and in 28 other inbred strains. Interestingly, and as compared to the two other *Lp* alleles, this mutation segregated in a recessive manner where all heterozygous *Ska^{m17Jus}* /+ mice analyzed appeared normal and homozygous *Ska^{m17Jus}* / *Ska^{m17Jus}* had a looped-tail appearance at a penetrance of 46%. In addition, 71% of homozygous females had imperforate vagina. Examination of homozygous *Ska^{m17Jus}*/*Ska^{m17Jus}* embryos revealed spina bifida in 13% but no severe craniorachischisis. These embryos also showed modest inner ear polarity defects. Complementation studies demonstrated the severe craniorachischisis in 62% and spina bifida in 12% of *Ska^{m17Jus}*/+; *Lp*/+ compound heterozygous embryos. This study suggests that *Ska^{m17Jus}* represents a new hypomorphic allele of *Lp*, providing an important tool for molecular and cellular studies of the underlying pathogenic mechanisms.

1321/T

Evidence of adenomyosis in fetuses : Another emerging piece in resolving the endometriosis puzzle. *J. Martinovic[1,2], D. Rambeau[3], J. Gogusev[3], C. Bergeron[1], A. Benachi[5].* 1) Unit of Fetal Pathology, Department of Pathology, Laboratory Cerba, St Ouen L'Aumone, France; 2) AP-HP, Unit of Fetal Pathology, Department of Genetics, Antoine Béclère Hospital, Paris, France; 3) Gynecology and Obstetrics Office, 5 rue de la Pompe, Paris, France; 4) Institut Cochin, UM3, Genomics and Epigenetics of Infertility and Placental Diseases, Paris, France; 5) AP-HP, Department of Gynecology and Obstetrics, Antoine Béclère Hospital, Paris, France.

BACKGROUND: Endometriosis affects approximately 10% of the female population in their reproductive years and represents one of the most common human diseases. The most widely accepted theory of origin is Sampson's theory of reflux menstruation. Sampson's classification of heterotopic endometrial tissue is based on pathogenesis : 1) "direct or primary endometriosis" [adenomyosis]; 2) "peritoneal or implantation endometriosis"; 3) "transplantation endometriosis"; 4) "metastatic endometriosis"; and 5) "developmentally misplaced endometrial tissue". METHODS: In order to test the hypothesis of congenital adenomyosis ("developmentally misplaced endometrial tissue"), in 2000, we designed a prospective study of uteri in fetuses terminated spontaneously or for lethal malformations. Histology with systematic serial sections were performed in 420 fetal uteri. FINDINGS: Adenomyosis was observed in a total of 10 fetuses aged from 19 to 37 weeks. There was no increase in the threshold toward adenomyosis in the fetuses presenting malformations of the uro-genital system. INTERPRETATION: These data suggest that adenomyosis might be present from the fetal stage, with possible genetic backgrounds in some cases. Furthermore, our results enhance a novel etiopathogenetic concept of adenomyosis as a developmental defect of differentiation or migration of the mullerian duct system during embryogenesis.

1322/T

RET mediated gene expression profiling of ENS precursors. *R.M.W. Hofstra[1], Y. Sribudiani[1], R.S.N. Fehrmann[1], G. Burzynski[1], M. Metzger[2], J. Osinga[1], G.J. te Meerman[1], A.J. Burns[2], N. Thapar[2].* 1) Genetics, University Medical Center Groningen, Groningen, Groningen; 2) Gastroenterology and Neural Development Units, Institute of Child Health, University College London, London, United Kingdom.

Activation of the RET receptor is believed to trigger many important signal transduction routes crucial for the migration, proliferation and differentiation of the neural crest stem cells (NCSCs) that are responsible for the formation of the enteric nervous system (ENS), the intrinsic innervation of the gastrointestinal tract. To identify pathways and genes involved in/or triggered by RET activation, we performed gene expression profiling using Microarray Affymetrix GEneChip Mouse Genome 430 2.0 platform on GDNF (the RET ligand) stimulated and non-stimulated NCSCs. For this we isolated YFP labeled-NCSCs from embryonic mouse guts (E14.5) of Wnt1-Cre/LoxP/R26-YFP transgenic mice. The YFP-positive NCSCs were isolated by FACS sorting and short term cultured in selection media with or without GDNF. The data were analyzed by Gene Set Enrichment Analysis (GSEA) and single-gene analysis methods. Not only does this approach provide information on GDNF-induced RET signaling in NCSCs, it may also be helpful in identifying candidate genes for Hirschsprung disease (HSCR), a congenital disorder characterized by a lack of neurons in the distal part of the colon, which is caused by aberrant migration, proliferation or differentiation of NCSCs. Pathways that were up-regulated during GDNF stimulation were those important for ATP-synthesis, cholesterol-synthesis and lipid metabolism. Several important signaling pathways for ENS development and more generally, embryonic development were found to be significantly down-regulated upon GDNF stimulation. These included the Notch, TGF-β/Smad and Wnt signaling pathways. Genes involved in adherens Junctions formation were down-regulated which could lead to a loss of cell-cell contact, a process crucial for cell migration. Genes involved in the cell growth arrest and apoptosis were down-regulated, which nicely correlates with the observed proliferation of the stimulated cells. By single-gene analysis, we identified 72 genes that were differentially expressed between NCSCs treated with GDNF and untreated cells after Bonferroni multiple testing correction ($p < 0.05$). Among these were one known HSCR gene, ECE1, and 6 other genes located in the HSCR susceptibility loci (3p21, 9q31 and 16q23). In summary, here we provide a profile of pathways and genes that are expressed in ENS precursors and regulated by the RET signaling. These data might prove helpful in identifying possible candidate HSCR predisposing genes.

1323/T

The role of *Interferon regulatory factor 6* (Irf6) in the development of the placenta. *A.L. Smith[1], M. Meister[4], M. Hoinski[2], M. Dunnwald[4], D. Hoffmann[5], B. Yang[6], B.C. Schutte[1,2,3].* 1) Genetics Program, Michigan State University, East Lansing, MI; 2) Microbiology and Molecular Genetics, Michigan State University, East Lansing, MI; 3) Pediatrics and Human Development, Michigan State University, East Lansing, MI; 4) Department of Pediatrics, The University of Iowa, Iowa City, IA; 5) Anatomy and Cell Biology, The University of Iowa, Iowa City, IA; 6) Obstetrics and Gynecology, The University of Iowa, Iowa City, IA.

IRF6 is necessary for craniofacial, limb, and skin development in humans and mice. Recent studies in other animal models suggest that *IRF6* also has a role in the development of extra-embryonic tissue. Specifically, Irf6-deficient zebrafish (Danio rario) and frog (Xenopus laevis) show defects in their primary surface epithelium (Sabel, Dev. Biol. 2009), the extra-embryonic cells that surround the early embryo. In mammals, the extra-embryonic tissues are derived from trophectoderm and develop into the placenta. Previous studies show that Irf6 is expressed in murine placenta. We hypothesize that *Irf6* is expressed in the trophectoderm and is required for proper development of the placenta. Wildtype and *Irf6*-deficient placentas were collected at embryonic day 14.5 (E14.5) and 17.5 (E17.5) from matings between mice heterozygous for an *Irf6* null allele. Placental sections were stained with Hematoxylin and Eosin and Periodic Acid Schiff (PAS) for histological analysis and to identify trophoblast glycogen cells, and immuno-stained with Irf6 antibodies to detect Irf6 expression. In human placenta, we observed that Irf6 is expressed in the syncytiotrophoblasts that surround the placental villae. In placenta from E14.5 wild type mice, we observed Irf6 in the full range of differentiated trophoblasts of the junctional zone, which includes spongiotrophoblasts, giant cells, and trophoblast glycogen cells, as well as the decidua and the uterine lining. In *Irf6*-deficient placentas Irf6 expression is unaffected only in the decidua and uterine epithelium, as the both of these tissues are maternally derived. Placentas deficient for *Irf6* have more clusters of trophoblast glycogen cells in the labyrinth zone than wildtype placentas at E14.5 ($n=4$, $p=0.03$). Preliminary data also suggests that excess trophoblast glycogen cell clusters in the labyrinth zone of *Irf6*-deficient placentas persists through E17.5. The expression data and the morphological abnormalities suggest that *Irf6* has a role in the development of the placenta in addition to its known role in craniofacial development. The correlation between expression of IRF6 in human and murine placenta will allow future analysis into the conserved role of this gene in early development. These observations may be relevant clinically because DNA variation in *IRF6* contributes risk to non-syndromic cleft lip and palate. Future studies will test whether this DNA variation also affects development of the placenta.

1324/T

Expression of Lox-1, a gene activating inflammatory pathways both in atherosclerosis than in cancer, and of its alternative splicing isoforms during mouse development. *L. Vecchione[1], L. Diano[1], L. Campagnolo[2], L. Rocchi[1], G. Siracusa[2], J.L. Mehta[3], G. Novelli[1,3,4], F. Amati[1].* 1) Department of Biopathology and Diagnostic Imaging, Tor Vergata University of Rome; 2) Department of Public Health and Cell Biology, Tor Vergata University of Rome; 3) Department of Internal Medicine, University of Arkansas for Medical Sciences; 4) PTV Medical Hospital Tor Vergata University.

LOX-1 (Lectin-like oxidized low-density lipoprotein receptor-1) is the primary endothelial receptor of oxidized LDL (oxLDL). Both in vitro and in vivo experiments have shown this receptor to be important in the initiation of atherosclerosis and to be upregulated by pro-atherogenic factors, e.g. shear stress, tumor necrosis factor (TNF-α) and oxLDL itself. Recently, it has been demonstrated that LOX-1 is important for maintaining the transformed state in different cancer cell lines and for tumor growth, suggesting that it acts in a molecular pathway connecting cancer and atherosclerosis. Despite the amount of data on LOX-1 function in adult tissues, very little is known about its expression and localization during embryo development. We analysed the mRNA expression level of Lox-1 at various developmental stages from 4.5dpc (days post coitum) to 18.5dpc by RT-PCR and quantitative real time PCR (qRT-PCR). Lox-1 is expressed in all the developmental stages we analysed with the highest levels at 7.5dpc, 8.5dpc and 9.5dpc, critical time points in mouse cardiogenesis. Two novel alternative splicing isoforms were detected in all the developmental stages analysed. The first, named Lox-1D2D5, lacks exons from 2 to 5 while the second, Lox-1D3D5, lacks exons from 3 to 5. Both isoforms retain the C-type lectin domain, that is the functional domain for the oxLDL binding, highly conserved among species. Both isoforms seem to be specific of embryonic and foetal stages since we don't find them in mouse adult tissues. By immunofluorescence assays, we showed a plasma membrane localization for Lox-1 but not for the isoforms, thus suggesting that Lox-1 isoforms may not have the capacity to recruit the receptor to the plasma membranes than the Lox-1 full length. Whole-mount in situ hybridization performed on 9.5dpc mouse embryos, revealed Lox-1 expression mainly in the heart and portions of the vasculature. Both isoforms co-localize with Lox-1 full length. So our expression data suggest a possible involvement of Lox-1 (and probably of its alternative splicing isoforms) in the processes of murine cardiogenesis and angiogenesis.

1325/T

Mouse models reveal the role of SOX7 in the development of diaphragmatic hernias and cardiovascular malformations associated with recurrent 8p23.1 deletions. *M. Wat[1], M. Garcia[2], Y. Chen[1,4], Z. Yu[1], R.J. Schwartz[3], B. Lee[1,4], M.E. Dickinson[2], D.A. Scott[1].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Molec Physiology & Biophysics, Baylor College of Medicine, Houston, TX; 3) Biology and Biochemistry, University of Houston, Houston, TX; 4) Howard Hughes Medical Institute.

Recurrent interstitial deletions of a region of 8p23.1 flanked by low copy repeats are associated with a spectrum of anomalies that can include congenital diaphragmatic hernia (CDH) and cardiovascular malformations (CVMs). We hypothesize that haploinsufficiency of *SOX7* contributes to the development of these phenotypes. To test this hypothesis we created *Sox7*$^{+/-}$ mice. Approximately 15% of these mice have retrosternal CDH in which a portion of the liver and gallbladder have herniated into the thoracic cavity and are encased in a thin membrane. This type of retrosternal sac hernia is identical to that seen in some patients with 8p23.1 deletions and suggests that *SOX7* is required for normal diaphragm development. *Sox7*$^{-/-}$ mice die in utero around E10.5, with the majority exhibiting enlarged pericardial sacs and failure of yolk sac vascular remodeling. Several *Sox7*$^{-/-}$ mutants displayed hypoplastic hearts whereas others had hearts morphologically similar to those of wild-type littermates. To determine if these cardiovascular phenotypes were primarily due to abnormalities in cardiac development, we conditionally ablated *Sox7* in cardiac tissues using an *Nkx2.5-Cre*. *Sox7*$^{-/flox}$*;Nkx2.5* $^{Cre/+}$ mice were recovered in Mendelian ratios and did not exhibit cardiovascular anomalies. This suggests that the effects of *Sox7* on cardiac function may be caused primarily by a defect in vascular development. This is consistent with the high level of *Sox7* expression seen in the developing vasculature.

1326/T

Tracing the derivation of embryonic stem cells from the inner cell mass by single cell RNA-Seq analysis. *K. Lao[1], T. Tang[2], C. Barbacioru[1], S. Bao[2], C. Lee[2], E. Nordman[1], X. Wang[1], M. Surani[2].* 1) Molec Cell Biol, Applied Biosystems, part of Life Technology, Foster City, CA; 2) Wellcome Trust/Cancer Research UK Gurdon Institute of Cancer and Developmental Biology, University of Cambridge, Tennis Court Road, Cambridge, CB2 1QN, UK.

The molecular mechanism underlying the transition from the inner cell mass (ICM) of blastocysts to pluripotent embryonic stem cells (ESC) is not fully understood. This is partly because of the apparent heterogeneity amongst a small group of cells, which poses difficulties in investigating this question. Using single cell RNA-Seq transcriptome analysis at the resolution of single cells, we have analyzed the dynamic molecular network within individual cells from the ICM outgrowth and the established ESC. This study has identified molecular changes that accompany this transition. Our study shows that key genes that confer the property of self-renewal are up regulated as ICM cells progress to ESC. We also detected very significant global changes of transcript variants from individual genes, amongst which the general metabolism genes are strongly over-represented. Furthermore, there was a global increase in the expression of repressive epigenetic regulators with a concomitant decrease in gene activators. The unique ESC epigenotype may thus be sustained while retaining an inherent plasticity for differentiation. Moreover, changes in miRNAs result in one set that targets early differentiation genes, and the second set targets ESC specific pluripotency genes to maintain a delicate balance between pluripotency and a capacity for rapid differentiation. In conclusion, our study provides insight into the dynamic and systematic molecular changes that occur during cell fate decisions from identical cells. During the conversion of ICM cells to ESCs, there is an evident arrest of a normal developmental program, which is subverted in vitro in favor of a dynamically stable status for unrestricted self-renewal while retaining the full potential to undergo differentiation into all the diverse cell types. We demonstrate how both the retention of the expression of a full set of master genes allows inheritance of a key property of the ICM, namely pluripotency, while the up regulation and down regulation of other crucial genes permits exit from a normal developmental program, which at the same time confers the key property of unlimited self-renewal. Changes in epigenetic regulators apparently allow for the stable transmission and robust maintenance of the newly acquired epigenotype in ESCs between exceptionally fast cell generations.

1327/T

Genetic background of *Prop1* mutants provides remarkable protection against hypothyroidism induced hearing impairment. *S.A. Camper[1], Q. Fang[1], A.M. Giordimaina[1], M. Mustapha[1,2], D.F. Dolan[1], T.J. Jones[1], A.H. Mortensen[1], M.T. Fleming[1], Y. Raphael[1], K.R. Johnson[3].* 1) Dept Human Genetics, Univ Michigan Med Sch, Ann Arbor, MI; 2) Stanford University, Palo Alto, CA; 3) The Jackson Laboratory, Bar Harbor, ME.

Hearing impairment occurs in 1/2000 births and ~1/2 are genetic. Hypothyroidism is a cause of genetic and environmentally induced deafness. Congenital hypothyroidism affects 1/3500 children, causing growth insufficiency, mental impairment, and permanent hearing deficits if untreated. Maternal hypothyroidism and environmental thyrotoxin exposure can impair children's hearing. The sensitivity of cochlear development and function to thyroid hormone (TH) mandates understanding TH action and identification of TH dependent genes. There are several examples of such genes that are relevant to genetic deafness: i.e. Prestin (*SLC26A5*, *DFNB61*) and *KCNQ4* (*DFNA2A*). The *Prop1* and *Pou1f1* mutant mice carry mutations in different pituitary transcription factors, each resulting in the inability to produce pituitary thyrotropin and lack of detectable serum TH. Despite the same TH deficit, these mutants have very different hearing abilities: *Prop1* mutants are mildly affected, while *Pou1f1* mutants are completely deaf. Intercrosses and genetic mapping studies show that this difference is attributable to the genetic backgrounds. Using embryo transfer we discovered that factors intrinsic to the fetus are the major contributor to this difference, not maternal effects. There are multiple, permanent abnormalities in the cochlear development of *Pou1f1* mutants that contribute to their profound deafness. We analyzed *Prop1* mutants to identify processes that are protected by their genetic background. Outer hair cell (OHC) function develops slowly. It depends on Prestin and KCNQ4 expression, which is normal in mature *Prop1* mutants. The endocochlear potential and KCNJ10 expression in the stria vascularis are normal in mature *Prop1* mutants. Hypothyroidism affects innervation and synapse remodeling *Pou1f1* mutants, but no differences in neurofilament or synaptophysin staining are evident in *Prop1* mutants. The synaptic vesicle protein otoferlin (*DFNB9*) normally shifts expression from OHC to IHC as temporary afferent fibers beneath the OHC regress in the first postnatal week. *Prop1* mutants exhibit persistent, abnormal expression of otoferlin in apical OHC, possibly indicating incomplete regression of afferent fibers. Thus, the genetic background of *Prop1* mutants is remarkably protective for most functions except otoferlin expression in the cochlear apex. The *Prop1* mutant is an attractive model for identifying the genes that protect against deafness due to hypothyroidism.

1328/T

Cellular suppression of *Lgl1* induces tropoelastin expression and augments response to lipopolysaccharide (LPS). *L. Montermini[1], I. Mandeville[1], N.B. Sweezey[2], F. Kaplan[1,3,4].* 1) Montreal Children's Hospital Research Institute, Montreal , Quebec, Canada; 2) Hospital for Sick Children, Toronto, ON, Canada; 3) Dept.of Pediatrics, McGill University, Montreal,PQ, Canada; 4) Dept.of Biology, McGill University, Montreal,PQ, Canada.

Background: *Lgl1* (also known as crispld2), modulates lung branching and alveogenesis. Absence of *Lgl1* in null mice is embryonic lethal. Postnatal *Lgl1* $^{+/-}$ mice show impaired lung maturation and features common to human BPD including distal airspace enlargement, disruption of elastin fibers, elevated tropoelastin (TE) and increase in pro-inflammatory cytokines. All these features are exacerbated by hyperoxia. Native Lgl1 binds LPS. Recombinant Lgl1 inhibits LPS binding to target cells and suppresses LPS-induced cytokine production. Hypothesis: *In vitro* deficiency of *Lgl1* confers increased susceptibility to LPS-induced inflammatory cytokine production and induces elastin expression in developing lung fibroblasts. Methods: Plasmids encoding *Lgl1* shRNAs were used to stably suppress *Lgl1* expression in NIH3T3 and Human Fetal Lung fibroblasts (HFL). Specificity and potency of the targeting sequence were validated by qRT-PCR and Western Blot. Cells lines expressing stable clones were assessed for TE expression by qRT-PCR and WB. NIH3T3 fibroblasts were exposed to 1μg/mL of LPS for 6-24hrs and assessed for interleukin (IL) 6 expression by qRT-PCR. Results: In NIH3T3 and HFL cells lines that stably expressed an *Lgl1* shRNA, *Lgl1* mRNA and protein was suppressed by 80%. In NIH3T3-Lgl1^{KD} and HFL-Lgl1^{KD} cells, *Lgl1* suppression was associated with markedly reduced cell growth. An increase in TE mRNA and elastin protein was observed in NIH3T3-Lgl1^{KD} and HFL-Lgl1^{KD} cells respectively. LPS-exposed NIH3T3-Lgl1^{KD} cells had significantly elevated levels of IL-6 compared to PBS-exposed NIH3T3-Lgl1^{KD} controls. Conclusion: Our results suggest that *Lgl1* is involved in TE mRNA regulation. *Lgl1*, secreted by fibroblasts adjacent to epithelium may protect these cells from endotoxin-induced inflammation. The *in vitro* properties of *Lgl1* support the hypothesis that it is a molecular regulator of perinatal inflammation and of downstream effects on alveogenesis.

1329/T

A *Sox10* sensitized mouse ENU mutagenesis screen: uncovering pathways in development and disease. *D.E. Watkins-Chow[1], K.E. Leeds[1], R. Mullen[1], D.L. Silver[1], K. Buac[1], H.W. Hwang[1], I. Matera[2], S.K. Loftus[1], D.M. Larson[1], A. Incao[1], W.J. Pavan[1].* 1) Genetic Disease Research Branch, NHGRI, NIH, Bethesda, MD; 2) Laboratorio di Genetica Molecolare, Istituto G. Gaslini, Genova, Italy.

Melanocytes are specialized, neural crest-derived cells responsible for pigment production in the skin. Genetic interference of neural crest development can present as altered pigmentation in skin and/or hair and can be associated with debilitating diseases (neurocristopathies) including deafness, blindness, cleft lip, congenital megacolon, and albinism. Disruption of genes that regulate pigmentation can also affect a diverse array of tissues, due to inherent pleiotropic roles of genes that have been co-opted for function in non-neural crest-derived structures. We have used a *Sox10* sensitized mouse ENU mutagenesis screen to uncover previously uncharacterized pathways in melanocyte development, to provide insights into development of additional organ systems, and to generate models relevant for dissecting human disease etiology. This screen identifies mutations that increase the phenotypic severity of *Sox10* haploinsufficient mice (*Sox10$^{LacZ/+}$*) that carry a mutation in a transcription factor essential for melanocyte development. From analysis of 600 pedigrees, we have identified five dominant modifiers of the *Sox10* phenotype (*Mos1-5*) and four recessive modifiers of the embryonic *Sox10^{LacZ}* expression pattern (*msp1-4*). The causative mutations associated with these modifiers affect genes involved in a variety of functions including hedgehog, neuregulin, and semaphorin signaling as well as ribosomal and RNA binding proteins. Comparative analysis of melanoblast development confirms that these mutations affect different time points in development and that different mechanisms lead to the observed melanoblast phenotypes. Further characterization of genes identified in the screen will contribute to our understanding of human genome function, provide additional disease models for human neurocristopathies and identify additional candidate pathways for melanoma progression.

1330/T

Studying Molecular Bases of Muscular Dystrophies in *Drosophila* Model System. *D. Lyalin, N. Nakamura, K. Koles, V. Panin.* Dept of Biochemistry-Biophysics, Texas A&M Univ, College Station, TX.

O-mannosylation is a posttranslational modification of proteins with *O*-linked mannose attached to serine or threonine residues of protein backbones. This unusual type of glycosylation is thought to be important for several aspects of cell interactions, including cell adhesion, migration, and interaction with extracellular matrix. POMT1 and POMT2 are the two *O*-mannosyltransferase genes that have been described in mammalian genomes to date. Notably, mutations in these genes have been linked to dystroglycanopathies, including the Walker-Warburg syndrome, a severe form of human muscular dystrophy. One of few known targets of *O*-mannosylation in humans is *Dystroglycan* (*Dg*), and its abnormal glycosylation underlies developmental and physiological defects in a number of muscular dystrophies.

Drosophila rt and *tw* genes encode homologs of mammalian POMT1 and POMT2 *O*-mannosyltransferases, respectively. Mutations in these genes result in “rotated abdomen” phenotype, a clockwise rotation of abdominal segments. It is not known what causes the rotation of the abdomen in *Drosophila*. We studied temporal requirements for both genes and spatial requirements of *tw* for the abdomen development. We found that abdomen rotation phenotype could be rescued by *tw* or *rt* expression during an unusually big “window” of developmental stages. The results of these experiments will be discussed from the perspective of using *Drosophila* as a model system for the investigation of molecular and genetic mechanisms of *O*-mannosylation and would help to shed light on underlying cause of muscular dystrophies in humans.

1331/T

Patterns of sensory processing and their relationship to the neurobehavioral phenotype of children with Smith-Magenis syndrome (SMS). *R.S. Morse[1], H. Hildenbrand[2], A.C.M. Smith[1].* 1) NHGRI/Office of the Clinical Director, NHGRI, NIHOCD, NHGRI/NIH, Bethesda, MD; 2) Rehabilitative Medicine Dept, NIH, Bethesda, MD.

Smith- Magenis Syndrome (SMS) is a rare (1/15,000) microdeletion syndrome of chromosome 17 p11.2 associated with a specific pattern of physical, developmental and behavioral characteristics. The neurobehavioral phenotype is distinct and complex, characterized by high rates of outbursts/tantrums, attention-seeking, impulsivity, aggression, hyperactivity, distractibility, toileting difficulties, stereotypies (repetitive or self-stimulatory behaviors), sleep disturbance and self-injurious behaviors (Dykens & Smith, 1998). We suspect that underlying sensory processing deficits contribute to previously observed maladaptive behaviors, social difficulties and functional deficits that characterize the syndrome. This cross-disciplinary study investigates the relationship between sensory modulation and maladaptive behaviors characteristic of SMS using two validated instruments derived from the disciplines of occupational therapy and behavioral psychology. The Sensory Profile (SP) Caregiver Questionnaire and Child Behavior Checklist (CBCL) were collected from 25 parents of individuals (13F/12M; ages 3-25yrs; mean 7.16 yrs) with a confirmed SMS diagnosis. Results: Clinically meaningful low scores for one or more of the SP quadrants were documented in 24/25 (96%) of SMS subjects, indicative of sensory processing/modulation problems (Registration = 22; Seeking = 18; Sensitivity = 17; Avoiding = 21). Only one individual scored within the normal limits for all four SP quadrants (male; 3 years of age). On the CBCL, 20/25 (80%) SMS subjects had clinically significant high total scores for maladaptive behavior. Spearman Correlation Coefficients revealed statistically significant inverse relationships ($p=<0.05$) between the SP quadrant scores and the total scores on the CBCL. These results support the hypothesis that in individuals with SMS sensory modulation difficulties are associated with maladaptive behavior and functioning. Further examination of the relationship between patterns of sensory processing and maladaptive behaviors may expand the behavior management approach and contribute to improved social participation and daily function in individuals with SMS.

1332/T

Background Strain and Natural Selection Improves Survival of HIBM Murine Model. *Y. Valles-Ayoub[1,2], Z. Khokher[1,2,4], A. Haghighatgoo[1,2], D. No[1,2,4], S. Esfandiarifard[1], C. Saechao[1], R. Carbajo[1,4], C. Creencia[3], S. Darvish[1,2], B. Darvish[2], D. Darvish[1,2].* 1) HIBM Research Group, Inc, Reseda, CA; 2) VA Greater Los Angeles (VA-GLA/UCLA), Los Angeles, CA; 3) Tissue Procurement Core Laboratory, Department of Pathology and Laboratory Medicine, UCLA School of Medicine, Los Angeles, CA; 4) Los Angeles Mission College, Sylmar, CA.

Recessive form of Hereditary Inclusion Body Myopathy (HIBM, IBM2, MIM:600737) is an adult onset muscle wasting disorders caused by hypomorphic GNE, the rate-limiting enzyme of sialic acid (Sia) biosynthesis. Unlike human patients, mice bearing the GneM712T/M712T genotype in C57BL/6 background strain suffer severe glomerular hematuria, incomplete podocyte development, and do not survive beyond the first few days of life. We crossed heterozygous mice (GneM712T/+) of B6 strain with FVB strain mice. In mixed inbred FVB;B6 background (N1), the homozygous mice show attenuated glomerular disease and survive longer (mean survival 23.48 ± 13.99 weeks, n=73). Within the first 2 generations, 26% of the homozygous mice survived passed the age of 40 weeks, and within the subsequent 3 generations the frequency of homozygous mice surviving pass age of 40 weeks has increased to 44%. Additionally, the homozygous mice (GneM712T/M712T) living past the age of 42 weeks begin to show muscle pathology. In summary, the background strain affects the disease phenotype, and natural selection may have an influence on long term maintenance of mouse models of human disease.

1333/T

Elucidating the Mechanism of Cardiac Teratogenicity in a Murine Model of Maternal PKU. *N.J. Seagraves[1,2], K.L. McBride[1,2].* 1) The Research Institute at Nationwide Childrens Hos, Columbus, OH; 2) The Ohio State University, Columbus, OH.

Phenylketonuria (PKU) is an inborn error of metabolism due to phenylalanine hydroxylase (PAH) deficiency which leads to elevated serum phenylalanine (Phe). Elevated Phe levels during pregnancy [Maternal PKU (MPKU)] cause heart and other defects. The mechanism of Phe teratogenicity upon the heart remains elusive. The BTBR Pahenu2 mouse provides a model to characterize the MPKU associated cardiovascular malformations (CVMs). We hypothesize there is a maternal serum Phe level and developmental period of exposure required to induce CVMs in offspring of mouse PKU females and the genetic background will influence the manifestations of CVMs. We established four exposure groups (control<360μM, low 360-600, mid 600-900, high>900) to determine the critical maternal Phe level. We screened 190 exposed BTBR fetuses and observed gross defects of the outflow tract (OFT) and vessel morphology including coarctation of the aorta. CVMs occurred in a dose-dependent manner as maternal serum Phe levels increase, from 5.6% of the controls to 20% in the high group (Nonparametric test for trends, p=0.03). We performed timed Phe exposure during gestation. Preliminary data indicates E8.5-E12.5 as the critical period. Early exposed fetuses have higher rates of transposition of the great arteries (TGA) while later exposure have truncus arteriosus (TA), double outlet right ventricle (DORV) and interrupted aortic arch (IAA). Further experiments are required to determine a more limited time period. We have generated congenic mice to investigate the effects of genetic background upon incidence and phenotypic variation of CVMs. We have not observed a difference in the incidence of CVMs among strains. We have observed phenotypic differences on each of the four Pahenu2 strains. The majority of affected fetuses on the BTBR background have TGA, while affected BL6 Pahenu2 have Dextrocardia with IAA, C3H/HeJ Pahenu2 have DOLV, and FVB/N Pahenu2 have TA. Defects of OFT and vessel morphology implicate the abnormalities involving cardiac neural crest cells (cNCCs). Using chick neural tube explants, to date we have not observed Phe exposure to affect migration or growth of the explant. Experiments to characterize cell signaling are ongoing. These results provide strong evidence that the murine model of MPKU is an excellent model to investigate the mechanism of Phe teratogenicity on heart development, which can aid in the understanding of the development of CVMs.

1334/T

***ESRRG* as a Candidate Gene for Human Congenital anomaly of the kidney and urinary tract (CAKUT).** *D.R. FitzPatrick[1], R. Berry[1], L. Harewood[1], J. Moss[1], M. Fisher[1], P. Branney[1], M. Whiteford[2], A. Howatson[3], N. Hastie[1], P. Hoenstein[1], D. Brownstein[4], L. Pei[5], R. Evans[5].* 1) Med Dev Gen Section, MRC HGU, Edinburgh, United Kingdom; 2) Department of Clinical Genetics, Yorkhill Hospital, Glasgow, United Kingdom; 3) Department of Paediatric Pathology, Yorkhill Hospital, Glasgow, United Kingdom; 4) Molecular Pathology, University of Edinburgh, Edinburgh, United Kingdom; 5) The Salk Institute, Howard Hughes Medical Institute, La Jolla, CA.

Congenital anomaly of the kidney and urinary tract (CAKUT) are common disorders of human development affecting the renal parechyma, renal pelvis, ureter, bladder and urethra that show evidence of shared genetic aetiology, although the molecular basis of this remains unknown in the majority of cases. We have previously reported a de novo, apparently balanced reciprocal translocation, t(1;2)(q41;p25.3) [Joss et al., 2003, Clin Genet, 63, 239-40], associated with non-syndromal bilateral renal agenesis. We performed breakpoint mapping using interphase FISH on nuclei extracted from archive tissue sections. Expression analysis in embryonic mouse kidneys of all the genes within 500Kb of both breakpoints implicated the gene encoding the nuclear steroid hormone receptor *ESRRG* as a strong candidate gene for CAKUT. We have found that Esrrg protein is detected throughout early ureteric ducts as cytoplasmic staining with nuclear localization seen only in the distal tip. In 14.5-16.5 dpc (days post conception) mouse embryos Esrrg localizes to the subset of ductal tissue within the kidney, liver and lung. The renal ductal expression becomes localized to renal papillus by 18.5 dpc. Perturbation of Esrrg function was then performed in embryonic mouse kidney culture: Pooled siRNA was used to inactivate Esrrg and a specific small-molecule agonist to induce abberent activation of Esrrg. Both result in severe abnormality of early branching events of the ureteric duct. Analysis of mouse embryos with a targeted inactivation of *Esrrg* on both alleles (*Esrrg*-/-) identified agenesis of the renal papillus with normal development of the cortex and remaining medulla. Taken together these results suggest that Esrrg is required for early branching events of the ureteric duct that occur prior to the onset of nephrogenesis. These finding confirm ESRRG as a strong candidate gene for CAKUT.

1335/T

Cranio-Encephalic Developmental Anomalies In A Mouse Model Of Fgfr3-Related Chondrodysplasia. *F. Di Rocco, E. Mugniery, N. Kaci, A. Jonquoy, C. Benoist, A. Munnich, L. Legeai-Mallet.* INSERM U781 Paris Descartes University, PARIS, France.

The fibroblast growth factors and their receptors regulate several cellular processes during embyonic and postnatal development. FGFR3 (Fibroblast Growth Factor Receptor 3) mutations are responsible for long bone anomalies such as achondroplasia or thanatophoric dysplasia (TD) but also craniofacial synostosis such as Muenke syndrome or Crouzon syndrome with acanthosis nigricans. Aim of the study is the analysis of FGFR3-related anomalies of cranial growth with a knock-in mouse model. Using the cre-lox system Fgfr3 mice express the mutation Y367C corresponding to the mutation Y373C responsible of TD type I in humans. The skull and the craniocervical junction of Fgfr3 mice (n:14) were compared to wild type (WT) controls (n:16). A macroscopic analysis was performed after alizarin blue and alcian red staining. It was completed by Xrays, Computed Tomography (CT) and Magnetic Resonance Imaging (MRI). Fgfr3 mutation induces an important deformation of the vault. All P21 fgfr3 mice presented a brachycephaly with a reduction of the anterioposterior lenght of the skull and brain and an increase of their height. They all had a defect in the ossification of the midline (all of mutant mice), going from an interfrontal defect to a complete absence of fusion of frontal and parietal bones. The nasal, the occipital bones and the atlas vertebra were reduced in size (79%,47%,48%, respectively, p<0.001) whereas the frontal and parietal bone sizes were unaffected. The interparietal bone size increased (116%, p=0.004). The shape of the skull was affected with a reduction of the angle between the frontal and nasal bones (139° vs 174° in WT, p=0.004). The mandible was prognatic in all mice. The foramen magnum was reduced in size, with a crowding of neural structures and a disappearance of cerebrospinal fluid signal at MRI. The cranial base was abnormal with an increased angle (140° vs 124° in WT, p=0.003) and a fusion of the clivus and sphenoid bone. In mutant newborns and E 16.5 embryos the interfrontal and interparietal distances were increased and the clivus abnormal. However its fusion with the sphenoid was absent in embryos and apparent at birth in most mice. Fgfr3 mutation disrupts the cranial base but also the skull vault. The anomalies progress during embryonic and postnatal development. The mouse cranial phenotype correlates with human FGFR3-related pathologies and highlights the primordial role of FGFR3 and endochondral ossification in normal craniofacial growth.

A familial translocation as a model for decoding regulatory mechanisms associated with an inherited epimutation. *S. Minocherhomji[1], H. Goo Kim[4], C. Hansen[1], M. Bak[1], K. Henriksen F.[1], P. Guldberg[2], J. Michael Hertz[3], H. Hilger Ropers[4], Z. Tümer[1], N. Tommerup[1], V. Kalscheuer M.[4], A. Silahtaroglu[1]*. 1) Wilhelm Johannsen Centre for Functional Genome Research, ICMM, Faculty Of Health Sciences, University of Copenhagen. Blegdamsvej 3B, DK-2200, Denmark; 2) Institute of Cancer Biology, Danish Cancer Society, DK-2100 Copenhagen, Denmark; 3) Department of Clinical Genetics Aarhus University Hospital, DK-8000, Aarhus C, Denmark; 4) Max-Planck Institute for Molecular Genetics, Ihnestrasse 73, D-14195 Berlin, Germany.

Epigenetic modifications are first established at the time of gametogenesis in an allele specific manner and are maintained throughout development in differentiated cells. Imprinted regions, known to replicate asynchronously within the human genome, are marked by allele specific epigenetic modifications including DNA methylation and higher order chromatin structure. Inheritance of these epigenetic modifications, particularly the state of genomic DNA methylation has so far been disputed in the literature. Here, we report the altered state of particular epigenetic mechanisms affecting the disks large-associated protein 4 (*DLGAP4*) gene, induced by the balanced chromosomal translocation t(8:20)(p12;q11.23) downstream of exon 1, in individuals of a family having early onset non-progressive cerebellar ataxia. We observed the presence of an inherited transgenerational epimutation affecting the promoter region of the brain specific DGLAP4 isoform in individuals affected by the translocation. CpG dinucleotides present within and around transcription factor binding sites juxtaposed to the promoter CpG Island of the disrupted gene on the translocated allele of *DLGAP4*, become de novo hypermethylated compared to the retained normal hypomethylation state of the unaffected allele on chromosome 20. The *DLGAP4* locus affected by the translocation and involving chromosomes der8 and der20, becomes asynchronously replicating, whereas the normal allele of the gene on chromosome 20 remains early replicating. A perturbed landscape of histone modification marks consisting of both active and inactive marks is observed around the *DLGAP4* locus, individually corresponding to the unmethylated and methylated alleles. At the level of mRNA expression we show the long DLGAP4 transcript that could be disrupted in individuals with the translocation, to be specifically expressed in fetal and adult cerebellum, particularly in the Purkinje cell layer of both phenotypically normal mouse and human brains. An elevated mono-allelic expression level of the widely expressed short isoform of the DLGAP4 gene, downstream of the breakpoint, is seen to correlate with the translocation affected allele. This translocation, apart from associating *DLGAP4* as a candidate gene for early onset non-progressive cerebellar ataxia, serves as a model for understanding the effects of transacting regulatory mechanisms of epigenetic marks.

Genome-wide methylation data analysis on the SOLiD™ System. *G. Marnellos[1], D. Krissinger[1], G. Meredith[1], M. Dudas[1], K. Clancy[2], C. Adams[1]*. 1) R&D/Epigenetics, Life Technologies, Carlsbad, CA; 2) R&D/Synthetic Biology, Life Technologies, Carlsbad, CA.

DNA methylation is an epigenetic modification crucial for organism development and normal gene regulation; aberrations in methylation are, among others, characteristic of many cancers in mammals. Next-generation sequencing technologies are enabling new methods for methylation profiling. Life Technologies has introduced a versatile MBD2 protein-based system (MethylMiner™) for the enrichment of methylated sequences from genomic DNA. This enrichment step along with the use of SOLiD™ System sequencing, allows for focused evaluation of genome-wide methylation patterns. This approach is an efficient and cost effective alternative to shotgun bisulfite sequencing of the entire genome to interrogate methylation marks, as only about 1% of the human genome is methylated and requires interrogation. Here we describe a comprehensive workflow for mapping and analyzing MBD2-enriched fractions of genomic DNA as well as bisulfite converted reads sequenced on the SOLiD™ System that employs freely-available public software tools and our own scripts and programs. The workflow enables characterization of methylation patterns at different levels of resolution, from broad genome region comparisons and profile differences between samples, to individual methyl C resolution. It provides the following functionality: • Mapping of unconverted and bisulfite-converted reads • Filtering of clonal reads • Mapping statistics: distribution of reads on chromosomes, coverage and read depth statistics, C and CpG counts in mapped readsPeak-finding in MBD2-enriched reads • Methylation analysis: methylation status of C residues in various sequence contexts, and bisulfite conversion efficiency • Level of enrichment in various genome regions (exons, introns, CpG islands, repeats, etc.) • Visualization of mapped reads and MBD2-enriched peaks with publicly available genome browsers (e.g. the UCSC or IGV browser) We have implemented this analysis pipeline analyze human data sets (IMR90 and MCF-7 cell lines), mainly MBD2-enriched fractions, bisulfite-converted and unconverted reads. Results showed good agreement with publicly available methylation data: peaks in MBD2-enriched reads have high coverage of genome regions with higher densities of published methyl-CpGs. This analysis workflow is a convenient and flexible solution for users which will allow the integration of methylation date with results from other SOLiD™ System applications (e.g. ChIP-seq and RNA-seq).

Effect of heroin self-administration on epigenetic regulation of the BDNF gene in the nucleus accumbens of rats. *Q. Liu, F. Theberge, S. Fanous, B. Hope, Y. Shaham.* Behavior Neurosci Res, NIDA/NIH, Baltimore, MD.

CpG islands in gene promoter regions are usually hypomethylated and the levels of DNA methylation in the gene promoters are regulated by environment with long-term effects on gene expression. Changes of chromatin structure could also cause long-term gene expression changes that are influenced by histone modification. BDNF is known to be involved in the behavioral effects of abused drugs, and recent studies also suggest a role of DNA methylation and histone modifications. Therefore, we have begun an investigation of the effect of heroin self-administration (0.075 mg/kg/infusion; 10 days for 6 h/d; each infusion was paired with a discrete tone-light cue) or saline (control condition) self-administration on DNA methylation in BDNF promoter regions and histone modification in the nucleus accumbens of rats that were trained to self-administer. After ten days forced abstinence, half of the heroin self-administered rats were re-exposed to the previously heroin-paired cues in a 30 min extinction test (n=6) while the other half were not; saline-trained rats were not given the extinction test. We then measured DNA methylation in BDNF promoter I, IV and VI regions by bisufite sequencing and histone post-translational modifications of phospho-acetylation of H3, di-acetylation of H3, tri-methylation of H3, and di-acetylation of H4 by Western blot analysis. Preliminary results suggested that the pattern of DNA methylation of the promoter IV of BDNF gene at specific CpG sites was reduced in the heroin-trained rats exposed to the heroin cues during testing versus the heroin-trained rats that were not exposed to the cues. We did not observe any significant changes of histone modification in nucleus accumbens of the two groups. The functional significance of these DNA methylation changes is currently unknown.

Brain weight is strongly correlated with DNA methylation across the extended IGF2-H19 imprinted region. *J. Mill, R. Pidsley, C. Troakes, E. Dempster.* SGDP Research Centre, Institute of Psychiatry, King's College London, London, United Kingdom.

Insulin-like growth factor 2 (IGF2) is a maternally imprinted gene that resides within a cluster of imprinted genes on chromosome 11p15.5, encoding a hormone involved in prenatal growth and development. Aberrant imprinting of the IGF2 gene is associated with congenital disorders such as Beckwith-Wiedermann Syndrome and Silver Russell Syndrome, which are characterized by growth abnormalities. More subtle epigenetic heterogeneity at IGF2 is also a feature of normal populations, and has been shown to be influenced by environmental factors including prenatal exposure to famine. Interestingly, prenatal exposure to famine is a risk factor for several psychiatric conditions including schizophrenia. In this study, we hypothesized that epigenetic variation across the differentially methylated regions (DMRs) regulating expression of IGF2, and its reciprocally-imprinted neighbor H19, may impact upon brain development, and particularly the cerebellum which is one of the largest structures in the brain and has a long developmental period. Using bisulfate-based fine-mapping approaches we quantitatively assessed inter-individual differences in DNA methylation across multiple DMRs at 11p15.5 in the cerebellum using two independent collections of post-mortem brain tissue carefully characterized for brain weight. We found that methylation across multiple DMRs in the 11p15.5 region was strongly correlated with total brain weight, with some evidence for sex-specific effects. Furthermore, a combined genetic-epigenetic analysis across the H19 imprinting control region (ICR) uncovered strong evidence for parent-of-origin-specific effects of SNPs on brain size. Our data have important implications for the field of psychiatric epigenetics, given the known association between brain weight and psychiatric disorders including schizophrenia and autism.

Simple, automatable NGS library preparation method for global DNA methylation profiling in cancer research and diagnostics. *E. Kamberov, T. Kurihara, J. Langmore, V. Makarov, J. M'Mwirichia.* Rubicon Genomics, Inc., Ann Arbor, MI.

Next-generation DNA sequencing has revolutionized epigenetic research by enabling genome-wide sequencing and profiling of differentially methylated DNA regions associated with cancer and other diseases. Current protocols for preparing libraries for NGS DNA methylation analysis usually require microgram quantities of DNA and mechanical fragmentation, preparation of DNA ends, ligation of adaptors, gel size fractionation, library amplification, numerous purification steps, and isolation of methylated DNA by immunoprecipitation (MeDIP) or magnetic bead binding (MBD), which together require days of preparation time. We present a streamlined, automatable process (NGS-MethylPlex) for preparing libraries for methylation analysis using the Illumina Genome AnalyzerTM (GA) and results of genome-wide methylation profiling of human prostate cancer and benign cell lines using NGS-MethylPlex libraries. NGS-MethylPlex is substantially simpler, more sensitive, and faster than other sample preparation methods and requires only 50 ng of input DNA and 5 h total preparation time. The NGS-MethylPlex process is initiated by digesting input DNA with methylation-sensitive restriction enzymes, followed by attachment of universal sequences and subsequent PCR amplification. A second round of enzymatic treatment depletes non-GC rich sequences, and an additional amplification ensures enrichment of highly methylated DNA fragments. NGS-MethylPlex libraries were synthesized from 50 nanograms of genomic DNA isolated from LNCaP prostate cancer cells and PrEC benign prostate epithelial cells, and the libraries were sequenced using the Illumina Genome AnalyzerTM (GA). A Hidden Markov Model (HMM)-based algorithm detected enriched regions from mapped reads obtained in each sequencing run, and while both cell lines had a total of ~55,000 methylated regions each, LNCaP cells exhibited a seven-fold enrichment for promoter CpG island methylation compared to PrEC cells. Several methylated regions were validated by multiple independent approaches including bisulfite sequencing. Detailed promoter analysis revealed diverse methylation patterns around transcription start sites, including direct methylation of CpG islands, methylation of regions flanking CpG islands, and methylation of sites devoid of CpG islands. Methylated promoters correlated with gene repression, and there was an enrichment of novel regions methylated in LNCaP cells that were also methylated in prostate cancer tissues.

Genetic and Epigenetic Alterations in Colorectal Cancer. *M.R. Schweiger[1], C. Grimm[1], L. Chavez[1], M. Kerick[1], S.T. Boerno[1], A. Fischer[1], K. Zatloukal[3], C. Roehr[1], B. Timmermann[2], A. Dahl[4], M. Isau[1], C. Barmeyer[5], R. Herwig[1], B.G. Herrmann[2], H. Lehrach[1].* 1) Vertebrate Genomics, Max Planck Institute, Berlin, Germany; 2) Max Planck Institute, Berlin, Germany; 3) Medical University Graz, Austria; 4) Technical University, Dresden, Germany; 5) Charité University Hospital, Berlin, Germany.

Changes in DNA methylation patterns of specific genes are commonly found during colorectal cancer progression. The recent development of next generation sequencing (NGS) technologies has brought about the possibility to investigate DNA methylation patterns in a genome-wide and unbiased manner. One of these technologies, the MeDIP technology, utilizes an antibody against methylated cytosine to immunoprecipitate and thereby enrich methylated DNA regions. We have adapted the MeDIP protocol to Illumina's Genome Analyzer as well as Applied Biosystem's SOLiD platform to identify precipitated DNA fragments in colon cancer cell lines as well as colon normal and tumor tissue samples. We will present our epigenetic studies in combination with whole exome sequencing results from the same patients. This combination of genetic and epigenetic experiments brings further access towards the identification of novel disease-causing genomic alterations in a genetically complex disease such as cancer.

1342/F

BRCA1 germline mutations and age-acquired methylation at stem cell target genes. *J. Zhuang[1], A. Teschendorff[2], M. Zikan[3], A. Jones[1], P. Pohlreich[4], D. Cibula[3], S. Peri[5], A. Bellacosa[6], I. Jacobs[1], M. Widschwendter[1].* 1) Gynecological Oncology Dept, UCL, London, UK; 2) Medical Genomics Group, UCL Cancer Institute, London, UK; 3) Oncogynecologic Center, Obstetrics and Gynecology Dept, Charles University Prague, Prague, Czech Republic; 4) Biochemistry and Experimental Oncology Dept, Charles University in Prague, Prague, Czech Republic; 5) Biostatistics Dept, Fox Chase Cancer Center, Philadelphia, PA; 6) Epigenetics and Progenitor Cells Program Dept, Fox Chase Cancer Center, Philadelphia, PA.

Women with BRCA1 germline mutations experience up to 80% risk of developing breast cancer. Age is the most important risk factor for cancer. Recently, CpGs become increasingly methylated with age are found to be heavily enriched for stem cell polycomb group target genes (PCGTs). PCGTs both reversibly repressed in stem cells and required for differentiation, and more likely to undergo cancer-specific promoter DNA hypermethylation than non-target. We demonstrated a signature comprising 69 age-hypermethylated CpGs mapping to PCGTs (Age-PCGTs) derived from peripheral blood cells distinguishes preneoplastic and neoplastic cells from their normal counterparts, whereas that of 156 age-hypermethylated CpGs not mapping to PCGTs (Age-NonPCGTs) is not. We hypothesised individuals with particularly high risk of developing a cancer are predisposed to premature hypermethylation at Age-PCGTs compared to non mutation carriers. PCGTs are discovered to be underexpressed in luminal progenitors compared with luminal cells (OR=2.76, P<1e-8) and the majority of Age-PCGTs showed underexpression in luminal progenitors (P=0.03), consistent with PCGTs being critically involved in the differentiation process of the breast epithelium which appears to be disrupted in BRCA1 mutation carriers. We also established if the Age-PCGT methylation signature is modified in peripheral blood DNA from women with BRCA1 mutation compared to controls. The results were validated in a set of 30 healthy age matched women and 30 breast cancer patients. The Age-PCGT methylation signature significantly discriminated BRCA1 carriers from controls irrespective of cancer status but not the Age-NonPCGT signature. We analyzed expression of Age-PCGTs in age-matched primary human mammary epithelial cells in women with and without BRCA1 mutation and observed an underexpression of Age-PCGTs but not of Age-NonPCGTs in BRCA1 mutation carriers. Also, Age-PCGTs were significantly underexpressed in a set of BRCA1 mutant basal cancers than age-matched non-BRCA1, suggesting the difference in expression might persist in tumour specimens. Finally, we illustrated genes that are hypermethylated and suppressed in tissue samples from BRCA1 mutation carriers to be generally enriched for PCGTs. This is the first report demonstrating an interaction between the germline genome and age leading to a specific alteration of the epigenome may eventually contribute to breast cancer.

1343/F

Subtelomeric Methylation in Patients with Dyskeratosis Congenita and their Unaffected Family Members. *S.M. Gadalla[1,2], H. Katki[3], F.M. Shebl[4], N. Giri[1], L. Mirabello[1], P.M. Lansdorp[5], B.P. Alter[1], S.A. Savage[1].* 1) Clinical Genetics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD; 2) Cancer Prevention Fellowship Program, National Cancer Institute, Rockville, MD; 3) Biostatistics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Rockville, MD; 4) Infections and Immunoepidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Rockville, MD; 5) Terry Fox Laboratory, British Columbia Cancer Research Center, Vancouver, BC, Canada.

Dyskeratosis congenita (DC) is an inherited bone marrow failure and cancer susceptibility syndrome, caused by germline mutations in telomere biology genes. DC patients have very short telomeres (below 1st percentile for age). Recent data suggest that epigenetic regulation of telomeric chromatin impacts telomere length (TL). In mouse models and in-vitro studies, subtelomeric methylation was involved in TL regulation. We hypothesize that epigenetic factors may contribute to DC etiology and hence evaluated the role of subtelomeric methylation in DC. We identified 40 patients with DC (7 DKC1, 5 TERC, 4 TERT, 11 TINF2, 13 without mutations in known DC genes) and 51 unaffected mutation-free family members. All subjects were participants in the NCI's Inherited Bone Marrow Failure Syndrome cohort. D4Z4 subtelomeric repeat CpG methylation in leukocyte DNA was determined after bisulfite modification. Lymphocyte TL was measured by flow-FISH. Associations between DC, TL and % subtelomeric methylation were calculated using odds ratios(OR)and 95% confidence intervals(CI) from multivariable logistic regression models. Compared with unaffected family members, patients with DC were younger (median=14.4 vs. 45.6 years) and had very short TL (median=3.7 vs. 6.4 Kb). After adjusting for age and TL, our data suggested a positive association between subtelomeric hypermethylation and DC (OR=2.6, 95%CI=0.6-11.3, p=0.2). This association was statistically significant only in patients with a mutation in telomerase complex genes (DKC1, TERT, or TERC), or those without a mutation in the known genes (OR=1.8, p=0.04, and OR=30.9, p<0.0001, respectively), but not in patients with a TINF2 mutation (OR=1.6, p=0.2). We next evaluated the association between TL and subtelomeric methylation in cases and controls separately. Longer telomeres in DC patients were associated with higher levels of subtelomeric methylation; the reverse was true for controls (OR= 1.4 vs. 0.6, P-interaction=0.03). In conclusion, subtelomeric methylation may be associated with DC after accounting for age and TL, especially in patients without mutations in known DC genes. Absence of this association in patients with TINF2 mutation may indicate that methylation aberrations in patients with DC are telomerase dependent. Subtelomeric hypermethylation may protect against accelerated telomere shortening in DC. Our ongoing studies include mechanisms of epigenetic regulation of TL and its relationship to DC etiology.

1344/F

Whole exome, MeDIP-seq and RNA-seq analysis of monozygotic twins discordant for greater than 20 traits. *S.V. Ramagopalan, L. Handunnetthi, G.C. Ebers.* Dept Clinical Neurology, Oxford Univ, Oxford, United Kingdom.

Monozygotic twins have been widely studied to dissect the relative contributions of genes and the environment in human diseases. We report here a pair of female twins markedly different in appearance and discordant for more than 20 traits including, height, weight, personality, spinal stenosis, scoliosis, migraine, neuropathy, biliary cirrhosis, diabetes, hypertension, asthma, osteoporosis, hypertelorism and precocious puberty. These twins, were believed to be dizygotic but obstetric history of a common amniotic sac was validated by DNA testing. The extreme difference in phenotype observed here may be unparalleled. The discordance for many unrelated and unlinked conditions suggested diffuse epigenetic differences. Here we present the whole exome, messenger RNA transcriptome and DNA methylome sequences of peripheral blood mononuclear cells, CD4+ lymphocytes and buccal tissue from this twin pair. This twin pair implicates an epigenetic basis for the conditions for which they are discordant and twin-twin comparisons in them might be a rosetta stone for identifying key epigenetic differences for several common conditions. We believe our results will have more general implications for understanding the aetiology of these complex traits.

1345/F

A ChIP-Seq method for generating epigenome-wide profiles histone (H3K9) acetylation in post-mortem human brain tissue from clinical-pathologic epidemiologic studies. *C. Aubin[1], J. Schneider, MD, MS[2], G. Srivastava, PhD[3], A. Meissner, PhD[1,5], M. Szyf, PhD[6], D. Bennett, MD[2], P. De Jager, MD, PhD[1,3,4].* 1) Medical and Population Genetics, The Broad Institute of Harvard and MIT, Cambridge, MA; 2) Rush Alzheimers Disease Center, Rush University Medical Center, Chicago, IL; 3) Program in Neuro-Psychiatric Genomics, Department of Neurology, Brigham & Women's Hospital, Boston, MA; 4) Harvard Medical School, Boston, MA; 5) Department of Stem Cell and Regenerative Biology, Harvard University and Harvard Stem Cell Institute, Cambridge, MA; 6) Department of Pharmacology and Therapeutics, McGill University, Montreal, QC, Canada.

Cognitive decline is a complex function of experiential, genetic, and epigenetic factors that lead to the accumulation of neuropathologies or alter the brain's capacity to tolerate or compensate for the deleterious effects of neuropathologies. Over the past 15+ years, the Religious Orders Study and Rush Memory and Aging Projects have enrolled 2,500 persons who agreed to annual clinical evaluation and organ donation. More than 850 brains are already available. We are establishing a chromatin immunoprecipitation/ sequencing (ChIP-Seq) pipeline to generate epigenome-wide profiles of histone (H3K9) acetylation in fixed dorsolateral prefrontal cortex (DLPFC) tissue at the Broad Institute of Harvard and MIT. We identified the Millipore anti-H3K9Ac mAb (catalog # 06-942, lot: 31636) as a robust mAb for our ChIP experiment. Optimum sonication intervals have been shown to vary due to fixation interval in human cell lines. Therefore, we examined the effects of variations of fixation interval as well as post mortem interval (PMI, interval between death and autopsy) on the sonication interval best suited to fragment chromatin from this tissue for ChIP. Brain tissue (n=20) sampled from each quartile of fixation interval and PMI were sonicated for a range of times (6, 8, 10, and 12 minutes). A 10 minute sonication treatment was optimal to produce chromatin fragments with the desired proportion of target segments (length of 150-700 bp per Bioanalyzer assessment). At this time, we do not see a correlation between optimum sonication interval and either fixation interval or PMI; fixation times in excess of 200 hours and PMI in excess of 48 hours produced adequate material for library construction. Using 500mg of gray matter from the DLPFC tissue produced an average of 23.3ng of DNA fragments. Sequencing data from libraries derived from our ChIP is currently being produced. At the time of the conference, we will report on the extent of interindividual variation within the sequence data produced from the first 100 samples to be processed, and we will update our protocol on the optimal parameters with which to execute H3K9 acetylation profiling epigenome-wide in fixed brain tissue.

1346/F

Characterization of chromatin signatures using low cell number chromatin immunoprecipitation. *A.J. Notini[1], J.A. van den Bergen[1], D. Belluoccio[2], M. Burton[1], P.S. Western[1], A.H. Sinclair[1], S.J. White[1].* 1) Murdoch Childrens Research Institute, Royal Children's Hospital, Melbourne, Australia; 2) Agilent Technologies Pty Ltd, Melbourne, Australia.

A fundamental goal of modern biology is understanding how genes are regulated both temporally and spatially. It is becoming clear that this control is not only dependent on DNA sequence; rather epigenetic factors such as CpG methylation and histone modifications also play a major role. Diverse histone modifications are associated with different characteristics of transcriptional regulation, and techniques such as chromatin immunoprecipitation (ChIP) have started to reveal the complexity underlying this regulation. To date most genome-wide studies using this approach have used cultured cells as it is necessary to have millions of cells to obtain sufficient material for downstream applications. We have developed a method that can use as few as 100,000 cells per IP. Specifically, we have used this approach to study chromatin modifications in a purified population of somatic cells derived from embryonic mouse gonads. Following IP, the resulting material is amplified and hybridized onto custom arrays containing targeted genomic sequences for 28 genes known to be involved in gonad differentiation and development. We have used antibodies specific for histone modifications, including anti-H3K4me1, H3K4me2, H3K4me3, H3K4me27 and H3K36me3 to identify enhancers, active/inactive chromatin and transcript elongation. We will present chromatin profiles for somatic cells of the embryonic ovary and testis during different stages of development. In conclusion, we have developed low cell number ChIP to examine epigenetic changes during mouse gonad development. This approach can be applied to any biological question where the amount of starting material is limited.

1347/F

Analysis of DNA Methylation in Facioscapohumeral Muscular Dystrophy (FSHD). *C.H. Huichalaf[1,2], D. Gabellini[1,3].* 1) Regenerative Medicine, San Raffaele Scientific Institute, Milan, Milan, Italy; 2) International Ph.D Program in Cellular and Molecular Biology Università Vita Salute San Raffaele, Milan Italy; 3) Dulbecco Telethon Institute, Milan, Italy.

FSHD, the third most common muscular dystrophy, is an autosomal disorder with an incidence of 1:14.000. It is characterized by asymmetric muscle weakness and variable penetrance. FSHD is linked to deletion of the D4Z4 3.3 kb macrosatellite repeat, located in 4q35. In normal individuals 11 to 100 D4Z4 are found, while FSHD patients carry 1 to 10 units. While the human genome average GC content is 42%, each D4Z4 repeat unit contains 73% GC. Furthermore, in D4Z4 the CpG dinucleotide frequency is 10% compared to the average human genome frequency of 1%. As a result, in healthy subjects the region occupied by the D4Z4 repeats represents one of the more extended CpG islands of the human genome. This makes D4Z4 an excellent candidate for regulation mediated by DNA methylation, a common modification of mammalian DNA usually associated with gene repression. DNA methylation is executed by DNA methyltransferases (DNMTs) and usually occurs at cytosine residues of CpG dinucleotides. A few studies have been published regarding the methylation status of D4Z4 in FSHD. Unfortunately, all of them were based on the use of methylation-sensitive restriction enzymes and provided information on just two of the more than 300 CpGs present in the D4Z4 repeat. Our goal is to study DNA methylation across the entire D4Z4 repeat in healthy subjects and FSHD patients. We are doing this using a combination of bisulfite sequencing and methyl DNA precipitation assay. Our preliminary findings indicated that D4Z4 is highly methylated in healthy subjects, but this methylation is not uniformly distributed inside D4Z4. We have also found that this methylation does not correlate with the number of CpGs inside the region, and we have evidence for non-CpG methylation on the D4Z4 repeat. These studies are very relevant to develop therapeutic approaches aimed at controlling altered 4q35 gene expression in FSHD.

1348/F

Alterations in Maternal DNA Methylation are Associated with Congenital Heart Defects. *S. Chowdhury, M.A. Cleves, S.L. MacLeod, S.W. Erickson, W. Zhao, P. Hu, C.A. Hobbs.* Pediatrics Department, College of Medicine, University of Arkansas for Medical Sciences, Arkansas Children's Hospital Research Institute.

Background: Congenital heart defects are the most common structural birth defects. The etiology of the majority of CHDs are unknown, but are thought to result from an interaction of multiple genetic, epigenetic, and environmental and factors. Altered folate metabolism has been shown to be associated with CHDs, and is also implicated in altered DNA methylation patterns. Although evidence linking genetic and metabolic alterations in folate metabolism and CHDs exists, the relationship between maternal DNA methylation and CHDs remains relatively unexplored. We sought to investigate if alterations in maternal DNA methylation could be detected between mothers with CHD-affected pregnancies and mothers with unaffected pregnancies. Methods: The proposed study builds on the National Birth Defects and Prevention Study (NBDPS). Blood was collected from Arkansas NBDPS participants who delivered a singleton live birth with a non-syndromic CHD, and Arkansas NBDPS mothers who had a live birth without a major defect. Using a case-control study design, maternal DNA methylation was measured using three methods. In 180 cases and 187 controls, LINE-1 methylation was assayed via Methylight methodology, and gene-specific methylation was interrogated for over 14,000 genes in over 27,000 CpG sites by the Infinium® HumanMethylation27 BeadChip. Global DNA methylation was assessed in a subset of 56 cases and 52 controls by immunoassay. Lifestyle information was available for all subjects to perform covariate adjustments. Results: A 5% decrease in LINE-1 methylation resulted in a 15% increased risk of CHDs (OR=1.15; 95% CI: 1.03, 1.27; P=0.010). Multiple genes encompassing various cellular functions were found to be differentially methylated in cases when compared to controls. Within these genes, GDF3, EGFR, MAP4K5, and UGDH were significantly hypermethylated in cases, and have previously been identified as critical genes in heart development. Significant global DNA hypomethylation was observed in cases when compared to controls (p=0.045). Conclusions: Our findings indicate that maternal global DNA hypomethylation and gene-specific hypermethylation is associated with an increased risk of CHDs. Aberrations in maternal DNA methylation converge with previous evidence that indicate folate-dependent genetic and metabolic susceptibilities increase the risk of CHDs. These results suggest that further investigation into maternal epigenetic mechanisms as they affect CHD risk is warranted.

1349/F

Epigenomics of Vascular Cell Phenotypic Modulation in Atherosclerosis. *L. Mills[4], B. Wamhoff[1,2,3], B. Blackman[1,3], J. Connelly[1,2].* 1) CVRC; 2) Department of Medicine Cardiovascular Division; 3) Department of Biomedical Engerinnering; 4) Molecular Cell and Developmental Biology, University of Virginia, Charlottesville, VA.

Phenotypic modulation of both endothelial cells (EC) and smooth muscle cells (SMC) from quiescent to proliferative, inflamed, and migratory phenotypes occurs in vivo and leads to the progression of atherosclerosis. Regions of the vasculature that are subject to specific blood hemodynamic forces, including low time-average and oscillatory shear stresses, characterize regions of the artery predisposed to phenotypic modulation. We have previously defined a model system that recapitulates human hemodynamics in a culture system that mimics a vessel. This system was shown to recreate the phenotypes of ECs and SMCs found in atheroprone regions in vivo. We have confirmed that the same phenotypic changes occur in human aortic ECs and human aortic SMCs. When these two cell types are subjected to low time-averaged and oscillatory flow the expression of anti-inflammatory markers TEK, KLF2 and NOS3 decreases in ECs and the expression of the differentiation markers ACTA2, KLF4 and MYOCD decreases in SMCs. These results are the same expression changes that are found in diseased regions of arteries in vivo. Using this model we are testing the hypothesis that changes in DNA methylation status of genes in ECs and SMCs undergoing phenotypic modulation play a role in atherosclerosis initiation and progression. We have assayed DNA methylation using methylated DNA immunoprecipitation (Me-DIP) and quantitative real time PCR. We see enrichment of the highly methylated HIST1H2BA locus, in aortic smooth muscle cells and no enrichment of the promoter region of GAPDH. We are currently assessing methylation changes in smooth muscle cells on a genome wide scale using Solexa sequencing. Candidate regions will be identified, confirmed using bisulfite cloned sequencing and DNA from diseased and healthy human aortic tissues will be profiled to verify that changes seen in this system are also seen in tissue in which disease progresses.

Evidence that early growth influences adiposity at age 9-13 years and is mediated by epigenetic regulation of gene expression. *A. Groom[1], D. Swan[2], S.M. Korada[3], H.J. Cordell[4], J.C. Mathers[1], M.S. Pearce[5], N.D. Embleton[3], C.L. Relton[1].* 1) Human Nutrition Research Centre, Institute for Ageing and Health, Newcastle University, Newcastle upon Tyne, Tyne and Wear, United Kingdom; 2) Bioinformatics Support Unit, Newcastle University, Newcastle upon Tyne, Tyne and Wear, United Kingdom; 3) Newcastle Neonatal Service, Royal Victoria Infirmary, Newcastle University, Newcastle upon Tyne, Tyne and Wear, United Kingdom; 4) Institute of Human Genetics, Newcastle University, Newcastle upon Tyne, Tyne and Wear, United Kingdom; 5) Institute of Health and Society, Newcastle University, Newcastle upon Tyne, Tyne and Wear, United Kingdom.

Early environmental events in postnatal life are postulated to cause aberrant epigenetic marking and precipitate altered expression of specific genes. This in turn may affect body composition and metabolic health in childhood.

Participants were drawn from a nutritional intervention study of preterm infants carried out in early postnatal life. Anthropometric, biochemical and nutrient markers in early life and at 9-13 years of age were collected. Blood and saliva samples were also collected at age 9-13 years for DNA and RNA analysis. Up-regulation of gene expression in 'slow growers' (n=12) versus 'rapid growers' (n=12) was assessed. 'Slow' and 'rapid' growth was determined by differences in z-scores for weight between term and term plus 12 weeks. Levels of DNA methylation at 7 CpG sites within *TACSTD2* were analysed by Pyrosequencing®.

245 loci were upregulated in females who were 'slow growers' versus females who were 'rapid growers' and 352 in males who were 'slow growers' versus males who were 'rapid growers'. Of these genes *TACSTD2* was selected for further investigation. *TACSTD2* was up-regulated 2.56-fold in males and 4.07-fold in females who were 'slow growers' compared to 'rapid growers' (p=0.0001). Methylation levels of *TACSTD2* (mean across 7CpGs) in DNA extracted from saliva and blood (n=52) were closely correlated (rho= 0.87, p=0.0001). However, methylation levels from saliva were considerably lower (mean % (SD) = 38.7 (15.4) compared to 66.9 (16.3)). *TACSTD2* methylation was lower in 'slow growers' and was also associated with an increase in total body mass at age 9-13 years (blood p=0.012, saliva p= 0.001). This latter association was driven by fat mass; change in fat mass per percentage change in DNA methylation; blood -146.4g (95% CI -242.4, -50.3) p=0.004; saliva -149.3 (95% CI -235.2, -63.3) p=0.001).

Preterm infants with a slower growth trajectory in early post natal life display considerable differences in gene expression levels and gene-specific DNA methylation levels at age 9-13 years when compared to infants who grew rapidly. These results show an association between early growth, epigenetic regulation of gene expression and body composition in childhood.

The authors wish to acknowledge the BBSRC for funding, grant ref BBF0079811.

A search for the silencing gene of mouse dactylaplasia. *H. Kano, T. Toda.* Physiology and Cell Biology, Kobe Univ., Kobe, Hyogo, Japan.

Dactylaplasia, characterized by missing central digital rays, is an inherited mouse limb malformation that is clearly dependent on a two-locus interaction between Dac and mdac (modifier of Dac). The dactylaplasia phenotype depends on the genotype at the mutated locus, Dac, and also requires homozygosity for a recessive allele at another unlinked locus, mdac. An LTR retrotransposon insertion was identified in the Dac locus on mouse chromosome 19. However, some mouse strains display normal phenotype despite carrying the insertional mutation. This is because of the presence of modifier allele, mdac, on mouse chromosome 13. The mdac is polymorphic (mdac/Mdac) among the inbred mice. The LTR retrotransposon insertion on the mdac background is unmethylated and the mice display the dactylaplasia phenotype. On the other hand, the insertion on the Mdac background is methylated and the mice display the normal phenotype. The aim of this study is to identify mdac/Mdac. Backcrossing test and haplotype block analysis refined the mdac locus to the ~1 Mb region. Among several genes, we focus on a gene, a member of zinc finger proteins. The gene has a SNP in its coding region, which causes an amino acid substitution between the mdac allele and the Mdac allele. Now, we are creating transgenic mice to confirm the role of the gene. The transgene was cloned from the Mdac allele and was microinjected into fertilized oocytes of the mdac background. By crossing the transgenic mouse with the dactylaplasia mouse, we expect that the LTR retrotransposon insertion would be methylated and the dactylaplasia phenotype would be suppressed by the presence of the transgene.

Seq + PA: Combining Sequencing (Seq) and Individual Peak Analysis (PA) for Quantification of DNA Methylation and Minor Sequence Variation Detection. *E. Schreiber, A. Tobler, C. Davidson.* Applied Biosystems, Life Technologies, Foster City, CA. USA.

Fluorescent DNA sequence traces generated by Sanger sequencing on automated capillary electrophoresis (CE) instruments primarily reveal the composition and exact sequence of nucleotide bases. However, an additional layer of information may be present in the peak height of a given base reflecting a measure of abundance. Here we report a novel method, Seq+PA, that allows the separation of the four dye traces used in BigDye® Terminator 3.1 sequencing chemistry and inclusion of a 5th LIZ® dye-labeled size standard. This enables alignment by size of multiple samples and subsequent data analysis of each individual peak characteristics, such as size, height and area by GeneMapper® software. We have used the Seq+PA method for direct bisulfite PCR sequencing and were able to detect methylated cytosines in CpG pairs to a level of 5%. We have also applied the method for sensitive detection of somatic mutations. To that end, DNAs with a normal or mutant genotype at codon 12 in the KRAS gene were mixed in various ratios and processed for PCR and Seq+PA analysis. The mutant allele was noticeable at a 5% level. Taken together, the method described here has the potential to enable a more quantitative analysis of DNA sequence traces for sensitive detection of minor sequence variations. Disclaimer: For Research Use Only. Not intended for any animal or human therapeutic or diagnostic use.

An adverse effect of ICSI on ovogenesis is suggested by concurrence in the same patient of trisomy 21 and Angelman syndrome. *M.G. Pomponi[1], L. Morciano[2], R. Pietrobono[1], F. Gurrieri[1], G. Neri[1,2].* 1) Medicina di Laboratorio, Genetica Medica, Roma, Roma; 2) Servizio di Genetica Medica, Ospedale “G: Panico”, Tricase.

Recent studies on the outcome of assisted reproductive technology (ART) have raised concern regarding the potential association between ART and chromosomal aneuploidy, imprinting anomalies, and congenital defects. It is still debated whether this association has a stochastic nature or is rather the result of a cause-effect relationship between infertility itself, induced superovulation and in vitro culturing of the embryo. We here report on a child, conceived with intracytoplasmic sperm injection (ICSI), who is affected with trisomy 21 and Angelman syndrome due to a sporadic imprinting alteration. Methods: we confirmed the diagnosis of Angelman syndrome by methylation sensitive Southern blot analysis and MLPA analysis using a commercially available Kit (SALSA MS-MLPA kit ME028-B1 Prader-Willi/Angelman (MRC-Holland). Genotyping of the propositus, his parents and maternal grandmother was performed with microsatellite markers from the PWS-AS critical region. Sequencing of the imprinting center was performed by standard procedures. Results: the molecular analysis showed that chromosomes 15 were of bi-parental origin in the propositus, therefore the altered methylation pattern was due to an imprinting defect. Such defect was de novo because no deletion or mutation was found in the imprinting center. In addition, haplotype analysis showed that the propositus inherited from his mother the grandmaternal haplotype for the 15q11-q13 region. We also confirmed that trisomy 21 was due to maternal non-disjunction, as expected. This is to our knowledge the second report of a double adverse effect of ART on the embryo, suggesting a vulnerability of the maternal genome to the ART-related treatment, the first being the one of a twin boy with Beckwith-Wiedemann syndrome and a 47, XXY caryotype (Yoon et al., 2005).

Promoter methylation of *PDE11A* and *KITLG* modifies the risk of familial testicular cancer. *L. Mirabello, C.P. Kratz, S.A. Savage, M.H. Greene.* Clinical Genetics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, Maryland, USA.

Testicular germ cell tumors (TGCT) are the most frequent cancers among young men. No high-penetrance cancer susceptibility gene has been identified despite a high familial risk and likely inherited susceptibility. Recent genomic studies have identified several candidate loci associated with TGCT: *PDE11A*, *KITLG*, *SPRY4*, and *BAK1*. Mouse models suggest that transgenerational epigenetic interactions control susceptibility to TGCT in mice with a *Dnd1* mutation. These five genes are all involved in development of the normal testis and/or male infertility (a TGCT risk factor). Aberrant DNA methylation contributes to carcinogenesis, and may represent an alternative mechanism for TGCT susceptibility. We hypothesized that the promoter regions of these candidate genes (*PDE11A*, *KITLG*, *SPRY4*, *BAK1*, and *DND1*) may be regulated through epigenetic changes and investigated the association between promoter methylation and TGCT in multi-case familial testicular cancer family members. Pyrosequencing assays were designed to examine methylation at CpGs in the promoter CpG island of each gene in peripheral blood DNA from 153 TGCT probands and 116 healthy male relatives from 101 multiple-case families. Adjusted logistic regression models were used to investigate the association between promoter methylation of each gene and TGCT risk. Methylation levels for each promoter region, and for each individual CpG site, were categorized into tertiles, based on the distribution in the controls. A statistically significant upward trend was observed for *PDE11A* when comparing the middle and highest tertiles of methylation to the lowest [odds ratio (OR)=1.55, 95% confidence intervals (CI) 0.82-2.93, and 1.94, 95% CI 1.03-3.66], respectively; P_{trend}=0.042). A significant trend in the opposite direction was observed for *KITLG* when comparing the middle and highest tertiles to the lowest (OR=0.99, 95% CI 0.55-1.79, and 0.46, 95% CI 0.24-0.89, respectively; P_{trend} = 0.031). Our results suggest that TGCT susceptibility is associated with promoter methylation of novel candidate genes, and that ***PDE11A* is inactivated** and ***KITLG* activated** in familial TGCT cases compared with healthy male relatives. Both findings fit prior observations regarding how each gene/pathway modifies TGCT risk. This is the first study to investigate promoter methylation of these genes. Our data provide new insight into the complexity of TGCT genetics. Larger studies are warranted to further explore our preliminary findings.

Safeguarding the human FMR1 promoter: the methylation barrier in its 5'-upstream region. *A. Naumann[1], S. Weber[1], A. Hoogeveen[2], E. Fanning[1,3], W. Doerfler[1,4].* 1) Institute for Virology, Erlangen University, Erlangen, Germany; 2) Department of Genetics, Erasmus Medical College Rotterdam, Nederland; 3) Department of Biological Sciences, Vanderbilt University, Nashville, TN 37235, USA; 4) Institute of Genetics, University of Cologne, D-50674 Cologne, Germany.

Recent studies of the methylation profile in the 5'-upstream region of the human FMR1 promoter revealed a distinct boundary between a highly methylated genome segment and the unmethylated, active promoter of the human FMR1 gene (Naumann et al., AJHG 85, 606-616, 2009). By using the bisulfite sequencing procedure, this boundary was located at a site about 700 nucleotides upstream of the (CGG)n repeat in the human FMR1 gene. The boundary is present in the genomes of all human cell types investigated as well as in the equivalent region in the mouse genome with only 46.7% homology. Nuclear proteins bind specifically to that DNA sequence. The region is thought to serve as a barrier against the spread of DNA methylation into the FMR1 promoter and thus to help maintaining its functionality. We have now investigated the methylation profile in that genome segment in different FRAXA premutation and mutation carriers. The barrier is lost in the genome of FRAXA males, but is preserved in premutation females and in high functioning males. In premutation females, the methylation profiles in that region are identical to those of normal females with one chromosome exhibiting the barrier as in healthy male chromosomes, the other allele being strongly methylated as can be expected. In a high functioning male genome with a (CGG)n repeat expansion (n = 330; Smeets et al. Human Mol. Genet. 4, 2103-2108, 1995), the methylation boundary is preserved and thus explains the normal activity of the FMR1 promoter. This finding further documents the importance of an intact methylation barrier in maintaining the function of the FMR1 promoter. In primary FRAXA fibroblasts, although not in peripheral mononuclear cells of FRAXA individuals, with loss of the methylation boundary, a genome segment well upstream of the methylation barrier has become hypomethylated. It is conceivable that this aberrant loss of methylation points to a structural instability in the boundary region in FRAXA genomes. We pursue the possibility that the chromatin structure at the methylation barrier is key to the functionality of the human FMR1 promoter. This research was supported by the Thyssen Foundation, Cologne, Germany (to W.D.), the Institute of Virology, Erlangen University Medical School, the Alexander von Humboldt Foundation, and by National Institutes of Health grant GM52948 (to E.F.).

Are there changes in DNA methylation in response to chronic consumption and withdrawal of folic acid? *K.S. Crider[1], C. Bean[1], R.J. Berry[1], T.P. Yang[3], J.O. Brant[3], S.A. Rasmussen[1], L. Hao[4], Z. Li[4], D. Maneval[2], E. Quinlivan[2], L.B. Bailey[2].* 1) National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, GA; 2) Food Science and Human Nutrition Department, University of Florida Gainesville, FL; 3) Center for Epigenetics University of Florida College of Medicine Gainesville FL; 4) Peking University Health Science Center, Beijing, China.

We evaluated the effect of folic acid supplementation and withdrawal on DNA methylation at 1505 loci in 802 genes using bead array technology. Blood samples from 96 Chinese women (stratified by three methylenetetrahydrofolate reductase [*MTHFR*] genotypes) participating in a double-blind randomized trial of folic acid supplementation (100, 400, 4000 μg/day) were screened for changes in DNA methylation level and pattern at five time points: baseline, 1, 3 and 6 months supplementation and after a 3 month withdrawal of supplementation. Preliminary analysis showed overall mean baseline methylation patterns were highly correlated among the three MTHFR genotypes ($r^2 > 0.99$). At baseline > 99.4% of these loci had little variation in mean betas (ratio of methylated/unmethylated), with between -5 and +5 percent methylation difference between the three MTHFR genotypes. After supplementation the variation among individuals in locus-specific DNA methylation levels increased compared to the variation at baseline. The vast majority (>99.9%) of mean changes in methylation from baseline at each locus at any time point were between -20 and +20 percent. CpG sites that showed significant mean change ($p < 0.01$) from baseline to any time point were more likely to be part of non-CpG islands vs. CpG islands (OR 5.3 95% CI 3.9-7.1) and from loci on the X chromosome vs. autosomes (OR 3.3 95% CI 1.8-6.2). There were more loci with significant changes ($p<0.01$ and change in percent methylation of > +/-10) from baseline at any point during supplementation among those with either the variant TT (6.6%) or heterozygous CT (4.5%) genotype compared with the CC (2.5%) genotype. After withdrawal of folic acid there were limited numbers of loci with significant differences from baseline (CC 0.5%, CT 0.9% and TT 0.7%). No individual sites showed consistent long-term changes in DNA methylation in response to folic acid supplementation and withdrawal. However, specific CpG sites may be more susceptible to increased variability in methylation level in response to folic acid exposure; additional analysis and studies are ongoing. This work was supported by a collaborative CDC agreement and the GCRC Grant # MO1-RR00082.

Genomewide search for imprinting and maternal effects in eczema. *J. Esparza Gordillo[1,2], K. Rohde[2], A. Bauerfeind[2], H. Schulz[2], N. Hübner[2], Y.A. Lee[1,2].* 1) Ped Pneumology/Immunology, Charite Univ Med, Berlin, Germany; 2) Max-Delbrück-Centrum (MDC) for Molecular Medicine, Berlin-Buch, Germany.

Eczema is a frequent inflammatory skin disease with complex etiology. Epidemiological studies have shown that children of eczema-affected mothers have a higher risk to develop the disease than children of eczema-affected fathers. This parent-of-origin (POO) effect may be due to genomic imprinting, feto-maternal interaction during pregnancy/lactation (maternal effect), or to maternal inheritance of the mitochondrial genome. However, few studies have aimed to identify such effects in eczema. We aimed to detect POO effects in eczema by analyzing 270 complete nuclear families with eczema, from which genome-wide high-density array SNP data was available (Esparza-Gordillo et al. 2009). Interestingly, in these families the frequency of eczema is much higher in the mothers than in the fathers (32% versus 18%, respectively), supporting the existence of POO effects. We have analyzed the genotype data according to the method of Weinberg (Weinberg, 1999). This method classifies families by mating types regarding the number of alleles carried by the father, mother and sibs and carries out a logistic regression over strata of the mating types containing information on imprinting and maternal effects. The independent imprinting and maternal effects can then be identified by appropriate likelihood ratio tests. Importantly, our scan tends to identify genomic regions containing predicted or experimentally confirmed imprinted genes, supporting the validity of our approach ($P < 0.05$). Additionally, we have used gene expression arrays to quantify the total mRNA levels in peripheral blood mononuclear cells (PBMCs) from a subset of these families. We are currently applying the method of Belonogova et al. (2009) in order to detect POO effects at the expression level. This new and powerful method enables the detection of expression differences among reciprocal heterozygotes by applying a regression model which includes a main allelic effect and an imprinting effect. Based on the genome-wide scan for POO in eczema, we will select 100 SNPs for follow-up in a set of 1000 independent complete nuclear families with eczema. We will prioritize hits which simultaneously show an imprinted pattern on disease risk and on gene expression or those located in imprinted regions (http://igc.otago.ac.nz/home.html). This is the first study to date performing a genome-wide POO association analysis in eczema and will increase our knowledge on this very interesting aspect of the disease etiology.

1358/F

Quantification of Methylation Levels by Next-generation Sequencing. *G. Wu[1], N. Yi[1], D. Absher[2], D. Zhi[1].* 1) Biostatistics, University of alabama at Birmingham, Birmingham, AL; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL.

Recently, next-generation sequencing-based technologies enable DNA methylation profiling at high resolutions and at low costs. Methyl-Seq and Reduced Representation Bisulfite Sequencing (RRBS) are two such technologies allowing for interrogating methylation levels at CpG sites throughout the entire human genome. With rapid reduction of sequencing cost, these technologies would enable epigenotyping a large cohort for associating phenotypes and epigenetic changes in a near future. Existing methylation quantification methods typically make binary calls of methylated versus unmethylated. However, many biological samples are consisting of heterogeneous mixtures of cells with variable methylation levels, for which the desirable quantification is often to estimate the percent of DNA molecules being methylated at each CpG site, which is called beta values in methylation microarrays. Meanwhile, the count-based sequencing analysis has its own properties: first, due to the random sampling nature, the sequencing coverage is not uniform and the estimate of beta values has heterogeneous variances. Moreover, the methylation levels at nearby sites or the same sites in different tissue sample libraries are correlated. Finally, quantification shall account for technical biases. Therefore, it is in urgent need to understand the statistical issues related to the quantification of methylation levels for these emerging technologies, with the goal of developing an accurate quantification method. In this paper, we discuss two methods for Methyl-Seq quantification. The first method, Maximum Likelihood estimate, is both conceptually intuitive and computationally simple. However, this estimate is truncated at extreme methylation levels and does not provide variance estimation. The second method, based on Bayesian hierarchical models, allows for variance estimation of methylation levels, and provides a flexible framework to adjust technical biases in the sequencing process. We compare previously proposed binary method, Maximum Likelihood method, and Bayesian methods using both simulation and real Methyl-Seq data. Our results show that the Bayesian methods outperform competing methods, displaying higher correlations with microarray beta value and larger areas under ROC curves. In addition, we apply these quantification methods to simulation data and show that, with sequencing depth above 300, Methyl-Seq offers a more consistent quantification than microarrays.

An Information Resource to Support Epigenomics Research. *G. Schuler, R. Cohen, I. Fingerman, T. Hassan, S. Jiang, L. McDaniel, W. Ratzat, X. Zhang.* NCBI/NLM, NIH, Bethesda, MD.

Epigenomics is an emerging field of research aimed at understanding how—despite sharing a common genomic sequence—different cell types and lineages acquire distinct patterns of gene expression. The amount of data available from a few large-scale projects and many individual investigators has more than doubled in the past six months. We have developed an information resource on the NCBI website specifically aimed at highlighting epigenomics data (at www.ncbi.nlm.nih.gov/epigenomics). Epigenetic factors being examined include genomic DNA methylation, histone post-translational modifications, chromatin organization, and abundance of non-coding regulatory RNAs. Generally speaking, most experiments involve targeting specific regions of the genome using reagents like nucleases, methylation-sensitive restriction enzymes, and antibodies directed against methylcytosine or modified histones and then using either tiling arrays or massively-parallel sequencing for signal detection. Raw data from these experiments, together with extensive meta-data, are stored in the NCBI's GEO (Gene Expression Omnibus) and SRA (Sequence Read Archive) databases. The new Epigenomics resource provides a higher-level view, allowing users to search and browse the data based on biological attributes like cell type, differentiation stage, and health status, among many others. Data have been pre-mapped to genomic coordinates (to make "genome tracks"), so users are not required to be familiar with or manipulate the raw data. Tracks may be visualized in either the NCBI or UCSC genome viewers or may be downloaded to the user's computer for local analysis. Comparisons across tracks reveal loci that may play important biological roles and are candidates for further experimental study. At the time of this writing, the database includes 951 individual tracks derived from analysis of 260 biological samples (updates will be presented at the meeting).

Exclusion of the GNAS locus in PHP-Ib patients with broad GNAS methylation changes provides evidence for an autosomal recessive form of the disorder. *E. Fernandez-Rebollo[1], G. Perez de Nanclares[2], B. Lecumberri[3], S. Turan[4], E. Anda[5], G. Perez-Nanclares[6], D. Feig[7], S. Nik-Zainal[8], M. Bastepe[1], H. Jüppner[1,9].* 1) Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA; 2) Molecular Genetics Lab, Research Unit, Hospital de Txagorritxu, Vitoria-Gasteiz, Spain; 3) Endocrinology Service, Hospital La Paz, Madrid, Spain; 4) Department of Pediatric Endocrinology, Marmara University School of Medicine, Istanbul, Turkey; 5) Endocrinology Service, Hospital de Navarra, Navarra, Spain; 6) Endocrinology and Diabetes Research Group, Hospital de Cruces, Barakaldo, Spain; 7) Endocrinology and Metabolism, Mount Sinai Hospital and University of Toronto, Toronto, Ontario, CA; 8) Department of Medical Genetics, Addenbrooke's Hospital NHS Trust, Cambridge CB2 2QQ, United Kingdom; 9) Pediatric Nephrology Unit, Department of Pediatrics, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

Pseudohypoparathyroidism type Ib (PHP-Ib) is characterized by hypocalcemia and hyperphosphatemia due to PTH-resistance in the proximal renal tubules, which usually occurs in the absence of Albright's Hereditary Osteodystrophy. Most patients affected by autosomal dominant PHP-Ib (AD-PHP-Ib) carry maternally inherited microdeletions up-stream of GNAS (STX16del4-6 or STX16del2-4), which are associated with a loss of methylation restricted to GNAS exon A/B. Some AD-PHP-Ib patients carry microdeletions within GNAS (delNESP55/delAS3-4 or delAS3-4), which are associated with loss of all maternal methylation imprints. These latter epigenetic changes are often indistinguishable from those observed in patients affected by the sporadic form of PHP-Ib (sporPHP-Ib). We now investigated six females with PHP-Ib, who showed broad GNAS methylation changes and who were heterozygous for several microsatellite markers throughout the telomeric end of chromosome 20q, thus excluding a large deletion or partial paternal uniparental isodisomy (patUPD20) involving only small portions of the GNAS locus. The eleven children of these affected females are healthy and lack evidence for GNAS methylation changes. Furthermore, two of the sporadic PHP-Ib females had two and three children, respectively, who had inherited either the grandmaternal or the grandpaternal allele for the GNAS locus. These findings make it unlikely that the form of PHP-Ib that is present in our patients follows an autosomal dominant or an X-linked recessive trait. Instead, it appears plausible that the disorder in these cases is caused by a homozygous or compound heterozygous mutations in a gene involved in the establishment or maintenance of GNAS methylation.

Homologous pairing of chromosome 15q11-q13 is associated with significant disruption of gene expression in human maternal chromosome 15 microcell transferred neurons. *S. Horike[1], K.N. Leung[2], D.H. Yasui[2], M. Oshimura[3], J.M. LaSalle[2], M. Meguro-Horike[4,5].* 1) Frontier Science Organization, Kanazawa University, Kanazawa, Ishikawa, Japan; 2) Medical Microbiology and Immunology, School of Medicine, University of California, Davis, USA; 3) Department of Biomedical Science, Institute of Regenerative Medicine and Biofunction, Tottori University, Yonago, Tottori, Japan; 4) Advanced Science Research Center, Kanazawa University, Kanazawa, Ishikawa, Japan; 5) JSPS Research Fellow.

Autism is a common neurodevelopmental disorder characterized by abnormalities in social, communicative, and behavioral functioning. Although the etiology of autism remains largely unknown, cytogenetic and genetic studies have suggested that autism may be influenced by genomic imprinting of 15q11-q13, through maternal copy number gains of 15q11-q13 occurring in 1-3% of autism cases. In this study, we focused on the homologous pairing of 15q11-q13 in human neuronal cells. Homologous pairing of 15q11-q13 was previously observed to be deficient in Rett Syndrome (RTT), Angelmann Syndrome (AS), and autism brain (Thatcher *et al*, 2005), and altered in maternal 15 q duplication (idic15) brain (Hogart *et al*, 2009). Our aim is to understand how the homologous pairing of 15q11-q13 is organized in the mammalian brain and associated with gene expression within the paired regions. Therefore, we investigated the impact of an extra human chromosome 15 on normal maternal to paternal 15q11-q13 interactions in a cell culture model. In this study, to model 15q11-q13 maternal duplication in a neuronal cell line, a paternal or maternal copy of human chromosome 15 was transferred into the human SH-SY5Y neuronal cells by microcell fusion. Then, FISH analysis was performed using probes to *SNRPN* and *GABRB3* to compare how the homologous alleles of 15q11-q13 are organized in human neuronal cells with a paternal or maternal copy of human chromosome 15. SH-SY5Y cells show an increase in the percentage of 15q11-q13 paired alleles following induced differentiation with 16 nM PMA. In contrast, homologous pairing of 15q11-q13 was disrupted in human neuronal cells with an extra maternal copy of human chromosome 15. Moreover, gene expression analysis of 15q11-q13 transcripts demonstrated significantly decreased expression of *SNRPN*, *GABRB3*, *CHRNA7* transcripts despite increased maternal dosage. Thus, our study revealed that gene expression can be altered in unexpected ways through epigenetic changes resulting from increased maternal 15q11-13 dosage, similar to what has been previously observed in a human brain sample with maternal 15q duplication and disrupted homologous pairing. Molecular investigation of gene expression in our autism model cells with an extra copy of 15q11-q13 provides insight into the potential complexities of other copy number variations in autism.

1362/F

Development of an ICON-probe based rapid diagnostic assay for imprinted diseases. *T. Kubota[1,2], S. Ishida[1], K. Miyake[1], T. Nakane[2], S. Saitoh[3], T. Hirasawa[1].* 1) Fac Med, Epigenetic Med, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Cntr for Genet Med, Univ Yamanashi Hospital, Chuo, Yamanashi, Japan; 3) Dept Pediatrics, Hokkaido Univ, Sapporo, Hokkaido, Japan.

Methylation-specific PCR (MSP) assay, which distinguishes the maternal allele from the paternal allele based on DNA methylation, is currently used to make a diagnosis of imprinted Prader-Willi (PWS) and Angelman (AS) syndromes. Recently, ICON (Interstrand Complex with Osmium for Nucleic acids) probe has been developed, which can crosslink to a methylated CpG in a unique sequence, and the osmium-DNA complexation inhibits subsequent PCR reaction. Taking advantage of use of this principle, we developed a new diagnostic assay for imprinted diseases.

We treated genomic DNA from three control individuals and two AS patients (in those DNA methylation pattern had been confirmed by MSP assay) with ICON probes designed either within the promoter region (ICON1) or within the downstream region of exon 1 (ICON2) of *SNRPN* gene. The treated samples were amplified using two primer pairs (SN-1, SN-2), which encompass the probe regions, respectively, and a control primer pair (LIS) within the *LIS1* gene region, using real-time PCR.

As a result, PCR amplification efficiency with ICON1 at the target region (SN-1) and that with ICON2 at the target region (SN-2) were lower in the controls (50% methylation) compared with AS patients (0% methylation) [ICON1: control 89±15%, AS 189±93%; ICON2: control 77±13%, AS 127±62%], whereas PCR amplification efficiency with ICON1 at the non-target regions (SN-2, LIS1) and those with ICON2 at the non-target regions (SN-1, LIS1) were not different between controls and AS patients.

These results suggest that crosslink of ICON probes to the *SNRPN* methylated allele inhibit PCR reaction in controls, indicating that ICON-based assay can distinguishes between the methylated allele and the unmethylated allele of *SNRPN*, which will be used for diagnosis of AS. Since this assay is faster than the conventional MSP assay because it does not include tedious bisulfite-treatment step, it potentially become one of the simplest method to screen CpG methylation in various research samples. We are currently improving the sensitivity of the assay in order to distinguish between controls (50% methylation) and PWS patients (100% methylation) at the *SNRPN* locus.

Search for epimutations at differentially methylated regions in abnormal pregnancy. *K. Nakabayashi, Y. Yamaguchi, H. Torisu, N. Sugahara, M. Kusumi, K. Hata.* Dept Maternal-Fetal Biol, Natl. Res. Inst. for Child Health and Development, Setagaya, Tokyo, Japan.

Genomic imprinting, an epigenetic phenomenon whereby genes are differentially expressed according to their parental origin, is known to be crucial for placental development and fetal growth in mammals. Most imprinted loci contain a differentially methylated region (DMR) harboring allelic DNA methylation inherited from the male or the female gamete (germline DMR). Mutations/epimutations affecting DMRs cause rare imprinting disorders such as Silver-Russell syndrome (SRS) and Beckwith-Wiedemann syndrome (BWS). Whether imprinted genes also play critical roles in the more common abnormal pregnancy cases such as preeclampsia and intrauterine growth restriction (IUGR) is an important question yet to be fully evaluated. With the aim of addressing this question, we established quantitative COBRA (Combined Bisulfite Restriction Analysis) assay conditions for 30 DMRs from 22 loci that include the majority of known human imprinted DMRs. Using this COBRA assay system, we initially measured DNA methylation levels at these 30 DMRs in twenty blood samples from healthy individuals and twenty placental tissues from normal pregnancies, and determined the extent of tissue specificity and individual varieties of methylation levels. Subsequently, we have screened for epimutations at these DMRs in the placental tissues from approximately 100 IUGR cases. In two cases, among the DMRs examined, only H19- and IGF2-DMRs were found to be hypomethylated compared to the normal controls. Several other cases showed hyper- or hypo-methylation at the DMRs other than those in the H19/IGF2 locus, and are being further characterized. The genetic etiologies of IUGR are largely unknown and considered to be diverse. Our results suggest that placental epimutation at DMRs may account for the growth restriction phenotype of a subset of IUGR cases.

Genetic characterization of the murine Angelman syndrome imprinting center. *E.Y. Smith[1], C.R. Futtner[2], S.J. Chamberlain[3], A.J. DuBose[1], R.A. Hallett[1], J.R. Resnick[1].* 1) Dept of Molecular Genetics & Microbiology, University of Florida, Gainesville, FL; 2) Duke University, Durham, NC; 3) Dept of Genetics and Developmental Biology, University of Connecticut, Farmington, CT.

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are distinct neurological disorders resulting from improper gene expression from the imprinted domain on chromosome 15q11-q13, the PWS/AS locus. This locus is controlled by a bipartite imprinting center consisting of the PWS-IC and the AS-IC. Evidence suggests that the PWS-IC functions as a positive element to activate gene expression from the paternal allele. The AS-IC functions in the oocyte to inactivate the PWS-IC and thus silence the paternally expressed genes on the future maternal allele. The PWS-IC is located within a region of 4.3 kb just 5' to and including exon one of *SNRPN*. The AS-IC is contained within 0.88 kb, 35 kb upstream of *SNRPN*. Importantly, the AS-IC includes two of several *SNRPN* alternative upstream exons.

The PWS/AS locus is well conserved in the mouse but a murine AS-IC remains uncharacterized. As in humans, the mouse *Snrpn* locus includes several upstream exons postulated to function in silencing the maternal allele. We have taken a transgenic approach to study the potential regulatory role of these alternative exons. To do so, we utilized the bacterial artificial chromosome (BAC) 425D18, which contains *Snrpn* and approximately 120 kb of 5'sequence in which three alternative upstream exons reside. We first confirmed that this BAC transgene displayed proper imprinted expression in multiple transgenic lines thus demonstrating the presence of a functional AS-IC. Imprinting was further examined by analysis of the epigenetic status of the *Snrpn* differentially methylated region (DMR), which lies within the PWS-IC.

To determine whether the upstream exons on the 425D18 BAC confer silencing upon maternal transmission, we used recombineering techniques to create targeted deletions of these exons. Deletion of the three upstream exons resulted in robust *Snrpn* expression upon both maternal and paternal transmission of the transgene as well as a loss of the epigenetic imprint at the *Snrpn* DMR. These results indicate that the three upstream exons comprise the AS-IC on the 425D18 BAC. The discovery of the murine AS-IC in our transgenic model system has led to novel approaches for studying imprinting mechanisms at the PWS/AS locus.

Monoallelic expression of NLRP7 and NLRP2: implications for autosomal recessive phenotypes resulting from mutations in imprinted maternal effect genes. *S. Wen[1, 2], M. McCarthy[1], X. Wang[1, 2], W. Liu[1, 2], C. Goodrich[3], I. Van den Veyver[1, 2].* 1) OB-GYN, Baylor College of Medicine, Houston, TX; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Rice University, Houston TX.

Objectives: Women with autosomal recessive mutations in NLRP7 in 19q13.42 have recurrent biparental hydatidiform moles with loss of DNA methylation at various paternally methylated imprinting control regions (ICRS). Women with autosomal recessive mutations in the neighboring and highly homologous NLRP2 gene have offspring with Beckwith-Wiedemann syndrome due to loss of imprinted DNA methylation at ICR2 in 11p15. A recent genome-wide screen suggested that NLRP2 is an imprinted gene itself. The goals of this study were to confirm mono-allelic expression and imprinting of NLRP2, determine if NLRP7 is monoallelically expressed and imprinted, and to describe models that explain how mutations in an imprinted gene can result in autosomal recessive inherited disorders. Methods: We designed primers for amplification of expressed single nucleotide polymorphisms (SNPs) in coding exons of NLRP2 and NLRP7 with a high frequency of heterozygosity. We then performed PCR amplification followed by direct sequencing of amplicons of genomic DNA from four human cell lines (HeLa, PA-1, BeWo, HEK293T) to find heterozygous SNPs. RNA was prepared and RT-PCR performed for all heterozygous SNPs. Results: Heterozygosity for several SNPs was confirmed in HeLa and PA-1 cell lines, but not in the BeWo and HEK293T cells. RT-PCR and sequence analysis of SNPs rs269950, rs269951, rs775883 was consistent with monoallelic expression of NLRP7 in the HeLa and PA-1 cell lines. Similar analysis of SNP rs1043680 and a novel coding SNP were identified, confirmed monoallelic expression of NLRP2 in the HeLa cell line, but not in the PA-1 cell line. Conclusion: Although our findings of mono-allelic expression do not yet confirm that NLRP2 and NLRP7 are imprinted genes, they are highly suggestive considering prior reported data on NLRP2. Experiments to determine the parental origin of the expressed alleles in human cell lines for which parental genotypes can be determined and in hybrid mouse crosses are ongoing. We propose a model that implicates (1)expression during the time of general erasure of imprinting marks in primordial germ cells and (2)persistence of the gene product in haploid gametes to explain the autosomal recessive inheritance, as opposed to the expected imprinted inheritance of disorders caused by mutations in imprinted maternal effect genes. Our data also raise the possibility that we have identified a novel imprinted gene cluster that contains at least two imprinted genes.

1366/F

Identification of novel germline DMRs by CpG island methylation profiling of Dnmt3L$^{mat-/-}$ embryos. *W. Yoshida, S. Sato, C. Tayama, M. Kusumi, K. Hata, K. Nakabayashi.* Dept. of Maternal-Fetal Biol., Natl. Res. Inst. for Child Health and Development, Setagaya, Tokyo, Japan.

Genomic imprinting, an epigenetic phenomenon whereby genes are differentially expressed according to their parental origin, is known to be crucial for placental development and fetal growth in mammals. Most imprinted loci contain a differentially methylated region (DMR) harboring allelic DNA methylation inherited from the male or the female gamete (germline DMR). Several germline DMRs have been shown to govern imprinted gene expression as a cis-acting imprinting-control region (ICR). *Dnmt3L*, a *Dnmt3* methyltransferase family member lacking a functional methyltransferase domain, is shown to be essential for the establishment of DNA methylation at DMRs during the maturation of germ cells. Mouse embryos produced from *Dnmt3L*$^{-/-}$ females arrest in development by embryonic day 10.5, and completely lack maternal methylation at germline DMRs. As an approach to identify novel DMRs, we obtained DNA methylation profiles for 16,000 CpG islands of these mutant and wild-type embryos (day 9.5) using the methylated-DNA immunoprecipitation (MeDIP) technique followed by array hybridization. Comparison of the mutant/wild-type profiles allowed us to detect decreased levels of methylation at 16 known maternally methylated DMRs as well as 17 novel candidates. Bisulfite sequencing analyses of oocyte and sperm for the top six candidates have revealed that three of them are germline DMRs that are methylated in oocyte but unmethylated in sperm, and that two of them are secondary DMRs, whose differential methylation status is established post-zygotically. One of the newly identified germline DMR was located approximately 180 kb away from the cluster of imprinted genes, *Xlr3b*, *Xlr4b*, and *Xlr4c* on the chromosome X. Since this is the first DMR mapped in the vicinity of these genes, it represents a primary candidate for the ICR of this imprinted chromosomal domain. To determine if the other newly identified DMRs are involved in the regulation of imprinted gene expression, allelic expression analysis is being conducted for the genes located close to the DMRs.

Domain-wide tissue-specific differences in DNA methylation levels from Methyl-seq analyses. *D.I. Schroeder, D.H. Yasui, W.T. Powell, R. Woods, S.W. Chadwick, J.M. LaSalle.* Medical Microbiology and Immunology, UC Davis, Davis, CA.

In mammals, DNA methylation at CpG sites (mC) has traditionally been considered a repressive mark in the genome, as high DNA methylation in intergenic sequences and repetitive elements prevents spurious transcription while lack of DNA methylation in promoters and CpG islands promotes gene transcription. Surprisingly, though, recent genome-wide DNA methylation sequencing (Methyl-seq) analyses have shown that high CpG methylation is common in gene bodies where it positively correlates with transcription. Gene bodies contained in partially methylated domains (PMDs, genomic sequences with less than 70% average methylation over several hundred thousand bases) showed decreased expression compared to those contained in highly methylated domains (HMDs). We sought to better understand the role of PMDs in gene regulation, particularly in neurons, by comparing published Methyl-seq data from lung fibroblasts with new data from human neuroblastoma cells (SH-SY5Y). SH-SY5Y DNA was bisulfite converted, Solexa sequenced, and the reads mapped to the genome. Many PMDs were tissue-specific, with neuronal HMDs (N-HMDs, domains that were HMDs in neuronal cells but PMDs in lung cells) enriched for genes involved in neurogenesis, synaptogenesis, cell adhesion, and synaptic signaling. Lung HMDs (L-HMDs) were enriched for genes involved in lung development and immune response. Affymetrix gene expression data from the two cell lines confirmed that N-HMD genes are enriched for genes with neuronal-specific expression and L-HMD genes are enriched for lung fibroblast-specific expression. In addition, individual CpG sites outside of CpG islands were more consistently methylated in N-HMDs compared to those in PMDs. These data suggests that, at least in human cell lines, partially methylated domains encompass clusters of genes repressed in a tissue-specific manner, while highly maintained methylated CpG sites are found within and around a subset of actively expressed tissue-specific genes. Analyses of postmortem human tissues by these approaches and the examination of differential modifications of methylcytosine and hydroxymethylcytosine are in progress.

Association between Parental Age and DNA Methylation Patterns in Newborn Umbilical Cord Blood. *R. Adkins[1], F. Tylavsky[2], J. Krushkal[2].* 1) Le Bonheur Child Med Ctr, Univ Tennessee-Hlth Sci Ctr, Memphis, TN; 2) Department of Preventive Medicine, Univ TN Health Sci Center, Memphis, TN.

In recent years, industrialized nations have witnessed a dramatic increase in the average age of women giving birth. While epidemiological and clinical genetic studies show an increased incidence of pregnancy complications, chromosomal abnormalities, and certain disorders such as cancer and neurocognitive diseases in the offspring of older parents, the molecular mechanisms of this increase are yet to be fully understood. Decreases in the levels of DNA methylation in adult tissues with age in a tissue-dependent manner have been well documented. However, much less is known about the influence of parental age on levels and patterns of DNA methylation in the offspring. We investigated the influence of parental age on neonatal genome-wide DNA methylation patterns. The patterns of methylation in umbilical cord blood were assayed at 27,578 CpG sites genome-wide in 168 newborns and related to numerous parental and newborn characteristics, including parental age. We observed a generally negative genome-wide correlation between parental age and leukocytic DNA methylation of autosomal probes in the newborn. Methylation of 144 CpG probes belonging to 142 genes was significantly correlated with maternal age at the genome-wide level. A correlation with paternal age was also present, but was weaker than that with maternal age. The products of many genes whose methylation levels were decreased in children of older mothers are involved in mesodermal development, neurological regulation, glucose/carbohydrate metabolism, nucleocytoplasmic transport, and transcriptional regulation. Many of the hypomethylated genes and probes were found to be involved in processes related to cancer development, and therefore changes in their methylation may be predisposing the newborn to increased cancer risk, in agreement with previous epidemiological observations. While age-related changes in DNA methylation in adults have been documented previously, we believe this is the first demonstration of an effect of parental age on DNA methylation patterns in the next generation at birth.

Pediatric age-related DNA methylation changes. *R.S. Alisch, B. Barwick, B. Lynch, J.O. Mowrey, S.T. Warren.* Dept Human Gen, Emory Univ Sch Med, Atlanta, GA.

It is widely accepted that there are age specific DNA methylation (DNAm) changes and that they may contribute to human disease, including cancer. Previous studies have identified age-related differentially methylated loci (DML) in adults, suggesting that age-related DNAm changes manifest later in life, and epigenetic studies targeting pediatric cohorts might be less susceptible to this confounding factor. Here, we use a high-throughput approach to characterize the methylation status of 27,578 CpG loci in whole blood-extracted DNA from 281 children aged 4-17 years, and find DNAm changes associated with age. These pediatric DML significantly overlap with age-related DML identified in adults ($p<1x10-15$), suggesting that age-related methylation changes occur not only throughout adulthood but also earlier in life. These pediatric DML also significantly overlap with DML previously implicated in adult diseases such as systemic lupus erythematosus ($p<0.05$), indicating that many of these DML may be confounders and not associated with disease. Together, these findings corroborate previous studies by identifying loci with age-dependent methylation status in both pediatric and adult subjects and call for consideration of age as a covariate in methylation studies regardless of cohort age.

Epigenetic Alterations In Radiation Induced Genomic Instability. *U. Aypar[1], W.F. Morgan[2], J.E. Baulch[1].* 1) Department of Radiation Oncology, University of Maryland School of Medicine, Baltimore, MD; 2) Biological Sciences Division, Pacific Northwest National Laboratory, Richland, WA.

Radiation-induced genomic instability (RIGI), results in an increased frequency of genetic alterations in the progeny of irradiated cells. RIGI is thought to be an early event in radiation-induced carcinogenesis, but it is unknown how this process is initiated. Epigenetic changes including aberrant DNA methylation and altered microRNA expression can be induced by radiation exposure and have been associated with some cancers. We are testing the hypothesis that irradiation results in epigenetic alterations that are perpetuated in clones with RIGI. The human-Chinese hamster ovary hybrid cell line GM10115 was irradiated using iron ions or x-rays and clones were obtained. Irradiation induced DNA damage in GM10115 cells and RIGI in clones (114, 118, CS9, LS12, 115, Fe5.0-8) was determined using micronucleus formation and fluorescence in situ hybridization analysis of chromosomal rearrangements. To study epigenetic changes, the post-irradiation status of genome-wide, repeat element, specific locus methylation, and microRNA profiles were evaluated. Arbitrary priming methylation sensitive PCR is being used to identify changes in methylation at random sites within the genome and combined bisulfite restriction analysis (COBRA) is being used to identify changes in methylation at LINE-1 and alu repeat elements. Methylation sensitive specific locus methylation assays and bisulfite sequencing is being used to detect aberrant promoter methylation for genes of interest. Preliminary data indicate that early effects of radiation exposure include aberrant genome-wide, repeat element methylation (LINE-1, alu) and alterations in some microRNAs. The genomically unstable clones also exhibited aberrant DNA methylation as well as altered microRNA profiles. Specifically, in unstable clones we observed global hypomethylation, hypermethylation of LINE-1 and hypomethylation of alu. Altered microRNA profiles were observed in unstable clones when compared to stable clones and the parental cell line. The array results are being validated with qRT-PCR and mRNA targets of the altered miRNAs will be determined based on mRNA arrays. These results suggest that the early effects of radiation exposure include alterations in epigenetic endpoints. Delayed effects include perpetuation of RIGI that appears to be associated with aberrant repeat element and global DNA methylation, and altered microRNA profiles.

High-resolution DNA methylation profiles in monozygotic twins. *J.T. Bell[1,2], G.J. Brock[3], B. Zhang[3], C.L. Hyde[3], J.M. Harris[1], R. McEwen[4], B. Dougherty[3], S. Phillips[4], F.M.K. Williams[1], W. Jun[5], G. Burgess[4], S. John[3], T. Spector[1].* 1) Department of Twin Research and Genetic Epidemiology, Kings' College London, London, UK; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 3) Pfizer Global Research & Development, Groton, CT, USA; 4) Pfizer Global Research and Development, Sandwich Laboratories, Sandwich, UK; 5) Beijing Genomics Institute (BGI), Chinese Academy of Sciences (CAS), Beijing, China.

DNA methylation is an important epigenetic mechanism involved in gene regulation and disease. Recently, studies of discordant monozygotic (MZ) twins have identified epigenetic changes as susceptibility factors in complex traits. We examined DNA methylation profiles in twenty-five MZ pairs of twins discordant for objective pain sensitivity, determined experimentally via heat-induced pain. DNA methylation was assayed in whole blood samples using a high-resolution MeDIP-sequencing (MeDIP-seq) approach. Following MeDIP, sequencing data were generated using the Illumina GAII platform, resulting in over 25 million paired-end reads per lane using 2 lanes per individual for a total of 100 lanes. Preliminary analyses using stringent alignment criteria indicate that MeDIP-seq fragment coverage was over approximately 819 Mb (26.6%) of an individual's genome, not accounting for repeats or CpG content. We examine the distribution of DNA methylation patterns genome-wide, comparing MeDIP-seq results to functional sequence annotations. To determine the effect of DNA methylation on pain sensitivity, we first assess power to detect differentially methylated regions (DMRs) that contribute to pain sensitivity differences. We then evaluate the role that epigenetic mechanisms play in sensitivity to pain by calculating DMRs using two complementary approaches testing for associations between epigenetic and phenotypic variation. Our findings have implications for epigenetic studies of phenotypically discordant MZ twins that may provide a powerful tool for identifying genomic regions that contribute to complex traits.

1372/F

High Density DNA Methylation BeadChip with Single CpG Site Resolution. *M. Bibikova, B. Barnes, C. Tsan, V. Ho, B. Klotzle, J. Le, D. Delano, R. McCauley, K. Gunderson, J.-B. Fan, R. Shen.* Dept Research & Dev, Illumina, Inc, San Diego, CA.

DNA methylation is one of the best known epigenetic modifications in human cells. Changes in DNA methylation patterns play a critical role in development, differentiation and diseases such as multiple sclerosis, diabetes, schizophrenia, aging, and multiple forms of cancer. We developed a new generation of genome-wide DNA methylation BeadChip which allows high-throughput methylation profiling of human genome. The new high density BeadChip will assay over 450K CpG sites. The innovative content includes coverage of 96% of RefSeq genes with multiple probes per gene, 95% of CpG islands from the UCSC database, CpG island shores and additional content selected from whole-genome bisulfite sequencing data. The well-characterized Infinium® Assay is used for analysis of CpG methylation using bisulfite-converted genomic DNA. In this assay, unmethylated cytosines (C) are converted to uracil (U) when treated with bisulfite, while methylated cytosines remain unchanged. The assay design employs single probe assays for CpG loci with up to two underlying CpG dinucleotides, and two-probe assays for CpG loci with multiple underlying CpG sites, with one probe querying the "unmethylated" allele and the other probe querying the "methylated" allele. The assays are designed under the assumption that methylation is regionally correlated (within 50 base pairs) and that all CpG sites underlying the probe are assumed to be "in phase" with the queried CpG site. For the BeadChip development, we used methylation standards created by de-methylating gDNA with Phi29 whole genome amplification, methylating the amplified DNA with SssI methylase and mixing the unmethylated and methylated DNA in a 1:1 ratio to create a 50% methylation state. 500 ng gDNA input is used for bisulfite conversion and is sufficient for two assays. Reproducible DNA methylation profiles were obtained between replicates (an average R^2 of 0.98). We applied this technology to DNA methylation analyses in normal DNA samples derived from multiple tissues and cancer cell lines of different tissue origin. Highly specific methylation signatures were obtained for each sample type. The ability to determine genome-wide methylation patterns will rapidly advance methylation research and ultimately lead to the development of powerful tools for diagnosis, prognosis, and treatment of human diseases.

In-vitro embryo culture results in widespread alterations in preimplantation mouse blastocysts. *S. Brown[1], G. Brown[2], L. Brown[1].* 1) Dept OB/GYN, Univ Vermont, Burlington, VT; 2) Pathology Department, Memorial Hospital, Jasper, IN.

Super-ovulation and in-*vitro* embryo culture have been reported to result in altered genomic methylation, both at the blastocyst stage as well as in fully developed offspring. Most reports have focused on specific loci and most have reported that embryo manipulation is associated with hypomethylation. Given the public health importance of assisted reproductive technology (ART), it is important to increase our understanding of the alterations in genomic methylation caused by ART techniques. To this end, we have previously developed and validated a method for large-scale methylation analysis, based on methylation-sensitive DNA amplification followed by microarray assessment (ClinChem 2010). The method allows the simultaneous assessment of ~16,000 randomly chosen genomic loci.

In the present study, we have applied our method to the study of a series of preimplantation mouse blastocysts that were either flushed from the oviduct and cultured in-*vitro* beginning at 0.5 (E0.5) days post conception (experimental group) or were recovered from the uterus at E3.5 of normal gestation (control group). All embryos were normal in appearance and all had reached the blastocyst stage of development. Genomic DNA was prepared and subjected to methylation-sensitive amplification and then assessed by hybridization to a custom-designed microarray. Each hybridization was performed twice, with dye reversal, and resulting data were normalized by averaging the dye-reversed data. Non-methylated prokaryotic DNA was "spiked-in" to each experiment as a means of assessing data quality and normalization.

We found that genomic methylation was strikingly similar among control embryos, with pair-wise correlation coefficients of ~.95. Methylation in the experimental embryos was more variable, with pair-wise correlations of ~.65. Comparisons between experimental and control embryos showed that, in all cases, there was evidence of marked hypermethylation at the majority of loci in the in-vitro cultured embryos. The specific loci showing hypomethylation in the experimental embryos appeared to be non-random, suggesting that the impact of embryo culture on genomic methylation is variable and depends on genomic location. Future studies will be directed at understanding how in-*vitro* embryo culture results in these effects.

1374/F

DNA Methylation of the Oxytocin Receptor (OXTR) in Autism Spectrum Disorder (ASD). *D.T. Butcher[1], D. Grafodatskaya[1], R. Zhang[1], C. Zhou[1], S.W. Scherer[2], W. Roberts[3], E. Anagnostou[4], R. Weksberg[1].* 1) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Canada; 3) Autism Research Unit, The The Hospital for Sick Children, Toronto, Canada; 4) Bloorview Research Institute, Toronto, Canada.

Epigenetics refers to alterations of genome function that are heritable through cell division but unrelated to changes in the primary DNA nucleotide sequence. Multiple epigenetic mechanisms that are essential for normal growth and development work in concert to regulate gene expression including, DNA methylation, non-coding RNAs, covalent modifications of histone proteins, and chromatin conformation. The study will focus on alterations in DNA methylation patterns. Autism spectrum disorders (ASD) are a group of childhood onset neurodevelopmental disorders characterized by problems in social interaction and communication as well as repetitive behaviours. The prevalence of ASD is estimated to be 1 in 110 with a male to female ratio of 4:1. Studies in children with autism have demonstrated lower levels of oxytocin (OXT) in the blood compared to normally developing, age-matched children. Previously in a small study increased DNA methylation of the oxytocin receptor (OXTR) has been demonstrated in lymphocytes of patients with autism. These changes were also demonstrated in post-mortem samples from the temporal cortex of autism patients. It has been suggested that dysfunction of the OXT pathway is associated with features of autism such as repetitive behaviour and impaired social cognition. Treatment of patients with ASD with OXT to ameliorate these behaviours has been proposed. We hypothesized that increased DNA methylation of the CpG island in the 5' UTR of oxytocin receptor (OXTR) could be a modulator of response to oxytocin (OXT) treatment. To determine the clinical significance of this DNA methylation variation, we undertook a methylation analysis of OXTR in a large OXT-naive cohort. Using quantitative sodium bisulfite pyrosequencing a number of CpG sites in the 5'-UTR CpG island of OXTR were analyzed which revealed a statistically significant increase in DNA methylation in the blood of males with ASD. We are currently correlating these DNA methylation patterns to a battery of clinical measures including, social cognition and repetitive behaviours, which have been collected for these patients. DNA methylation of OXTR could be an important modulator of response to oxytocin (OXT) treatment in which case the methylation pattern of OXTR could be a useful tool in determining the appropriateness of OXT treatment trials for individual patients.

UVB radiation induces epigenetic modification in retinal pigment epithelial cells. *W. Chou[1,2], K. Chen[1,2], Y. Wang[1,2], S. Juo[1,2].* 1) Departments of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 2) Department of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan.

Purpose: Environmental factors are known to alter the fundamental epigenetic programming of the human genome. Ultraviolet (UV) radiation can damage ocular tissues and have phototoxic effects on the retina. The age-related macular degeneration (AMD) is caused by an increases in apoptotic cells in the RPE compared with normal retinas. SIRT1 has been found to function as a deacetylase for numerous protein targets involved in various cellular pathways, including stress responses and apoptosis. However, the role of SIRT1 in UV induces epigenetic modification remains unknown. The purpose of the study was to determine whether the UVB radiation induce alterations in human retinal pigment epithelium (RPE) cells by apoptosis and epigenetic regulation. Therefore, this study may gain more insight to AMD. Methods: ARPE-19 Cells (human retinal pigment epithelium cells) were exposed to different doses of UVB (0-75 mJ/cm2). Cells were incubated for 24 hours, and cell number was measured with trypan blue exclusion assay. Apoptosis and global DNA methylation were detected by flow cytometry. The mRNA expression of the SIRT1 gene (normalized to GAPDH gene) was detected by quantitative real-time PCR. Results: We found UVB radiation dose-dependently decreased cell viability and increased apoptosis in ARPE-19 cells. UVB radiation induced significant alterations in global methylation signatures of DNA in ARPE-19 cells. UVB down-regulated the SIRT1 gene expression in ARPE-19 cells. Furthermore, 5-aza-2'-deoxycytidine (AZA), an demethylating agent of hypermethylated DNA, could increase the mRNA expression of SIRT1 in ARPE-19 cells. But AZA only partly increase UVB-induced down-regulation of SIRT1 mRNA. Conclusions: We have demonstrated a regulation of DNA methylation under UVB exposure in the human RPE. Our results showed that epigenetic modification can regulate the SIRT1 gene expression of RPE cells. We are currently studying other genes that are also influenced by the epigenetic modification caused by UVB. Our studies suggest a new mechanism for UVB-induced AMD.

Identification of early diagnostic markers for prostate cancer using the epigenome-wide screening of plasma circulating DNA. *R. Cortese[1], P. Boutros[2], A. Kwan[1], O. Bryzgunova[3], A. Bondar[3], M. Park[1], S. Jarmalaite[4], A. Laurinavicius[5], Z. Kaminsky[1], P. Laktionov[3], A. Petronis[1].* 1) The Krembil Family Epigenetics Laboratory, Centre of Addictions and Mental Health, Toronto, Ontario, Canada; 2) Informatics and Biocomputing Platform, Ontario Institute for Cancer Research. MaRS Centre, South Tower. 101 College Street, Suite 800. M5G0A3. Toronto, ON Canada; 3) Institute of Chemical Biology and Fundamental Medicine, SD RAS, Lavrentiev Ave. 8, Novosibirsk, 630090, Russia; 4) Department of Botany and Genetics. Faculty of Natural Sciences. Vilnius University, Ciurlionio 21. LT-03101 Vilnius. Lithuania; 5) National Center of Pathology, Baublio 5, Vilnius 2600, Lithuania.

Tumor-specific DNA methylation changes can be detected not only in malignant cells, but also in the cell-free circulating DNA (cirDNA) in blood and other bodily fluids of cancer patients. Aberrant DNA methylation identified in early stages of cancer can be used as a biomarker for early detection. We performed a large-scale microarray-based analysis of the cirDNA methylome of prostate cancer (CaP) and benign prostate hyperplasia (BPH) patients, as well as unaffected controls. To achieve this, we first developed a protocol for large-scale methylome analysis of cirDNA. Universal DNA adaptors were ligated to the ends of cirDNA fragments, followed by digestion with DNA methylation-sensitive and -specific restriction enzymes. cirDNA fragments that survived enzymatic hydrolysis were amplified by adaptor-mediated PCR and labeled with biotinylated nucleotides. This enriched differentially methylated DNA fraction was hybridized to commercially available microarrays containing 12,000 CpG islands. Following extensive quality control and data normalization, univariate multiple-testing adjusted statistical analyses were used to identify specific loci exhibiting differential methylation between cases and controls. As a proof of principle, we have identified DNA methylation profiles in cirDNA of 20 prostate cancer patients, 20 benign prostate hyperplasia patients, and 20 unaffected control individuals. We selected a profile of seven DNA regions showing significant disease-specific differences in cirDNA methylation. These novel candidates were verified using sodium bisulfite treatment-based mapping of methylated cytosines. First, the whole bisulfite-treated cirDNA was amplified using a random-primer based strategy. The genes and loci of interest were further amplified using specific primers that bind to the bisulfite-converted DNA, and analyzed by pyrosequencing. Tumor-specific DNA methylation markers in cirDNA can potentially serve as non-invasive biomarkers for early diagnostics of cancer, monitoring the efficacy of anti-cancer therapies, and tumor reoccurrence.

Methylomic profiling in monozygotic twins discordant for major psychosis. *E.L. Dempster, R. Pidsley, L. Schalkwyk, T. Toulopoulou, M. Picchioni, E. Kravariti, R. Murray, J. Mill.* Institute of Psychiatry, King's College London, London, United Kingdom.

Studies of major psychosis (schizophrenia and bipolar disorder) have focused primarily on the interplay between genetic and environmental risk factors although recent research implicates a role for epigenetic processes in mediating susceptibility. Because monozygotic (MZ) twins share a common DNA sequence, the study of discordant twins represents an ideal design for investigating the contribution of epigenetic factors to disease etiology. We performed genome-wide methylomic profiling on peripheral blood DNA samples obtained from a unique set of MZ twin-pairs discordant for major psychosis (n=25 twin-pairs, 50 individuals) using the Illumina Infinium 27K Methylation array. Numerous loci demonstrated FDR-significant disease-associated DNA methylation different between twins for both schizophrenia and bipolar disorder, with a combined major psychosis group showing even strong epigenetic differences. Significant within twin-pair DNA methylation differences were independently quantified using the Sequenom EpiTYPER system and/or Pyrosequencing, and also assessed in post-mortem brain tissue from affected individuals and controls. Overall, our data provide further evidence to support a role for DNA methylation differences in the etiology of major psychosis.

The level of DNA methylation may regulate the activity of CpG poor promoter of the *OTC* gene. *L. Dvorakova[1], J. Minks[2], M. Hnizdova Bouckova[1], H. Treslova[1], G. Storkanova[1], H. Vlaskova[1], L. Stolnaya[1], M. Jirsa[3], M. Hrebicek[1].* 1) Inst Inherit Metabol Disorders, Charles Univ, First F Med, Prague 2, Czech Republic; 2) Dept. of Medical Genetics, Faculty of Medicine, University of British Columbia, Vancouver B.C., Canada; 3) Laboratory of Experimental Hepatology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

Ornithine carbamoyltransferase (OTC) is a mitochondrial matrix enzyme, the deficiency of which causes the most common inherited defect of the urea cycle. The human *OTC* gene (Xp21.1) is expressed almost exclusively in the liver and its promoter lacks a CpG island. The *OTC* gene promoter and three dominant transcription start sites located at positions c.-169, c.-119 and c.-95 were recently described in Luksan et al., Hum Mutat, 31 (4), E1294 - E1303.

To find out if methylation contributes to tissue-specific expression of *OTC* gene we compared methylation status in autoptic samples (liver and blood) of four males, thus avoiding the confounding contribution of X-chromosome inactivation to the overall DNA methylation patterns. The methylation profile of 19 CpG dinucleotides in 1 kb region covering the promoter, 5' UTR, the first exon and a part of the first intron of the *OTC* gene was probed by bisulfite sequencing, when at least 10 cloned PCR products were analyzed. The results show that there are two distinct areas with respect to CpG methylation; 10 CpGs located 500-700 bp upstream of the *OTC* transcription start sites were heavily methylated (cca 90%) in both blood and liver. However, nine CpGs encompassing the transcription start sites (cca 230 bp upstream and 250 bp downstream from the start sites) were remarkably less methylated in the liver samples (~45%) than in blood (~90%). In conclusion, the level of methylation at CpGs surrounding transcription start site region inversely correlates with the known expression of *OTC* in the examined tissues, suggesting that despite the absence of CpG island, DNA demethylation is involved in regulation of *OTC* gene transcription. We speculate that aberrant DNA methylation patterns may contribute to phenotype variability of OTC deficiency or may explain the disease manifestation in patients in which the causative mutation was not found. Support: IGA MZCR NR/9364-3, VZ MSMCR 0021620806, VZMZCR64165.

Novel Epigenetic Biomarkers of Type 2 Diabetes Susceptibility. *H.R. Elliott[1], M.S. Pearce[2], J.C. Mathers[1], M. Walker[3], C.L. Relton[1].* 1) Human Nutrition Research Centre, Institute for Ageing and Health, Newcastle University, Newcastle-upon-Tyne, Tyne and Wear, United Kingdom; 2) Institute for Health and Society, Newcastle University, Newcastle-upon-Tyne, Tyne and Wear, United Kingdom; 3) Human Nutrition Research Centre, Institute of Cellular Medicine, Newcastle University, Newcastle-upon-Tyne, Tyne and Wear, United Kingdom.

Background Genotype clearly plays a role in type 2 diabetes (T2D) susceptibility. However, the role of DNA methylation and its interaction with genotype is poorly understood. This study aims to identify whether variation in DNA methylation pattern is associated with risk of T2D or associated traits. A targeted approach was adopted; genes which harboured SNPs identified by genome wide association studies (GWAS) were analysed for variation in methylation patterns. In addition, we investigated if variation in DNA methylation pattern was associated with T2D-related traits

Methods Methylation analysis was conducted in two genes, *FTO* and *ADCY5*, using the Sequenom® EpiTYPER® platform, a high-throughput MALDI-TOF based system. DNA samples were derived from the *Relationship between Insulin Sensitivity and Cardiovascular Disease* (RISC) cohort; a group of healthy individuals aged between 30-60 years of age. DNA samples were collected at baseline and 3 year follow-up alongside detailed biological, physiological and lifestyle measures.

Results DNA methylation was analysed at 11 CpG sites in *ADCY5* (average n=304) and 10 CpG sites in *FTO* (average n=287). Spearman's tests for correlation between methylation and T2D related traits revealed a number of statistically significant observations including an inverse relationship between *ADCY5* methylation and fat free mass (rho -0.179;*p*=0.001) and an association with age (rho 0.148;*p*=0.007). In *FTO*, methylation correlated with BMI (rho 0.139;*p*=0.011) and fasting glucose (rho 0.125;*p*=0.022).

Conclusion These data provide evidence that the Sequenom® EpiTYPER® is a valuable high-throughput system for population-based studies to assess variation in methylation in DNA derived from leukocytes. Both *FTO* and *ADCY5* genes showed inter-individual variation in methylation and in turn were associated with T2D-related traits within the RISC cohort. These data suggest that, in addition to effects of genetic polymorphisms on T2D risk, epigenetic variants in the same genes may also contribute to disease risk.

Cell-Specific Patterns of Methylation in the Human Placenta. *J. Ferreira[1], A. Grigoriu[2], S. Choufani[1], D. Baczyk[2], J. Kingdom[2], R. Weksberg[1,3].* 1) Gen & Genomics Program, Hosp Sick Children, Toronto, ON, Canada; 2) SLRI & Dept. Ob & Gyn., Mount Sinai Hospital, Toronto, ON, Canada; 3) Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada.

Epigenetic processes, such as DNA methylation, are known to regulate cell type specific gene expression in various organ systems. Alterations in these processes may be relevant to disease states such as severe IUGR or pre-eclampsia. DNA methylation variation among cell types within a tissue may complicate molecular investigations done at the tissue level. Therefore, our objective was to determine whether DNA methylation in the placenta is cell type specific. Placental samples from normal placentas obtained at 14 weeks (n=3) and 18-19 weeks (n=3) gestation were serially-digested using a trypsin-based protocol and Ficoll density column, followed by negative magnetic bead separation (CD45 and anti-fibroblast). Immunocytochemistry of plated fixed cells demonstrated 95% purity in C (cytokeratin-7) and 60-70% for fibroblasts (vimentin). Genomic DNA was extracted from whole placental villi, purified villous cytotrophoblasts (C) and mesenchymal core fibroblasts (F) using the QIAGEN MiniKit, bisulfite-modified and hybridized to the Illumina Methylation27 array that interrogates >27,000 highly-informative CpG sites covering >14,000 genes. Across the genome, the methylation pattern was similar amongst the different types of samples (r2= 0.90 - 0.95 [mean = 0.92]) and did not vary with gestational age (r2 = 0.97). Cluster analysis did not find a complete separation between the 3 components analyzed, but it showed two main clusters, one composed of placenta and C, the other one mainly of F. We identified 465 probes, corresponding to 386 genes, showing a statistically significant >20% difference in methylation between C and F. Interestingly, and as proof of principle, 6 of 8 probes mapping to the promoter regions of the beta chain of chorionic gonadotrophin genes were more methylated in F than C. Furthermore, probes that were more methylated in C were enriched (relative to the frequency in the array) for tumor suppressor gene related probes. Both of these findings suggest that epigenetic regulation of gene expression contributes to the functional specificity of cytotrophoblasts. Genome-wide specific methylation profiles of specific cell types in placenta will provide a useful resource for the interpretation of placenta methylation studies and will generate hypotheses regarding epigenetic regulation of cell specific expression patterns.

Characterization of a new maternal differentially methylated region at chromosome 18q23. *D. Grafodatskaya[1], R. Rajendram[1], S. Choufani[1], Y. Lou[1], D. Niyazov[2], R. Weksberg[1,3].* 1) Gen & Genome Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Department of Pediatrics, Ochsner Clinic Foundation, New Orleans, LA, USA; 3) Division of Clinical & Metabolic Genetics, The Hospital for Sick Children, Toronto, ON, Canada.

Terminal deletions of chromosome 18q are characterized by variable clinical phenotypes. Clinical features of 18q deletion syndrome include short stature, congenital aural atresia, delayed myelination and developmental delay. In addition 18q terminal deletions were reported in two patients with Beckwith-Wiedemann Syndrome-like macroglossia. The differences among phenotypes could be attributable to the size of the deleted region, as well as parent of origin effects if imprinted genes are located within the deletion. Here we report a patient with a 15 Mb de novo terminal deletion of chromosome 18q of paternal origin, typical BWS features and developmental delay. There were no identifiable molecular abnormalities in the chromosome 11p15.5 BWS critical region. We have generated DNA methylation profile of the chromosome 18q region using methylated DNA immunoprecipitation followed by Agilent CpG island array and have identified a new maternally differentially methylated region (DMR) located at the 18q23 between PARD6G and ADNP2 genes. Maternal pattern of DNA methylation was confirmed using methylation sensitive digestion with subsequent PCR amplification and sequencing in saliva samples of five trios informative for the SNPs within the DMR region. In addition we observed DNA methylation patterns consistent with a maternal parent of origin in blood sample of the patient carrying only maternal allele of 18q23 region and androgenetic hydatidiform mole, carrying two paternal genomes. These data suggest that the genes PARD6G and ADNP2 located adjacent to the newly identified DMR could be imprinted and potentially contribute to the different phenotypes of 18q terminal deletions.

Genome-wide DNA methylation profiling in 40 breast cancer cell lines. *L. Han[1,2], S. Zheng[1,2], S. Sun[3], T. Huang[4], Z. Zhao[1,2,5].* 1) Biomedical informatics, Vanderbilt University, Nashville, TN; 2) Bioinformatics Resources Center, Vanderbilt University, Nashville, TN; 3) Case Comprehensive Cancer Center, Case Western Reserve University, Cleveland, OH; 4) Human Cancer Genetics Program, The Ohio State University, Columbus, OH; 5) Department of Cancer Biology, Vanderbilt University School of Medicine, Nashville, TN.

DNA methylation plays important roles in gene regulation and functions. Aberrant methylation, either hypomethylation or hypermethylation, has been reported to cause various diseases, especially cancers. Breast cancer ranked the fifth according to the number of cancer deaths in the world. To systematically characterize the epigenetic modification in breast cancer, we examined the genome-wide methylation profiling in 40 breast cancer cell lines. We identified a gene signature consisting of 345 differentially methylated genes, which could be used to discriminate estrogen receptor (ER)-negative and ER-positive breast cancer cell lines. This gene signature is promising for diagnosis and therapies of breast cancer. In the follow up functional analysis of this gene signature, three enriched networks could be highlighted. Interestingly, one of these networks contained estrogen receptor, implying its functional importance of ER-centric module. Finally, we examined the correlation between methylation and expression of these breast cancer cell lines. Very few genes showed significant correlation, suggesting that gene expression regulated by methylation is a complex biological process.

Epigenetic Regulation of Osteoblast Differentiation and Genetic Variation. *T. Karaoli[1], A. Lira[2], W. Chen[2], V. Gilsanz[3], C.R. Farber[2], J.J. Connelly[1].* 1) Cardiovascular Research Center, University of Virginia, Charlottesville, VA; 2) Center for Public Health Genomics, University of Virginia School of Medicine, Charlottesville, VA; 3) Children's Hospital, Los Angeles, CA.

Osteoporosis results from an imbalance between bone resorption by osteoclasts and bone formation by osteoblasts. It is a major cause of morbidity in aged individuals and as such becomes important to molecularly define. Epigenetically regulated genes involved in bone formation could be used as drug targets for use in the modulation of osteoporosis. To identify such genes, we integrated gene co-expression network and epigenetic analyses. By applying Weighted Gene Co-expression Network Analyses to DNA microarray data generated from bone in 96 inbred mouse strains, we identified COL15A1 as a member of a co-expression network that plays an important role in osteoblast function. To epigenetically define COL15A1 in the process of bone development, we examined COL15A1 mRNA levels in differentiating primary mouse osteoblasts in vitro. We found that COL15A1 was significantly upregulated by day 8 of osteogenic differentiation (OD). Next, we inhibited DNA methylation in proliferating osteoblasts and found that loss of DNA methylation leads to an increase in COL15A1 mRNA levels. These levels are similar to the levels at day 8 during OD suggesting that the change in COL15A1 gene expression during OD may be solely controlled by loss of DNA methylation. Work is ongoing to assess COL15A1's role in OD and the epigenetic regulation that is governing the expression of this gene. In addition to beginning to define the function and regulation of COL15A1, we hypothesized that if the regulation of this gene leads to changes in bone phenotype then polymorphisms associated with bone density measurements in humans should exist. To determine if genetic variation in COL15A1 was associated with osteoporosis-related traits, we asked if SNPs spanning COL15A1 were associated with vertebral cancellous bone density (CBD) in 95 young Caucasian females. A total of three SNPs were associated with CBD at P<1.0 x 10-4. These variants spanned the COL15A1 promoter through intron 2. Studies are on going to determine if these polymorphisms affect the epigenetic or transcriptional regulation of COL15A1. The functional, epigenetic and genetic data we present suggest that COL15A1 may be important in bone formation and that a more rigorous validation of this gene in relation to osteoporosis is warranted. In addition, this study provides proof of principle for a genomewide study of epigenetically regulated loci involved in bone formation to identify manipulatable targets in bone disease.

Quantification of the methylation at the GNAS locus identifies subtypes of sporadic pseudohypoparathyroidism type Ib. *S. MAUPETIT[1], C. BALLOT[1], V. MARIOT[1], C. REYNES[2], C. SILVE[1], A. LINLGART[1].* 1) INSERM U986, Hôpital Saint Vincent de Paul, 82 av Denfert Rochereau, 75014 PARIS, France; 2) INSERM U 973, MTi Université Paris Diderot, Rue Hélène Brion, 75013 Paris, PARIS, France.

BACKGROUND: Pseudohypoparathyroidism type Ib (PHP-Ib) is due to epigenetic changes at the imprinted GNAS locus including loss of methylation at the A/B differentially methylated region (DMR) and sometimes at the XL and AS DMRs and gain of methylation at the NESP DMR. Objective: To investigate if quantitative measurement of the methylation at the GNAS DMRs identifies subtypes of PHP-Ib. DESIGN AND METHODS: In 19 patients with PHP-Ib and 7 controls, methylation was characterized at the four GNAS DMRs through combined bisulfite restriction analysis and quantified through cytosine-specific real-time PCR in blood lymphocyte DNA. Results: A principal component analysis using the percent of methylation at 7 cytosines of the GNAS locus provided three clusters of subjects (controls n=7, autosomal dominant PHP-Ib with loss of methylation restricted to the A/B DMR n=3 and sporadic PHP-Ib with broad GNAS methylation changes n=16) that matched perfectly the combined bisulfite restriction analysis classification. Furthermore, we identified three sub-clusters of patients with sporadic PHP-Ib that displayed different patterns of methylation: incomplete changes at all DMRs compatible with somatic mosaicism (n=5), profound epigenetic changes at all DMRs (n=8), and unmodified methylation at XL in contrast with the other DMRs (n=3). Interestingly, PTH level at the time of diagnosis correlated with the percent of methylation at the A/B DMR. Conclusion: Quantitative assessment of the methylation in blood lymphocyte DNA is of clinical relevance, allows the diagnosis of PHP-Ib and suggests that, at least in some patients, the epigenetic defect is mosaic.

Efficient whole-genome DNA methylation analysis of the Human Reference Genome (HuRef). *G. Meredith[1], M. Dudas[1], E. Levandowsky[2], T. Gilbert[2], D. Krissinger[1], G. Marnellos[1], V. Sheth[2], C. Adams[1], C. Lee[2], T. Harkins[3].* 1) R & D, Life Technologies Corp, Carlsbad, CA; 2) Beverly, MA; 3) Foster City, CA.

Aberrant DNA methylation is characteristic of many cancers and differences in methylation have been observed in a wide variety of genomic contexts; for example, both within "classic" promoter-associated CpG islands and also in distal, non-CpG island regions. Establishing a method to broadly and efficiently survey DNA methylation patterns genome-wide is the objective of the work presented. The method combines the power of methyl-CpG binding domain (MBD) proteins to sensitively and selectively bind methylated DNA sequences with the coverage, precision, and accuracy provided by high-throughput sequencing. Notably, MBD-affinity capture can also be used to sub-fractionate genomic DNA based on its average methyl-CpG content. To illustrate this method, Human Reference Genome (HuRef) DNA was enriched and salt-fractionated with a commercial MBD-based affinity reagent and high-throughput sequencing libraries, both bisulfite converted and unconverted, were prepared from each of the three fractions. The libraries were sequenced using error correcting codes and paired-end technology that yielded 75 bp read-lengths from one end and 30 bp read-lengths from the opposite end on a SOLiD 4 System. Peak analysis of the distribution of mapped unconverted reads permitted the discovery of thousands of locations of putative methylation in different genomic locus classes; the low salt fractions were depleted of CpG islands and enriched for exons while the highest salt fraction was enriched for CpG islands, exons, and promoter regions. Methylation at a large number of these positions was confirmed by bisulfite-sequencing of the same libraries. We conclude that such enrichment and fractionation, when coupled to high-throughput sequencing with or without bisulfite conversion, can be used to efficiently survey the majority of DNA methylation marks within samples of genomic DNA and to discover genomic loci of differential methylation. This method and reference dataset are intended to provide the community with a tool for large-scale methylation studies.

DNA Methylation profiles distinguish Idiopathic Pulmonary Fibrosis from Normal Lung Tissue. *E.I. Rabinovich[1], Z. Yakhini[2], I. Steinfeld[2], K. Pandit[1], G. Yu[1], L.J. Chensny[1], N. Kaminski[1].* 1) PACCM, University of Pittsburgh, Pittsburgh, PA; 2) Technion-Israel Institute of Technology - Haifa/IL.

BACKGROUND: Idiopathic Pulmonary Fibrosis (IPF) is a pulmonary disease, characterized by extracellular matrix deposition, myofibroblast foci formation and alveolar epithelial cell hyperplasia, probably caused by interaction between susceptibility genes and diverse environmental factors. Little is known about the role of epigenetic changes in determining the lung phenotype in IPF. OBJECTIVES: To identify the global methylation patterns that characterize Idiopathic Pulmonary Fibrosis (IPF). METHODS: DNA was extracted from 12 IPF lungs,10 control lungs, and 10 lung adenocarcenomas using Qiagen DNeasy Blood & Tissue kit. Global methylation patterns were obtained using the Methylated DNA Immunoprecipitation (MeDIP) method and Agilent human CpG Islands Microarrays. Data analysis was performed using DNA Analytics 4.0.81 Software Validation was performed using EpiTYPER MassARRAY (Sequenom). RESULTS: Six hundred twenty five CpG islands were differentially methylated (false discovery rate<5%) between IPF and control lungs. EpiTYPER MassARRAY analysis validated a subset of these regions. The genes associated with the differentially methylated CpG islands are involved in apoptotis, Wnt, and ubiquitination pathways. Analysis of cancer samples revealed that IPF lungs represented an intermediate methylation profile between cancers and controls CONCLUSION: IPF lung exhibit significant changes in their methylation from controls. Interestingly, some of these changes are similar to those that are seen in Cancer.

1387/F

Evaluating DNA methylation and gene expression variability and identifying its underlying causes in the human term placenta. *W. Robinson[1], L. Avila[1], D. Diego-Álvarez[1], R. Yuen[1], M. Peñaherrera[1], D. McFadden[2], P. von Dadelszen[3].* 1) Dept Med Gen, Univ British Columbia, Vancouver, BC, Canada; 2) Dept Pathology, Univ British Columbia, Vancouver, BC, Canada; 3) Dept ObGyn, Univ British Columbia, Vancouver, BC, Canada.

Background: Abnormal placental growth and function may be influenced by genetic errors (e.g. trisomy) as well as epigenetic changes, such as those involving altered DNA methylation. However, before an association between DNA methylation and placental pathology can be investigated, normal intraplacental variation and the effects of sample location, local cell composition, gestational age, as well as mode of delivery and sample processing needs to be understood. Methods: To further our understanding of normal variability in DNA methylation, detailed sampling was obtained from 14 normal term placenta. Sites exhibiting variable methylation (KISS1, PTPN6, CASP8, APC, AR, and LINE1) were quantified by pyrosequencing. Expression of genes specific to a subset of placental cells (CDH1, CDH11, ID2, PLAC1 and KISS1) were evaluated by real-time PCR. Multiple sites from 5 placentae were also evaluated using the Illumina Beadarray technology for both expression and methylation. Results: Despite considerable intra-placental variability, significant inter-placental differences in gene expression and methylation were present. Most variability was not correlated with site location or depth. However, processing time (0-24 hours) had a dramatic effect on mRNA level for some genes including KISS1; In contrast, DNA methylation for the sites examined, including KISS1, remained relatively constant over this same time period. Observed correlations in expression and methylation from unrelated genes are suggestive that much methylation and expression variability largely reflects cell-composition differences between samples rather than true differences in gene expression at the cellular level. Sites that are differentially methylated in different placental cell types can be used to infer cell composition associated with abnormal placentation, while those methylation differences that are not influenced by cell type may be more informative for understanding the cellular/physiological changes between normal and abnormal placentae.

1388/F

Methylation of *HSPA4* in umbilical cord blood DNA from Children of Mothers with Mood Disorders. *J.W. Schroeder[1,2], V. Kilaru[2], K.N. Conneely[2], D.J. Newport[1], Z.N. Stowe[1], J.F. Cubells[2], A.K. Smith[1].* 1) Department of Psychiatry and Behavioral Sciences, Emory University, Atlanta, GA; 2) Department of Human Genetics, Emory University, Atlanta, GA.

Maternal illness can alter the intrauterine environment that constitutes the developmental context for the fetus. Mood (MD) and anxiety disorders (AD) in women are common during pregnancy and can result in long-lasting, stress-related outcomes in offspring. We hypothesize that DNA methylation may mediate some of these effects. In this study, we examined methylation patterns in DNA extracted from umbilical cord blood of 41 neonates whose mothers sought evaluation for psychiatric disorders during pregnancy, comparing the offspring of women with DSM-IV MD (N=28) and AD (N=8) as determined by SCID interview, to those with no Axis-1 diagnosis (ND, N= 5). Genomic DNA was interrogated across 27,578 CpG sites using the Illumina HumanMethylation27 BeadChip yielding a β value, which estimates the proportion of cytosine methylation at each CpG locus. For each CpG, we assessed the ability of the β value to predict maternal psychiatric diagnosis using a linear mixed model that included random effects to adjust for potential chip effects. The β values for each locus were adjusted with a conservative Bonferroni correction (α=1.81E-6) to minimize type I errors. We found several CpG loci that were nominally significant ($p<0.05$) in comparisons of MD vs. ND (N=1355; 5.98E-7<p<0.05) and AD vs. ND (N=1835; 2.65E-5£p<0.05). One locus, cg13778073, showed decreased methylation meeting criteria for experiment-wide significance (t=6.48; p=5.98E-7) in MD vs. ND samples; this locus resides near the transcriptional start site of *HSPA4*, which encodes heat shock protein A4 (HSPA4). In a *post hoc* examination, the methylation patterns in the offspring of women with major depressive disorder vs. ND (t=5.04; p=7.35E-5) and bipolar disorder vs. ND (t=4.47; p=2.91E-3) were consistent with the combined MD vs. ND test. HSPA4 is a chaperone protein involved in folding and regulation of the glucocorticoid receptor, which transduces signals mediated by cortisol, the major output hormone of the hypothalamic-pituitary-adrenal (HPA) axis. The HPA axis is often dysregulated in patients with psychiatric disorders. Our results suggest that maternal psychiatric diagnosis may alter maternal or fetal HPA axis function leading to detectable differences in methylation of genes related to cortisol function. Validation of the result is underway in addition to an extended evaluation of the methylation status of CpGs in the surrounding region in umbilical cord blood and placental tissue from these neonates.

1389/F

Differential DNA Methylation in Posttraumatic Stress Disorder and Related Phenotypes. *A.K. Smith[1], K.N. Conneely[2], V. Kilaru[1], K.B. Mercer[2], T.E. Weiss[1], B. Bradley-Davino[1], Y.L. Tang[2], C.F. Gillespie[2], J.F. Cubells[1,2], K.J. Ressler[2].* 1) Psychiatry & Behavioral Sci, Emory University SOM, Atlanta, GA; 2) Human Genetics, Emory University SOM, Atlanta, GA.

Human and animal studies suggest that DNA methylation mediates persistent changes in gene function following chronic stress, and a recent study reports that genes are differentially methylated in subjects with Posttraumatic Stress Disorder (PTSD). We evaluated 110 African American subjects matched by age and sex, and stratified into four roughly equal categories: with and without PTSD diagnosis (Clinician-Administered Posttraumatic Stress Disorder Scale), and with and without a history of childhood trauma (Childhood Trauma Questionnaire). Total Life Stress (TLS) was assessed in all subjects using the Stressful Events Questionnaire. We evaluated DNA from the peripheral blood of each subject using the HumanMethylation27 BeadChip and analyzed both global methylation (average β value across 27,578 CpGs) and methylation at individual CpG sites for association with PTSD, childhood trauma, and TLS using a linear mixed model that included random effects to adjust for potential chip effects. We noted an increase in global methylation in subjects with a current PTSD diagnosis compared to controls (P=.0035). Also, 2156 CpG sites were nominally associated with current PTSD (4.90E-6<P<.05, 7.8% of sites), 1446 CpG's with child abuse (2.17E-5<P<.05, 5.2%), and 5089 with TLS (1.16E-7<P<.05, 18.5%). CpG sites in 2 genes (*KRTHA5* and *NPFFR2*) associated with TLS met criteria for experiment-wide significance following Bonferroni adjustment (P<1.81E-6). KRTHA5 is activated in response to p65/RelA, and NPFFR2 is activated in response to inflammatory pain. Given these results and reports of immune system dysregulation in subjects with trauma history, we measured plasma levels of proinflammatory cytokines (IL6, IL2 and TNFa) using a multiplex ELISA and examined the association between these immune response markers with PTSD, child abuse, and TLS. While subjects with child abuse have higher TNFa (P=.038), we observed no other associations with child abuse or PTSD. However, IL6 (P=.019), IL2 (P=.039) and TNFa (P=.0044) concentrations increased with increasing TLS scores. Our results suggest repetitive psychosocial stress may alter global or gene-specific DNA methylation patterns potentially associated with peripheral immune dysregulation. Analyses are currently being performed to validate these observations and to evaluate further the role of DNA methylation in the development of stress-related disorders.

1390/F

Genetic variants associated with altered DNA methylation in schizophrenia. *K.R. van Eijk[1], M.P. Boks[2], F. Colas[3], E. Strengman[1], E. Janson[1], R.S. Kahn[2], S. Horvath[4], R.A. Ophoff[1,2,3,4].* 1) Medical genetics, University Medical Center Utrecht, The Netherlands; 2) Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, The Netherlands; 3) Center for Neurobehavioral Genetics, Neuropsychiatric Institute, University of California, Los Angeles, USA; 4) Department of Human Genetics and Biostatistics, University of California, Los Angeles, USA.

There is compelling evidence that epigenetic modifications play a role in schizophrenia susceptibility. Using a genome wide approach we investigated DNA methylation in whole blood and the extent to which differences between patients and controls are related to genotype. In a sample of 179 medicated patients and 172 controls, we obtained DNA methylation levels using Illumina HumanMethylation27 BeadChip and genotype data using Illumina 550k array. We used a linear model to analyze DNA methylation differences at 27,578 CpG sites. Differences smaller than detection sensitivity of the arrays were discarded. For the CpG sites associated with schizophrenia, we subsequently calculated association of DNA methylation levels with genotype (mQTLs) using a linear model with age as covariate and gender and disease status as factors. Analyses were performed in PLINK and R. After FDR correction for multiple testing we found 7,346 CpG sites that showed significant differences between cases and controls. Of these, 591 CpG sites showed a significant association with genotype. For 291 CpG sites the association to disease status was entirely due to genotype effect. Our results show the presence of vast differences in DNA methylation levels in whole blood of schizophrenia patients of which a small fraction is entirely regulated by genetic variants. The genes linked to these CpG sites are therefore prime candidate genes. We also identified 300 CpG sites associated with schizophrenia where genetic variation is associated with DNA methylation differences over and above the association with schizophrenia. Although further study is required to gain a better understanding of the biological relevance of these findings, these analyses can facilitate our understanding of diseases susceptibility.

Bisphenol A Decreases the Methylation Status and Expression of Estrogen Receptor Alpha in C57BL/6 Mouse Embryo Brains. *J.T. Wolstenholme[1], K.H. Cox[1], E.F. Rissman[1], J.J. Connelly[2].* 1) Biochem & Molecular Genetics, University of Virginia, Charlottesville, VA; 2) Cardiovascular Medicine and Cardiovascular Research Center, University of Virginia School of Medicine, Charlottesville, VA.

Bisphenol A (BPA) is an environmental endocrine disruptive compound found in plastics; it accumulates in the blood of embryos, infants, children and adults. Exposure to such endocrine-active compounds alters normal hormonal function, affects neural organization and ultimately may modify behavior and lead to neurological disorders. Given that humans born after 1950 have been exposed to increasingly high levels of BPA from the time they were conceived, we have undertaken a behavioral and epigenetic study in the mouse to further characterize the affects of BPA exposure. BPA has two modes of action: as an endocrine-active compound and as a DNA hypomethylator. We hypothesize that in utero BPA exposure causes persistent, epigenetically trackable alterations in the brain and these changes influence social behaviors in mice and potentially in humans. Recently, we have shown that *in utero* exposure to BPA at human-relevant doses alters typical social interactions in C57BL/6 mice. Here, we report the ability of BPA to affect methylation and expression of estrogen receptor alpha (*Esr1*) in embryonic mouse brains. Female C57BL/6J mice were placed on phytoestrogen-reduced chow with or without 5mg/kg BPA, yielding equivalent blood levels as reported in humans. A week later, females were mated, checked for plugs and brains from gestating embryos were collected at embryonic day 18.5. To identify epigenetic mechanisms underlying these altered behaviors, the methylation status of several candidate genes with or without BPA exposure was determined. Methylated DNA was immunoprecipitated and subjected to quantitative PCR. We find that both a conserved promoter region shown to change with licking and grooming in the rat and a region within the CpG island in the second exon of *Esr1* is hypomethylated in BPA exposed embryos compared to controls. Interestingly, *Esr1* mRNA levels are decreased following BPA exposure but maintain sexually dimorphic expression. In stem cells, DNA methylation in the body of genes has recently been show to increase gene expression, suggesting that the methylation changes we see in the second exon of Esr1 may drive the change in gene expression. Studies are underway to identify genome-wide BPA-induced alterations in the DNA methylome in order to identify candidate epigenetically regulated genes that may play a role in human behavioral disorders. This work is supported by NIH grants R01MH08711 and Autism Speaks grant #4892 (EFR).

OxLDL up-regulates miR-29b leading to epigenetic modifications of MMP-2/MMP-9 gene: a novel mechanism for cardiovascular disease. *K.C. Chen[1], C.Y. Hu[3], Y.S. Wang[1], W.C. Chang[2], S.H. Juo[1,2].* 1) Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 2) Department of Medical Genetics, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Graduate Institute of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan.

Background: MicroRNAs (miRNAs) are small non-coding RNAs and can control gene expression by binding to their target genes for degradation and/or translational repression. Epigenetic mechanisms are defined as heritable changes in gene expression that do not involve coding sequence modifications. Both miRNA expressions and epigenetic regulations play an important role in maintaining physiological functions and are also related to disease development. However, few studies report that miRNAs-mediated epigenetic regulations involve in atherosclerosis. **Purpose:** We investigated a miRNA-regulated epigenetic mechanism for MMP-2/MMP-9 genes using human aortic smooth muscle cell (HASMC) treated with oxidized low density lipoprotein (oxLDL). **Methods:** Primary HASMC were grown in medium 231 and co-cultured with 40 μg/ml oxLDL for 48 h. Cell migration was measured by wound healing and transwell migration assays. The expression levels of MMP-2, MMP-9, DNA methyltransferase (DNMT) 1, DNMT3a, DNMT3b and miR-29b were respectively estimated by either quantitative real-time-PCR (Applied Biosystems.) or western blot analysis. DNA methylation levels of MMPs were measured by methyl-specific PCR. 400 ng DNMT3b shRNA or 50 nM antagomiR-29 (Applied Biosystems.) was transfected into HASMC with lipofectamine 2000 (Invitrogen) to knockdown DNMT3b or miR-29b, respectively. **Results:** oxLDL significantly increased HASMC migration through MMP-2/MMP-9 up-regulation. DNA methylation levels of MMP-2/MMP-9 were also decreased in oxLDL-treated HASMC. Either mRNA or protein level of DNMT3b showed a dose-dependent down-regulation in oxLDL-mediated HASMC. Knockdown DNMT3b expression by DNMT3b shRNA enhanced oxLDL-induced DNA demethylation levels of MMP-2/MMP-9. The expression of miR-29b, directly targeting to DNMT3b, was up-regulation by oxLDL treatment in a dose-dependent manner. OxLDL-mediated MMP-2/MMP-9 up-regulation and DNMT3b down-regulation were both attenuated after knockdown miR-29b expression by antagomiR-29b. Knockdown miR-29b expression also abolished oxLDL-mediated DNA demethylation of MMP-2/MMP-9. **Conclusions:** We find that oxLDL can up-regulate miR-29b expression resulting in DNMT3b down-regulation in HASMC. oxLDL-mediated miR-29b expression epigenetically regulated MMP-2/MMP-9 genes involved in HASMC migration. These results show that miRNAs-mediated epigenetic regulations may be a novel mechanism in atherosclerosis.

microRNA's role and genetics in alcoholism. *A. Pietrzykowski[1], O. Anees[1], Y. Wang[1], N. Boulghassoul-Pietrzykowska[1,2].* 1) Department of Animal Sciences, Rutgers University, New Brunswick, NJ; 2) Capital Health, Internal Medicine Residency Program, Trenton, NJ.

Alcoholism is a worldwide disease with a strong genetic component. However the exact genetic and molecular underpinnings of this debilitating disease are yet to be determined. We have recently discovered that exposure of neurons to alcohol leads to the development of tolerance to its effects by upregulating expression of one of microRNA species, called miR-9, in these cells. microRNAs belong to a family of short, non-coding RNAs and are essential regulators of gene expression. They don't encode proteins but regulate mRNA stability by RNA:RNA interactions. Typically, one microRNA can regulate expression of hundreds of targets. miR-9 is abundant in leukocytes regulating their key developmental stages and functions. Malfunction of leukocytes in alcoholism can contribute to immunosupression and cancer associated with alcohol abuse. We observed that in humans, two out of three miR-9 genes are located within loci of high susceptibility to alcoholism. Interestingly, a promoter of each miR-9 gene has a completely different structure suggesting differential expression of each miR-9 gene. Together, our findings describe new mechanisms of alcohol actions and could provide novel explanation of polygenic nature of alcoholism.

Characterization of newly designed Sirtuin 1 FRET and fluorogenic substrates. *V. Rakhmanova, N. Nguyen, W. Cruz Jr, B. Sun, A. Hong.* AnaSpec, Inc., Fremont, CA.

Sirtuins comprise a unique class of nicotinamide adenine dinucleotide (NAD+)-dependent histone deacetylases (class III HDACs). Sirtuin 1 (SIRT1), the human homolog of yeast Sir2 (Silent Information Regulator 2), has been implicated in various cellular processes, including genomic stability, DNA repair, p53-mediated apoptosis and adipogenesis. It represents a treatment target of age-related diseases and type II diabetes. Recently, there has been much interest in characterizing small molecules that affect sirtuin activity. Resveratrol, an anti-aging compound found in red wine, has been reported to act as a SIRT1 activator, and this property has been proposed to account for its anti-aging effects. However it was determined that activation of sirtuins by resveratrol was observed mostly for an AMC (7-amino-4-methylcoumarin) coupled fluorogenic substrate generating blue fluorophore. To facilitate sirtuin drug discovery, we developed two new substrates, fluorogenic Green SIRT1 and 520 FRET SIRT1 substrates. The former substrate, derived from p53 sequence, releases a green fluorophore after incubation with SIRT1-containing samples and developer. This fluorophore can be detected with excitation/emission= 490/520 nm. The peptide for the FRET substrate was derived from the human FOXO3 sequence surrounding the deacetylation site of SIRT1. This peptide is coupled to a quencher, QXL™ 520, and a fluorophore, 5-carboxyfluorescein (5-FAM). Upon reaction of the FRET substrate with sirtuin and developer, an increase of fluorescence can be monitored at excitation/emission=490/520 nm. Both substrates are highly sensitive and detect activity at nanogram level of SIRT1. The substrates were validated for use in inhibitor screening assay with a previously described SIRT1 inhibitor. The long wavelength fluorescence of the green dyes employed in these two substrates is less interfered by the autofluorescence of cell components and test compounds. Resveratrol tested in the 520 FRET SIRT1 based assay showed no effects on enzyme activity. Interestingly, when the fluorogenic Green SIRT1 substrate was used in the assay, we were able to detect an increase of SIRT1 activity by resveratrol only at low concentrations of NAD+ and not at high concentrations. The assay with AMC based commercial substrate however, showed increase of sirtuin activity after incubation with resveratrol at a wide range of NAD+ concentrations.

1395/F

γH2AX in pluripotent stem cells: more than a DNA damage response signal? *C. Giachino[1], Y. Sanchez-Ripoll[2], V. Minieri[1], J. Foster[2], B. Kumpfmueller[2], V. Turinetto[1], P. Porcedda[1], L. Orlando[1,2], M. Welham[2].* 1) Department of Clinical and Biological Sciences, University of Turin, Orbassano, Italy; 2) Department of Pharmacy and Pharmacology, University of Bath, Bath,UK.

Histone H2AX phosphorylation (γH2AX) is the earliest indicator of DNA double strand break (DSB) and the main signal that triggers DSB repair. Recently, it has been shown that mouse embryonic stem cells (mESCs) have very high basal levels of γH2AX, even when they have not been exposed to genotoxic agents. We have confirmed this finding and have also observed high basal levels of γH2AX in mouse induced pluripotent stem cells and mouse blastocyst inner cell masses. In contrast, hESCs exhibited low basal levels of γH2AX, despite high sensitivity to genotoxic agents and a rapid repair response. To investigate whether γH2AX is linked to DNA repair signalling or plays an alternative role in pluripotent mouse cells, levels of γH2AX were examined following (i) treatment with genotoxic agents; (ii) mESC differentiation, where a decrease correlated with differentiation or (iii) inhibition of de-acetylation, methylation or key signalling pathways. The results of these analyses will be presented and potential roles discussed.

1396/F

X-chromosome wide DNA methylation analysis of human males and females in multiple tissues. *A. Cotton[1,2], J. Affleck[1,2], I. Wilson[3,4], M. Peñaherrera[1,5], D. McFadden[5,6], M. Kobor[1,5], W. Lam[3,4], W. Robinson[1,5], C. Brown[1,2].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Molecular Epigenetics Group, Life Sciences Institute, Vancouver, BC, Canada; 3) British Columbia Cancer Research Centre, Vancouver, BC, Canada; 4) Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada; 5) Child & Family Research Institute, Vancouver, BC, Canada; 6) Department of Pathology, University of British Columbia, Vancouver, BC, Canada.

DNA methylation is one epigenetic change that occurs during X-chromosome inactivation and distinguishes the inactive X (Xi) from the active X (Xa) in 46, XX females. It is well established that CpG island promoters on the Xi are hypermethylated compared to the Xa. Using the Illumina Infinium array we examined 1081 probes in 597 promoters on the X in human male (n=19) and female (n=24) tissues (n=5). Little variability in methylation was observed between muscle, spinal cord, brain and kidney, while placenta showed hypomethylation consistent with previous reports. 65% of the probes are associated with CpG islands, of which over 10% are unmethylated in non-placental tissue in both males and females. As the majority of genes known to escape inactivation are unmethylated, the 16 novel genes that fail to show promoter methylation are candidates to escape X-chromosome inactivation. Furthermore, 12% of island probes showed a tissue-specific methylation pattern, suggesting that for some genes escape from inactivation may vary between tissues. Methylation at CpG island promoters is thought to be an important epigenetic lock in maintaining gene silencing; however, further roles for methylation are not well-characterized. To examine more than promoters we used MeDIP on male and female blood followed by hybridization to a NimbleGen 2.1M array containing the X. We confirmed an X-chromosome-wide decrease in hypomethylated CpG island promoters in female versus male blood. Both male and female non-genic and intronic regions show moderate to high methylation whereas exonic regions show a bimodal pattern of methylation with the majority being highly methylated. Non-promoter high density islands are similarly hypomethylated in both males and females, whereas non-promoter intermediate density islands are moderately methylated in both sexes. Elucidation of the X methylation pattern in chromosomally normal tissues allows us to compare how chromosomally abnormal tissues are methylated. We are analyzing deviations from the normal XaXi status of 46, XX females that occur in triploids and sex-chromosome aneuploids. Contrasting methylation patterns between the Xa and the Xi highlights regions where differences in methylation may in turn have an effect on gene silencing. Determining the regions where methylation correlates with gene silencing is not only of importance in understanding X-chromosome inactivation but may also inform studies of other epigenetic regulatory pathways.

Informed consent for biobank research: a mixed-methods study in cancer patients. *J. Mancini[1, 2], I. Pellegrini[2], C. Chabannon[3], F. Viret[3], N. Vey[3], C. Julian-Reynier[2].* 1) LERTIM, Aix-Marseille Université, Marseille, France; 2) Inserm, UMR 912, Marseille; 3) Institut Paoli-Calmettes, Marseille.

Biobanks have become strategic resources for biomedical research. Cancer patients' information and consent are key issues but might be suboptimal. We investigated the quality of patients' informed consent when they are solicited to grant access to their own biological specimen for research projects. A mixed-methods design was used to study the experiences of cancer patients who had a tumour or blood sample cryopreserved in a French Regional Cancer Centre (Paoli-Calmettes Institute). Nineteen patients (aged 28-82) treated for colorectal cancer or leukaemia were in-depth interviewed using grounded theory methodology and 574 patients (aged 20-89, response rate=77.0%) treated for colorectal, breast cancer or a haematological malignancy answered to a self-administered questionnaire on average 16.5 months after their cancer diagnosis. In the quantitative survey, 213 patients (37.1%) declared they had given consent. The others mainly did not, or couldn't remember, they had received the consent form; only two patients (0.9%) refused explicitly to consent. There was a poor concordance between declared and actual consent (Kappa=0.23) traducing a poor recall of the consent process. The majority of patients (60.8%) stated that a signed consent should be mandatory for biobank research, 90.9% judged satisfactory to participate in this decision, and only 6.6% would let the physician deciding alone in this context. Only a third (37.0%) of patients that had received the consent form, understood that the consent included an authorisation to access to medical files. Qualitative survey pointed out feelings of personal valorisation for the patients through their participation to the research and highlighted different profiles of participating to the research. Some patients recalled precisely practical details and their answers while others could not even remember if they had been solicited. In order to maintain an opt-in procedure valuable for patients, quality of consent and communication should be improved.

1398/T

Cardiogenetics: Developing a Model for Successful Implementation of Personalized Genetic Medicine. *D.A. McDermott, L.L. Cohen, S.M. Dolan, R.W. Marion.* Montefiore-Einstein Center for CardioGenetics, Departments of Pediatrics, Divisions of Cardiology and Genetics; Medicine, Division of Cardiology; and Obstetrics and Gynecology and Women's Health, Division of Reproductive Genetics, Albert Einstein College.

Recent advances in molecular medicine and pharmacogenomics have led to the belief that the era of personalized medicine (PM) is upon us. Although the ability to identify asymptomatic individuals' genetic susceptibility to disease is possible, new developments in cardiogenetics raise additional challenges not only with the capability of identifying mutations causing lethal arrhythmias and tailoring evidence-based medical management, but also resolving ethical, legal, and social issues (ELSI) that arise in the clinical setting. The Montefiore-Einstein Center for Cardiogenetics (MECCG) represents the leading edge of this PM revolution. Located in the Bronx, NY, the MECCG is a multidisciplinary clinic composed of medical genetics and genetic counseling, pediatric and adult cardiology, psychology and social work, and pathology that focuses primarily on individuals and families with a history of, or risk for, sudden cardiac death. Genetic testing of numerous individuals evaluated by the clinic has identified mutations in genes known to be causative for cardiac channelopathies such as the Long QT syndromes (LQTS) and Brugada syndrome. The information gleaned from genetic testing, in conjunction with personal and family history is used to guide personalized recommendations for these individuals as it pertains to medical management and preventive lifestyle factors. We will present clinical vignettes that illustrate some of the ELSI issues that will be equally pertinent in other PM clinical settings. We are currently planning focus group meetings for individuals followed at the Center, to better evaluate the translation of complex genetic information, appropriate timing of such information, and modes of family communication. Information from these focus groups will be critical in allowing further personalization of recommendations for current and future patients, and will serve as a model for other such multidisciplinary programs. Preliminary thematic findings from these focus groups will hopefully improve the infrastructure for PM-guided health care.

1399/T

Copy Number Variation at Genomic Regions Containing Short Tandem Repeats Used in Forensic Genetic Identity Analysis. *R.E. Pyatt[1,2], A.K. Bailes[1], D. Ell[1], L. Erdman[1], A. McKinney[1], C. Weber[1], D. Lamb-Thrush[1,3], C. Astbury[1,2], S. Reshmi[1,2], J.M. Gastier-Foster[1,2,3].* 1) Dept. of Laboratory Medicine, Nationwide Children's Hospital, Columbus, OH; 2) Dept. of Pathology, Ohio State University, Columbus, OH; 3) Dept. of Pediatrics, Ohio State University, Columbus, OH.

Copy number variation (CNV) typically refers to genomic segments that are 1 kilobase in size or larger and can vary from the normal, two copy state. Approximately 5-12% of the human genome is believed to exhibit CNV in normal individuals. Microarray-comparative genomic hybridization (array-CGH) is now routinely used clinically for the assessment of copy number changes and chromosomal imbalances for constitutional disorders. Over the last five years in our laboratory, routine array-CGH analysis using custom BAC and oligonucleotide platforms has identified 7 cases of CNV at genomic regions containing short tandem repeat (STR) loci used in genetic identity analysis. The examination of CNV at these loci was limited to alterations of 1 kb in size or smaller. These STRs are the core loci for CODIS (COmbined DNA Index System), the United States national database of convicted offender profiles. This set of STRs was originally selected based on their high levels of heterogeneity, minimal PCR amplification artifacts, lack of association to pathogenic alterations, and rare microvariant alleles which can complicate profile interpretation. We identified CNV including deletions of regions containing D13S317 and vWA, and duplications of regions containing TH01 and Amelogenin. Both deletions (1) and duplications (2) of the region containing TPOX were also noted. Duplication CNV ranged in size from 175 kb to 995 kb and deletion CNV from 247 kb to 505 kb. A review of The Database of Genomic Variants revealed that duplication CNV containing TPOX and deletion CNV containing D21S11 have been previously reported. In instances where individuals are heterozygous for STRs within duplicated CNV, amplification of these regions could result in peak height imbalances for the heterozygous allelic profiles. As empirical interpretation of DNA mixtures in forensic casework is based on heterozygous STRs demonstrating similar allele peak heights from a single individual, allelic imbalances due to duplication CNV could incorrectly suggest a mixture rather than a single DNA source. These results show that regions containing STRs used in genetic identity analysis appear to be susceptible to variation in copy number which can have direct and important implications in mixture interpretation as a part of forensic casework. Consequently, the Database of Genomic Variants may currently under-represent CNV at these loci.

1400/T

Genetic Burden in a Rural Population of Andhra Pradesh, India. *A. Jyothy, K. Venkata Karunakar, B. Pullareddy, M. Srinivas, M. Sujatha.* Cell and Molecular Biology, Institute of Genetics and Hospital for Genetic Diseases, Osmania University, Hyderabad,Andhra Pradesh, India.

Genetic disorders are the most burdensome of all human afflictions. Every year, thousands of families are affected by the birth of an abnormal child. About 0.5% of new borns have a chromosomal abnormality with moderate to severe phenotypic effects. Another 0.5-1% suffer the consequences of single gene defects (dominant, recessive or X-linked) and about 2% have a malformation that may be due in part to heritable factors. Altogether about 4% of new borns have a serious defect that is recognized at birth or within their first year. Facilities to detect genetic disorders are available for urban population but not in rural areas where majority of Indian people live. Genetic screening is the systematic search of populations for persons with latent, early, or a symptomatic disease. It is highly useful for medical intervention and research, for reproductive information, for enumeration, monitoring and surveillance, and for registries of genetic disease and disability. The present study was carried out to identify genetic disorders in a rural population and provide management and counseling. A total of 14,929 households including a total population of 73,551 individuals were screened by door to door survey in Mahboob Nagar district of Andhra Pradesh, India. Reproductive performance of the women showed that the percentage of still births was high followed by abortions and premature births. The prevalence of genetic disorders was assessed and Genetic counseling was offered to all these cases for proper management and prevention of these disorders.

1401/T

Considerations in consenting participants to whole-genome sequencing research protocols. *J.C. Sapp, F.M. Facio, L.G. Biesecker.* National Human Genome Research Institute, NIH, Bethesda, MD.

Novel sequencing technologies call for new approaches to informed consent. Controversy exists regarding the return of variant results from large-scale sequencing protocols, and a major challenge is that there is a paucity of data regarding how to inform research participants about the possible availability of variant data in a way that is both meaningful and appropriate. We describe here our protocol for informed consent for two large-scale sequencing studies at our Institute. Our approach to the consent discussion and process in each protocol is distinct and dependent upon the aims of the study and the target cohort. The ClinSeq™ study has enrolled over 800 participants and a primary research aim is to investigate the return of different categories of genetic variant results to adult participants, the majority of whom are healthy. In contrast, our rare disease sequencing protocol aims to elucidate the molecular etiology of rare phenotypes in a largely pediatric population (likely to be cognitively impaired) by sequencing affected probands and both parents. As participants in both protocols may choose to learn individual genotype results, informed consent of participants in both studies centers on this issue. Our approaches converge with respect to the variety of possible results, limitations of sequencing technology and challenges in interpretation, options for withdrawal given that some data will be deposited in publically-available databases, and override of requests not to receive results in instances where results are of medical urgency. The studies' distinct scientific aims and participant characteristics mandate some differences in approach as well. Because the rare disease protocol ascertains families, sequencing data are often generated for minors and cognitively-impaired participants and a greater emphasis is placed on the implications that results could have on family relationships; this is not a focus of the ClinSeq™ study. As well, the consent discussion differs with respect to the threshold used for the return of results, which is much broader in the ClinSeq™ study. Informed consent of participants to these two studies has proved challenging, complex, and nuanced. We conclude that approaches to the return of results and informed consent of participants in protocols involving whole-genome/exome sequencing should include careful consideration of specific research aims and participant characteristics.

New technology, new challenges: Barriers to informed decision-making for first trimester aneuploidy screening. *R.M. Farrell, P.K. Agatisa.* Bioethics and OB/GYN, Cleveland Clinic , Cleveland , OH.

Purpose: First trimester aneuploidy screening was developed to identify fetal risk for aneuploidy several weeks earlier than conventional second trimester modalities. This study investigated key aspects of the decision-making process for this new form of prenatal genetic screening for the purpose of identifying barriers to informed decision-making and improving informed consent. Methods: Pregnant patients (N=93) were recruited from outpatient OB/GYN clinics in Northeastern Ohio. Participants completed a self-administered, multiple-choice questionnaire assessing knowledge and decision-making factors for first trimester aneuploidy screening, demographics, gestational age, and reproductive history. Data analysis was performed using R 2.9.1. Results: Participants demonstrated a low baseline understanding of the key concepts associated with first trimester aneuploidy screening. Specific knowledge gaps pertained to Down syndrome with 40% of participants unfamiliar with intellectual disabilities and 64% unfamiliar with health issues associated with Down syndrome. Participants were unfamiliar with the indications for first trimester aneuploidy screening, with 42% unable to correctly identify current recommendations for universal screening of all pregnant women regardless of maternal age and 62.3% unfamiliar or uncertain about testing procedures. Only 31.9% were able to correctly identify personal risk from the screening test result in contrast to 60.7% who were incorrect or uncertain about interpretation of an abnormal test result. Participants demonstrated knowledge gaps about follow-up testing for an abnormal result, with only 35.1% aware of the role of second trimester sequential or integrated protocols. In terms of immediate follow-up diagnostic testing, 67.8% were familiar with chorionic villus sampling but only 29.4% demonstrated understanding of its procedure-related risks. Conclusions: While first trimester aneuploidy screening provides fetal genetic information at an earlier time in the pregnancy, it also introduces novel challenges for informed decision-making. Our data demonstrate significant challenges for the process of patient education and informed consent for this new test. These findings have important implications for prenatal genetic counseling, particularly in light of the rapid pace of clinic translation of new prenatal genetic testing options.

1403/T

Genomic Risk Profiling: Physician attitudes and use in personal and clinical care. *S.B. Haga[1], M.M. Carrig[2], J.M. O'Daniel[1], L.A Orlando[3], L.A. Killeya-Jones[1], A. Cho[1,3].* 1) Inst Genome Sci & Policy, Duke Univ, Durham, NC; 2) Department of Psychology and Neuroscience, Duke University; 3) Department of Medicine, Duke University.

Genomic risk profiling involves the analysis of single nucleotide polymorphisms (SNPs) linked to a range of diseases and traits through statistical associations. There is considerable controversy as to how, and even whether, to incorporate these tests into routine medical care. Since little is known about their clinical impact, physician attitudes, or physician uptake, we surveyed a national group of primary care clinicians who are currently offering testing as part of their practice. The group, MDVIP, established a partnership with Navigenics, Inc in 2008 to provide testing at no cost to network physicians and a discounted cost to their patients, if physicians completed four educational modules. One third of respondents ordered a test for themselves and 42% for a patient. The odds of having ordered personal testing were 10.51X higher for those who felt well-informed about genomic risk testing ($p<0.0001$, 95% CI [3.79-29.15]). Of those who did not order a test for themselves, 53% were concerned about life and long-term/disability insurance discrimination and 49% about health insurance discrimination. Respondents were almost evenly divided about their intentions to order testing for their patients in the next 6 months (34% did vs. 39% did not). Ordering a test for their patients was 2.82X higher among respondents who had ordered testing for themselves ($p=0.028$, 95% CI[1.12-7.12]). The odds of ordering testing in the near future for patients were 2.9X lower for internists than family medicine practitioners ($p=0.040$). Of those who had ordered testing for patients, the following concerns were associated with a lower relative frequency of intention to order testing in the future: insurance coverage ($p=0.014$), uncertain clinical utility ($p=0.034$), unfamiliarity with testing ($p=0.016$), and concern about ability to communicate genomic risks ($p=0.040$). Among respondents who had never ordered a genomic risk test for a patient, there was a significant association between the uncertain clinical utility of testing when considering testing personally and for a patient ($p<0.0001$). This is the first study to assess initial uptake, interest, and concerns of genomic risk testing among primary care physicians. Our findings demonstrate that, with educational and interpretive support, primary care physicians are willing to include this type of information in a patient's risk assessment, even as concerns about uncertain clinical utility remain.

1404/T

Connecting geneticists with the public: changing our perspectives. *J.M. O'Daniel[1, 2], S.B. Haga[1], M.K. Rosanbalm[3], G.M. Tindall[1], L. Boles[4], T.M. Livingston[4].* 1) Duke Institute for Genome Sciences & Policy, Duke University, Durham, NC; 2) Illumina, Inc, San Diego, CA; 3) Center for Child and Family Policy, Social Sciences Research Institute, Duke University, Durham, NC; 4) Museum of Life & Science, Durham, NC.

Given the rapid pace of genetic and genomic research and technology development, it is increasingly important for the public to gain an understanding of genetic concepts and associated ethical and policy issues so as to enable informed deliberation of how it may affect their lives. Likewise, it is essential for genetic researchers to be aware of public perceptions and potential concerns about their work. Researchers, however, may be hesitant to take on the part of engaging the public due to their own perceptions of public knowledge and attitudes as well as concern for their ability to communicate with diverse, lay audiences about the importance and relevance of their work. To address these issues, we developed and piloted the Genome Diner discussion activity as a means to facilitate the engagement of genetic/genomic researchers with members of the local community. For the two year pilot, the community groups were composed of middle school students and their parents. In total 40 researchers, 76 students and 83 parents/guardians participated in one Genome Diner session. Program impact was assessed via pre/post surveys for each participant group. The most significant changes were demonstrated by researchers' responses. Researchers' assessment of public adult understanding of genetics concepts and whether the public believed research affected them increased significantly following participation ($p < .001$, $p < .01$ respectively). Positive changes were also measured in regards to researchers' perceptions about how the public viewed both genetic research and researchers including whether researchers liked interacting with subjects ($p < .01$) and whether participating in research was safe ($p < .01$). Post-Diner, researchers were also more convinced of the impact of researcher-community interaction on the conduct and focus of their research ($p < .01$). Lastly, researchers noted that the program increased their knowledge of strategies for communicating science ($p<.001$) and building relationships with diverse peoples ($p<.01$). In conclusion, through an interactive discussion with students and parents, researchers gained valuable insight of public perspectives about genome science research and technology. By building trust and essential relationships between the two groups, the engagement format of the Genome Diner program presents a novel method to better inform both the public and the researchers whose work may depend on their opinions and participation.

1405/T

Five clusters were assumed in the structure of the public attitude toward the genome research by the latent class analysis in Japan. *Z. Yamagata[1], T. Maedea[2], K. Muto[3], A. Tamakoshi[4], A. Nagai[1], I. Ishiyama[5].* 1) Dept of Health Sciences, Univ Yamanashi, chuo, Japan; 2) The Institute of Statistical Mathematics, Tokyo, Japan; 3) The Institute of Medical Science, The University of Tokyo, Tokyo; 4) Aichi Medical University, Aichi, Japan; 5) Teikyo-Gakuen Junior College, Yamanashi, Japan.

[Aim] The aim of this study was to clarify the structure of the public attitude toward the genome research by the latent class analysis. [Methods] The nationwide surveys about the attitude toward the genome research were conducted in 2005, 2008 and 2009 in Japan. The participants were comprised of 4,000 people (age, 20-69), selected from the Japanese general population by using the two-step stratified random sampling method. [Results] Five clusters were assumed as an explanation model of six variables related to the knowledge of genome and attitudes toward genomic research promotion about three themes; basic genome research, genome research related to agriculture and medicine at the survey in 2005. They were able to be named “Group of aggressive promotion” (40.8%), “Group of passive support” (20.2%), “Group not making judgment” (18.5), “Group making prudent judgment” (16.5%), and “Group not interested in genome”. The results in 2008 and 2009 were almost the same as that in 2005. It is possible to forecast to which cluster to belong according to respondent’s attribute, and we can forecast the reaction to other questions by using a cluster oppositely. For examples, “Group of aggressive promotion” is the layer of a high academic background, and is positive to donate their blood for the genome research, “Group making prudent judgment” is high academic background persons as same as “Group of aggressive promotion”, and is interesting in the science and technology, but is negative to the blood donation for the research.

Psychological and Behavioral Impacts of Direct-to-Consumer Personalized Genomic Risk Testing. *C.S. Bloss[1], E. Silver[2], L. Ornowski[1,3], M. Cargill[2], V. Vanier[2], N.J. Schork[1,4], E.J. Topol[1,3,4].* 1) Scripps Genomic Medicine, Scripps Translational Science Institute, and Scripps Health, La Jolla, CA; 2) Navigenics, Foster City, CA; 3) Scripps Clinic, La Jolla, CA; 4) Dept of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA.

Direct-to-Consumer (DTC) personalized genomic tests are controversial for many reasons, one being a lack of information regarding the impact of this type of testing on consumers. We examined the psychological and behavioral impacts of genomic testing with the Navigenics Health Compass (23 conditions assessed), a currently marketed genomic test, in a sample of convenience recruited between October 2008 and September 2009. A cohort of 3639 individuals was recruited from health and technology companies. Participants purchased the Health Compass at a discounted rate. We measured dietary fat, exercise behavior, and anxiety symptoms at baseline and an average of 5 months post-testing (follow-up), as well as test-related distress and intention to complete health screening behaviors with greater frequency at follow-up. A total of 2059 individuals completed follow-up. Primary analyses showed no significant differences in covariate-adjusted measures of fat intake ($p = .90$), exercise behavior ($p = .70$), or anxiety symptoms ($p = .77$) between baseline and follow-up. The number of health screening behaviors participants intended to complete with greater frequency post-testing was significantly increased from zero (Mean = 2, $p < .001$). Secondary analyses incorporating genetic risk estimates revealed that intention to complete screening behaviors with increased frequency was positively correlated with average estimated lifetime risk (ELTR) across the conditions assessed ($r_s = .048$, $p = .030$). A similarly positive correlation was also observed for test-related distress ($r_s = .18$, $p < .001$), however, over 90% of the sample had scores indicating no distress. DTC genomic testing did not result in significant short-term psychological risks, and data suggest that testing may be associated with increased compliance with recommended health screening practices. In the sample as a whole, no significant improvements in diet or exercise behaviors were observed.

Reprogenetics and Cross Border Reproductive Care: What’s So Unique With Reprogenetics? *V. Couture, C. Bouffard.* Division of Genetics, Department of Pediatrics, Université de Sherbrooke, Sherbrooke, Quebec, Canada.

Introduction: It is only in recent years that procreative tourism, also known as crossborder reproductive care, has attracted the interest of the scientific community because of the depth of the ethical, legal and social issues it raises. Despite this sudden concern, little research has been done on the particular situation of reprogrenetics. Moreover there is still confusion regarding the many ethical, legal and social issues associated with this crossborder reprogenetics. A large part of the work published does not always distinguish between procreative tourism to overcome infertility and the one based on the diagnosis of genetic or hereditary diseases and chromosomal abnormalities. Based on the literature on reproductive tourism, we developed an analytical frame of the ethical, legal and social issues that are specific to reprogenetics tourism. Methods: Qualitative analysis of the literature on reproductive tourism (n=151) from the major database provider in clinical sciences and social sciences (OVID, Journals@Ovid Full Text; EBSCO, 14 databases including MEDLINE, ERIC and CINAHL).Results: Four levels of analysis have emerged from the literature. The first level has allowed a mapping of reprogenetic tourism integrating: a) the diversity of legal frameworks between different states b) the location of centers of excellence and c) the users’ itineraries. The second level involves the mobility of practitioners and b) and of biological material. Third, the scarcity of reprogenetic services compared to those dedicated to fertility. This scarcity is based on: a) its high cost and b) the level of expertise required for its implementation. The fourth level reflects the interaction and the unique relationship established between the user and the caregiving personnel. It integrates: a) the linguistic and symbolic issues of cross-cultural counseling, b) the responsibility and the accountability of practitioners in monitoring and in referencing) and c) the psychological stress specific to users of reprogenetic services. Conclusion: Although there are many interrelationships between the medical, reproductive and reprogenetic tourisms, each has a configuration of its own. Reprogenetics has always been the object of major ethical and moral considerations. A better understanding of the actual state of the practice is a “fundamental condition” to the development of norms and guidelines that are adapted to the social changes and are equitable and people-centered.

Enrolling Children with Mitochondrial Disease in a Research Biobank: The Challenge of Meaningful Assent. *L. Eisenberg[1], A. VanDenBoom[2], W. Highsmith[1, 2], D. Oglesbee[1, 2].* 1) Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 2) Medical Genetics, Mayo Clinic, Rochester, MN.

Title 45 of the US Code of Federal Regulations, §46.408 states that every IRB overseeing research with minors “shall determine that adequate provisions are made for soliciting the assent of children.” Assent is defined as a child’s affirmative agreement to participate in research, which is a complement to traditional informed consent granted by the child’s guardian. Federal regulations grant IRBs leeway in defining what constitutes “adequate provisions,” as the statute only states that age, maturity, and psychological state should be assessed when reviewing a child’s capability of assenting. It is unclear if merely soliciting assent is sufficient, or if assent must be obtained in order to proceed with enrollment. As part of the development of a biobank studying mitochondrial diseases, we examined the practice of obtaining assent through an analysis of previously published literature. We then formulated contemporary guidelines for obtaining assent, and utilized our strategy during biobank recruitment over the last six months. Our analysis showed that there are few common practices regarding assent. Minimum ages for assent ranged from seven to fifteen years old, depending upon the researcher’s conclusion about the age at which a child is able to appreciate the risks and benefits of research participation. There was also varying credence given to the impact of a child’s cognitive delays or symptoms limiting cognitive function on the assent process. The relatively rarity of mitochondrial disease makes it necessary for us to obtain consent for our biobank through the mail, a complexity largely neglected in assent research. Furthermore, few studies deemed a child’s refusal to assent as grounds to exclude the child from participation. Some minors with mitochondrial disease will never develop the capacity to give meaningful assent. Participation is unlikely to directly benefit the enrolled child, and this leads to reluctance to utilize children as research subjects. However, without research on children, it is difficult to advance understanding of diseases that are terminal in childhood. Therefore, it is important to standardize guidelines for assent and enhance the potential of research studies to directly benefit children. Thus far, none of our assented pediatric participants have refused to participate. Our experience suggests that by actively seeking assent, it is possible to meet high ethical standards while not significantly decreasing participation.

1409/T

Use of GWAS markers from HapMap 3 can be used to create a SNP-based individual information panel with high information content and very little population bias, which could provide an improvement over the current STR-based CODIS 13 forensic DNA panel. *J. Fagerness[1, 2, 3], R. Siburian[1, 2, 3], S. Purcell[1, 2, 3], B.M. Neale[3], C. O'Dushlaine[3], A. Kirby[3], M.A. Rivas[3], J.W. Smoller[1, 2, 3], M.J. Daly[3], D.L. Pauls[1, 2, 3].* 1) Dept Psychiatry, Massachusetts Gen Hosp, Boston, MA; 2) Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts Gen Hosp, Boston, MA; 3) Center for Human Genetic Research, Massachusetts Gen Hosp, Boston, MA.

The FBI was given formal authority to establish a National DNA Index System (NDIS) in 1994 and has been using a 13 short tandem repeat (STR) marker panel as a way to forensically test individual identity for the purposes of law enforcement. In 2005 the DNA Fingerprint Act was passed and the Combined DNA Index System (CODIS) database has quickly grown to over seven million profiles. We wanted to assess the information content across a number of populations in order to determine how well the 13 CODIS markers uniquely identify any given individual from any given population. Using popSTR (http://spsmart.cesga.es/popstr.php?dataSet=strs_local) we found that the information content in the 13 CODIS markers can vary by more than 10-fold from one population to the next. Given the dramatic improvements in genotyping technology, we identified 85 autosomal SNPs that are maximally and equally informative (>40% minor allele frequency (MAF)) in all 11 populations of HapMap3 and are represented on all 22 chromosomes at greater than 10Mb apart from one another, leaving negligible linkage disequilibrium (LD) between any SNP-pair. Further, these 85 SNPs confer a random match probability (RMP) of greater than one in $1x10^{25}$ for any given individual to any other individual. This is significantly better than the 13 CODIS marker's RMP of between one in $1x10^{9}$ to $1x10^{10}$. In order to verify that our 85 SNP panel was useful in more than just the 11 populations represented in HapMap 3 we used data from the Human Genetic Diversity Panel (HGDP) and popSTR. These two datasets contain similar populations allowing us to examine the information content of the 13 CODIS markers and compare them to the 44 of 85 SNPs that are present in the HGDP SNP dataset. The 44 SNPs vary in information content less than 1.5-fold and have an RMP of one in $1x10^{13}$. The power of equal information content becomes apparent when looking at the combinatorix algorithm for "cold-hit" cases. For example, not all of the CODIS markers contain equal information and certain populations have very little information in some of the 13 CODIS markers. Therefore, hundreds to thousands of "positive" matches can seemingly occur on any 9 out of the 13 CODIS markers, with certain populations having orders of magnitude greater chance for seeing these matches. Using this new technology and a genome-wide approach to human genetic variation should allow for stronger statistical proof of guilt or innocence in the justice system.

1410/T

Conducting high-throughput genomic research in the setting of a healthcare cooperative: recommendations from a consensus development panel. *S.M. Fullerton[1], S.B. Trinidad[1], D.C. Grossman[2], G.P. Jarvik[3], E.B. Larson[2], W. Burke[1,2,3].* 1) Dept Bioethics & Humanities, Univ Washington Sch Med, Seattle, WA; 2) Group Health Research Institute, Group Health Cooperative, Seattle, WA; 3) Medical Genetics, Univ Washington Sch Med, Seattle, WA.

As part of the electronic MEdical Record and GEnomics (eMERGE) Network, the Group Health Research Institute hosted a seven-month long consensus development process aimed at discussing genome-wide association studies (GWAS) and related whole-genome research and the ethical, legal, and social implications of pursuing such studies with Group Health members. Consensus development approaches are used for many purposes, including practice guideline development and healthcare priority-setting, to ensure the incorporation of different stakeholder views. Structured deliberative procedures can elicit and combine different types of evidence; promote accountability and transparency; and produce guidance that is acceptable to both experts and the public. Our consensus development panel, which was convened to develop research policy recommendations for Group Health leaders, comprised 13 members chosen to represent key stakeholders, including general Group Health members, researchers, healthcare providers, and legal and administrative representatives. The panel met in person seven times to deliberate on issues it identified as key priorities, including informed consent, return of research findings to participants, and sharing research data with researchers outside of Group Health. Informed by the results of several local empirical investigations and Group Health's commitment to trustworthy research practice, the panel arrived at 11 key recommendations, outlining the ways in which research risks should be described to prospective participants, the advisability of re-consenting subjects for research uses materially outside the scope of original consents, the need to offer aggregate - and where appropriate, individual - research findings to participants, and advocating for the transparent description of anticipated data sharing as part of the informed consent process. The panel also urged the Institute to avoid recourse to genetic exceptionalism in research review, while acknowledging public perceptions that genetic research can be more risky than other forms of health research. These recommendations formed the basis of a final report presented to the Group Health Cooperative Board of Trustees in December 2009.

Deriving Individual Genotypic Barcodes from Gene Expression Data. *K. Hao[1], E.E. Schadt[1,2].* 1) Research Genetics, Rosetta Inpharmatics, Seattle, WA; 2) Department of Medical Genetics, University of Washington, Seattle, WA.

Backgrounds. mRNA profiling study simultaneously captures the expression pattern of many genes. The expression levels are often under genetic control, characterized as expressional quantitative trait loci (eQTL). A growing amount of mRNA expression data has been deposited into public databases, which may expose the identity of participants. Methods. Employing published eQTLs as the prior, we developed a Bayesian approach to predict genotype based on mRNA expression data. The predicted genotype on many eSNPs forms an inferred genotype vector for each individual, which can reveal individual's identity. We evaluated this novel approach on three large human cohorts. Results. We find strong eQTLs are highly consistent among studies on the same tissue and across different tissues (e.g. liver and adipose). Such high consistency allows us to use published eQTLs and predict eSNP genotypes of an independent mRNA expression dataset. On empirical data, our method was shown to offer very high accuracy. In within-tissue scenario (eQTLs and testing data are on the same tissue type), we resolved 98% testing subjects' identity at p£1E-5 confidence level. In cross tissue scenario, we resolved 92% subjects' identify at p£1E-5. Conclusions. Individual's identity can be accurately resolved using mRNA profiling data. We discuss a number of implications. For example, this novel method provides quality control against DNA-RNA pair mis-annotation in eQTL studies. More importantly, deriving genotypic information from mRNA expression datasets of public domain may unmask participant's identity.

Ethical implications emerging from research into the genetic and genomic aspects of autism spectrum disorders: A qualitative study of parental opinions in Japan. *J. Higashijima[1], K. Takahashi[2], M. Oi[1], K. Kato[2].* 1) Kanazawa University, Kanazawa City, Ishikawa, Japan; 2) Kyoto University, Kyoto City, Kyoto, Japan.

The tragic history of eugenic social policy is a dreadful example of past social reactions to genetic research into the human mind and behavior. This history demonstrates the necessity of considering the social and ethical implications of each research project in the research field. Today, genetic and genomic research related to autism spectrum disorders (ASD) has grown to become one of most prominent research areas concerning the human mind and behavior. As such, consideration of the social and ethical implications of this research is essential for both the scientific community and society at large (Journal of Genetic Counseling, 15, 41-50; American Journal of Medical Genetics, Part C, 142C, 52-57). As part of this process, an examination of the voices of related parties in each cultural context is essential. The aim of the current research is to clarify and examine Japanese parental attitudes towards, and knowledge regarding, genetic and genomic ASD research. The data was collected through semi-structured interviews with parents of at least one child diagnosed with ASD. Approval for this study was obtained from the Medical Ethics Committee of Kyoto University, Japan. The core questions were divided into four parts: (i) Demographics; (ii) Parental knowledge of gene mutation; (iii) Parental knowledge of ASD research; and (iv) Parental attitudes toward ASD research, focusing especially on genetics. The 50 interviews conducted for this study revealed several controversial issues for researchers, medical personnel, and genetic counselors to discuss. In general, our results showed that Japanese parents had little scientifically valid knowledge of genetic and genomic ASD research, even though they expressed serious interests and concerns about the matter. Parents were highly ambivalent about super early diagnosis and prediagnosis, as a result of the close relationship between these subjects and abortion, parental mental health, the Japanese social support system, and social attitudes to ASD. Clarification of the existence of any genetic differences between people with and without ASD was also regarded as controversial. In this presentation, we will discuss the issues mentioned above in detail.

Individual Return of Research Results (IRRS) and Incidental Findings (IFs) in Stem Cell Research: Exploring the Ethical & Legal Implications. *R. Isasi, B.M. Knoppers.* Centre of Genomics & Policy, McGill University, Montreal, PQ, Canada.

Recognizing that incidental findings (IFs) are intrinsic to the general research endeavor, an emerging debate centers on whether providing feedback to research participants (IRRS) is an ethical duty of researchers. Even if the definitional issues are solved, the development of what would be the best mechanisms to manage IRRS and the roles and responsibilities of all stakeholders e.g. (researchers, participants, licensing/oversight bodies, ethics review committees, biobanks, etc) is still in its infancy. The emergence of an ethical duty to provide IRRS not only argues for a re-evaluation of such roles and responsibilities, but also for the reappraisal of the traditional informed consent process, which usually maintains that no individual results will be returned. In the specific context of stem cell research, the scientific and ELSI implications concerning IIRS and the discovery and management of IFs are rarely addressed. Notable exceptions are recommendations adopted by the EGE of the European Commission and guidelines adopted by the US National Academies of Science. In the abovementioned policies, the potential discovery and management of clinically significant information are considered essential elements of the informed consent process. Furthermore, these policies call on stem cell banks to adopt protocols governing the delivery IRRS back to donors. Given the peculiarities of stem cell research, both the general research and clinical contexts could serve only as ethicalguidance concerning the establishment of appropriate mechanisms addressing the IRRS and IFs. A prospective and nuanced analysis must address questions such as: Do stem cell researchers have a duty to return research results to research participants ? Do different sources of stem cell lines warrant a different policy approach? Who, when, how and to whom should research results and IFs be communicated? Finally, will policies pertaining to IFs strength or weaken donors' rights (autonomy, privacy and confidentiality, etc.)? This presentation will provide a prospective analysis of the scientific, socio-ethical and legal issues arising from the disclosure of IRRS and the identification of IFs in the context of stem cell research (e.g. embryonic and iPs cell lines). Drawing from examples arising from the general research context, we will further explore policy approaches and mechanisms so as to address the identification, management and disclosure of IRRS and IFs.

1414/T

The eMERGE Consortium: An NIH-supported model for integrating bioethics into leading-edge genomic research. *B. Koenig[1], S. Fullerton[2], A. Lemke[3], C. McCarty[4], E. Wright Clayton[5].* 1) Mayo Clinic 200 First St. SW Rochester MN, 55906; 2) University of Washington 1959 NE Pacific Avenue Seattle, WA 98195; 3) Northwestern University 676 N. St. Clair Street, Suite 1260 Chicago, IL 60611; 4) Marshfield Clinic Research Foundation 1000 North Oak Avenue - MLR Marshfield, WI 54449; 5) Vanderbilt University 2525 West End Ave., Suite 400 Nashville, TN 37203.

Genomic research technologies are evolving rapidly, generating unprecedented ethical challenges. Ethical, legal, and social issues (ELSI) include: requirements for sharing of genotype and phenotype data collected by NIH-funded researchers; recognition that new models of biobank governance are required when data are shared widely; increasing evidence that research participants expect to receive research results; and the increasing integration of sensitive electronic medical record (EMR) information into genomic research. Furthermore, simple "de-identification" of data is an inadequate strategy to protect human subjects and may not ensure trust in the research enterprise. The eMERGE network is a "proof-of-principle" consortium created by NIH to develop, disseminate, and apply innovative approaches to research that links DNA biorepositories with phenotypes obtained directly from the EMR. While funding several genome-wide association studies and associated bioinformatics research, the eMERGE network simultaneously funded bioethics researchers at 5 institutions (Group Health/UW, Marshfield, Mayo, Northwestern, Vanderbilt). Empirical bioethics research and analysis is fully integrated into ongoing genomic research. The Consent and Community Consultation (CCC) workgroup is tasked with identifying challenging ethical issues and developing guidance for researchers. The CCC is divided into sub-groups targeting the following areas: the identifiability of DNA and EMR data, return of results, IRB oversight, engagement with communities, data sharing, and informed consent. The consortium's goal is to produce recommendations and best practices for researchers and policy makers not only within eMERGE, but also for the research community at large. Outcomes of empirical bioethics research, comparisons of diverse approaches to community engagement, and development of model informed consent language have directly informed eMERGE research protocols, oversight, and the development of new research infrastructure. The eMERGE network represents a novel approach to conducting bioethics research in the context of a large multi-center research project. Through the eMERGE experience, we illustrate a novel approach to bioethics research, demonstrating how empirical studies inform normative deliberation, which in turn informs the creation of recommendations and best practices developed in direct collaboration with colleagues in bioinformatics, basic science, and clinical genomics.

1415/T

The General Public's Understanding and Perception of Direct-to-Consumer Genetic Test Results. *J.W. Leighton[1], K. Valverde[1], B. Bernhardt[2].* 1) Arcadia University Genetic Counseling Program, Glenside, PA; 2) Penn Center for the Integration of Genetic Healthcare Technologies, Division of Medical Genetics, Hospital of the University of Pennsylvania, Philadelphia, PA.

Direct-to-consumer (DTC) genetic testing allows consumers to discover their risk for developing common complex disorders without involving a medical professional. Consumers may not understand test results, leading to negative consequences including unnecessary concern, false reassurance, or unwarranted changes in screening behaviors. To investigate consumers' perceptions and understanding of DTC test results, an online survey was posted on facebook.com that included questions relating to 4 sample test results for risk of developing colorectal cancer, heart disease, and skin cancer. Genetic counselors (GCs) were used as a comparison group and completed the same survey through the NSGC listserv. 145 individuals from the general public (GP) and 171 GCs completed the survey. A significant difference ($p<.05$) was found between the GP and GCs understanding of genetic test results in 3 of 4 scenarios. When results were presented in terms of relative risks, GP respondents were significantly more likely to misinterpret risks than were GCs. When presented with a scenario providing results indicating a slight reduction in absolute risk, GP respondents were significantly more likely to believe their risk was "much lower." With respect to medical management, the GP thought results in all four scenarios would be significantly more helpful than did GCs. Although the majority of GP respondents rated the results either very easy or easy to understand, they often were unable to correctly interpret the results. For example, in the scenario involving a relative risk of 1.45 for developing colon cancer, 71 of the GP respondents felt that results were easy to understand, but only 42 (59%) of them correctly interpreted the results. These findings imply that the GP has the potential to misinterpret DTC results without appropriate assistance. Further research is needed exploring optimal methods of providing DTC test results and ways to minimize the risk of negative consequences for consumers.

1416/T

Developing Global Genetics. *K. Leppig[1], M. Laurino[2], D. Sternen[3], J. Thompson[3], G. Snudden[4].* 1) Gen Services, Group Hlth Cooperative, Seattle, WA; 2) Public Health Genetic Department, University of Washington, Seattle, WA; 3) Genetic Medicine, Seattle Children's Hospital, Seattle, WA; 4) BlueGnome Limited, Cambridge, UK.

The development of global genetics in emerging countries has been addressed in recent ASHG and ACMG annual meetings. While health care in emerging countries has initially focused on areas of nutrition and infectious disease, there has been an increased recognition that genetic services can improve healthcare for both individuals and a population. A number of clinical geneticist and genetic counselors who have worked in emerging countries have been approached for assistance in developing clinical care and education programs in emerging countries. While individual efforts are essential, the development of a global genetics requires a coordinated effort between medical professionals in emerging and developed countries. Ongoing projects that serve as examples include a partnership to develop clinical genetics programs at Hue College of Medicine and Pharmacy, Vietnam and the development of the first genetic counseling program at University of Manila, the Philippines. Challenges identified thus far include difficulties working with diverse cultural, language and social differences. With limited trained clinical geneticist and genetic counselors, there is a need to develop robust training programs within the emerging countries partnering with established genetic programs. The advances in technology are essential for developing cost-effective genetic testing for genomic and metabolic disorders. The successful development of global genetics will depend on the coordination of training genetic professionals,application of technologic advances in genetic testing, the development of the necessary infrastructure, and a commitment from those in the medical genetics community.

1417/T

Attitudes and beliefs of Hispanics in South Florida regarding participation in genomic research. *R.J. Martinez, M.J. Gavier, S.E. Hahn, J.L. Robinson, B.T. Lemelman, M.A. Pericak-Vance, M.L. Cuccaro.* John P Hussman Inst Human Genomics, Univ Miami, Miami, FL.

The success of genomic research relies on participation from diverse populations. Representation of minorities in genomic studies is paramount to ensure potential ethnic differences are considered in disease patterns. Hispanic populations are underrepresented in genomic research. The urgency to include Hispanic populations in genomic research has led to development of targeted, culturally sensitive, community-based enrollment strategies. Nonetheless, limited data exist on the attitudes, beliefs, and perceptions of the Hispanic community concerning participation in genomic research. The goal of this research was to identify barriers to participation in genomic research among Hispanics using a focus group methodology. Focus group participants were recruited from South Florida in Miami-Dade County, which has a large rapidly growing Hispanic population (62% Hispanics, U.S. Census Bureau). Focus groups were organized by ethnicity (Colombia, Cuba, Dominican Republic, Honduras, Peru, and Puerto Rico). The groups ranged in size from 7-10 participants (average 9 per group). Participants were 38% male and 62% female. Average age of participants was 46 years(sd=13.5). All focus group sessions were conducted and analyzed in Spanish by multicultural facilitators using a standard format. The primary qualitative data were derived from analysis of common ideas, categories, and themes (e.g., access to health/ genetic studies information, knowledge/ understanding of genomic research, perceptions/attitudes regarding genomic research, cultural barriers/motivators to participation in genomic research, and effective communication strategies). These data were compared across the different Hispanic groups and will be used to develop specific recruitment strategies for each group. Our initial results revealed several prominent concerns such as access to trusted sources of medical/ genetic information for their respective communities and the perception that genomic research was not beneficial to their community. We will present passages for each of the themes by groups. Focus groups are valuable tools for exploring the attitudes and beliefs of community members. To increase participation of Hispanic groups in genomics studies it is crucial that we use focus groups to identify specific barriers. The knowledge generated from such focus group research can help investigators tailor recruitment procedures and improve participation rates among Hispanic individuals.

1418/T

Attitudes toward genetic testing in Japan: National surveys in 2005, 2008 and 2009. *K. Muto[1], A. Nagai[2], A. Tamakoshi[3], T. Maeda[4], I. Ishiyama[5], Z. Yamagata[1].* 1) Dept Pub Policy, IMS, Univ Tokyo, Tokyo, Japan; 2) Dept. of Health Sciences, School of Medicine, Univ. of Yamanashi, Chuo, Japan,; 3) Aichi Medical University, Aichi, Japan; 4) The Institute of Statistical Mathematics, Tokyo, Japan; 5) Teikyo-Gakuen Junior College, Yamanashi, Japan.

[Aim] The aim of this study is to explore attitudes toward genome research applied to medicine among the general population of Japan, focusing on willingness to undergo genetic tests for disease susceptibility and pharmacogenetic tests. [Methods] Postal questionnaire surveys were conducted in 2005, 2008 and 2009 in random samples of the general public in Japan. The questionnaire included items on genetic knowledge, attitudes toward the application of genomic studies to medicine and crop science, basic genomics research, and technology. We analyzed the data with a focus on the attitudes toward the application of genomic studies to medicine. [Results] There were 2171 participants in 2005 (response rate, 54%), 1613 in 2008 (response rate, 54%) and 2005 in 2009 (response rete, 50.1%). In both surveys, most respondents had positive attitudes toward these genetic tests. The logistic regression analysis showed that significant predictors of the willingness to undergo both genetic tests were to perceive more benefit and having positive impression and interest in the research. Considering that the use of genetic testing is likely to increase in the near future, we propose that more information about genome and communication between scientists and the public should be provided in Japan.

1419/T

The HumGen Spanish Portal, a tool for Public Health Genomics in Latin America: Improving, legal and policy frameworks, based on knowledge transfer networks. *P.F. Oliva - Sanchez[1,2,3], J. Zaga - Galante[2], R. Isasi[3], A. Carnevale[1], B. Knoppers[3].* 1) ELSI Dept, National Institute of Genomic Medicine, México City, Distrito Federal, Mexico; 2) School of Health Sciences, Dept. Medicine, Anahuac University, Mexico; 3) HumGen International Project,Centre of Genomics and Policy at McGill University (CGP), Canada.

Public health genomics (GSP) is a multidisciplinary field that concerns responsible and effective translation of knowledge and risk-based genomic technologies. Through the genomic variation in populations and gene - environment interactions, it designs and develops applications for improving health and prevention, based on genomic knowledge. One of the challenges in translational genomic medicine, in addition to its analytical and clinical validation, are the ethical, legal and social issues (ELSI) surrounding this genomic applications. In response, since January 2008, the National Institute of Genomic Medicine in collaboration with the Centre of Genomics and Policy at McGill University (CGP) in Canada, have been successfully developing the Spanish HumGen Portal. This is a researchable database, where normative texts related to human genetics ELSI issues are compiled, combining documents with national, regional and international influence. The selection of these laws is done through a process of rigorous qualitative research. The portal is aimed at the general public, but with an emphasis on decision-makers with the capacity to formulate policies on matters related ELSI genetics and human genomics. The developing countries are facing a problem, the applied genomics research to public health have a significant advance, but the legal information is not developed in tandem with scientific advances. HumGen is a valuable tool transfer knowledge, accessible and free, strengthening the content of these strategies through the analysis of Comparative Law. In the portal there are 64 laws and policies, of which 54% are regional normative texts of the Latin American countries, 24% are national laws and policies and 22% are decrees of international organizations. The topics included in the international and regional documents are: ethical principles in human genetics research, data protection, genetic diversity and patents. National laws focus on cloning, human reproduction and stem cells. Latin American countries are not taking a future perspective, because they do not regulate and legislate the technology derived from research in human genetics. The promotion of this portal in legislative and professional forums through knowledge networks, is one of principal strategies that will help to the development of regulatory frameworks in the Spanish speaking countries appropriate to the current scientific progress.

Patients' and researchers views of the etiology of addiction: the interplay of social and genetic factors. *J.E. Ostergreen[1], J.B. McCormick[1,2], M. Dingel[3], B. Partiridge[1], M.E. Robinson[1], B.A. Koenig[1,2].* 1) Health Sciences Research, Mayo Clinic and College of Medicine, Rochester, MN; 2) Medicine, Mayo Clinic and College of Medicine, Rochester, MN; 3) University of Minnesota-Rochester, Rochester, MN.

Research on the biology of addiction has implicated a number of neurotransmitter systems in both the reinforcement and dependence-inducing effects of various substances including nicotine and alcohol. One of the more widely studied is the dopamine system, which is thought to be involved in brain reward functions. Mounting evidence from neuroscience, bio-behavioral, and pharmacological studies suggests that genetic factors are involved in vulnerability to substance addictions including alcohol and nicotine. Evidence for the genetic basis of smoking was first suggested by family and twin studies, and more recently, genetic association studies examining the role of specific candidate gene variants. The science is moving quickly and producing exciting findings with potential clinical application. To ascertain how biological understanding of addiction may be influencing prevention and treatment measures, we did a NIH funded study aimed at examining the complex interplay of the social and scientific "causes" of addiction. We have interviewed patients undergoing treatment for either alcohol or nicotine dependence. Our informants expressed varied interpretations of the "causal" elements of their addiction. For some, addiction is all genetic; for others environmental factors are more important. A few expressed anxiety that an "addiction gene" would mean loss of free will and control; others saw hope that a genetic link would mean less stigma and more social acceptance of the "addiction disease." To complement these data we investigated researchers' concepts of addiction as a biological question and a public health problem. Analysis reveals that some scientists view addiction as a condition with both genetic and environmental components. They acknowledge the complexity of not just GxE interactions but also gene/gene interactions in determining the underlying biological basis of addiction. Some also noted that defining an addiction phenotype is a limitation in study design and analysis. Our researcher participants refer to addiction as a disease and a behavior, and view pharmacological and behavioral therapies as important options. Determining biological underpinnings of addiction uses a reductionistic approach and can influence how the research findings are translated from bench to clinic. Ascertaining what researchers' and patients' view as the etiology of addiction is critical to informing public health policies targeted at treatment and prevention.

Privacy concerns regarding large prospective genetic research. *J. Scott, D. Kaufman, S. Devaney, J. Murphy Bollinger.* Gen & Pub Policy Ctr, Johns Hopkins Univ, Washington, DC.

Objective: Large prospective studies that use DNA annotated with medical, lifestyle and environmental data are important research tools. However, the breadth of information collected and the potential to widely share these data with researchers raises privacy concerns among potential participants. To explore public concerns about privacy and access when considering participating in such studies, we conducted 10 focus groups with 89 people across the US. **Methods**: Between October 2009 and January 2010, 8 focus groups were conducted in-person in DC, Philadelphia, and Denver and 2 groups were conducted online. Participants represented a range of demographics including race, gender, age, ethnicity, socioeconomic status, and social networking behavior. We described a potential US cohort study that would protect participants' information by (1) removing all personal identifiers and replacing them with a code; and (2) only sharing coded data with those researchers whose applications have been approved by the NIH. We asked participants about privacy issues and opinions on data access and sharing. Participants were also asked whether law enforcement should have access to the database to solve a crime or to identify victims of a mass tragedy. We asked participants their opinions about the implications of certificates of confidentiality (COCs) and GINA on privacy. **Results**: Most participants said that coding as described would provide adequate privacy protection, and most supported sharing data with qualified researchers. However, majorities in all focus groups did not want insurance companies or employers to have access to the research database for fear of discrimination. Almost all focus group participants vehemently opposed law enforcement accessing the database for fear it would deter people from participating. While a few individuals were willing to let law enforcement access the database in the event of a mass tragedy, most held firmly to their belief that law enforcement should not have access. Participants were unaware of the recent passage of GINA and most were not reassured by the protections it offered. There was unanimous support for researchers obtaining COCs. **Conclusions**: Privacy concerns are important to potential research participants. The concerns center on how the study information in the database could be used against them, especially by insurers and employers. Protections afforded under GINA did little to reassure participants.

1422/T

Analysis of Exome Sequence Data for Potentially Returnable Research Results. *H.K. Tabor, NHLBI's Exome Sequencing Program—and Lung Project and ELSI Project Teams.* Ctr Pediatric Bioethics, Seattle Children's Hosp, Dept of Pediatrics, University of Washington, Seattle, WA.

Exome sequencing is rapidly becoming an important tool for the identification of genes involved in rare Mendelian traits and perhaps common complex traits as well. As the popularity of this approach increases, researchers are facing new ethical challenges regarding the return of clinically important results to research participants. Because the coding regions of nearly all genes are targeted by exome sequencing, variants of *possible* clinical significance are likely to be found in nearly every participant. Whether such research findings should be returned to participants, how this is best done, and what might be the impact has been a topic of vigorous debate within genetics and bioethics. To date, this debate has been informed primarily by research findings in linkage or GWAS studies, where the identification of clinically significant findings is predicted to be a rare event. There are virtually no data about the range of possibly returnable findings that might be identified with exome sequencing. We analyzed exome data from 65 persons with cystic fibrosis (CF) sequenced as part of a study to identify genetic modifiers of CF. We cataloged known and novel variants in CFTR and selected genes involved in Mendelian disorders, risk for common diseases, and pharmacological traits. CFTR was included to compare exome results to those from previously obtained clinical testing. Exome sequencing identified several novel variants in CFTR that were not identified by clinical testing and missed one variant that had been found by clinical testing. In 70% of participants, we found variants of potential clinical importance in at least one gene other than CFTR. Twenty percent of participants had variants of potential clinical importance in two or more genes. These results suggest that exome sequencing will identify a potentially large number of clinically important and possibly returnable findings, including novel changes and changes of unknown significance. However, exome sequencing will not identify all pathogenic variants in coding regions. Accordingly, exome sequencing presents new and unique challenges for investigators who consider return of results. These findings have implications for the development of policies and procedures for return of results for experimental approaches utilizing either exome or whole genome sequencing. No decisions have been made yet about whether to return findings for this cohort.

1423/T

Attitudes on DNA Ancestry Tests. *J. Wagner.* Dept Anthropology, Penn State Univ, University Park, PA.

The DNA ancestry testing industry currently has 39 companies selling ~200 products and >500,000 customers. Yet the industry remains young and uncertain. No obvious industry-wide standards have been established regarding methods or communication of results. Where does one begin to evaluate the potential ethical, legal, and societal consequences of an industry that lacks a clearly defined product, clearly delineated market, or uniform commercial vision? The type and degree of the potential implications, however, must be dependent upon the attitudes on DNA ancestry tests held by those aware of the tests. Those attitudes are undoubtedly variable and changing, yet data on those attitudes are surprisingly scant. This anthropological study explored attitudes on DNA ancestry tests, including what motivates individuals to purchase the tests, how they value or interpret the scientific capabilities, and for what purposes they believe the results should be used. Questionnaires, designed and administered using Survey Monkey, were administered to general participants (N=176) recruited in State College, PA and to targeted participants (N=76) recruited through Facebook DNA ancestry-related groups. General results suggest individuals view the relationship between DNA ancestry and race in a more nuanced way than is frequently acknowledged. Test-takers are more knowledgeable about genetics generally. The main motivations for testing are education, entertainment, and curiosity. Results of this study do not support the oft-cited reasons for individuals avoiding DNA ancestry tests, namely fear of results, desire not to know, and privacy concerns. While individuals support use of DNA ancestry tests in research and support personal rights to access such information, individuals generally oppose most potential uses and are notably reluctant to permit such tests in litigation or law enforcement settings. Targeted results suggest individuals are motivated to get tested for genealogical purposes and are not motivated by legal purposes. Those who had not purchased tests avoided thembecause of cost and opportunity, not because of fear of results, preference not to know, and privacy concerns. These Facebook individuals were purchasing tests from multiple companies and reporting some changes in identity and behavior in light of the DNA ancestry testing, Results suggest the discussion about negative psychological effects of DNA ancestry testing may be overstated in the literature.

Determining the effect of bacterial infection of human remains on the quality and quantity amplifying of aged bone DNA. *a. ghasemi[1,2], m. Tavallaei[3], m. Naderi[3], s. Habibi[3], m.m. Aslani[4], a.t hajizade Sharif[5], n. Mahdieh[2], m. Sarafi Farzad[2], m. Kargar[1], f. Kafilzadeh[1], a. Shirkavand[6,2], z. Zafari[7,2], s. Zeinali[8,2].* 1) 1Azad University of Jahrom, Fars, Iran; 2) 2Kawsar Human Genetics Research Center, Tehran, Iran; 3) 3Human Genetic Research Center, Baqyatallah Medical Sciences University, Tehran, Iran; 4) 4Microbiology Research Center, Pasteur Institute of Iran, Tehran, Iran; 5) 5Academic Center of Education, culture & Research, Yazd, Iran; 6) . 6Biology Group, Faculty of Sciences, Razi University, Kermanshah; 7) 7Khatam University, Tehran, Iran; 8) 8Biotechnology Research Center. 9 Pasteur Institute of Iran, Tehran, Iran.

One of the most important applications of DNA profiling is identification of human remains. These tests are applied for identification of human remains from natural disasters, wars, archaeological remains, in forensic laboratories. For this purpose, bone and teeth are the major source for genomic DNA. When a sample is aged, many problems may occur with the genomic DNA, such as DNA degradation and DNA contamination and presence of PCR inhibitors. These problems may lead to difficulties in performing PCR and act as inhibitory factors for PCR based techniques. To overcome these problems, we have checked the existence of bacterial DNA (as a contaminant) in DNA extracted from Iranian human remains from the 8 year Iran-Iraq war. We checked these DNA using ABI Identifier kit.We have tested probable effects of bacterial DNA on amplifying aged bone DNA .In spite of high volume of extracted DNA, we could not amplify aged bone DNA .We extracted DNAs from blood, aged bone (20-30 yrs ago) and bacteria. Artificial condition as a positive control for contaminated DNA was created by adding bacterial DNA to human blood DNA Using different aged bone and bacterial DNA dilutions along with PCR based methods; we tried to test their positive, negative or inhibitory effects on each other. Quantification of these effects is carrying out by real-time PCR. We also created artificial conditions as a positive control for contaminated DNA. For this, we simply added bacterial DNA to human bone DNA, In order to assess and check the inhibitory effects. Our experiments showed that bacterial DNA does not act as an inhibitory factor. Therefore, presence of bacterial DNA does not have any negative effect in amplifying DNA. Indeed it may act as a molecular marker to test human DNA for its ability to be amplified by PCR prior to using expensive kits.

1425/T

Role of DTC Relationship Testing Laboratories in Human Trafficking Prevention. *S.H. Katsanis.* Genome Ethics, Law & Policy, Institute for Genome Sciences & Policy, Duke University, Durham, NC.

Genetic identification technologies can deter human trafficking by confirming claims of biological relationship in immigration and adoption procedures. Over the last decade in Guatemala, reports of adoption fraud led the US Embassy to request DNA tests to confirm the relationship of a relinquished child and biological mother in adoption procedures. However, reports revealed that DNA testing also was conducted through fraudulent means, primarily through US-based direct-to-consumer (DTC) relationship testing (RT) laboratories. While the sources of fraud are under continuing investigation with Guatemalan authorities, the responsibility of the RT laboratories in maintaining chain-of-custody remains unclear. RT laboratories process over 400,000 cases per year including samples required for international adoptions and immigration. RT laboratories are subject only to professional oversight and guidelines. Of the 39 US laboratories offering RT, all are AABB certified, 11/39 are CLIA certified, and 14/39 are accredited for forensic testing. 32/39 companies market for immigration testing, 17/39 market testing for adoption, and 13/39 also offer ancestry testing. Authorities in Guatemala and other countries are working with US-based RT laboratories to develop cross-border DNA protocols to deter human trafficking. The lack of US federal oversight for RT laboratories warrants an evaluation of RT laboratory policies, particularly the retention of biological samples. Retaining a specimen makes it available for additional analysis using new technologies and for verification of a profile after a match. Yet, samples retained without legal authority have few privacy protections from the potential misuse or release of genetic material. Samples may be retained as source specimen (e.g., whole blood, saliva), stain cards, purified DNA, or amplified products. The policies for retaining samples collected by RT laboratories vary depending on 1) type of sample retained; 2) intended use of sample; 3) whether the sample was voluntary or required; 4) whether the laboratory is private or public; and 5) whether the laboratory follows CLIA or forensic oversight standards. Implementation of international DNA databases of missing persons to deter human trafficking could potentiate profound societal benefit. It is vital at this early stage to establish policies to guide laboratory operations and protect the individuals at risk of misuse of their samples and resulting profiles.

A Survey of Attitudes Toward Behavioral Genetic Testing. *A. Wise[1], J. Bosson-Heenan[1], J. Gruen[1,2].* 1) Yale University, New Haven, CT; 2) JS Genetics, New Haven, CT.

Though many genetic studies today seek to identify genetic markers associated with behavioral conditions, there is a dearth of research regarding the public's attitude toward using these research results for genetic testing. Is there a demand for genetic testing for behavioral conditions? What are the publics' concerns with such testing? Does interest depend upon how genetic the public perceives the condition to be? Our research study aims to examine attitudes toward genetic testing for behavioral conditions, such as attention deficit hyperactivity disorder (ADHD), dyslexia (a reading learning disability), and addiction (alcoholism, nicotine dependence, or other drug addictions). Subjects were recruited off the street and at local fairs, markets, and clinics in New Haven, CT to obtain the most representative and unbiased population possible. Participation in the study involved completing a brief 16-question survey that required approximately 5 minutes of the subject's time. Preliminary results of the survey indicate that ~80% of respondents believe that genetic testing should be made available for ADHD, dyslexia, and addiction. When queried if they personally would consider genetic testing for themselves or their children, the positive response rate remained the same when the result of the test was personalized treatment/therapy or an individualized education plan, dropping to ~75% when the testing result was a risk of developing the condition. A further drop in approval was seen when asked if prenatal testing should be made available (~60% yes). In general, individuals' responses did not appear to depend on how genetic or environmental they felt the conditions to be (percent of positive responses were similar across conditions, while overall addiction was felt to be less genetic than ADHD or dyslexia). When asked about their general concerns, participants voiced fears about subjects such as insurance coverage, accuracy of the result, abortions, stigmatization of children, and benefit of the knowledge versus risk of the test. Potential benefits focused on individualized approaches, early detection and preparation, possible cures or prevention, and general knowledge gain.

1427/T

Prevalence of genetic disorders in the northwest of Iran. *T. Mizani[1], S. Dastgiri[1], M.J. Bonyadi[2].* 1) Department of Community Medicine, Tabriz University of Medical Sciences; 2) Department of Medical Genetics, Tabriz University of Medical Sciences.

Background and aim: genetic disorders are responsible for a major proportion of mortality, morbidity, and handicap across the world varying by racial, ethnicity and cultural differences. The aim of this study was to estimate the prevalence of genetic disorders in the northwest of Iran. Methods & Materials: in this descriptive/cross-sectional study, 2968 cases (53% males and 47% females) with confirmed genetic disorders or carriers of the traits diagnosed by molecular methods were identified between 2005 and 2009. Prevalence rate, descriptive statistics and 95 percent confidence intervals were used for data analysis. Results: the study subjects included patients (n=1312), carriers (n=1474), suspected cases (n=157) and unknown cases (n=25). The most prevalent (for five years) disorders were identified as Familial Mediterranean Fever (20.6/100000, CI95%: 19.1-22.07), Inherited Deafness (11.4/100000, CI95%: 10.6-12.2), Spinal-Muscular Atrophy (11.1/100000, CI95%: 10.1-12.1), Cystic Fibrosis (7.9/100000, CI95%:7.1-8.2), Duchenne Muscular Dystrophy (7.8/100000, CI95%:6.2-8.7) and Down Syndrome (5.1/100000, CI95%:4.5-5.4). The overall prevalence of genetic disorders was higher in males compared to females (M/F = 1.1). Conclusion: estimating the true prevalence of the genetic disorders may help in the planning of health care and screening programs. The prevalence of these diseases in the region indicate the necessity to establish a population-based center for genetic disorders in the area. More population-based investigations are however needed to develop effective preventive strategies to control genetic disorders in the region.

1428/T

The NINDS Human Genetic Resource Center: A Resource for the Discovery of Genetic Risk Factors for Neurological Disorders. *K. Gwinn[1], E.R. Londin[2], M. Self[2], A. Ansbach[2], K. Reeves[2], R. Zhang[1], M.A. Keller[2].* 1) National Institute for Neurological Disorders and Stroke, Bethesda, MD; 2) Coriell Institute for Medical Research, Camden, NJ.

Neurological disorders affect an estimated 50 million Americans each year. Though there are rare familial forms of neurodegenerative diseases where the causative gene has been identified, most individuals diagnosed with neurodegenerative disorders such as Parkinsonism and Amyotrophic Lateral Sclerosis (ALS) have no identifiable genetic cause of disease. In most cases, these diseases are multifactorial, involving the interaction of many genes with environmental factors. Genome-wide association studies (GWAS) have identified genetic loci associated with neurodegenerative disorders. These studies require large numbers of cases and controls that can be facilitated by collaborative efforts to collect and manage biological samples and corresponding data. The National Institute of Neurologic Diseases and Stroke (NINDS) Human Genetic Resource Center (NINDS Repository) is a public resource established to provide a centralized and open resource of biological samples (DNA and cell lines) and corresponding phenotypic data collected. Many NINDS-funded researchers involved in neurodegenerative disease research have integrated into their study protocols the submission of biologic samples and data to the Repository. Since its inception in 2002, more than 30,000 individuals have been banked, with more than 16,000 samples from individuals with motor neuron diseases (2,221), epilepsy (742), Parkinsonism (3,719), cerebrovascular diseases (5,092), Tourette syndrome (194), neurologically-normal controls (3,761) and unaffected primary blood relatives (918) have been made publicly available through the Coriell Cell Repositories' web catalog (ccr.coriell.org). To aid high-throughput gene discovery, the Repository offers disease-focused panels of genomic DNA samples in 96-well plate formats as well as custom plate design services. Additionally, genotype data from over 4,000 NINDS Repository samples are available on dbGaP. More than 20,000 samples have been distributed to researchers by the repository since inception. Analyses of NINDS Repository samples have been published in more than 200 peer-reviewed scientific articles. Furthermore, the Repository has begun to establish and bank fibroblast cell cultures from individuals with neurodegenerative disorders for purposes of cellular reprogramming to induced pluripotent stem cells. The NINDS Repository facilitates genetic discoveries aimed at unraveling the genetic and cellular mechanisms that lead to neurological disorders.

1429/T

Clinical and ethical perspectives of a case of false positive in a prenatal diagnosis (PND) of Turner syndrome (TS). *A. BROUSSIN DUCOS, K. KRABCHI, R. DROUIN, C. BOUFFARD.* Genetics Service, Department of Pediatrics, Faculty of Medicine and Health Sciences, University of Sherbrooke (Quebec, Canada).

Following a prenatal diagnosis of trisomy 21 indicating a high risk, a pregnant woman chose to submit to an amniocentesis which revealed a fetal TS. Following a meeting in genetics where the parents were informed of genotype and phenotype of TS, they decided to continue the pregnancy. Subsequent morphological ultrasound showed that the fetus was male, which led to the realization of a PCR analysis. This establishes the existence of the SRY gene and the presence of a segment of chromosome Y. In postnatal, an analysis by microarray confirmed the loss of the Yq of the proximal portion of Yp and translocation of the remaining segment to the distal extremity of the 11q. Methodology: Qualitative approach, case study (a couple), analysis of 22 articles relating to the PND of TS. Results: Clinically, this case shows the need for further genetic testing to establish with certainty a PND of TS. Ethically, it raises the importance of providing patients with comprehensive information and the urgency to develop additional knowledge as regards to the problems caused by certain clinical and social practices in relation to a PND of TS. As an example, the fact that a decision to perform an abortion can be taken on the basis of incomplete information and an inaccurate diagnosis raises serious ethical questions, reinforced by the number of abortions, reported in the literature in relations to PND of TS. That the number of abortions is also higher for TS than for Klinefelter syndrome generates other questions regarding parental representations of TS and, more broadly, the socio-cultural representations of female and / or male infertility. Conclusion: Nevertheless, in the specific context of the clinical case investigated, we should retain that the implementation of complementary genetic investigation and the assurance of a genetic counsel would decrease the ethical, clinical and socio cultural problems inherent to an inaccurate PND of TS.

1430/T

Bioethics and socioethics: An urgent need for probative data to guide and regulate medical and social uses of reprogenetics. *C. Bouffard.* Dept Ped, Fac Med Hlth Sci, Univ Sherbrooke, Sherbrooke, PQ, Canada.

OBJECTIVES: With reprogenetic practice no longer confined to the research setting or futuristic scenarios, its medical and social uses are multiplying without showing signs of slowing down. In a worldwide market economy that fosters reproductive tourism and direct-to-consumer genetic testing, the deployment of reprogenetic practice is raising unprecedented ethical, legal, professional-code, and social issues. The greatest challenge will arise from the fact that the people who offer and access reprogenetic services will soon be exercising more power over reprogenetic practice than the policy makers and experts whose mandate is to regulate it. To meet this challenge, it will first be necessary to re-examine the foundations of the decision-making processes employed by the policy makers who establish the ethical and legal norms that govern reprogenetic practice and set up the health policies that determine the conditions of service delivery. METHODS: Ethnographic study conducted in France and under way in Quebec and the rest of Canada: Analysis of scientific, legal, and ethical literature; participant observation in clinics and laboratories for preimplantation genetic diagnosis (PGD), a paradigmatic reprogenetic practice (990 hours); 79 semi-structured interviews. RESULTS: When PGD had not yet been transferred to the clinical setting, it was understandable that the decision-making regarding the development, governance, and institutionalization of PGD and reprogenetic practices in general should be based on the speculations of policy makers and experts. Today, appropriate inquiry must be based on: 1) probative data about national and international conditions for the development and delivery of reprogenetic services; 2) the motivations of these services' users and providers; and 3) the impact of State intervention in citizens' reproductive lives. CONCLUSION: Given the issues raised by reprogenetics, if we wish our health policies and our legal, professional-code, and ethical norms to have their hoped-for efficacy and usefulness, it is important to re-evaluate the modes of operation that underlie our decision making; the more so since political, medical, and community policy makers will have a foundational impact not just on the conditions for service delivery but also on the future of new medical paradigms based on the use of the human embryo.

Signatures of natural selection in the first pilot experiment of the 1000 Genomes Project. *R.D. Hernandez[1], J.L. Kelley[2], S.C. Melton[2], A. Auton[3], G. McVean[3,4], G. Sella[5], M. Przeworski[2], 1000 Genomes Project.* 1) University of California, San Francisco, Department of Bioengineering and Therapeutic Sciences, San Francisco, CA, 94158; 2) University of Chicago, Department of Human Genetics, Chicago, IL, 60637; 3) University of Oxford, Wellcome Trust Centre for Human Genetics, Oxford, OX3 7BN, United Kingdom; 4) University of Oxford, Department of Statistics, Oxford, OX1 3TG, United Kingdom; 5) The Hebrew University, Jerusalem, Department of Evolution, Systematics and Ecology, Jerusalem, JR 91904, Israel.

Nearly 200 genomes from four populations have been resequenced at low coverage for the first pilot experiment of the 1000 Genomes Project. These data avoid many of the ascertainment biases that have plagued previous large-scale human data sets, allowing long standing evolutionary questions to be resolved. We used these data to characterize genomic signatures of natural selection using patterns of genetic diversity. We show that neutral diversity increases with genetic distance from coding regions, suggesting that selection on coding regions distorts patterns of diversity in their vicinity. In particular, we report a clear footprint of natural selection on diversity patterns around human-specific amino acid substitutions. In addition, we identified novel regions of the genome with extreme differences in allele frequencies between population samples. While all three findings reflect the action of natural selection, it remains unclear to what extent they are explained by adaptive evolution or purifying selection, with recent reports offering conflicting conclusions in this regard. To disentangle the relative contributions of the two evolutionary forces, we ran extensive simulations of the human genome, incorporating information about functional annotations, fine-scale genetic maps, and realistic demographic models of all four populations.

1432/T

The power of HLA for the discrimination of human populations. *W. Klitz[1], L. Gragert[2], M. Maiers[2].* 1) Pub Hlth, Univ California, Berkeley, CA; 2) National Marrow Donor Program, Minneapolis, MN.

PURPOSE: While only a fraction of human genetic variation is distributed between populations, of that variation the HLA complex appears to be the most powerful system in this regard for the discrimination of one human group from another. Here we utilized the high resolution HLA typing and exceptionally large and ethnically specified population sizes of the National Marrow Donor Program adult donor database to portray the genetic relationships among a number of Asian population groups. METHODS: We analyzed estimated HLA A-B-DRB1 haplotype frequencies in eight Asian-American populations, including (abbreviation and samples size in thousands), South Asia (SA, 211), Philippines (F, 57), Hawaii (H, 12), Vietnam (V, 27), other South East Asia (SEA, 29), China (C, 108), Korea (K, 97), and Japan (J, 30). RESULTS: The haplotype diversity in each population was very large: the ordered haplotype frequency list reached 50% of the sample ranging from 72 in the Filipino to 295 in the Other Southeast Asian group. Principal components analysis (PCA), neighbor joining (NJ) trees and a clustering package (cluto) were used to reveal relationships among the populations. PCA indicated that the South Asian and Other Southeast Asian groups fall at the center of the Asian populations. Three pairs of populations diverge in different directions, including a Pacific island group (F and H), an East Asia group (C and V) and a derived East Asian group (K and J). The NJ analysis found SA and SEA at the root with a single clade heading to all of the other populations. The cluto analyses revealed the HLA similarity of these same pairs, along with the specific most frequently associated haplotypes for each population. CONCLUSIONS: These results mirror the conclusion of a recent genome wide analysis of these same groups pointing to a founding population source for East Asian peoples from Southeast Asia. More generally this study points to the power of a single genetic system, the HLA complex, to define population differentiation in our species.

1433/T

DIVERGENOME: a bioinformatics platform to assist population genetics and genetic epidemiology studies. *W.C.S. Magalhaes[1], M.R Rodrigues[1], A. Sene[2], B. Araujo[2], M. Machado[1], A.A. Faria-Campos[2], G.B. Soares-Souza[1], M.L. Iannini[1], E. Tarazona-Santos[1].* 1) Departament of General Biology, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil; 2) Department of Computer Sciences, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil.

The huge amount of data that is emerging from human genetics and genomics initiatives requires appropriate bioinformatics tools that are suitable also for research groups of different sizes. Such tools should allow the storage of public and private genotypic and phenotypic data together with efficient and secure management, perform database integration, and facilitate recovery and visualization. Studies in different fields of genetics that require this capabilities are not limited to GWAS, but include: (a) Evolutionary inferences that use state-of-the-art methods to infer past demographic parameters of populations, such as statistical phylogeography approaches; (b) Inferences about the action of natural selection; (c) Epidemiological studies designed to capture rare polymorphisms responsible for complex traits; and (d) Screenings for mutations in families or small populations with high-incidence of specific genetic diseases. To address the requirements above, we are developing DIVERGENOME, a bioinformatics platform focused on academic use that includes two integrated components: (1) DIVERGENOMEdb a relational database; and (2) DIVERGENOMEtools. The former component DIVERGENOMEdb is suitable for storing different types of genotypic data (SNPs, re-sequencing, STR, CNVs) and phenotypic variables. Here users can store both public and private data, according to their interest. A set of resources for database integration are under development to combine information from different sources, such as metabolic pathways. DIVERGENOMEtools is a set of scripts (modules) that can be combined in a pipeline to handle a variety of popular file formats from population genetics and statistical software, so that users can convert the output file of specific software into the appropriate input file format of another. DIVERGENOMEtools can handle file formats for the following population genetics software: PHASE, FastPHASE, DNAsp, Haploview, STRUCTURE, SWEEP, and genetic epidemiology software such as GLU and PLINK. DIVERGENOME includes a set of quality control steps in its different components to ensure data integrity and is built with a modular architecture envisioning the easy integration of other data types, which opens up prospects for future improvements. A first version of DIVERGENOMEtools was developed focusing on facilitating re-sequencing studies, and is publicly available since May 2010 as a web-based re-sequencing pipeline at www.cebio.org/pipelineldgh.

A Novel Statistic for Testing Selection on Pair of Genes. *G. Peng, M. Xiong.* Dept of Biostatistics, University of Texas School of Public Health , Housotn, TX.

It is well known that gene function in a concert, rather than in isolation. Complex phenotype variations are caused by dynamic interaction among many genes and many environmental exposures through regulation and metabolism. Adaptations are often influenced by multiple interacted genes. However, in the conventional population genetics, most researches have primarily focused on natural selection acting on a single locus. Little attention has been paid to determining how the natural selection acts on multiple interacted genes in response to environmental perturbation. Recently, we performed genome-wide scan for natural selection in human population using 1000 genome pilot 1 data. We identified 14 pathways enriched with candidate selection genes including pathways, involved in the development of neural system, metabolism of carbohydrates and phosphates, cell communication and signal transduction. We found that all six pathways enriched by high genes in the recent paper by Amato et al. were also confirmed in our studies. A remarkable feature in our finding is that several pathways showed enrichment of selective signals in at least three populations. This strongly demonstrated that natural selection may jointly act on multiple genes. To reveal how multiple genes that are often organized into interacted networks are evolved to adapt dramatic changes in environment, lifestyle and culture, we used genome-continuum models and stochastic calculus to develop a unified framework for genome-wide scans for natural selection which can be used either to test selection on single gene or test selection on pair-wise genes. To evaluation the performance of the proposed statistics, we used software FREGENE to simulate the effects of natural selection on pair of genes and to compare our test with the results by simulations. Intensive simulations show that the test statistics work well. Finally, we performed genome-wide co-selection analysis using 1000 genome pilot 1 data. Since testing for all possible pair-wise co-selection across the genome in genome-wide co-selection analysis requires extremely large computation, we conducted pathway-based genome-wide co-selection analysis. We assembled 501 pathways from KEGG and Biocarta. The assignment of SNPs to a gene was obtained from NCBI human9606 database (version b129). We tested selection on all possible pair-wise of SNPs and constructed co-selection networks. The results will be presented in the conference.

Selection Detection in Gene Families Utilizing Phylogenetics. *G. Wyckoff, M. Yang.* Div Molec Biol & Biochem, Univ Missouri -Kansas City, Kansas City, MO 64110.

As divergent gene regions have differing functional significance, several modes of evolution will simultaneously occur within a single gene, which may make positive selection very difficult to detect at the whole gene level. Thus to be able to detect positive selection more effectively, we divide genes into functionally independent segments. Protein domains are a natural candidate for this kind of analysis: they are functionally important, distributed across different genes, and they have a common evolutionary history. In addition, they are widely seen as evolutionarily conservative, so the number of mutations at the same locus are more limited making selective inference more reliable. We hypothesized that the positively selected members in protein domain families will display altered phylogenetic patterns compared with other members, and therefore will distort tree shape. We then utilize this pattern for the detection of outliers among domain members, and for the discernment of the number of gene families where positive selection is pervasive. While there have been continuous studies in phylogenetic tree shape in the areas of macroevolution and biogeography (Gould et al. 1977; Raup et al. 1973; Rosen 1978; Schopf 1979; Simberloff 1987), the employment of phylogenetic trees as a primary mechanism for detecting positive selection at the molecular level has always been, in our opinion, underutilized. Here, we have applied this methodology to a set of protein domains that are important to human evolution and human disease. We further estimate the number of protein domains where positive selection has likely affected a significant number of genes containing those domains.

Correlation between Human and *Helicobacter pylori* ancestry in Colombian populations. *M.M. Torres[1], D. Cano[1], H. Groot[1], N. Ospina[1], L.E Bravo[3], M.B Piazuelo[2], P. Correa[2].* 1) Facultad de Ciencias , Universidad de los Andes, Bogota, Colombia; 2) School of Medicine, Vanderbilt University, Nashville, Tennessee,USA; 3) Facultad de Medicina, Universidad del Valle, Cali.Colombia.

Helicobacter pylori (*H.pylori*) is a human gastric bacterium involved in the peptic ulcers pathogenesis and constitutes a risk factor for gastric cancer. *H.pylori* strains from different geographic areas are associated with strong phylogeographic differentiation. Human DNA polymorphisms and DNA sequences from *H.pylori* have been used for the understanding of the human population migrations and can also explain the geographic differences in gastric cancer incidence. The main goal of the present study was to establish the genetic diversity of *H.pylori* isolates and their hosts in Colombian populations that have contrasting risk of gastric cancer and with different ethnic origins (Andean Mountains and Pacific coast) by mitochondrial DNA markers (HSV1-HSV2) and by multilocus sequence (7 housekeeping genes) of *H.pylori*. The mtDNA was sequenced from 86 subjects (65 from Pacific coast with somatic “mulato”phenotype and 21 from Andean Mountain with somatic “mestizo” phenotype). The ancestral genotypes of *H.pylori* were determined from 44 strains (40 from Pacific coast and 4 from Andean Mountains). We identified 79 unique mtDNA haplotypes clustered into amerind haplogroups (A-D) and African haplogroups (L0, L1, L2, L3). The 99% of population from Andean Mountain was of amerind origin and 1% European (Haplogroup H). The 74% of the Pacific coast populations were African in origin and the remainder 26% Amerind. The bacteria strains were assigned to populations according to their multilocus DNA sequences: those from pacific coast hosts yielded *hpEurope* (43%) and *hpAfrica1* (57%), all of those from Andean Mountains yielded *hpEurope*. None of the strains were hpAmerind. Finally, the great majority of the subjects with the Amerindian ancestry carried hpEurope genotype (14/20) and the African ancestry carried *hpAfrica1*genotype (16/23). Our results indicate that there is a high correlation between the ancestry of the host evaluated by mitochondrial DNA and the ancestral genotype of the *H.pylori* in the Andean Mountains. In agreement with previous reports, the low density or absence of hpAmerind genotype in our group reflects the tendency of this strain to disappear. The coastal populations is more heterogeneous, some carrying African and some European bacterial genotypes. This study also favors the hypothesis of Intrafamilial transmission of the *H.Pylori* . We confirm the potential usefulness of the study of the *H.pylori* genotype as a tool for inferring human migration.

1437/T

***CNTF* variations do to contribute to risk of POAG in Chinese population.** *J. Chen[1,2], L. Chen[2], Y. Zheng[1], J. Wang[1], S. Chiang[2], P. Tam[2], H. Chen[1,2], C. Pang[2], M. Zhang[1].* 1) Joint Shantou International Eye Center, Shantou University/The Chinese University of Hong, Shantou, Guangdong, China; 2) Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Hong Kong Special Administration Region, China.

Purpose The ciliary neurotrophic factor (*CNTF*) can stimulate the regeneration of axons of retinal ganglion cells (RGC), loss of which is one of the major characteristics of glaucoma. Recently protective effect of the gene has been implicated in animal model of glaucoma, while its role in in primary open angle glaucoma (POAG) patients remains to be elucidated. Therefore we investigated the potential genetic involvement of *CNTF* variations in POAG among two Chinese Han cohorts. **Methods** The current study subjects included a cohort of 130 POAG patients and 134 controls recruited in Shantou, a city in southern China, and another cohort of 102 POAG patients and 103 controls recruited in Hong Kong. Screening of *CNTF* mutations was performed by direct DNA sequencing of polymerase chain reaction-amplified exons and splice regions. $\chi 2$ test was used for association analysis for any SNP detected. *In silico* tools were used for predicting the impact of any missense variant detected. **Results** In total, eight variants including two SNPs , and 6 novel variants, were found in the two Chinese cohorts. Among these variants two novel variants including an intronic mutation IVS1-21T>G and a non-synonymous mutation c.223G>C, were identified in patients with normal-tension glaucoma from Hong Kong cohort, and were absent in Shantou and Hong Kong controls. However, 2 variants in 5’-UTR namely c.-135G>T and c.-22C>T, and 3 non-synonymous coding variants namely c.407G>A, IVS1-6G>A (rs1800169) and c.545A>G (rs6266), were detected in both patients and controls from either Shantou or Hong Kong cohort. In particular, the intronic SNP rs1800169, which was predicted to result in a change in alternative splicing and consequently a truncated loss-function CNTF protein, was found in controls as well as in patients from both Shantou and Hong Kong cohorts. Furthermore, an insertion c.103_104insA causing frame-shift mutation was only detected in Shantou controls. None of the detected SNPs showed any statistical significance ($P > 0.05$) in the association analysis. **Conclusions** The existing of these *CNTF* variations, especially the loss-of-function mutations in control subjects from the two Chinese cohorts is probably a strong evidence that excludes *CNTF* as a disease-causing gene of POAG. The *CNTF* gene seems to have no or only a very low contribution to risk of POAG in Chinese. The current findings thus warranted further studies.

1438/T

Founder effect of LCA5 p.Q279X mutation in the Ashkenazi Jewish population. *PW. Chiang[1], E. Spector[1], J. Picker[2], WK. Chung[3].* 1) Pediatrics, UC Denver DNA Diagnostic Lab, Denver, CO; 2) Childrens Hospital Boston, Boston, MA; 3) Department of Clinical Genetics, Columbia University, New York, NY.

Leber’s Congenital Amaurosis (LCA) is a rare inherited eye disorder that leads to retinal dysfunction and visual impairment at birth or in the first few months of life. LCA is an autosomal recessive condition and is the most common cause of inherited child blindness with the prevalence of two to three per 100,000 births. There are at least 15 genes associated with the condition. The mutation detection rate for patients with a confirmed diagnosis of LCA is approximately 50% ~ 60%. Due to the breakthrough in gene therapy in patients with mutations in RPE65 (one of 15 genes associated with LCA) and the potential of gene therapy for patients with other LCA gene mutations, the clinical utility of molecular diagnosis is increasing. We have taken a novel approach to molecular diagnosis of LCA by sequencing the entire coding regions of all genes known to be associated with LCA. A total of 181 PCR reactions are simultaneously sequenced. To date, we have examined 77 patients. Two of the LCA patients carried the same homozygous mutation in the LCA5 gene, namely p.Q279X:c.835C>T. Both patients are of Ashkenazi Jewish decent and there was no known consanguinity in either family. Interestingly, the same mutation was also previously identified in a consanguineous family and in two other non- consanguineous LCA patients of Ashkenazi Jewish decent by other investigators. All five patients presented with severe LCA. This finding prompted us to determine the carrier frequency of the c.835C>T mutation in the Ashkenazi Jewish population. We estimate the carrier frequency to be ~ 1 in 100 based on our initial study of 96 individuals of Ashkenazi Jewish descent tested in our laboratory. A larger analysis of 1,000 normal individuals of Ashkenazi Jewish decent is in progress. The c.835C>T mutation has not been identified in LCA patients of other ethnic groups suggesting a founder effect in Ashkenazi Jews. Finding a common mutation in LCA patients of Ashkenazi Jewish decent has important clinical implications including: (1) molecular diagnosis of LCA patients of Ashkenazi Jewish decent will be more efficient, faster, and less expensive (1 PCR vs. 181 PCRs); (2) carrier screening can be offered to individuals of Ashkenazi Jewish decent; (3) due to the severity of the disease caused by this mutation and due to the founder effect in the Ashkenazi Jewish population, LCA5 should become a strong candidate for gene therapy.

1439/T

Asymmetric mutation processes in stochastic models of microsatellite allele length distributions in humans. *B. Fendler, G. Atwal.* Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.

Microsatellites are frequent mutations throughout the genome, for which a short simple repeat sequence occurs. Genotyped microsatellite loci have been implicated in numerous diseases and can be used for linkage association mapping, making them useful biomarkers for causal genetic variants, phylogeny construction and forensic investigations. However, the observed distribution of repeat lengths in human populations is still not well understood from a quantitative perspective. Moreover, only the simplest dynamical models of allelic variability have been amenable to analytical methods, invoking stringent and unrealistic biological assumptions. We revisit and build upon the well known stepwise mutation model, and carry out extensive Monte Carlo simulations of the Moran model of microsatellite allelic evolution under a variety of different parameter regimes. In particular, we explore the effects of the interplay between drift and asymmetric mutation processes by independently varying the effective population size (N), the rate of deletion (η_d) and the rate of insertion (η_i). We also consider differing models of mutation processes that alter lengths by larger than one repeat unit, either by arithmetic or geometric progression. However, the arithmetic stepwise models do not lead to stationary distributions of allele lengths in the case of neutral evolution, and thus hampers the ability to infer mutation rates from population data. The neutral simulations of arithmetic mutation processes demonstrate that the allele length distributions evolve as Gaussian-like packets whose variance depends on N and whose mean increases with time when $\eta_i > \eta_d$ and decreases for $\eta_d > \eta_i$. We propose and simulate a geometric model of mutation in which the average allelic repeat length does not increase indefinitely even when $\eta_i > \eta_d$. This hypothesis is supported by earlier reported findings in which repeat increases were favored over decreases in the human CEPH reference family database. Fitting the simulations to experimental data by varying the mutation probabilities, we find mutation probabilities on the order 1×10^{-3}, within the accepted range of mutation rates (event/generation/loci).

Genotype imputation in American Indians. *A. Malhotra[1], W.C. Knowler[1], L.J. Baier[2], C. Bogardus[2], R.L. Hanson[1].* 1) Diabetes Epidemiology and Clinical Research Section, NIDDK, Phoenix, AZ; 2) Molecular Genetics Section, NIDDK, Phoenix, AZ.

Current technologies allow rapid and extensive genotyping of common SNPs. However, none of the available genotyping platforms has complete coverage. One solution has been the development of methods to impute untyped variants using information on linkage disequilibrium with typed markers. These methods have been implemented in various software programs including MACH (Markov Chain Haplotyping). To impute genotypes, these methods require a suitable reference population, most often one selected from HapMap. However, some populations, such as American Indians, are not represented in HapMap. While it has been suggested that a combination of HapMap populations (e.g., the combination of Chinese and Japanese (CHB+JPT) and Caucasian (CEU) samples) may be useful for imputation in American Indians, it is not known how the accuracy of such imputation compares with using an American Indian reference. In the present study, we assessed imputation procedures using data obtained from a genome-wide association study (454,154 SNPs with minor allele frequency >0.05) conducted in 1266 Pima Indians. Due to computation time, we restricted our analysis to 6 randomly selected chromosomes. For each chromosome, genotypes were masked (either 1% or 20% of SNPs available for a given chromosome). The masked genotypes were then imputed using MACH and quality was assessed using two measurements: 1) the proportion of genotypes that were correctly imputed when the most likely genotype was taken, and 2) the average estimated r^2 between the true and imputed genotype. Using the HapMap reference populations, an average genotype error rate of 10.7% and r^2 of 0.77 were observed. In contrast, use of the original Pima Indian data resulted in an average error rate of 1.6% and r^2 of 0.99. We further explored the number of Pima Indian individuals (25, 50, or 100 randomly selected) that would be needed to get highly accurate imputed genotypes within this population. For these analyses, average genotype error rates were 3.0%, 2.2%, 1.7%, respectively for 25, 50, and 100 reference Pima individuals, with $r^2 > 0.97$ in all cases. In conclusion, our results suggest that HapMap reference populations do not provide accurate imputation of genotypes in American Indians. A possible solution would be to sequence a reference American Indian population. As the results suggest, a sample size as small as 25 individuals can provide high imputation accuracy.

ABRAHAM'S CHILDREN IN THE GENOME ERA 2: A WORLDWIDE VIEW OF JEWISH DIASPORA GROUPS. *G. Atzmon[1,2], L. Hao[3], I. Pe'er[4], C. Velez[5], A. Pearlman[5], P.F. Palamara[5], E. Friedman[6], C. Oddoux[5], E. Burns[1], H. Ostrer[5].* 1) Department of Medicine, Albert Einstein College of Medicine, Bronx, NY; 2) Department of Genetics, Albert Einstein College of Medicine, Bronx, NY; 3) Center for Genome Informatics, New Jersey Medical School, University of Medicine and Dentistry of New Jersey, Newark, NJ; 4) Department of Computer Science, Columbia University, New York, NY; 5) Human Genetics Program, Department of Pediatrics, New York University School of Medicine, New York, NY; 6) The Susanne Levy Gertner Oncogenetics Unit, the Danek Gertner Institute of Human Genetics, Chaim Sheba Medical Center, 52621, Tel-Hashomer, and the Sackler School of Medicine, Tel-Aviv University, Tel-Aviv Israel.

Genome wide analysis of Jewish Diaspora groups that have formed over the past 2000 years provides an invaluable opportunity for understanding genetic origins and migrations and provides a framework for elucidating the genetic basis of complex disorders. Here, we have built upon our initial genome wide analysis of 7 ethnically diverse, healthy Jewish (European: Ashkenazi, Italian, Greek, Turkish, and Middle Eastern: Iranian, Iraqi, and Syrian) populations (AJHG online June 3rd, 2010) by analyzing members of an additional 9 Jewish communities (North African: Moroccan, Algerian, Tunisian, Djerban, and Libyan; and Georgian, Yemenite, Indian Bene Israel and Ethiopian). These 524 unrelated individuals were analyzed on Affymetrix v6 microarrays, then merged with results from the Human Genome Diversity Project and the Population Reference Sample studies that were comprised of 146 non-Jewish Middle Easterners (Druze, Bedouin and Palestinian), 30 northern Africans (Mozabite from Algeria), 1547 Europeans, and 653 individuals from other African, Asian, Latin American, and Oceanian populations. Principal component SNP and CNV analysis (PCA) and pairwise Fst distance showed that European, Middle Eastern, North African and Georgian Jewish populations formed a cluster clearly distinct from all major continental populations with each group demonstrating significant admixture with local populations. Yemenite, Ethiopian and Indian (Bene Israel) Jews fell outside this cluster. The North African Jewish cluster demonstrated proximity to the Sephardic Jewish. North African Jewish relationships showed a cline consistent with their geographic cline and the Tunisian Jewish population was statified into two subpopulations, one with proximity to Libyan and Djerban Jews and the other to Moroccan and Algerian Jews. Analysis of identity by descent revealed a high degree of segment sharing across most Jewish groups and endogamy within all of the Jewish populations that was especially high among the Indian and Djerban Jews. These results demonstrate the shared and distinctive genetic heritage of Jewish Diaspora groups that were formed during Classical Antiquity and indicate that both the flow of genes and the flow ideas has contributed to Jewishness.

1442/T

Resequencing of human type B scavenger receptor genes in Asia-Pacific populations. *K. Nakayama[1], A. Ogawa[1], Y. Yanagisawa[1], T. Gotoh[1], H. Miyashita[2], L. Munkhtulga[3], Y. Kagawa[4], S. Iwamoto[1].* 1) Divsion of Human Genetics, Jichi Medical University, Shimotsuke-City, Japan; 2) Jichi Medical University Hospital, Shimotsuke-City, Japan; 3) Health Science University of Mongolia, Ulaanbaatar, Mongolia; 4) Kagawa Nutrition University, Sakado, Japan.

CD36 and SR-BI belong to type B scavenger receptors that recognize various classes of lipoprotein and fatty acids. Genetic variations of CD36 and SR-BI were reported to be associated with lipid disorders, glucose intolerance, and hypertension in humans. In addition to the primary roles in lipoprotein metabolism, CD36 and SR-BI were implicated in other biological processes, for example, fat taste perception and malarial infection. Diversity of genes encoding CD36 and SR-BI (*CD36* and *SCARB1*) might have been shaped by natural selection relevant to their functions. In the present study, we investigated the variation of *CD36* and *SCARB1* in four Asia-Pacific populations. Resequencing of the whole coding exons and the flanking intronic region of *CD36* and *SCARB1* were performed against 380 individuals of Japanese, Mongolians, Thai and Palauans. A total of 23 polymorphic sites were observed in *CD36* and *SCARB1* and 15 of them were novel variants with allele frequencies of less than 5%. For *CD36*, Ser90Pro, which was the most prevalent loss-of-function variant of *CD36*, was common in Japanese (6%) but almost absent in other populations. Other loss-of-function variants of *CD36*, 329-330delAC and 1228-1239delATTGTGCCTATT, were found in Japanese and Thai with low frequencies (less than 1%) but were not detected in Mongolian and Palauans. For *SCARB1*, Thai uniquely possessed functional Gly2Ser variant and a novel 2bp deletion variant resulting in truncated proteins. Interestingly, among the four populations, variants altering amino acid sequences were most abundant in Thai. Since CD36 and SR-BI are host factors aiding infection and proliferation of malaria parasites, the functional variants of *CD36* and *SCARB1* may contribute to susceptibility to malaria as well as the variation in metabolic parameters in Thai population.

1443/T

A Wide STR Analysis of the Y Chromosome Haplogroups in Native American Populations. *V. Battaglia[1], N.M. Myres[2], U.A. Perego[1,2], V. Grugni[1], A. Achilli[1,3], J.E. Gomez-Palmieri[2], N. Angerhofer[2], S.R. Woodward[2], A. Torroni[1], O. Semino[1].* 1) Dip. Genetica e Microbiologia, Università di Pavia, Pavia, Italy; 2) Sorenson Molecular Genealogy Foundation, Salt Lake City, Utah, USA; 3) Dip. Biologia Cellulare e Ambientale, Università di Perugia, Perugia, Italy.

The settlement of the Americas represents the last major human colonization episode. It has been a topic of interest and controversy in numerous scientific fields, including genetics. While general archaeological, linguistic and molecular agreement on the Asian origin of Native Americans exists, the timing of their arrival, the routes followed, the number of population expansions/migrations involved, and the Asian source(s), have been, and still are, objects of discussion. Progress in the comprehension of the peopling of the Americas has been provided by studies on complete mitochondrial (mt)DNA (maternally transmitted) sequences, which document a higher level of molecular diversity and two distinct contemporary (15-17 kya) migration events from Beringia. While one entered the Americas following the Pacific coastline, the other moved through the ice-free corridor between the Laurentide and Cordilleran glacial sheets, suggesting they were derived from two separate founding populations. In comparison with mtDNA, the Native American Y-chromosome (Ycs) diversity is limited to two branches of haplogroups (hg) C and Q. Even though their resolution does not allow region/ethnic-specific sub-clades to be distinguished, the first hg is restricted to the North (Na-Dené speakers), while the second hg is spread from North to South, covering a wide part of the American continent. Here we report the preliminary analysis of 38 Ycs short tandem repeats (Y-STRs) from 2,025 samples belonging to the Sorenson Molecular Genealogy Foundation DNA database, with terminal paternal ancestry from a broad geographic area ranging from Mexico to Chile. Of these samples, 173 harbour the American specific hg Q1a3a-M3, which likely originated in the Beringian refuge during a long period of pause around the time of the LGM. The underlying molecular diversity indicates significant differences in haplotype (ht) distributions between North/Central and South Americans, suggesting different population histories in the two continental regions. In particular, two main ht branches have been observed: one pan-American and the other limited to samples from Peru, Bolivia, and Chile. These initial results are suggestive of a distinct Ycs founding lineage in South America with a discrete distribution which could likely represent the male counterpart of the coastline route previously identified through the mtDNA approach.

1444/T

A Novel Variant near *MTNR1B* Gene Affects Fasting Glucose Concentrations: Genetic Risk is Modulated by Obesity Status. *L.F. Been[1], J.L. Hatfield[1], A. Shankar[1], C.E. Aston[1,2], S. Ralhan[3], G.S. Wander[3], N.K. Mehra[4], J.R. Singh[5], J.J Mulvihill[1], D.K. Sanghera[1].* 1) Department of Pediatrics, University of Oklahoma HSC, Oklahoma City, Oklahoma; 2) General Clinical Research Center, University of Oklahoma HSC, Oklahoma City, Oklahoma; 3) Hero Dayanand Medical College & Heart Institute, Ludhiana, Punjab,India; 4) All India Institute of Medical Sciences, New Delhi, India; 5) Central University of Punjab, Bathinda, India.

Genome-wide association studies (GWAS) have identified variants in *G6PC2, GCK*, and *MTNR1B* affecting fasting blood glucose (FBG). In the pursuits of examining the role of these loci in our Asian Indian sample and also for searching causal variants in these genes, this study was undertaken. We genotyped five polymorphisms from these genes including *G6PC2* rs560887, *GCK* rs1799884, *MTNR1B* rs1387153, rs10830963, and a novel SNP discovered near 5' untranslated region in *MTNR1B*. These SNPs were studied in our diabetic case-control cohort comprising 2,222 subjects (1,201 cases and 1,021 controls). None of these SNPs was associated with type 2 diabetes (T2D) in this sample. Our data also could not confirm association of *G6PC2* and *GCK* with FBG phenotype. In *MTNR1B*, rs10830963 was associated with marginally increased HOMA-IR (insulin resistance) (β=0.13, p=0.026) and the novel SNP was linked to marginally decreased 2h glucose (β= -0.06, p=0.032) among controls. However, upon stratifying data by obesity, the minor allele carriers in the novel *MTNR1B* variant revealed a strong association with lower FBG levels in the non-obese group (β= -0.073, p= 0.002) compared to the obese group (β= 0.015, p=0.50). The effect was also significant in combined cohort (cases and controls) and remained confined to the non-obese group (β= -0.105, p=0.007). Our study for the first time reveals a strong association of a new variant in *MTNR1B* for affecting FBG levels in the absence of obesity. Future confirmation on a larger sample will be required to better define the role of this variant in glucose homeostasis.

1445/T

T45G Adiponectin Gene Polymorphism And Its Association With Hyperglycemia In Adult Filipinos Seen At The Philippine General Hospital - A Pilot Study. *E. Cutiongco[1], E. Paz-Pacheco[2], C. Josol[2], C. Sison[2], G. Jasul[2], F. Rocamora[1], A. Laurel[2].* 1) Institute of Human Genetics, National Institutes Health, University of the Philippines Manila; 2) Section of Endocrinology, Diabetes and Metabolism, Department of Medicine, College of Medicine, Philippine General Hospital, University of the Philippines Manila.

The gene encoding adiponectin is found in chromosome 3q27 where susceptibility loci for diabetes and metabolic syndrome have been mapped. Association of ADIPOQ gene single nucleotide polymorphisms (SNPs) with type 2 diabetes and impaired glucose tolerance or impaired fasting glucose has been found in some populations. The most commonly reported variant is the T/G polymorphism of SNP +45 in exon 2 which has been shown to be associated with diabetes and obesity in some Japanese, French Caucasians, Swedish Caucasians, Chinese, and Iranian subjects. However, studies among Pima Indians, another group of Japanese, and Korean subjects revealed conflicting results. Inconsistent data could be attributed to inter-ethnic differences in polymorphisms of the adiponectin gene. This is the first investigation on the association of T45G adiponectin gene polymorphism with hyperglycemia among Filipinos. A significant association may be exploited further in the search for novel approaches to the treatment and/or prevention of diabetes and the metabolic syndrome in Filipinos. Filipino subjects greater than 18 years old seen at the Philippine General Hospital were recruited and divided into hyperglycemic group and normoglycemic group using definitions recommended by ADA. Fasting plasma glucose, 2-hr post 75-gm anhydrous glucose random blood sugar, and serum adiponectin levels of eligible subjects will be taken. Direct sequencing was used to detect the T45G polymorphism of the adiponectin gene among the cases and controls. In this pilot study involving 36 normoglycemic and 32 hyperglycemic Filipinos, the T45G polymorphism compared to the homozygous GG allele which showed no significant association between this polymorphism and hyperglycemia (OR 1.03; CI 0.05-19.59). Interestingly, the homozygous TT appears to be a protective allele (OR 0.59 ; CI 0.03-0.93) compared to the T45G polymorphism.

1446/T

Association Between Estrogen Receptor-α Gene & Metallothionein-1 Gene Polymorphisms In Type 2 Diabetic Women Of Indian Population. *s.g.s.r. ganasyam shilpa reddy, ysr. murthy, T. Bhaskar.* Biochemistry, Institute of Genetics and Hospital for Genetic diseases, Osmania University ,Begumpet,Hyderabad 500016,andhra pradesh, India.

Background: Type 2 Diabetes Mellitus (DM) is a multifactorial disease where both genetic and environmental factors contribute to its pathogenesis. Estrogen plays an important role in type 2 DM pathogenesis. A number of polymorphisms have been reported in the estrogen receptor (ESR) α, including the Xba I and Pvu II restriction enzyme polymorphisms of ESR 1,which may be involved in disease pathogenesis. Metallothionein (MT) is a potent antioxidant that can affect energy metabolism. Very few studies have indicated the association between Estrogen Receptor-α and MT1A gene polymorphisms with type 2 DM. Methods: A total of 300 type 2 diabetic women and 100 age, sex matched controls, 50 healthy male controls were recruited. Using the PCR based RFLP method, the Pvu II and Xba I polymorphisms of ESR1 and rs 8052394, rs 11076161 in MT1A gene polymorphisms were analysed. Other parameters like lipid levels, serum superoxide dismutase activity (SOD), interleukin -6 and TNF α were analysed by ELISA method. Results: There was significant difference in Pvu II but not Xba I allele frequency between the type 2 DM and control groups (P=0.001 and P= 0.122). When the group was separated into men and women, the difference was significant in women (p<0.001) but not in men (p=0.854) with the Pvu II genotype. In addition, Pvu II genotype was associated with serum lipid changes. The frequency distributions of the G allele in SNP rs8052394 of MT1A gene were significantly associated with type 2 diabetic women. Serum levels of IL-6 and TNF-α were higher and serum SOD activity was significantly lower in the diabetic group than those in the control group. Conclusion: The above results are helpful to identify the Indian women with genetic predisposition to type 2 DM and to protect them from environmental risks.

1447/T

Frequency of 27-bp deletion mutation, another earwax determinant, in ABCC11 among the Japanese population. *A. Yamada[1,2], Y. Hori[1,2], Y. Ono[1,2], N. Matsuda[1,2], D. Starenki[2], N. Sosonkina[2], K. Yoshiura[3], T. Ohta[2], N. Niikawa[2].* 1) Sch Med, Sapporo Med Univ, Sapporo, Japan; 2) RIPHS, Health Sci Univ Hokkaido, Tobestu, Japan; 3) Dept Hum Genet, Nagasaki Univ Graduate Sch Biomed Sci, Nagasaki, Japan.

Human earwax is a dimorphic trait consisting of wet and dry types, which are determined mostly by a 538G/A SNP (rs17822931) in the ABCC11 gene. The wet type corresponds to GG or GA genotype, and the dry type to AA genotype. A 27-bp deletion (Δ27), a rare variant, downstream to the rs17822931 site in ABCC11 is another earwax determinant, acting as a loss-of-function mutation in a recessive manner. Either homozygotes for allele Δ27 or heterozygotes for Δ27 when the counterpart chromosome has allele A lead to the dry phenotype, regardless of cis-positioned allele G. Previous data of world-wide populations demonstrated that the highest allele-A frequencies (1.00-0.83) are observed in the East Asians and showed decreasing clines in its frequency from East Asia toward Europe and Southern Asia. The Δ27 allele was found only one in 334 Japanese, one in 50 Thai, two in 20 native North Americans, 9 in 30 Bolivia habitants, but none in Europeans and Africans. These data suggested that allele A origined in ancient Northeast Eurasians, while origin of the Δ27 remained unknown. Here we report results of a further study on the frequency of allele Δ27. Three such alleles were detected among 760 Japanese individuals and none in 397 Ukrainians: One Japanese is a homozygote for a haplotype A-Δ27 and the other a Δ27/WT and G/A double heterozygote. Thus, the allele frequency among the Japanese is 0.0019 (3/1520), being consistent with the previous data (0.0015, 1/334). Since a previously found Japanese has a G-Δ27 haplotype, a recombination occurred between the the rs17822931 and Δ27 cites, although the Δ27 might have arisen more recently than did allele A.

The male gene pool of the contemporary Mesopotamia marsh population supports their Semitic origin. *N. Al-Zahery[1], J.A. Irwin[2], V. Battaglia[1], M.A. Hamod[3], V. Grugni[1], A.S. Santachiara-Benerecetti[1], O. Semino[1].* 1) Department of Genetics and Microbiology, Pavia University, Via Ferrata 1, 27100 Pavia, Italy; 2) Research Department, Armed Forces DNA Identification Laboratory (AFDIL), 1413 Research Blvd, Rockville, MD 20850, USA; 3) Department of Biotechnology, Faculty of Sciences, Baghdad University, Baghdad, Iraq.

The origin of the modern Mesopotamia marsh people, which are locally called “Ma’dan” or “Marsh’s Arabs”, is a question of great interest. Based on their life-style (living in reed houses, grazing of water buffalo and other aspects) and local archaeological sites, many historians and archaeologists believe they may have Sumerian ancestry. Although little is known about the origin of Sumerians themselves, two main hypotheses have been advanced in this regard. According to the first, Sumerians were a group of populations which migrated from the “South East” following a seashore route through the Arabian Gulf, and settled down in the southern marshes of Iraq. According to the second, the advancement of the Sumerian civilization is the result of migration from the mountainous area of Anatolia to the southern marshes of Iraq where they settled, adsorbing previous populations. In order to shed some light on the genetic origin of the Mesopotamia marsh population, we investigated the male gene pool of 145 DNA samples of modern Mesopotamia people, still living in marshes in the south of Iraq. The analyses of Single Nucleotide Polymorphisms (SNPs) and Short Tandem Repeats (STRs) of the paternally transmitted Male Specific region of the Y chromosome (MSY) revealed that more than 80% of marsh Y chromosomes belong to (Hg) J1-M267, the autochthonous haplogroup of Middle Eastern/Semitic speakers with possible recent expansion and/or founder effect reflected by the reduced STRs variability. In particular, 90% of them were assigned to the J1e-M267-PAGE08 sub-haplogroup, which is the predominant Y chromosome lineage among Middle Eastern Arab populations (Yemen, Qatar, UAE, and Levant). Thus, these findings testify, at least from the paternal side, a strong Semitic Arabian component in the contemporary Mesopotamia marshes population, whereas no clear Anatolian and/or South Asian genetic evidence has been detected.

Natural Selection at High Altitude: Andean Patterns of Adaptation to an Extreme Environment. *A. Bigham[1], M.D. Shriver[2], L.G. Moore[3], F. Leon-Valerde[4], E.J. Parra[5], T.D. Brutsaert[6].* 1) Pediatrics, Univ Washington, Seattle, WA; 2) Department of Anthropology, Pennsylvania State University, University Park, Pennsylvania, USA; 3) Departments of Public Health Sciences, Anthropology and Obstetrics-Gynecology, Graduate School of Arts and Sciences, Wake Forest University, Winston-Salem, North Carolina, USA; 4) Departamento de Ciencias Biológicas y Fisiológicas, Universidad Peruana Cayetano Heredia, Peru; 5) Department of Anthropology, University of Toronto, Mississauga, Mississauga, Ontario, Canada; 6) Department of Exercise Science, Syracuse University, Syracuse, New York, USA.

High-altitude hypoxia, or the decrease in oxygen levels caused by lowered barometric pressure, challenges the ability of humans to live and reproduce. Human physiological responses to high-altitude have been extensively documented among long term high-altitude residents (i.e. Andeans and Tibetans). However, additional research is necessary to understand the genetic basis for the observed physiological traits. To this end, we performed a genome scan to identify selection nominated candidate genes or gene regions for high-altitude adaptation using the Affymetrix Inc. Genome-Wide Human SNP Array 6.0. We scanned across each chromosome to discern genomic regions with previously unknown function with respect to altitude phenotypes and examined groups of genes functioning in oxygen metabolism and sensing, such as the hypoxia inducible transcription factor (HIF) pathway, for evidence of directional selection. Candidate genes or gene regions were identified by comparing the patterns of variation between Andeans (n=49) and two low-altitude populations, Mesoamericans (n=39) and East Asians (n=90), using four tests for natural selection. The tests included the locus-specific branch length (LSBL), the log of the ratio of heterozygosities (ln*RH*), Tajima’s *D*, and a long-range haplotype test. Several genes including *NOS2A*, *PRKAA1*, *EGLN1*, and *TNF* as well as regions on chromosomes 12 and 15 showed significant evidence of natural selection. From these top candidates, ten single nucleotide polymorphisms (SNPs) were selected for further study and genotyped in a sample of n=141 Peruvian Quechua with associated resting and exercise phenotypic data. The subject participants included Q-SL subjects (Quechua sea-level) who were lifelong sea level residents transiently exposed to hypobaric hypoxia and Q-HA subjects (Quechua at high-altitude) who were lifelong residents of high-altitude. Significant associations were found for arterial oxygen saturation (SaO_2) and genotype at PRKAA1 and the candidate region on chromosome 15 (repeated measures ANOVA, $p<0.05$ after FDR correction). These markers, along with the group effect (i.e. born high or born low), display relatively large effects on SaO_2 with each explaining ~6-8% of the variance in this phenotype. Furthermore, the genotypic effects on SaO_2 are broadly similar between the Q-SL and Q-HA groups. The results provide key insights into the patterns of genetic adaptation to high altitude in Andean populations.

1450/T

Evidence of selection in the pigmentation genes SLC24A5 in Europeans, East Africans, and Southwest and Central Asians and SLC45A2 in East Asians and Native Americans. *M.P. Donnelly, W.C. Speed, A.J. Pakstis, J.R. Kidd, K.K. Kidd.* Department of Genetics, Yale University School of Medicine, New Haven, CT.

Skin pigmentation is one of the most recognizable human phenotypes and tends to vary on a latitudinal cline, even within Europe. The derived alleles of missense SNPs in SLC24A5 (rs1426654) and SLC45A2 (rs16891982) have both been implicated in light skin pigmentation among Europeans. We have collected data for these markers from 4474 individuals in 107 population samples. The derived alleles of both SNPs were observed at high frequencies throughout Europe, though the derived allele of rs16891982 is found at lower frequencies in Southern Europe. The derived allele of rs1426654 was also found at moderate to high frequencies 2 to 100% in East Africa, Southwest Asia, and Central Asia, whereas the derived allele of rs16891982 was seen at frequencies of 0 to 58% in these populations. At SLC24A5 a single allele of a 13-SNP (including rs1426654) haplotype covering ~146 kb accounts for ~95% of the chromosomes in Europe. At SLC45A2, we saw no significant LD around rs16891982. Using the REHH test, we found strong evidence of selection for the derived allele of rs1426654 in Europe as well as East Africa, Southwest Asia, and Central Asia where it had not previously been seen and were able to confirm the evidence of selection in East Africa using nHS. We saw no or very weak evidence of selection for rs1689192 using REHH or nHS among European and nearby populations. We did find previously unidentified evidence of selection in East Asians and Native Americans at a SNP about 15 kb upstream of SLC45A2. The allele showing evidence of selection at this SNP is found at high to moderate frequencies throughout the world except in Europe where it is virtually absent. Given its location it is likely part of or in LD with an upstream regulatory element upon which selection is/was acting. Taken together these results suggest several conclusions about the evolution of skin pigmentation in humans. First two SNPs shown to play a role in pigmentation in a region of the world can show different distribution patterns Second, it suggests that light skin among Europeans evolved both by means of natural selection and neutral factors. Finally, the evidence of selection in the upstream region of SLC45A2 in East Asians and Native Americans, suggests that though light skin pigmentation likely evolved separately in regions where light skin pigmentation is predominant, the evolution at some genes may have occurred independently through different variants. Funded in part by NIH Grant GM57672.

1451/T

Genome-wide scans of European population groups identify multiple loci with evidence for positive selection in Sardinians. *R. Kosoy[1], F. Macciardi[2,3], F. Taddeo[3], D. Cusi[4], S. Lupoli[5], H. Chen[6], M.L. Ransom[1], M.F. Seldin[1].* 1) Dept Biological Chemistry, Univ California, Davis, Davis, CA; 2) Department of Psychiatry and Human Behavior, Univ California, Irvine, Irvine, CA; 3) Genomics and Bioinformatics Unit, Univ of Milan - Fondazione Filarete, Italy; 4) School of Medicine. Dept. of Sciences and Biomedical Technologies. University of Milan, Italy; 5) INSPE, San Raffaele Scientific Institute, Milan, Italy; 6) Department of Genetics, Harvard Medical School, Boston, MA.

Identification of genes undergoing natural selection in various human populations may help identify genetic factors that increase or decrease the risk for specific diseases within that population. We applied multiple methods to detect signatures of positive natural selection using genome-wide scans of eight different European populations. The methods included Fst as a measure of population differentiation and two algorithms (XPEHH, and iHS), which detect the presence of extended identical haplotypes, arising due to a partial or a complete sweep in a population. In addition, we also used XPCLR, a likelihood method for detecting selective sweeps by modeling the multilocus allele frequency differentiation between pairs of populations. These methods were applied to 475,574 SNPs genotyped in English, Irish, Norwegians, Northern Italians, South Italians, Sardinians, Ashkenazi Jews and Arabs (number of individuals in each group between 70 and 780) in a total of 2035 individuals. A number of loci with strong evidence for positive selection were identified in the Sardinian population by pair-wise analyses with four other South European populations (Southern Italians, Northern Italians, Ashkenazi Jewish, and Arabic groups) and three North European populations (English, Norwegians, and Irish). In particular, multiple SNPs in 2p22.1 and 2q37.8 regions showed positive results with XPEHH scores > 0.9 and Fst scores > 0.14 for pair wise comparisons and with clearly defined boundaries. The first of the regions spans 440kb, and contains a part of a single gene, SLC8A1 (solute carrier family 8), previously suggested as a candidate for hypertension. The second region is 220kb long, and contains six genes, HDLBP, SETP2, FARP2, STK25, BOK, and THAP, the first of which codes for high density lipoprotein binding protein, whose likely function is in cell sterol metabolism. The pair-wise differences were strongest between Sardinian and other South European populations, suggesting that the natural selection at these genomic regions is largely confined to Sardinian population, and is not a part of the South Europe versus North Europe difference.

1452/T

Evolutionary origin of peptidoglycan recognition proteins. *A. Montano[1,2], F. Tsujino[2], N. Takahata[2], Y. Satta[2].* 1) Dept Pediatrics, St Louis Univ, St Louis, MO, USA; 2) Dept Biosys Sciences, School Advanced Sciences, The Graduate Univ. for Advanced Studies (SOKENDAI), Hayama, Japan.

Innate immunity is the ancient defense system of multicellular organisms against microbial infection. The basis of this first line of defense resides in the recognition of unique motifs conserved in microorganisms, and absent in the host. Peptidoglycans, structural components of bacterial cell walls, are recognized by Peptidoglycan Recognition Proteins (PGRPs). PGRPs are present in both vertebrates and invertebrates, and although some evidence for similarities and differences between them has been found, their evolutionary history and phylogenetic relationship have remained unclear. Such studies have been severely hampered by the great extent of sequence divergence among vertebrate and invertebrate PGRPs. Here we investigate the birth and death processes of PGRPs to elucidate their origin and diversity. We found that (i) four rounds of gene duplication and a single domain duplication have generated the major variety of present vertebrate PGRPs, while in invertebrates more than ten times the number of duplications are required to explain the repertoire of present PGRPs, and (ii) the death of genes in vertebrates appears to be almost null whereas in invertebrates it is frequent. These results suggest that the emergence of new PGRP genes may have an impact on the availability of the repertoire and its function against pathogens.

1453/T

The LPHN3 Common Haplotype Variant Predisposing to Attention-Deficit/Hyperactivity Disorder (ADHD) is Ancestral to the Protective Variant. *M. Muenke, M. Arcos-Burgos.* Med Gen Branch, NHGRI/NIH, Bethesda, MD.

Recently we identified (Latrophilin 3) LPHN3, a novel Attention Deficit/Hyperactivity Disorder (ADHD) susceptibility gene and showed that a LPHN3 common variant confers susceptibility to ADHD and predicts effectiveness of stimulant medication. LPHN3, a brain-specific member of the LPHN subfamily of G-protein coupled receptors, is expressed in ADHD-related regions, such as amygdale, caudate nucleus and cerebral cortex. Further, this ADHD susceptibility variant affect metabolism in neural circuits implicated in ADHD. Here by genotyping more than 300 SNP variants, including some spanning the LPHN3 genomic region associated to ADHD, in different species of monkeys (sanguinus (n=1), macaca mulatta (n=2)), and primates (gorilla gorilla (3), pan troglodytes (8), and pongo pygmaeus (2)) (a phylogeny covering ~70 millions years of evolution), we were able of reconstructing a phylogenetic tree showing that the LPHN3 variant of susceptibility is ancestral to the LPHN3 variant conferring protection against ADHD. Furthermore, the reconstructed phylogenetic tree suggests that the evolutionary splitting between these variants happens before modern humans separated from great apes. This phylogenetic scenario is in strong agreement with the suggested selective beneficial advantage of genetic variants conferring susceptibility to ADHD and consequently with the fact that the cluster of behaviors outlined by the ADHD syndrome are and/or were indeed very old and normal.

Using STRs to shed light on the origin of endemic HLA-B alleles in Amerindian populations. *K. Nunes[1], R.S Francisco[1], C. Hurley[2], B. Tu[2], W. Klitz[3], E.J.M Santos[4], D. Labuda[5], R. Barrantes[6], A. Ruiz-Linares[7], D. Meyer[1].* 1) Universidade de São Paulo, São Paulo, Brazil; 2) Georgetown University, Washington, USA; 3) Public Health Institute, Oakland, USA; 4) Universidade Federal do Para, Belém, Brazil; 5) Université de Montréal, Montreal, Canada; 6) Universidad de Costa Rica, San José, Costa Rica; 7) University College London, London, United Kingdom,.

Compared to populations from other regions, Amerindian populations display low genetic variation and high inter-population diversity. An additional and striking pattern in Amerindians was revealed for HLA-B locus, which carries a large number of alleles which are found exclusively in this region, and are present at a relatively high frequencies. This pattern of variation is unusual, given that Amerindian populations typical harbor alleles which constitute a subset of those found in Asia. In the present study we use HLA-B flanking microsatellites to better understand the evolutionary history of HLA-B alleles endemic to the Americas. The STRs D6S2927 and D6S2928 from MHC region were genotyped in 241 individuals from 22 Amerindian populations (3 North American, 3 Central American and 16 South Americans). These samples were previously typed for the HLA-B gene by PCR-SBT and/or genotyped by PCR-SSOP, allowing the inference of haplotype frequencies for the compound marker consisting of HLA-B and flanking STRs We compared the distribution of STRs allele frequencies for endemic and cosmopolitan alleles, for each lineage of HLA-B. Overall, STR frequencies were similar for cosmopolitan and endemic alleles, with exception of the HLA-B*3543 for the locus D6S2928 (p = 3.99 e-09). The alleles of the 35 lineage usually have the allele 261 at the D6S2928 locus, however, the HLA-B*3543 presents the allele 257. The comparison between the sequences of HLA-B points to a possible recombination event between a lineage 35 allele and some other allele of lineage 15, giving rise to HLA-B*3543. This is corroborated by the fact that the alleles of lineage 15 generally present allele 257 at locus D6S2928. We conclude that: 1) The finding of the same STR alleles associated to more than one HLA-B allele suggests that the gene conversion occurs in the HLA-B alleles at a faster rate than the mutation rate of the STRs. 2) The absence of allelic profile alteration on the STRs between the cosmopolitan and endemic alleles confirms the hypothesis that the majority of the endemic alleles arise by genic conversion, involving a few nucleotides of exons 2 and 3 of the HLA-B gene. 3) The allele HLA-B*3543, seems to have arisen by recombination among a lineage 35 allele (possibly 350101g) and an allele of the lineage 15.

1455/T

Estimation of Selection Intensity of an *ABCC11* SNP Determining Earwax Type. *J. Ohashi, I. Naka, N. Tsuchiya.* Doctoral Program in Life System Medical Sciences, Graduate School of Comprehensive Human Sciences, University of Tsukuba, Tsukuba, Ibaraki 305-8575, Japan.

Despite great progress in understanding the associations between genetic variants and traits in humans owing to genome-wide association study using a number of SNP markers, the effect of local adaptation on the difference in phenotype among human populations remains to be studied. A nonsynonymous single nucleotide polymorphism (SNP), rs17822931-G/A (538G>A; Gly180Arg), in the *ABCC11* gene determines human earwax type. The population frequency of rs17822931-A, which leads to dry earwax in a recessive manner, is much higher in Asians than in Africans, and the heterozygosity around rs17822931 is markedly reduced in Asian populations, implying that positive selection has acted on rs17822931-A in Asians. In this study, the selection intensity of rs17822931-A in East Asians was estimated by analyzing two microsatellite loci flanking rs17822931 in African (HapMap-YRI) and East Asian (HapMap-JPT and HapMap-CHB) populations. Under the assumption of a recessive selection model, computer simulations suggested that the selection intensity of rs17822931-A had been 0.01 in East Asians, and rs17822931-A is 40,120 years old. The present results provide a striking example that local adaptation has played a significant role in phenotypic diversification of human trait.

1456/T

The Thule Migration: Genetic Perspectives from the North Alaskan Slope. *M. Rzhetskaya, L. Armstrong, M.G. Hayes.* Northwestern University, Chicago, IL.

The nature of the Thule expansion from north Alaska to the Eastern Canadian Arctic appears to have been a very rapid migration, taking perhaps only 100-200 years for Alaskan Thule populations to reach their eastern terminus in Greenland. This migration is associated with a clear signal of near population replacement; the migrating Thule replacing, and perhaps interbreeding with, late Paleo-Eskimo populations - the Dorset. The Inupiaq speaking populations across northern North America are virtually monomorphic for mitochondrial haplogroup A (the remainder are D [<3%]), and this reduced genetic variability is not unexpected in small, isolated populations, such as the prehistoric Thule are likely to have been. Very little is known genetically of the North Alaskan Inupiat population, the local descendant of the most-likely source population for the subsequent Thule/Inuit inhabitants of the Eastern North American Arctic. Herein, we present our preliminary investigations into the mtDNA and haplotype frequencies of Inupiat populations from the Alaskan North Slope, and discuss the placement of this population in the geographical and temporal context of North American Arctic Prehistory.

Using standard methods, HVS1 of the mtDNA genome was sequenced using DNA extracted from saliva samples of consenting adults residing in four Alaskan North Slope communities. There is considerable variation among the four communities investigated although they hold the general North American Arctic pattern of haplogroup A being most common followed by haplogroup D. Most interestingly, the frequency of haplogroup D (14/102, or 13.7%) among the aggregate North Slope population is the highest observed among Inuit/Inupiaq speakers in the North American Arctic. When compared to the sub-haplogroup frequencies of their neighbors, the pattern of A2a and A2b frequencies is most similar to Siberian Eskimo. Haplogroup D3, which is found in among Greenland and Canada inhabitants, is found in North Slope populations, as is D2, which is found among Aleut and Siberian Eskimos and ancient Paleo-Eskimos. All Neo-Eskimo Eastern Arctic haplotypes are present at the North Slope, at least among contemporary populations, suggesting that the North Slope is a good source for Neo-Eskimo populations further east.

1457/T

Combining signatures of selection and disease-associated loci in three ethnic groups. *X. Sim[1], R.T.H. Ong[1,2], W.T. Tay[3], C. Suo[1], T.Y. Wong[3,4,5], E.S. Tai[5,6], K.S. Chia[1,5], Y.Y. Teo[1,5,7,8].* 1) Centre for Molecular Epidemiology, National University of Singapore, Singapore, Singapore; 2) NUS Graduate School for Integrative Science and Engineering, National University of Singapore, Singapore; 3) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore; 4) Centre for Eye Research Australia, University of Melbourne, Australia; 5) Department of Epidemiology and Public Health, National University of Singapore, Singapore; 6) Department of Medicine, National University of Singapore, Singapore; 7) Department of Statistics and Applied Probability, National University of Singapore, Singapore; 8) Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore.

Natural selection leaves an imprint on the genetic architecture of populations at the selected site and provides an insight to the evolutionary adaptations of the human genome. Often, the roles of environmental factors that shaped the selection or targets of the selection are not immediately clear. The study of positive selection therefore hinges on an understanding of the genotype-phenotype relationships and how these association signals could be rooted in regions of positive selection. Darwinian medicine has suggested that vulnerabilities to diseases are shaped by selection pressures and the process of selection has an important role in shaping the humans evolved defenses against infectious and immune diseases. Hence it is of great interest to combine evidences of selection and disease association to enhance the understanding of phenotype-genotype relationships in both chronic and infectious diseases. Different statistical methods have been developed to detect signatures of positive selection across the frequencies spectrum. While multiple populations are more useful to detect selection events that has risen to fixation in one population and not in another, a characteristic of recent signature of positive selection (at frequencies of 30% to 80%) is unusually extended haplotypes that rise in frequency rapidly as recombination has yet to break down the long haplotype while the selected variant is passed down preferentially. With the availability of genome-wide data on three ethnic groups in Singapore, Chinese, Malays and Asian Indians of 2500 individuals in each cohort and sophisticated statistical algorithms such as iHS and XP-EHH, we surveyed the genome for selection signatures and associations with common diseases such as Type II Diabetes and complex traits including lipids traits. Our findings suggest the overlapping of selection signatures and diseases-associated loci could elucidate differences in diseases susceptibility in different populations and the importance of environmental variations across populations.

1458/T

Natural selection and sex-specific demography shape patterns of genetic variation across the genome. *J.D. Wall[1], A.E. Woerner[2], F.L. Mendez[3], J.C. Watkins[4], M.P. Cox[2], M.F. Hammer[2, 3].* 1) Inst Human Gen, Univ California, San Francisco, San Francisco, CA; 2) ARL Division of Biotechnology, University of Arizona, Tucson, AZ; 3) Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, AZ; 4) Department of Mathematics, University of Arizona, Tucson, AZ.

An analysis of six complete European genomes reveals that the ratio of X-linked to autosomal diversity deviates from the expected value of three-quarters. However, the direction of this deviation depends on whether a particular sequence is close to or far from the nearest gene. This pattern may be explained by stronger locally acting selection on X-linked versus autosomal genes, combined with larger effective population sizes for females than for males.

1459/T

Genetic Variation and Positive Selection at the WFDC locus in Hominids. *Z. Ferreira[1,3], A. Andres[1], W. Kretzschmar[1], J. Mullikin[1,2], W. Swanson[4], K. Gonder[6], S. Tishkoff[5], A. Stone[7], E. Green[1], B. Hurle[1], NISC Comparative Sequencing Program.* 1) NHGRI, NIH, Bethesda, MD; 2) NIH Intramural Sequencing Center, Bethesda, MD; 3) IPATIMUP Rua Dr. Roberto Frias, s/n 4200-465 Porto, PORTUGAL; 4) University of Washington Seattle, WA; 5) Departments of Genetics and Biology, University of Pennsylvania, Philadelphia, PA; 6) Department of Biological Sciences University at Albany, State University of New York, Albany NY; 7) Department of Anthropology, Arizona State University, Tempe, AZ.

The whey acidic protein (WAP) four-disulfide core domain (*WFDC*) genes encode protease inhibitors with roles in innate immunity and regulation of the endogenous protease kallikreins (*KLK*). Through a comparative genomics strategy that involved the re-sequencing of the *WFDC* centromeric sub-locus in twelve primates, it was previously shown that a striking number of contiguous *WFDC* genes and the neighboring seminal genes (semenogelin I and II - *SEMGI* and *SEMGII*) show strong patterns of positive selection in primates. It is unusual to find a series of tightly linked genes that all show robust patterns of positive selection, as hitchhiking effects make it difficult for successive selective sweeps of tightly linked loci. Despite this co-localization of positively selected genes, the *WFDC* locus does not stand out as particularly unusual in humans with respect to known genetic variation databases. We tested whether the levels and patterns of genetic variation within the *WFDC* locus differ among hominid species. We sequenced 19 genes of the *WFDC* locus, plus 54 evenly spaced non-coding regions in 71 humans from three HapMap populations and 68 western equatorial African chimpanzees from three *Pan* subspecies. A set of 47 unlinked and neutrally evolving loci was also surveyed to assess the general patterns of diversity. Overall, we generated ~23 and ~13 Mb of high-quality sequence data from humans and chimpanzees, respectively, enabling the identification of 541 human and 847 chimpanzee single-nucleotide polymorphisms (SNPs) and 487 human-chimp fixed differences. Ongoing research includes detecting recent positive selection events using classical neutrality tests and identifying both incomplete and complete sweeps as well as detecting differences at inter and intra-species level. Test significance is being assessed through coalescent simulations under different demographic scenarios. Unique features of this study include examining the dynamic nature of the *WFDC* locus in primates, capitalizing on the sheer number and verified demographic origin of the chimpanzee samples, and noting the lack of ascertainment bias in SNP collection. Our efforts offer insights on the evolutionary forces driving the rapid diversification of *WFDC* and *SEMG* genes in hominoids, and improve our knowledge about the biological dynamics of rapidly evolving genomic regions in primates.

1460/T

Patterns of genetic variation at CD-36 in diverse African populations: An examination of nucleotide variation at a malaria susceptibility locus. *F. Gomez[1,2], S.A. Tishkoff[1].* 1) Departments of Genetics and Biology, School of Medicine and School of Arts and Sciences, University of Pennsylvania, Philadelphia, PA; 2) Hominid Paleobiology Doctoral Program, Center for the Advanced Study of Hominid Paleobiology, Department of Anthropology,George Washington Univ, Washington, DC.

A central focus of human population genetics is creating a clear understanding of the evolutionary and demographic events that have shaped human genomic variation. It is clear that infectious disease has played an important role in driving human evolution and human population genomic variation. Additionally, malaria has arguably been one of the strongest selective forces during recent human evolution. In order to characterize signatures of natural selection due to malaria infection, and to identify potential functional variants, we have studied nucleotide variation at the *CD-36* locus. During a malarial infection, CD-36 that is expressed on vascular endothelial cells acts as a receptor for *P. falciparum* parasitized erythrocytes and is involved in the pathogenesis of cerebral malaria. Studies of nucleotide diversity at this locus have suggested that specific alleles may affect susceptibility to malaria. However, the data that describe allelic variation at this locus and its relationship to malaria susceptibility are not consistent across studies. Therefore, we have chosen to re-sequence *CD-36* in diverse African populations to better understand the scope of genetic variation at this locus and to identify variants that may influence susceptibility to malaria. A panel of ~300 individuals originating from Nigeria, Cameroon, Ghana, Tanzania, Kenya, and the Sudan were re-sequenced across an ~13 kb region of *CD-36*. Individuals from the Hap Map Chinese and European populations were also re-sequenced as comparative data. Using these data we have characterized levels of diversity and have used tests of neutrality to identify signatures of natural selection. We have also used these data to describe the frequencies of alleles that are known to cause CD-36 deficiency in African and Asian populations.

1461/T

Frequency spectrum estimation using low coverage sequence data. *S. Gopalakrishnan[1], P.L. St Jean[2], L. Li[2], M.G. Ehm[2], M.R. Nelson[2], S.L. Chissoe[2], J.C. Whittaker[3], V.E. Mooser[4], J. Novembre[5,6], S. Zöllner[1,7].* 1) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) GlaxoSmithKline, Dept of Genetics, RTP, NC; 3) GlaxoSmithKline, Dept of Genetics, Harlow UK; 4) GlaxoSmithKline, Dept of Genetics, Swedeland, PA; 5) Department of Ecology and Evolutionary Biology, University of California Los Angeles, Los Angeles, CA; 6) Interdepartmental Program in Bioinformatics, University of California Los Angeles, Los Angeles, CA; 7) Department of Psychiatry, University of Michigan, Ann Arbor, MI.

Large sequencing projects, such as the 1000 Genomes project, provide us an opportunity to examine population genetics questions with sequence level data. However, the design of many of these projects involves low to moderate per-individual coverage. Under this design, the estimated genotypes for individuals are biased towards the reference sequence. Pooling data from all the samples can overcome this bias for sites with intermediate minor allele frequencies. This leads to an underestimation of the number of sites with low minor allele frequencies. It is important to accurately estimate the site frequency of these rare variants in order to make unbiased population genetic inferences. Here, we introduce a method to use complete sequence alignment information to estimate the site frequency spectrum of rare variants from low coverage data. At each site, we combine the likelihood of the aligned sequence data with theoretical population genetics priors in a Bayesian framework to estimate its contribution to the frequency spectrum. We combine evidence across all sites to estimate the site frequency spectrum. We use importance sampling to make the estimation computationally tractable at higher allele frequencies and large sample sizes. We test our method using simulation schemes with haplotypes simulated to mimic populations with various levels of diversity. We quantify the performance of our method using the Kullback-Leibler divergence between the true and estimated frequency spectra. In addition, we use resequencing data from a dataset with the exons of 202 genes sequenced at an average depth of 30x in ~ 15,000 individuals, as part of the QPOC study. We generate low coverage data by thinning the sequence data. We verify that we recover the original site frequency spectrum by applying our method to the thinned dataset. Using the true, corrected and uncorrected frequency spectra, we quantify the effect of bias in the frequency spectrum estimation on downstream population genetic inferences.

1462/T

Evidence of natural selection at genetic regions associated with HIV-1 control is geographically restricted. *Y.C. Klimentidis[1], B. Aissani[2], S. Shrestha[2].* 1) Section on Statistical Genetics, Department of Biostatistics, University of Alabama at Birmingham, Birmingham, AL; 2) Department of Epidemiology, University of Alabama at Birmingham, Birmingham, AL.

HIV susceptibility and pathogenicity exhibit both inter-individual and inter-group variability. The etiology of inter-group variability is still poorly understood, and could be partly linked to genetic differences between groups. These genetic differences may be traceable to different regimes of natural selection in the 60,000 years since human radiation out of Africa. Here, we examine population differentiation and haplotype patterns at several loci identified through genome-wide association studies on HIV-1 -control, as determined by viral-load setpoint in Caucasian and African-American populations. We use the genome-wide SNP dataset on the Human Genetic Diversity Panel of 53 world-wide populations to compare measures of FST and extended haplotype homozygosity (EHH) at these candidate regions to the rest of the genome. We find that the Europe-Middle East pair-wise FST in the associated regions is elevated compared to the rest of the genome, while the sub-Saharan Africa-Middle East pair-wise FST is very low, suggesting that genetic differentiation (diversifying/positive selection) occurred outside of sub-Saharan Africa, while balancing or purifying selection occurred in sub-Saharan Africa. We also find greater EHH, indicative of recent positive selection at these associated regions, among all population sub-groups except for sub-Saharan Africans and Native Americans. These findings corroborate findings from other studies suggesting recent evolutionary change at immunity-related regions among Europeans, and shed light on the potential genetic and evolutionary origin of population differences in HIV-1 control.

1463/T

Retrotransposons in the orangutan (*Pongo*) lineage: a new evolutionary tale. *M.K. Konkel[1], J.A. Walker[1], B. Ullmer[2], L.G. Chemnick[3], O.A. Ryder[3], R. Hubley[4], A.F.A. Smit[4], M.A. Batzer[1] for the Orangutan Genome Sequencing and Analysis Consortium.* 1) Department of Biological Sciences, Louisiana State University, Baton Rouge, LA 70803, USA; 2) Department of Computer Science, Center for Computation and Technology (CCT), Louisiana State University, Baton Rouge, LA 70803, USA; 3) Conservation and Research for Endangered Species (CRES), Zoological Society of San Diego, San Diego, CA 92112, USA; 4) Institute for Systems Biology, Seattle, WA 98103, USA.

Orangutans *(Pongo)* are the only living Asian ape and are highly endangered. We investigated the mobile DNA composition (mobilome) of the orangutan draft genome sequence derived from a female of Sumatran origin *(Pongo abelii)*. Similar to other primate genomes, about half of the orangutan draft genome sequence is comprised of repetitive sequences. As expected, no DNA transposon activity was detected in the orangutan lineage. L1 (long interspersed element 1, LINE1) is the only active autonomous non-LTR retrotransposon in the orangutan lineage and shows a mostly linear evolution. The orangutan-specific L1 lineage appears to be derived from L1PA3. SVA elements have been active throughout the evolution of orangutans and appear to be currently undergoing retrotransposition. Similar to L1, the orangutan-specific SVA subfamilies show a mostly linear evolution. We found evidence of expansion of SVA and L1, with ~1800 and ~4700 orangutan lineage-specific insertions, respectively. This translates to a retrotransposition rate comparable to other sequenced primate genomes. In contrast, *Alu* elements appear to be relatively quiescent and have propagated at a very low rate in orangutans. The identification of polymorphic and population-specific *Alu* insertions indicates that *Alu* retrotransposition may be ongoing, albeit at a very low rate. In addition, we investigated the population structure within orangutans. For this purpose, we performed a Structure analysis with 37 orangutans - 18 Bornean *(Pongo pygmaeus)* and 19 Sumatran - using polymorphic retrotransposon markers. These elements were selected from the orangutan draft genome and also from Illumina paired-end reads from a Bornean orangutan. The orangutans of Bornean origin were clearly distinct from the Sumatran population with almost no evidence of ongoing admixture. In addition, Sumatran orangutans showed clear evidence of population substructure. The distinction of Sumatran from Bornean orangutans supports the relatively recent notion that Bornean and Sumatran orangutans represent separate species.

1464/T

Humans and other primates show varying selection pressures on Matrix Metalloproteinase 9 (MMP9), a gene responsible for placental invasion. *A. Lobell, M. Ruvolo.* Department of Human Evolutionary Biology, Harvard University, Cambridge, MA.

The ability to produce healthy offspring is critical to evolutionary fitness and is a phenotypic trait controlled largely by reproductive genes. Among humans, polymorphisms in the placentally-expressed Matrix Metalloproteinase 9 (MMP9) gene are associated with pathologies of pregnancy caused by insufficient transfer of nutrients across the placenta. While the negative health effects of these pathologies are well known, the evolutionary genetics of human placental invasion has not been characterized. Understanding the molecular evolution of human placental invasion is important because extremely deep placental invasion is a uniquely human trait that likely underlies key adaptations including increased brain size. Humans' deep placental invasion arose in the context of more ancient evolutionary changes that increased placental invasion in haplorhine primates (tarsiers, monkeys, apes, and humans). Our study investigates the forces that shaped MMP9 evolution in humans and other haplorhines in order to link adaptive change in placental invasion to its underlying genetic mechanisms. Using maximum likelihood analysis and a new full Bayesian test for positive selection on complete MMP9 coding sequences from 18 mammalian species, we demonstrate statistically significant signals of adaptive evolution ($\omega > 1$) in MMP9 only at the phylogenetic points in haplorhine evolution where increases in placental invasion arise. An intensification of positive selection is detected in regions critical to MMP9's enzymatic ability within the human/chimpanzee/gorilla clade and along the human lineage. These results suggest that increased placental invasion was the primary selection pressure acting on MMP9 in non-human primates and along the human lineage. However, an analysis of 10.5 Kb of resequencing data from 50 diverse human chromosomes does not find signals of recent adaptation for increased placental invasion in MMP9. Instead, patterns of variation in human MMP9 suggest the action of competing selection pressures that may be related to MMP9's role as a human oncogene.

1465/T

Frequencies of the Alzheimer's disease associated *TOMM40* poly-T allele in different ethnic groups. *M.W. Lutz[1], A.M. Saunders[1], D.G. Crenshaw[1], I. Grossman[2], D.K. Burns[1,2], T. Swanson[2], K. Whitfield[3], M. Hauser[4], A.D. Roses[1,2].* 1) Deane Drug Discovery Institute, Duke University, Durham, NC; 2) Cabernet Pharmaceuticals, Inc, Durham NC; 3) Psychology and Neuroscience, Duke University, Durham, NC; 4) Medicine, Duke University, Durham, NC.

A variable length poly-T polymorphism, rs10524523 (523), in *TOMM40* is significantly associated with age of onset of late-onset Alzheimer's disease (AD) for >85% of the Caucasian population. Phylogenetic analyses demonstrate that for Caucasians, *APOE4* is in LD with long (L, 21-30 T residues) 523 poly-T alleles 98% of the time but there are two distinct groups of polyT lengths in LD with *APOE3*: short alleles (S, 14-18 T residues) or very long alleles (VL, 30-39 T residues). Moreover, the L and VL poly-T alleles are associated with earlier age of onset of AD. Allele length frequency distributions for the poly-T were evaluated in diverse population samples as a first step towards translating the Caucasian findings to worldwide populations. Han Chinese, Japanese and Korean (Far Eastern, FE) and Ghanan population samples were genotyped for length of the 523 poly-T and for *APOE* genotype. The lengths of the poly-T alleles linked to *APOE4* were similar in the FE groups and Caucasians (21-30 T residues). In the Ghanan sample, there were no L alleles of the length that is most common in the other populations. For FE and Ghanans, there were also two distinct length distributions of poly-T tracts linked to *APOE3*. However, the length distributions of the 523 alleles (S and VL) connected to *APOE3* were shifted to shorter lengths in all of the FE populations. For Caucasians, the S alleles were rarely less than 14 T residues in length whereas S alleles of 11-13 T residues were common in the FE groups and the frequency of alleles of 15-16 residues was relatively reduced in these populations. The FE VL forms were generally 27-32 residues long whereas the length of the Caucasians VL alleles peaked at 33-37 residues. The Ghana sample was enriched for S alleles compared to Caucasians, perhaps linked to the frequent *APOE2* allele in this population, but there was an absence of the shorter length S alleles seen in FE groups. These data demonstrate that the distributions of 523 poly-T lengths differs in populations with different evolutionary histories. The size distributions may differ in various ethnic groups, but the risk of AD may be ultimately be predicted by the specif1c sizes of two 523 alleles inherited by each individual. Formal phylogenetic mapping of multiple ethnic groups is currently in progress.

1466/T

Detecting population structure and exploring demographic history. *C. Mair, V. Macaulay.* University of Glasgow, Glasgow, United Kingdom.

It is well established that genetic differences between human populations are associated with geographical distance. The population structure that such observations identify can be studied by various techniques. We will concentrate on principal components analysis (PCA), a dimension-reduction technique with a long history in population genetics, but which has become popular recently as a straightforward way of controlling Type 1 errors in association studies that arise because of (usually hidden) population structure. The emphasis here is different: to learn about the population structure itself by the method. By using the most significant components of single-nucleotide polymorphism (SNP) variation obtained through PCA, we will examine how the structure captured in these components allows us to estimate the parameters in simple demographic models. We will consider a population split model parameterized by split times T when ancestral populations fission into independent daughter populations, as well as an island model in which populations exchange migrants at a constant rate m arbitrarily far into the past. Do the first few principal components contain information to distinguish these models and, if so, can their respective parameters be well estimated? These questions will be addressed using SNP-like data sets simulated under the coalescent process.

Human and great ape blood lipid profiles indicate novel metabolic differences that could influence physiological and cognitive processes. *K. Ramaswamy[1], P.A. Watkins[2], A.B. Moser[2], C.B. Toomer[2], S.J. Steinberg[2], H.W. Moser[2], M.W. Karaman[1], P.K. Dranchak[1], J. Hey[3], K.D. Sigmund[4], D.R. Lee[5], J.J. Ely[5], O.A. Ryder[6], J.G. Hacia[1].* 1) Department of Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA, 90033; 2) Hugo W. Moser Research Institute at Kennedy Krieger, and Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD, 21205; 3) Department of Genetics, Rutgers University, Piscataway, NJ 08854; 4) Department of Preventive Medicine, University of Southern California, Los Angeles, CA 90089; 5) Alamogordo Primate Facility, New Mexico, NM 88330; 6) Institute for Conservation and Research, Zoological Society of San Diego, Escondido, CA 92027.

It has been proposed that anatomical differences in human and great ape guts arose in response to the historic diets and energy demands of each species. To investigate functional genomic consequences of these differences, we compared their physiological levels of phytanic acid, a branched chain fatty acid that can be derived from the microbial degradation of chlorophyll in ruminant guts. Phytanic acid is a potent activator of PPAR and RXR transcription factors and can modulate the activity of lipid metabolic pathways. Despite their trace dietary phytanic acid intake, all great ape species had elevated red blood cell (RBC) phytanic acid levels relative to humans on diverse diets. Furthermore, chimpanzees, unlike humans, showed sexual dimorphism in RBC phytanic acid levels. We provide indirect evidence that great apes, unlike humans, derive significant amounts of phytanic acid from the hindgut fermentation of plant materials. This would represent a novel reduction of metabolic activity in humans and affect the interpretation of human and great ape transcriptomes. Furthermore, we observed species-specific differences in RBC plasmalogen (ether phospholipid) levels and molecular composition. Similar to phytanic acid, plasmalogens are metabolized by peroxisomes and, in addition, are critical for brain and male reproductive functions. We provide evidence that cross-species differences in plasmalogen metabolism are responsible our observations and likely affect the membrane composition of diverse tissues. Overall, we suggest that differences in branched chain fatty acid and plasmalogen metabolism among humans and great apes influence the functions of major organ systems and processes ranging from cognition to reproductive biology.

1468/T

Music as a novel marker in the study of prehistoric human migrations. *T. Rzeszutek[1], P. Savage[1], V. Grauer[2], S. Brown[1].* 1) Psychology, Neuroscience & Behaviour, McMaster University, Hamilton, Ontario, Canada; 2) Independent Scholar, Pittsburgh, PA.

The study of prehistoric human population history is often fraught with controversy owing to incongruent evidence among various markers of present-day genetic and cultural diversity. While archaeological evidence can be used to calibrate the conclusions drawn from present-day diversity, the fickle nature of the fossil record leaves some migration histories unresolved. Our work analyzes the potential of music - in particular, vocal music - to serve as novel migration marker, bolstering established migration work and shedding light on regions of the world whose settlement history is contested. One such migration is the recent expansion of Austronesian-speaking peoples across the Pacific within the last 6000 years. The dominant hypothesis posits a recent origin in Taiwan, with a rapid movement southwards and eastwards to populate Polynesia during the following 3500 years. While this model is strongly supported by both archaeological evidence and the present-day distribution of linguistic diversity, our goal was to analyze whether music could serve as a novel line of evidence in the study of Pacific prehistory. A critical concern regarding any migration marker is its time depth. In order to examine this for music, we analyzed correlations between musical diversity and mitochondrial-DNA diversity in 9 Taiwanese aboriginal tribes for which both types of data were available. A sample of 226 choral songs was analyzed using 39 binary characters representing significant structural features of music (e.g., rhythm, interval size, melodic contour, etc.). The musical samples were restricted to ritual musics, which constitute the most conservative (i.e., slowly changing) component of a culture's repertoire. Mantel tests showed a significant correlation between musical distance and genetic distance among these 9 tribes, suggesting that music may have a time depth comparable to widely-used genetic markers like mitochondrial DNA. This work demonstrates that music has the potential to enrich the conclusions drawn from other markers, and establishes methods for employing it as a tool in the study of prehistoric human movements throughout the world. At the same time, we want to capitalize on music's own unique dynamics of change over time and place, particularly its capacity for admixture. In other words, music might not only be able to support the narratives told by other migration markers but shed new light on the histories of population movement and cultural contact.

Genetic Structure and Diversity of Gujjar Population of North India. *J. Saini, K. Matharoo, B. Ddoza, A.J.S. Bhanwer.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Molecular markers such as Alu insertion polymorphisms and RSP's can be used to define the differential Genetic structure or Genomic Diversity in Human populations. The present population study is targeted on Gujjar population of North India, which is a nomadic, pastoral tribe of North India with historical importance but uncertain origin. Gujjars are included in group of transhumant which migrate to Punjab during winters and back to Kashmir and Ladakh during summers. Their primary occupation is cattle rearing and marginal farming. Gujjars follow monogamy, clan (gotra) exogamy and caste endogamy. Gujjar population follows endogamy and thus has differential genetic structure due to separation from other populations. However, there is paucity of molecular genetic studies deciphering the genetic structure and diversity of Gujjar population in North India. Thus keeping in mind the whole scenario, the present study was designed to analyze the molecular markers in Gujjar population of North India. A total of 131 individuals of Gujjar population of North India were analyzed for Alu insertion polymorphism at PV92, ACE and APO loci; and Restriction Segment Polymorphism at ESR loci. Statistical analysis was done using SPSS 16.0. Heterozygosities for all three loci were calculated using the estimated allele frequencies for present population. Hardy Weinberg equilibrium was tested through $\chi 2$ goodness of fit test. Nei's measures of gene diversity, FST and FIS have been calculated. In present analysis all 4 studied loci (PV92, ACE, APO and ESR) were found to be polymorphic. The heterozygosity for all the loci ranged from 0.213-0.564. The average heterozygosity for each of the loci was substantially different from each other with ACE loci exhibiting maximum heterozygosity and APO exhibiting minimum heterozygosity of 0.564 and 0.213 respectively. Very high frequency value for (+) allele at APO insertion loci shows that this locus is reaching fixation in Gujjar population. Value of FIS indicates a maximum reduction of heterozygosity of 18.7% due to inbreeding ($P < 0.001$) at PV92 loci. This indicates that PV92 is derived from one common ancestor which led to substantial hidden inbreeding in Gujjar population. It was estimated from pair wise Genetic Distance analysis with other reported population from the region that Gujjar population has maximum genetic affinity with Jat Sikh population followed by Bania, Rajput and Brahmins.

1470/T

Risk of tuberculosis among close contacts to TB patients: the role of CCL5 and CCR5 gene polymorphisms and environmental factors. *M.R. Reichler[1], C.C. Luo[1], B. Chen[1], E. Sigman[1], F. Maruri[2], T. Sterling[3] for the TB Epidemiologic Studies Consortium.* 1) Division of TB Elimination, Centers for Disease Control and Prevention, Atlanta, GA; 2) Tennessee Department of Health, Nashville, TN; 3) Vanderbilt University, Nashville, TN.

Background: Single nucleotide polymorphisms (SNPs) in chemokine ligand 5 (CCL5) and chemokine receptor 5 (CCR5) have been implicated in susceptibility to HIV infection. Chemokines play an important role in host immune response to tuberculosis (TB), but the contribution of SNPs in chemokine genes to TB susceptibility is not known.

Methods: We enrolled U.S.-born contacts with latent TB infection or active TB disease with >180 hours of exposure to smear+, culture+ TB patients at 9 sites. Blood was collected and genotyped for CCL5 SNP IN 1.1 and CCR5 SNP Δ32. Epidemiologic data were collected by contact interview. Pair-wise analysis was conducted using X^2 tests with homozygous wild genotype as the referent group. This analysis was limited to contacts of black race/ethnicity.

Results: Among 285 contacts, 21 had active TB and 264 had a positive tuberculin skin test (TST+) but not active disease. Compared with TST+ contacts, contacts with active TB were more likely to have the homozygous mutant genotype for CCL5 IN 1.1 (OR=3.31, P=.13). There was no association for CCR5 Δ32 (OR=1.25, P=.76). For CCL5 IN 1.1, the association between mutant genotype and TB was significantly increased for contacts who used alcohol (OR=20.5, P<.001) or street drugs (OR=11.25, P=.04).

Conclusions: In this U.S. population, active TB in contacts after exposure to *M. tuberculosis* was associated with homozygous mutant genotypes for CCL5 gene SNP IN 1.1, particularly for contacts who used alcohol or street drugs. These findings suggest that the risk of active TB after *M. tuberculosis* exposure may be modulated by genes and environmental factors such as use of alcohol and street drugs.

1471/T

The Genetic Basis and Evolutionary History of PTC Bitter Taste Perception in Africa. *M.C. Campbell[1], A. Ranciaro[1], A. Froment[2], D. Zinshteyn[3], J.-M. Bodo[4], D. Drayna[5], P. Breslin[6,7], S.A. Tishkoff[1,3].* 1) Dept Gen, Univ Pennsylvania Sch Med, Philadelphia, PA; 2) Ecoanthropology and Ethnobiology Musée de l'Homme, Paris, France; 3) Department of Biology, University of Pennsylvania, Philadelphia, PA; 4) Ministry of Scientific Research and Innovation, Yaoundé, Cameroon; 5) National Institute on Deafness and Other Communication Disorders, Rockville, MD; 6) Monell Chemical Senses Center, Philadelphia, PA; 7) Department of Nutritional Sciences, Rutgers University, New Brunswick, NJ.

Bitter taste perception is an important dietary adaptation which may have evolved to prevent the accidental ingestion of harmful plant toxins. The ability to taste the bitter synthetic compound phenylthiocarbamide (PTC) is a highly variable trait in humans and is also correlated with the ability to detect naturally bitter substances in food. A large proportion of the phenotypic variance in PTC taste sensitivity has been attributed to genetic variability at TAS2R38, a bitter taste receptor gene, located on chromosome 7. In order to better understand the genetic basis and evolutionary history of PTC taste perception, we examined sequence variation within a 2975 bp region encompassing the 1002 bp coding exon of the TAS2R38 gene, in 588 individuals from more than 50 ethnically diverse populations from East and West Central Africa, as well as in a comparative sample of 132 non-Africans from different geographic regions. We also examined genotype-phenotype associations in a large subset of Africans, totaling 463 individuals, from the above sampled populations. Our analyses uncovered higher levels of nucleotide and amino acid haplotype variability, including an excess of rare non-synonymous polymorphisms, in Africans relative to non-Africans. The estimated time to the most recent common ancestor (TMRCA) of genetic variation within the TAS2R38 coding region is ~2.3 million years, consistent with the pattern expected under ancient balancing selection. The diverse amino acid haplotypes present in African populations were also associated with a broader range of PTC taste sensitivity than is typically observed outside of Africa. In addition, we found that several rare non-synonymous polymorphisms significantly modify PTC sensitivity in African populations, demonstrating the effect of single amino acid substitutions on bitter taste perception. This research provides further information regarding the genetic basis of phenotypic variation in Africa, and serves as a model system for understanding the influence of natural selection, as well as common and rare amino acid variation, on variable traits in humans.

1472/T

Ancient and recent demographic events influence mitochondrial DNA diversity in an immigrant Basque population. *M. Davis, S. Novak, G. Hampikian.* Department of Biological Sciences, Boise State University, Boise, ID.

The Basques are an ancient people, considered by many anthropologists to represent the oldest extant European population. Because of this, they have been the subject of numerous sociological and biological investigations. The Basque Diaspora, a relatively recent demographic expansion of the Basque population, has until now been overlooked in genetic studies. Samples were taken from 53 individuals with Basque ancestry in Boise, Idaho, and the mitochondrial DNA (mtDNA) sequence variation of the first and second hypervariable regions were determined. Thirty-six mtDNA haplotypes were detected in the sample. Comparing the genetic diversity in the Idaho sample with other Basque populations, signatures of founder effects were observed, consistent with both the recent and ancient history of Basque mitochondrial lineages. There has been a marked alteration of haplogroup frequency and diversity, and there is a slight reduction in other measures of diversity in the NW Basque population compared to the native Basque population. We have found a relatively high percentage of the Cambridge Reference Sequence (rCRS) haplotype for hypervariable regions I and II, which is absent in previous studies of Basque mtDNA, and rare in other Spanish populations. The amount of nucleotide diversity is consistent with a sample that is predominantly haplogroup H, which is especially common in the Basque regions of Europe, due to ancient migrations and expansions out of glacial refugia. This is the first report of mtDNA diversity in an immigrant Basque population, and we find that the diversity in NW Basques can be explained by the recent history of migration, as well as the phylogeography and diversity of the major European haplogroups.

1473/T

Defining population structure within Southern Africa to advance studies of human disease. *V.M. Hayes[1], D.C. Petersen[2], A.J. Schork[3], R-A. Hardie[2], R. Wilkinson[4], P. Venter[5], S.C. Schuster[6], N.J. Schork[3].* 1) Human Genomics, J. Craig Venter Institute, San Diego, CA; 2) Lowy Cancer Research Center and Children's Cancer Institute Australia, University of New South Wales, Randwick, NSW, Australia; 3) The Scripps Research Institute and The Scripps Translational Science Institute, San Diego, CA; 4) Blood Transfusion Services, Windhoek, Namibia; 5) Department of Health Sciences, University of Limpopo, South Africa; 6) Department of Biochemistry and Molecular Biology, Pennsylvania State University, State College, PA.

Although Africa is home to one-sixth of the world's population and is the epicenter of many globally significant infectious diseases, medical research tailored to African populations has been limited. As a result, the benefits of genome-wide association studies for defining human disease susceptibility, resistance and drug response, have not materialized for the continent. One of the main reasons for this limitation is that African representation in current DNA databases has largely been restricted to the Yoruba people of Nigeria. In an attempt to define the extent of genetic diversity within Africa, in 2010 the first Southern African genomes were sequenced, representing the diverse Niger-Congo B (Bantu) and Khoisan (click-speaking) linguistic groups. Whole genome and/or exome sequencing of five individuals resulted in the identification of 1.3 million novel DNA variants. In this study we use both current content genotyping arrays (>1 million SNPs) and the novel Southern African variant content (927,000 informative SNPs) to define the genetic diversity and population structure that exists within Southern Africa. It is clear from our studies that the Khoisan people not only represent an ancient divergent and broadly defined grouping with unique sub-population genetic structure, but are genetically distinct from the Bantu and Yoruba people. We also demonstrate a highly diverse Bantu population structure that is genetically distinct from the West African Yoruba. Ultimately, the smaller blocks of linkage disequilibrium in these older and diverse populations will provide an opportunity to overcome some of the limitations of current Eurocentric studies by facilitating disease-relevant casual variant identification. This data will drive host-genetic research efforts at the NIAID sponsored Genome Sequencing Center for Infectious Diseases at the JCVI.

1474/T

Western Eurasian Y chromosomes found in the Chinese Salar ethnic group. *Y. Lu, H. Li.* MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai 200433 China.

Salar is a small Western-Turkish-speaking population living mostly in Qinghai province of China. The most similar languages to Salar are all far in Turkmenistan. Historical records suggested that they may be descendants of the Turkic nomadic tribes in Central Asia. In this study, 141 Salar Y chromosomes were analyzed for 39 SNP and 14 STR markers to investigate the potential imprints of their western ancestors. The most frequent haplogroup (hg) in this population sample is Hg R, comprising 40% of all Y chromosomes. Most of these Hg R samples belong to R1a1 (M17), which distributes in a wide geographic region including South Asia, East Europe, Central Asia, and South Siberia. Other four Western Eurasian haplogroups (G-2%, H-5%, I-3%, J-3%) were also found in Salar Y chromosome gene pool. These paternal lineages of Salar are absent in their East Asian neighbors but frequent in Central Asia. Y-STR-based analyses also grouped Salar to Central Asians. On the other side, Salar also has low frequencies of the East Asian specific Hg D and Hg O, suggesting possible gene flow from their neighboring populations. This Y chromosome study demonstrated that Salar well keeps the Western Eurasian paternal lineages of their Central Asian ancestors although they may have migrated to Central China for about 800 years.

1475/T

Alleles from SNPs at the SLC24A5 and SLC45A2 genes are associated with the presence of freckles and eye, hair and skin pigmentation in Brazil. *C.T. Mendes-Junior[1], N.C.A. Fracasso[2], L.R. Zanão[1], C.C.F. Andrade[2], M.S. Silva[1], L.A. Marano[2], C.E.V. Wiezel[2], E.A. Donadi[3], A.L. Simões[2].* 1) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, 14040-901, Ribeirão Preto-SP, Brazil; 2) Departamento de Genética, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, 14049-900, Ribeirão Preto-SP, Brazil; 3) Divisão de Imunologia Clínica, Departamento de Clínica Médica, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, 14048-900, Ribeirão Preto-SP, Brazil.

SNPs from the SLC24A5 (solute carrier family 24, member 5) and SLC45A2 (solute carrier family 45, member 2) genes have been associated with variation in eye, hair, and skin pigmentation across worldwide populations. Protein products of both genes are involved in cross-membrane transport, and their expression in melanocytes are required to regulate melanogenesis and for melanosome maturation. The present study aimed at verifying the influence of the genetic diversity of such genes in the presence of freckles and determination of eye, hair, and skin pigmentation in a highly admixed population sample. The determination of eye, hair, and skin pigmentation of unknown samples found in crime scenes would be of great value for forensic caseworks. To achieve that goal, a SNP from the SLC24A5 gene [rs1426654 G>A (Ala111Thr)] and five SNPs spread across the SLC45A2 gene [rs732740 (intron 1 T>C), rs3776549 (intron 2 G>A), rs250417 (intron 4 G>C), rs16891982 (exon 5 G>C; Leu374Phe), and rs35394 (intron 5 A>G)] were evaluated in 150 unrelated individuals from the Ribeirão Preto area, a city located at the Northwestern region of the São Paulo State, Southeastern Brazil. DNA was extracted by a salting-out procedure and SNPs were genotyped either by PCR-RFLP or Allele-Specific PCR, followed by Polyacrylamide Gel Electrophoresis (PAGE). Even though SNP rs732740 was monomorphic (considering the 99% threshold), alleles from every remaining SNPs presented statistically significant associations with at least one of the four considered morphological features. It is noteworthy that most of the observed associations concerns SNPs rs1426654 (Ala111Thr) and rs16891982 (Leu374Phe), both of them located at the peptide-coding region of SLC24A5 and SLC45A2, respectively. For instance, alleles 111Thr (rs1426654) and 374Phe (rs16891982) were observed in association with fair pigmentation features (like pale skin, green/blue eyes, and/or blond hair), while alleles 111Ala 374Leu are associated with dark pigmentation. The present results corroborate previous findings and emphasize the role played by SNPs at SLC24A5 and SLC45A2 in the determination of pigmentation aspects of human populations. FINANCIAL SUPPORT: This study was supported by CNPq/Brazil (Grant 478843/2009-7).

1476/T

Geographic approaches to rare SNPs in human populations. *T.B. Mersha[1], R.A. Wilke[2].* 1) Cincinnati Children's Hospital Medical Center, Department of Pediatrics, University of Cincinnati, Cincinnati, OH, USA; 2) Division of Clinical Pharmacology, Vanderbilt University Medical Center, Nashville, TN, USA.

The simultaneous study of genomic loci across numerous populations will facilitate a better understanding of the role of genetic variation in different geographic regions. We examined global allele frequencies across all HapMap populations at 3.7 million SNPs to search for loci under recent selection pressure, with a goal toward identifying variants that contribute to ecotypic phenotypic divergence. By examining private SNPs in HapMap samples from geographically separated populations, we demonstrate that 463 loci (mapping to 38 genes) were fixed (delta= 1). These private loci included four non-synonymous coding SNPs: rs4536103 (NEUROG3), rs1385699 (EDA2R), rs11946338 (ARHGAP24), and rs4422842 (CACNA1B), and regulatory variants in four additional genes (IER5L, NPNT, SESTD1 and EXOC6B) were undergoing recent positive selection. Over all, very few genes in the human genome had extreme allele frequency differences among populations, and the bulk of variations at the nucleotide levels are not visible at the phenotypic level. We explore pathway-oriented strategies to identify signaling mechanisms that may have influenced human adaptation to different environments. These fixed SNPs contribute to variability in several cellular processes. As the clinical community moves toward application of genome-wide SNP scanning in large practice-based cohorts, our pathway-oriented approach has relevance to pharmacogenomic data. An improved understanding of these pathways in genomic regions of fixed loci may help explain race/ethnicity-specific variability in treatment outcome as ancient genes are exposed to modern drugs.

1477/T

Genetic Heterogeneity in Parents of cleft Probands and the Chromosome 8q24 cleft lip/palate associated region. *T. Murray[1], T.H. Beaty[1], J.B. Hetmanski[1], K.Y. Liang[1], I. Ruczinski[1], T. Wu[1], P. Patel[1], R.A. Redett[2], M.L. Marazita[3], J.C. Murray[4], R.G. Munger[5], A. Wilcox[6], R.T. Lie[7], Y.H. Wu-Chow[8], H. Wang[9], S. Huang[9], X. Ye[10], V. Yeow[11], S.S. Chong[12], S.H. Jee[13], K. Christensen[14], A.F. Scott[2].* 1) Dept Epidemiology, Johns Hopkins Univeristy, Baltimore, MD; 2) School of Medicine, Johns Hopkins University, Baltimore, MD; 3) Health Sciences, University of Pittsburgh, Pittsburgh, PA; 4) Children's Hospital, University of Iowa, Iowa City, IA; 5) Utah State University, Logan, UT; 6) Epidemiology Branch, NIEHS/NIH, Durham, NC; 7) University of Bergen, Bergen, Norway; 8) Chang Gung Memorial Hospital, Taoyuan, Taiwan; 9) Health Science Center, Peking University, Beijing, China; 10) School of Stomatology, Wuhan University, Wuhan, China; 11) KK Women's and Children Hospital, Singapore; 12) National University of Singapore, Singapore; 13) Epidemiology and Health Promotion, Yonsei University, Seoul, South Korea; 14) University of Southern Denmark, Odense, Denmark.

The 8q24 region showed the strongest evidence of linkage and association with non-syndromic cleft lip with or without palate (CL/P) in our recently published GWAS among trios of European descent, but was much weaker among Asians. Of the 78 SNPs in this region, 43 had signals; 20 had $p<10^{-8}$ among Europeans. In Asians, only 17 SNPs were nominally ($0.05>p>0.0001$) significant. By examining measures of SNP information content within our 13 recruitment sites (Europe, Asia, US) separately, we searched for clues which might help to explain the difference in statistical signal in 8q24. We conducted principal components analysis (PCA) on 38,188 SNPs in 3816 parents of CL/P cases, and also assessed the heterozygosity and the distribution of mating types at each SNP in the 8q24 region. We generated TDT p-values by site and compared the observed genotype distribution in CL/P offspring to the expected given the parents using a 2df chi-squared test. In addition to detecting strong differences between European and East Asia populations via PCA, we observed a genetic north-south cline extending from Korea through China to Singapore, while the Philippines clustered separately. Hierarchical clustering in the 8q24 region based on SNP heterozygosity revealed two major clades, European and Asian, which is consistent with PCA results. Within the Asian clade, the Philippines occupied a separate branch from other Asian sites. Clustering SNPs by heterozygosity showed all the SNPs with $p<10^{-6}$ in the TDT had high heterozygosity in Europeans, but low heterozygosity in Asians. SNPs with high heterozygosity in Asians showed no evidence of linkage and association. Additionally, clustering p-values from the TDT by recruitment site revealed Norway and Utah provided the strongest evidence of association, while all other sites were grouped together as a separate clade. Further TDT analysis of Norway and Utah as a combined group resulted in genome-wide significant p-values , while Maryland, Iowa, Denmark and Pittsburgh combined showed only nominal evidence ($0.01>p>0.000001$). Shandong, Hubei and Sichuan Provinces and Taiwan showed similar patterns of deviation of case genotype from expected across 8q24, while Korea, Philippines and Singapore clustered together. Although our results suggest the 8q24 CL/P-associated region is differentiated between Europeans and East Asians, there could be variants in this region which are associated with CL/P in Asians but were absent from our GWAS panel.

1478/T

Worldwide distribution kidney disease susceptibility alleles and haplotypes around the MYH9 gene. *T.K. Oleksyk[1], G.W. Nelson[2], P. An[2], W. Guiblet[1], J.B. Kopp[3].* 1) Department of Biology, University of Puerto Rico at Mayaguez, Mayaguez, PR., Puerto Rico; 2) Laboratory of Genomic Diversity, SAIC-Frederick, Frederick MD; 3) Kidney Disease Section, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda MD.

MYH9 was recently identified as renal susceptibility gene (OR 3-8, $p<10^{-8}$) for major forms of kidney disease disproportionately affecting individuals of African descent. The risk haplotype (E-1) occurs at much higher frequencies in African Americans (≥ 60%) than in European Americans (<4%), revealing a genetic basis for a major health disparity. We reconstructed *MYH9* haplotypes from 4 tagging single nucleotide polymorphisms (SNPs) spanning introns 12-23 using available data from HapMap Phase II, and by genotyping 938 DNAs from the Human Genome Diversity Panel (HGDP. The E-1 risk haplotype followed a cline, being most frequent within sub-Saharan African populations (range 50-80%), less frequent in populations from the Middle East (9-27%) and Europe (0-9%), and rare or absent in Asia, the Americas, and Oceania. The fixation indexes (F_{ST}) for pairwise comparisons between the risk haplotypes for continental populations were calculated for *MYH9* haplotypes; F_{ST} ranged from 0.27-0.40 for Africa compared to other continental populations, possibly due to selection. Uniquely in Africa, the Yoruba population showed high frequency extended haplotype length, as well as high population differentiation in HapMap Phase II data, also observable only in the Yoruba population from HGDP. The population-specific divergence in *MYH9* risk allele frequencies among the world's populations may prove important in risk assessment and public health policies to mitigate the burden of kidney disease in vulnerable populations.

1479/T

Diversity of KIR2DL4 in Amerindian populations. *M. Pincerati[1], J. Guerreiro[2], E. Santos[2], P. Martin[3], M. Carrington[3], D. Meyer[1].* 1) Universidade de São Paulo, São Paulo, Brazil; 2) Laboratório de Genética Humana e Médica, Universidade Federal do Pará, Belém, Pará, Brazil; 3) Cancer and Inflammation Program, Laboratory of Experimental Immunology, SAIC-Frederick Inc., National Cancer Institute-Frederick, Frederick, MD, USA.

The KIR2DL4 gene is unusual among KIR genes in that it exhibits structural characteristics of both an activating and an inhibitory receptor. KIR2DL4 is one of the KIR genes that shows a strong signature for balancing selection, frequently presenting higher diversity than expected under neutrality. Genetic polymorphisms in KIR2DL4 result in functionally distinct variants, which can influence expression of KIR2DL4. Based on the presence of 9 or 10 adenine residues at the end of exon 6, which encodes the transmembrane domain, two common allele groups, 9A and 10A, have been described. 9A alleles are not expressed on the cell surface due to the splicing out of the transmembrane domain. 10A alleles can be further subdivided into 10A-A allotypes and 10A-B allotypes, which cannot be detected on the cell surface. Analyses of these polymorphisms have shown that these allele groups are maintained at intermediate frequency in some populations, possibly by natural selection. Native American populations are of particular interest for studies of natural selection, since they occupy an extensive geographic territory with environmental heterogeneity. The aim of this study was to characterize the allelic variability of KIR2DL4 in Amerindian populations from the Amazon region, so as to investigate the role of natural selection in shaping variability at this locus. We sequenced exons 3, 5 and 7-9 of KIR2DL4 gene in 234 samples from 15 Amerindians tribes. We found 9 alleles, with the highest frequencies for *00501, *00102 (0.58 and 0.34 respectively) and the lowest frequencies for *011, *00801, *00201 and *00103, *002, *00502, *006. We also analyzed the distribution of 9A and 10A variants in our populations. In contrast to most populations already studied, there is a low frequency of 9A alleles in Amerindian populations (0.93 for 10A variant and 0.07 for 9A). In addition, the 10A-A subgroup (represented by *00501) and the 10A-B subgroup (represented largely by *00102) are maintained at high frequency in these populations. These results might indicate that for Amerindian populations, the 10A subgroups is more relevant than the 9A group. We also performed a Ewens-Watterson test to verify departure from neutrality of allele frequencies and found no evidence for natural selection acting on KIR2DL4 in the Amerindian population.

1480/T

Haploid and autosomal variation within a linguistic continuum of the Uralic-speaking people of Eurasia. *K. Tambets[1], S. Rootsi[1], M. Metspalu[1], B. Yunusbayev[1,2], E. Metspalu[1], M. Reidla[1], E. Khusnutdinova[2], L. Osipova[3], T. Kivisild[1,4], R. Villems[1].* 1) Estonian Biocentre and Dept. of Evolutionary Biology, University of Tartu, Tartu, Estonia; 2) Institute of Biochemistry and Genetics, Ufa Research Centre, Russian Academy of Sciences, Ufa, Russia; 3) Institute of Cytology and Genetics, Siberian Branch of Russian Academy of Sciences, Novosibirsk, Russia; 4) The Leverhulme Centre for Human Evolution, University of Cambridge, UK.

For about last two decades the examination of uniparentally inherited genetic marker systems revealing the variation embedded in mtDNA and Y chromosome has been the main tool in the studies of human genetic origins. Within few recent years the analysis of the genome-wide SNP data of individuals from different populations has started to give promising new insights in the field of human population genetics. The uniparentally inherited markers have shown slightly different demographic scenarios for the maternal and paternal lineages of North Eurasian, particularly of European Uralic-speaking populations. The geographical location of a population has evidently been the most important component that dictates the proportion of western and eastern mtDNA types in the gene pool of Uralic-speakers. Thus, the palette of maternal lineages of the Uralic-speakers resembles that of their geographically close European or Western Siberian Indo-European and/or Altaic-speaking neighbours, respectively. At the same time, the most frequent North Eurasian Y chromosome type N1c, that is also a common link between almost all Uralic-speakers, is with few exceptions rare, if present at all, among Indo-European-speakers of Western and Southern Europe. Here we combine genome-wide high density SNP data (650 000 SNPs, Illumina) with uniparentally inherited mtDNA and Y-chromosome variation of 16 Uralic-speaking populations to assess their place on the genetic landscape of North Eurasia. By the use of principal component and structure-like analysis on the autosomal data we show that the proportions of western and eastern ancestry components among the Uralic-speakers are determined mostly by geographical factors. The westernmost populations from Europe, both Uralic- and Indo-European speakers, are similar in their pattern of ancestry components and show low levels (<10%) of the eastern component. Conversely, the eastern ancestry component is dominant (60-70%) in the gene pool of the Siberian Uralic-speakers. In general, the genome-wide analyses corroborate the results of mtDNA analysis and do not reflect the common genetic characteristics between western and eastern Uralic-speakers at the level seen in case of N1c. Interestingly, among Saami from North Europe, who are often considered as =84outliers" in genetic studies, the dominant western component is accompanied by 30% of eastern component making them more similar to Volga-Uralic populations than to their closest neighbours.

Fine-scale characterization of Genetic Structure in a Mexican Cohort. *H. Tang[1], N. Johnson[2], F. Zakharia[1], I. Romieu[3], M. Shriver[5], S. London[4].* 1) Dept Genetics, Stanford Univ Sch Med, Stanford, CA; 2) Dept. Statistics, Stanford University, Stanford, CA; 3) National Institute of Public Health, Cuernavaca, Mexico; 4) Epidemiology Branch, National Institute of Environmental Health Sciences, Research Triangle Park, NC; 5) Dept. of Biological Anthropology, Penn State University, University Park, PA.

High-density genotype data has enabled extensive surveys of human population genetic structure at a global level as well as within the African and Eurasian continents, where geography is shown to be a major determinant of population structure. In contrast, genetic structure in recently admixed populations, such as the African Americans and the Hispanics, is influenced both by historical geographic isolation and by recent migration. Limited by the amount of data and by the available analytic tools, current understanding of population structure in these populations is largely limited to the estimation of the continental-level ancestry proportions. In this study, we report fine-scale characterization of genetic structure in a cohort of 500 parents-offspring trios recruited from Mexico City as part of a genome-wide association study of asthma. Using the genotypes of more than 500,000 SNPs, we estimate the relative contribution from the European, African and Native American ancestral populations. The ancestral origin of each chromosomal segment is inferred using a novel computational approach; accordingly, the genome of a single individual is partitioned into components that correspond to the continental-level ancestry. The European component of the genome in the Mexican individuals shows strongest affinity to Spanish / Portuguese populations from southwest Europe. In contrast, the Native American component of the Mexican genomes is much more heterogeneous: while the Native American ancestry of most Mexicans in our cohort can be traced to the indigenous groups of Nahua, Mixtec, and Tlapanec, residing in the State of Guerrero, a small group of individuals appear to have substantial ancestry from the Mayans of the Yucatan Peninsula, as well as from the Quechua and Aymara groups in Peru and Bolivia. Our study demonstrates the feasibility of characterizing sub-continental-level population structure in the Hispanics populations, as well as the importance of accounting for such population structure in the design and analysis of genome-wide association studies.

Variation in IRF5-TNPO3, followed by STAT4 and HLA regions, are the Strongest Trans-Ethnic Risk Factors for Systemic Lupus Erythematosus (SLE). *T.J. Vyse[1], P.S. Ramos[2], K.M. Kaufman[3], J.A. Kelly[3], C. Gallant[4], A. Delgado[4], S.A. Chung[5], L.A. Criswell[5], R.P. Kimberly[6], M.E. Comeau[2], A.H. Williams[2], L. Russell[2], C.O Jacob[7], B.P. Tsao[8], M.E. Alarcón-Riquelme[3,4,9], K.L. Moser[3], P.M. Gaffney[3], J.B. Harley[3], C.D. Langefeld[2], International Systemic Lupus Erythematosus Genetics (SLEGEN) Consortium.* 1) Dept Rheumatology, Imperial College, London, United Kingdom; 2) Dept Biostatistical Sciences, Wake Forest Univ Health Sciences, Winston Salem, NC, USA; 3) Arthritis and Immunology Program, Oklahoma Medical Research Foundation, Oklahoma City, OK, USA; 4) Dept of Genetics and Pathology, Uppsala University, Uppsala, Sweden; 5) Rosalind Russell Medical Research Center for Arthritis, University of California, San Francisco, CA, USA; 6) Dept Medicine, University of Alabama at Birmingham, Birmingham, AL, USA; 7) Keck School of Medicine, Univ of Southern California, Los Angeles, CA, USA; 8) School of Medicine, Univ of California, Los Angeles, CA, USA; 9) Center for Genomic and Oncological Research, Pfizer-Universidad de Granada-Junta de Andalucia, Granada, Spain.

Despite a greater prevalence, there is a paucity of large-scale data on the genetics of SLE in African Americans, Hispanics and, to a lesser extent, Asians. Thus, the specific genetic variants predisposing to SLE and their overlap with European ancestry risk factors are largely unknown. We conducted a trans-ethnic study called Lupus Large Association Study 2 (LLAS2) consisting of 8436 SLE cases and 7554 controls of European (3977 cases and 3538 controls), African American (1679 cases and 1934 controls), Asian (1272 cases and 1270 controls) and Hispanic and Native American ancestries (1508 cases 812 controls). Selected from the SLEGEN European ancestry genome-wide association study (GWAS)(Harley et al, 2008), 7069 candidate SNPs were genotyped on an Illumina custom array; approximately 400 ancestry informative markers were included and principal components analysis and admixture estimates were computed. We computed ethnic-specific case-control association analyses adjusting for admixture and trans-ethnic meta-analysis using the weighted inverse normal approach. Strongest associated SNP in the region is reported. The most significant trans-ethnic variation is located in the IRF5-TNPO3 region (rs4728142, P=4.77x10-60), followed by STAT4 (rs11889341, P=4.66x10-53), HLA (rs3131379 in MSH5, P=1.17x10-52), ITGAM (rs9888739, P=5.38x10-31), BLK (rs13277113, P= 4.79x10-29), PTTG1 (rs2431697, P=6.55x10-24), TNIP1 (rs960709, P= 7.22x10-21), UBE2L3 (rs2298429, P=1.98x10-15), NMNAT2 (rs12146097, P=9.64x10-14), and TNFSF4 (rs10798269, P=5.69x10-12). Some regions are dominated by the European association (HLA, ITGAM, PTTG1 and NMNAT2), others by two or more ethnicities (IRF5-TNOP3, STAT4, BLK, TNIP1, UBE2L3, TNFSF4). Some regions share a similar pattern of association between two (IRF5-TNOP3, ITGAM) or more (STAT4, BLK, PTTG1, TNIP1, UBE2L3, NMNAT2) ethnic groups, while in others it is apparently discordant (HLA, TNFSF4). This is the first report of large-scale trans-ethnic mapping in SLE. This study shows that the IRF5-TNPO3 region is the strongest SLE trans-ethnic risk factor, and helps elucidate common versus ethnic-specific risk factors for SLE.

1483/T

Making a haplotype catalog with estimated frequencies based on SNP homozygotes: an application to the Japanese population. *Y. Yamaguchi-Kabata[1], N. Kumasaka[1], T. Tsunoda[2], A. Takahashi[1], N. Hosono[2], M. Kubo[2], Y. Nakamura[2,3], N. Kamatani[2].* 1) Ctr Genomic Med, RIKEN, Tokyo, Japan; 2) Ctr Genomic Med, RIKEN, Yokohama, Japan; 3) Human Genome Ctr, Inst Med Sci, Univ Tokyo, Tokyo, Japan.

Understanding the structure and frequencies of haplotypes is important for associating genetic polymorphisms with a given trait and for inferring the genetic genealogy of alleles in a population. SNP haplotypes can be determined without ambiguity when an individual does not have more than one heterozygous site in a given genomic region. In our previous study, using genome-wide SNP genotypes for 3397 individuals from the Japanese population, we examined the efficiency of determination of haplotypes and haplotype frequency estimation based on the proportion of SNP homozygotes in the sample. We applied this approach to a genome-wide SNP genotype data from about 19000 individuals from the Japanese population. As most Japanese fall into two main clusters (the Hondo and Ryukyu clusters), we selected individuals for both of the two clusters based on the result of PCA. Then we made a haplotype catalog for the Hondo Japanese from 18379 individuals. We compared the haplotype frequencies in the Hondo Japanese with the haplotype frequencies for the Ryukyu Japanese, which were roughly estimated from 504 individuals. Although haplotype frequencies in the Hondo and Ryukyu clusters were highly correlated in most genomic regions, we found the gene regions where the difference in haplotype frequencies was highly significant. There were functional biases in these highly differentiated genes; transporters and ion-channels were overrepresented. The catalog of real haplotypes with their estimated frequencies will be useful for identifying causative polymorphisms for a trait, which are linked to the most associated SNPs in a GWAS. Furthermore, the catalogue of haplotypes will be useful for a haplotype-based GWAS and detection of shared haplotypes that contain multiple variants that affect the trait.

1484/T

Association between Cystatin C polymorphisms and corpulence. *H. HOOTON[1,3], B. DUBERN[1,3,7], R. ALILI[1,3], F. ROUSSEAU[2], V. PELLOUX[1,3], C. HENEGAR[1,3,7], P. GALAN[4], S. HERCBERG[4], P. ARNER[6], T.I.A. SØRENSEN[5], K. CLEMENT[1,3,7].* 1) UMRS U872 équipe 7, INSERM, PARIS, France; 2) INTEGRAGEN, Paris, France; 3) University Pierre and Marie Curie, Paris, France; 4) INSERM U556, INRA U1125, CNAM EA3200, university Paris 13, nutritional epidemiology research unit, Paris, France; 5) Institute of preventive medicine, Copenhagen university hospital, centre for health and Society, Copenhagen, Denmark; 6) Karolinska institute, department of medicine, Huddinge, Lipid laboratory, Stockholm, Sweden; 7) Assistance publique hôpitaux de paris, paris France.

Background: Cystatin C, the most powerful endogenous inhibitor of cysteine protease Catepsin S, K and L, is a new adipose tissue synthesized molecule. Its expression rate in adipose tissue and circulating levels in blood are two to threefold higher in obese subjects than in lean controls. Work hypothesis: Our hypothesis is that common variants in Cystatin C gene could play a role in the evolution of BMI during lifetime. Methods: Tag SNPs were selected to obtain a full coverage of Cystatin C coding sequence (r^2= 0.8, MAF>5%) based on hapmap data. Tag SNPs were genotyped in 4300 subjects from the SUVIMAX study (BMI=23.78 +/-3.38 kg/m²), 750 women from the SPAWN cohort (BMI=21.73 +/-2.87 kg/m²) and 1500 Danish men from the Danish national birth cohort (DNBC) (BMI=27.00 +/-6.23 kg/m²). BMI measures at several time points were available in all three cohorts. Results: significant associations with time dependant BMI were found in each population ($p<0.05$). Concerning both SNPs, G/G carriers were less corpulent than A/G and A/A carriers in both the SUVIMAX population and the group of Danish men, but were more corpulent in the SPAWN cohort. Haplotype analysis revealed that AA carriers were more corpulent in the SUVIMAX and Danish groups and less corpulent in the SPAWN cohort than carriers of other haplotypes. This phenomenon is known as a flip-flop effect and has already been well described and discussed in the literature. Conclusions and perspectives: These results bring new insights into the role of Cystatin C in corpulence. Replication of these findings is ongoing in several other populations.

1485/T

Effect of Recent Admixture and Self-reported ancestry on genetic association for some susceptibility genes SLE among Hispanics. *J.E. Molineros[1], X. Kim-Howard[1], J.A. Kelly[1], B. Namjou[1], J.D. Reveille[5], L.M. Vila[5], J.C. Edberg[5], R. Ramsey-Goldman[5], M.A. Petri[5], E.E Brown[5], R.P. Kimberly[5], C.D. Langefeld[3], J.M. Anaya[4], M.E. Alarcon-Riquelme[1], K. Kaufman[1], J.B. Harley[2], S.K. Nath[1].* 1) Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) Oklahoma City Veteran's Hospital, Oklahoma City, OK; 3) Wake Forest University, Salem, NC; 4) Universidad del Rosario-Corporación para Investigaciones Biológicas, Bogota Colombia; 5) University of Alabama, Birmingham, AL.

Systemic Lupus Erythematosus (SLE) is an autoimmune disease with complex etiology. Recently admixed populations like Hispanics have an increased risk of developing the disease compared with European-Americans. This suggests the hypothesis that differences in genetic background may contribute to ethnic differences in SLE susceptibility. OBJECTIVES. Estimate ancestry proportions for Hispanics; correlate geographic distribution across ancestry; assess ancestry versus phenotype association; and assess the effect of individual admixture on genetic association in 3 SLE associated genes. METHODS. To estimate population structure we ascertained 1245 SLE cases and 619 controls from 5 geographical regions (Argentina, Colombia, Peru, Puerto-Rico, Mexico). We selected 94 Ancestry Informative Markers (AIMs) from 7 populations from HGDP data (Pima-Maya (Native American [NA]), European (CEPH), African (YRI), Bantu, Pigmy, San, Chinese-Japanese). We selected SLE associated variants from ITGAM (rs1143679), IRF5 (rs2070197) and STAT4 (rs10181656) to test the effect of population stratification on genetic association. RESULTS. The 3 ancestral populations model had the best fit and aligned along the NA, African (YRI) and European ancestral populations. Mean ancestry of Hispanics was 36%(NA), 9%(African) and 55%(European), however, ancestry proportion varied by geographical origin. Puerto-Rico had the largest African ancestry (20 controls/18 cases), followed by Colombians (13 controls/14 cases). Peru had the largest NA ancestry (85 control/87 cases), followed by Mexico (53 controls/56 cases), Colombia (36 control/25 case) and Argentina (22 control/32 cases). Puerto-Rico had the largest European ancestry (71 control/73 cases). Allele frequencies varied across populations from 3%-22% on rs1143679; from 26% to 59% on rs10181656, and from 9% to 34% on rs207019. Overall there was no association between phenotype and ancestry proportion, but when we subdivided the samples into their geographical regions, the NA ancestry was significantly associated in Argentinean and Colombian samples. All markers were significantly associated to SLE, when corrected for ancestry (local and global). The uncorrected (corrected) p-values for ITGAM, STAT4 and IRF5 were $4.9x1^{0-10}$ ($7.96x10^{-7}$), $8.32x10^{-6}$ ($2.31x10^{-5}$), and $8.75x10^{-13}$ ($4.1x10^{-12}$) respectively. We discovered significant allele frequency differences between populations and its implications on admixture mapping for SLE gene identification.

1486/T

The Prevalence and Haplogroup-Specific Distribution of Homoplasmic/Near Homoplasmic Pathogenic Mitochondrial DNA Point Mutations in the General Population. *R. Bai, S. Suchy, J. Higgs, G. Richard, S. Bale.* GeneDx Inc, Gaithersburg, MD.

It has been reported that at least one in 200 live births is heteroplasmic for one of the ten pathogenic mitochondrial (mtDNA) point mutations in cord blood (Am J Hum Genet 2008, 83:254). To estimate the frequency of homoplasmic/near homoplasmic pathogenic mtDNA mutations in the general population, the published complete sequence of the coding region or entire mitochondrial genome of over 6000 individuals from worldwide populations, listed in the Mitomap database (www.mitomap.org), were analyzed. The sequences with missing bases or from known patients were excluded from this analysis. The frequency of each nucleotide change (variant) from the revised Cambridge Reference Sequence (rCRS) was calculated. The mtDNA haplogroup for each sequence was assigned and the frequency of each variant in a specific haplogroup was calculated. The above information for the 48 confirmed pathogenic mtDNA point mutations listed in the Mitomap database were collected and compared. The overall frequency of the 48 mutations is 2.11% (133/6305). The overall frequency of the six common Leber's Hereditary Optic Neuropathy (LHON) mutations (G3460A, G11778A, T14484C, C14482G, G14459A and C14568T) is 1.57% (99/6305), among which the frequencies of G3460A, G11778A and T14484C are 0.24%, 0.82% and 0.40%, respectively. The overall frequency of the DEAF-associated mutations (A1555G, 1494T, A7445G and 7472insC) is 0.35%(22/6305), with the frequency of the A1555G mutation being 0.25%. The mutations associated with Leigh syndrome (LS), Mitochondrial Encephalomyopathy, Lactic Acidosis, and Stroke-like episodes (MELAS), Myoclonic Epilepsy and Ragged Red Muscle Fibers (MERRF) or Maternally Inherited Cardiomyopathy (MICM) are rare, probably due to the typical low heteroplasmy of these mutations in blood that is undetectable by sequencing. The haplogroup (HG)-specific frequency for G3460A is 1.95% in HG-J, 0.92% in HG-H, 0.57% in HG-C and 0.41% in HG-K; for G11778A, 3.53% in HG-F, 3.43% in HG-T, 2.18% in HG-H, 1.82% in HG-G, and 1.58% in HG-non-k U, 1.46% in HG-J and 0.9% in HG-unclassified M and HG-V; for T14484C, 6.82% in HG-J, 4.35% in HG-Q and 1.16% in HG-W; for A1555G, 1.1% in HG-X, 0.9% in HG-H and HG-non-k U. In conclusion, asymptomatic carriers of homoplasmic/near homoplasmic pathogenic mtDNA point mutations are common in the general population; most of these mutations are LHON or DEAF-associated mutations. These mutations are preferentially associated with certain mtDNA haplogroups.

1487/T

A Common Spinal Muscular Atrophy (SMA) Deletion Mutation is Present on a Single Founder Haplotype in the U.S. Hutterites. *J.X. Chong[1], A.A. Oktay[1], Z. Dai[2], K. Swoboda[3], T.W. Prior[2], C. Ober[1,4].* 1) Human Genetics, The University of Chicago, Chicago, IL; 2) Pathology, The Ohio State University, Columbus, OH; 3) Neurology and Pediatrics, University of Utah School of Medicine, Salt Lake City, UT; 4) Obstetrics and Gynecology, The University of Chicago, Chicago, IL.

SMA is an autosomal recessive (AR) neuromuscular disease that occurs in ~1 in 10,000 European births, making it the second most common lethal AR disease in European populations. In U.S. whites, ~1 in 40 are carriers. SMA is caused by the homozygous loss of Survival Motor Neuron 1 (*SMN1*) gene function due to a deletion or gene conversion event in 95% of cases; carrier and affection status are determined using quantitative measures of *SMN1* exon 7 copy numbers. A few cases of SMA had previously been reported in the Hutterites (Boycott et al. 2008; AJMG 146A:1088), a North American founder population that descended from <90 ancestors, but the carrier frequency in this population was unknown. In this study, DNA samples from one South Dakota Hutterite (S-leut) and 3 Montana Hutterites (L-Leut) with SMA due to the homozygous deletion of *SMN1* (as determined by a competitive PCR dosage assay), were genotyped with Affymetrix SNP arrays. A 9-generation pedigree connects these 4 individuals to their nearest common Hutterite ancestors (b. 1770's). The 4 individuals were all homozygous for a stretch of ~790 SNPs spanning 10 Mb across the locus, indicating a single founder haplotype. Using Affymetrix genotypes in an additional 1402 Hutterites, representing a population-based sample of South Dakota Hutterites (age 6-93 yrs), we identified 171 individuals who carried at least 9.3 Mb of the founder haplotype. Carrier status was confirmed in 63 representative individuals from the pedigree by the competitive PCR assay, yielding an overall SMA mutation frequency of 0.063 in the South Dakota Hutterites. The corresponding carrier frequency of 1 in 8 (12.5%) is the highest ever reported for SMA and the highest carrier frequency reported to date for an AR mutation in the Hutterites of South Dakota. However, because the genetic structure of the *SMN1* locus makes it prone to mutation and this study would not have identified *de novo* SMA mutations on different haplotypes, this carrier frequency is likely an underestimate of the true carrier frequency in the Hutterites. This is the first population-based study to directly assess SMA carrier status and to use haplotype analysis to determine carrier status in a founder population. The extremely high carrier frequency for this severe disease in the South Dakota Hutterites underscores the need for widespread carrier screening in this population.

Type II procollagen gene analysis and cephalometric linear measurements of the mandible: A comparative study. *s. morcos[1], a. el-kadi[1], t. mansour[2].* 1) FACULTY OF DENTISTRY, SUEZ CANAL UNIVERSITY, ISMAILIA, EGYPT; 2) cancer institute, CAIRO UNIVERSITY, CAIRO, EGYPT.

The present study was designed in order to estimate the relationship between both COL2A1 gene and mandibular morphology on different skeletal classes of malocclusion and also to evaluate this genetic marker as predictors of mandibular growth. The study was carried out on 30 patients both males and females of different skeletal Classes, where the patients were selected from the out-patient clinic of Faculty of Dentistry, Suez Canal University, with age range (18-30) years without any congenital anomalies in the craniofacial structures. The selected patients were divided into 3 groups according to their skeletal Class, as each group included 10 patients. For each patient, lateral cephalometric view was taken and blood sample was aspirated. The cephalometric linear measurements of the mandible were recorded from lateral cephalogram. DNA was extracted from the blood sample and then genetic analysis was done using PCR-RFLP (polymerase chain reaction - restriction fragment length polymorphism). The cephalometrice linear measurements of the mandible were compared with the genetic analysis results, statically analyzed and tabulated. The following conclusions could be drawn from the current study: 1- There was a relation between Type II procollagen (COL2A1) gene and both total mandibular length (Cd-pg) and mandibular body length (Go-Gn) and this relation was significant for both males and females.

1489/T

Population genomics and haplotype construction from diverse human genomes. *J.M. Kidd[1], S. Musharoff[1], B.M. Henn[1], F. De La Vega[2], C.D. Bustamante[1].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Life Technologies, Foster City CA.

Human population genomics studies have become a reality due to advances in short-read sequencing technology. In these studies, variant discovery entails mapping to a reference sequence, followed by identification of variant sites. This results in a set of genotypes for a given individual at positions along the genome. Phased haplotypes can be inferred from these genotypes either via parent-offspring trios or from phasing algorithms that incorporate allele frequency information from the same or similar populations. Alternatively, short phased haplotype segments can be reconstructed from the underlying paired-end sequence reads without relying on the sequencing of additional genomes for trio-based or allele frequency-based phasing methods. We apply this haplotype construction approach using paired end sequences to 12 diverse individual human genomes that have been sequenced with the SOLiD technology using libraries with a fragment size of 1 kb - 3 kb. Using the linking mate pair information, we physically phase a subset of heterozygous variants in these sequenced individuals and utilize the resulting segments to explore estimates of divergence within and between individuals of diverse ancestry.

1490/T

The African American risk allele for focal segmental glomerulosclerosis (FSGS), and hypertension-associated end-stage kidney disease (H-ESKD). *G. Genovese[1,2], S. Tonna[2,3], R. Lazarus[4], M. Pollak[2,5].* 1) Department of Mathematics, Dartmouth College, 6188 Kemeny Hall, Hanover, NH 03755; 2) Renal Division, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115; 3) Epigenetics in Human Health and Disease Laboratory, Baker IDI Heart and Diabetes Institute, Melbourne, Australia; 4) Channing Laboratories, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115, United States; 5) Division of Nephrology, Dept of Medicine, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA 02215, United States.

Genetic variation at the MYH9 locus has been shown to be responsible for the high incidence of focal segmental glomerulosclerosis (FSGS) and hypertension-associated end-stage kidney disease (H-ESKD) among African Americans. We performed a genome-wide association using 56 African Americans affected by biopsy-proven FSGS and compared the results with 1800 African Americans controls provided from Illumina. We determined continental ancestry in a 1MB region around MYH9 and still, the ancestry corrected case-control comparison showed that variants within a large region of 80kb, containing part of MYH9, associate with increased FSGS risk. This region spans multiple linkage disequilibrium blocks and variants associating with disease within this region are in linkage disequilibrium with variants which have shown signals of natural selection. Previous studies identified the E-1 haplotype as the best predictor for disease (~60% frequency in controls and ~88% frequency in our cases, p<10e-8). Our data suggests that a different haplotype defined by the risk alleles for SNPs rs2239785 and rs136187 (~31% frequency in controls and ~65% in our cases, p<10e-13) is more strongly correlated with disease and the frequency discrepancy for this haplotype cannot be explained alone by the discrepancy at the E-1 haplotype. This suggests that the association signal is actually stronger than thought by previous studies which might have underestimated the genetic effect of the MYH9 locus.

Introduction Ancestry informative markers (AIMs) have been used as a cost-effective way to estimate individual ancestral proportions in admixed populations such as African Americans and Latinos. We determined the accuracy of individual ancestry estimates derived from smaller AIMs panels compared to ancestry estimates using all genomewide data as the gold standard. Methods Latino participants of Mexican (n = 271) and Puerto Rican (n = 324) originwith asthma were recruited from the San Francisco Bay Area, New York City, Puerto Rico, and Mexico City. Genotyping was performed using the Affymetrix 6.0 GeneChip Array; after applying standard QC filters 729,685 markers remained for analysis. We used the intersection of Illumina-550 and Affymetrix 6.0 as our set of potential SNPs to encourage universal applicability of our marker panels. Ancestry information for each SNP was measured via pairwise In calculations. AIMs panels of 18, 36, 75, 150, 300, 600, 1200, and 2400 unlinked markers were selected. Individual ancestry was estimated using the program ADMIXTURE, specifying a three population model. Ancestral populations consisted of HapMap Yorubans and CEPH Europeans, as well as Maya and Nahua Native Americans. We compared differences in ancestry estimated with different size AIMs panels with ancestry estimated from genomewide markers. Mean and standard deviation of the difference in ancestry estimation between AIMs and genomewide data were calculated. Results There was an inverse correlation between the number of AIMs used to estimate ancestry and mean and standard deviation of the error in ancestry estimation. Using AIMs, African ancestry was consistently overestimated, while the major ancestral component (European in Puerto Ricans and Native American in Mexicans) was systematically underestimated. Using 300 or fewer AIMS consistently produced a standard deviation of ancestry estimation error of 10% or greater. Discussion Our results illustrate significant error in the estimation of individual ancestry using AIMs. There is both systematic bias resulting in overestimation of African ancestry (and underestimation of other continental ancestry) and random error. Such error is inversely proportional to the number of AIMs used. These findings may have implications for genetic association studies where ancestry is used to control for population stratification as well as for studies examining associations of individual ancestry estimates with a phenotype.

1492/T

Genome wide scan identifies loci associated with gait speed and handgrip in older Amish. *J.E. Hicks[1], J.R Gilbert[1], L. Jiang[2], A.C. Cummings[2], D.R. Velez Edwards[3], P.J. Gallins[1], L. Caywood[1], L. Reinhart-Mercer[1], D. Fuzzell[2], C. Knebusch[2], R. Laux[2], C.E. Jackson[4], M.A. Pericak-Vance[1], J.L. Haines[2], W.K. Scott[1].* 1) Hussman Institute for Human Genomics, University of Miami, FL, USA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA; 3) Vanderbilt Epidemiology Center, Vanderbilt University, Nashville, TN, USA; 4) Scott & White, Temple, TX.

Gait speed and handgrip strength are physical performance measures that assess lower and upper body strength, respectively. Both are strong predictors of incipient disability and mortality in older adults. Identification of polymorphisms affecting these traits would result in new potential avenues to promote healthy aging. Adults over 65 were enrolled in a population based door-to-door survey of Amish communities in Indiana and Ohio. The Anabaptist Genealogy Database was used to connect all 814 participants in a 13-generation pedigree. Genotyping was performed using the Affymetrix Genome-Wide Human SNP Array 6.0. Gait speed was measured by timing subjects on a 10ft walk. Grip strength was measured in each hand (three trials) with a dynamometer. Of the 814 participants, 519 had valid measured gait speeds, and 473 had valid measured grip strength. After quality control, 630,309 autosomal SNPs were analyzed for association with gait speed and grip strength using the GRAMMAR-GC method (accounting for pedigree relationships in a linear mixed model) in the GenABEL package. The data were adjusted for age, sex, height, and cognitive status in gait speed analysis, and age, sex, BMI, and cognitive status in grip strength analysis. Analysis identified 641 SNPs associated with gait speed at $p<10^{-3}$. The most significant result was at rs11050430 ($p=4.9x10^{-6}$) on 12p11, near TMTC1. A 137kb LD block on 14q21 containing 25 highly correlated SNPs was also strongly associated (smallest $p=5.3x10^{-6}$ at rs7154025, near LRFN5 and FBXO33A). This region was previously linked to successful aging (of which gait speed is a component) in a subset of this sample. Another 31kb LD block on 20q11 (10 SNPs) showed significant association (smallest p=8.4x10-6 at rs6069151). Grip strength analysis identified 551 SNPs associated at $p<10^{-3}$. The strongest association was on chromosome 3q29, near HES1 (at rs7629288, $p=5.5x10^{-6}$). Other SNPs showing strong association were rs2852230 ($p=6.6x10^{-6}$) on 11q23 within an intron of GRIK4. Another SNP on chromosome 11 showed association ($p=7.6x10^{-6}$). Analysis of these regions for functional variants that explain the association will aid in understanding the underlying biological processes of disability. The overlap of association with gait speed and linkage of successful aging on chromosome 14 suggests that analysis of continuous intermediate phenotypes will assist in identifying genes underlying successful aging in the Amish.

Pigmentation in Britain: Regional patterns and genotype-phenotype correspondence. *E.C. Røyrvik[1], W.F. Bodmer[1,2].* 1) Clinical Pharmacology, University of Oxford, Oxford, United Kingdom; 2) Cancer and Immunogenetics Laboratory, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, United Kingdom.

Large differences in external pigmentation are some of the most striking features in human populations, and some of the most notable of these differences are found in hair and eye color in Northwest Europe. These phenotypes are genetically determined, and many associated genetic variants have been identified. To investigate to what extent pigmentation phenotype is predictable from genotype, we have genotyped 2842 locally rooted individuals from different regions of Britain for a subset of these variants, and use their frequencies to estimate hair and eye color in these areas. The results are compared to observed frequencies from two large mid-19th and early 20th century surveys of 9470 British people from the same or adjacent areas.=AC The SNPs used include rs12913832 - a major determinant of brown versus non-brown eye color, and major variants of *MC1R* that cause red hair. Pairwise comparisons of color categories in the current and 19th/early 20th century local populations were conducted to investigate differences, either diachronic or geographical, between them. There are significant differences between different areas of Britain in terms of pigmentation. North Wales has a significantly higher proportion of dark eyes than the rest of the island, although South Wales also has a comparatively high count. Red hair is approximately equally frequent in all regions; the other main hair shades show a tendency to separate Wales and Southwest England from other areas at a significant level, in particular from East England. We find good general accord between the observed and estimated color frequencies in any given area. Small but regular underestimates of the observed values by the estimated values are likely due to the contribution to any given color category of alleles that are unknown or have a lesser effect, or to uncertainties in effect size of known variants. Our results indicate that average regional hair and eye color have remained relatively stable in Britain over the past century, and support that it is possible to predict normal pigmentation phenotypes from genotype data.

1494/T

Frequency distribution of NOS3, MIF, TNF-α and MPO gene polymorphisms in healthy Southeastern Anatolian Population. *T. Sever[1], S. Oguzkan Balci[1], M. Pehlivan[2], S. Budeyri[2], A. Bayram[3], A. Aydeniz[4], V.N. Ulgezer[1], S. Pehlivan[1].* 1) University of Gaziantep, Faculty of Medicine, Department of Medical Biology, Gaziantep, Turkey; 2) University of Gaziantep Faculty of Medicine, Department of Hematology, Gaziantep, Turkey; 3) Zirve University, Gaziantep, Turkey; 4) University of Gaziantep Faculty of Medicine, Department of Physical Medicine and Rehabilitation, Gaziantep, Turkey.

Objectives of Study: Endothelial nitric oxide synthase (NOS3), macrophage migration inhibitory factor (MIF), tumor necrosis factor-alpha (TNF-α) and myeloperoxidase (MPO) are important enzyme to chronic inflammatory disease, cancer, etc. The aim of this study was to determine NOS3 (+894, intron 4 VNTR), MIF (-173), TNF-α (-238, -308, -857) and MPO (-463) polymorphisms in healthy Southeastern Anatolian population and to show whether there was any difference by comparing with the results belonging to healthy individuals in various populations studied. **Methods:** The allele frequencies and distribution of genotype corresponding to seven polymorphisms in 4 different genes NOS3 (+894, intron 4 VNTR), MIF (-173), TNF-α (-238, -308, -857) and MPO (-463) were analyzed in healthy Southeastern Anatolian individuals. The study was conducted on 150 healthy random Turkish individuals which were living in Southeastern Anatolian at least three generations. The study was approved by the local ethical committee and informed consents were obtained from the patients. Genomic DNA was extracted from peripheral blood using the salting out procedure. Genotyping were performed by using PCR and/or PCR-RFLP method. **Results:** The observed genotype counts was deviated from those expected according to the HWE for NOS3 (+894) (p=0.01) and TNF-α (-857) (p=0.003) whereas NOS3 (intron4 VNTR), MIF (-173), TNF-α (-238, -308), MPO (-463) was not deviated (p>0.05). The results were compared according to the literature data if there is any difference between the healthy population of Southeastern Anatolian with the populations of 6-13 different countries. TNF-α (-308) polymorphism was different from Thailand, Brazil, India, United Kingdom, Chine, Japan, Tawain, Korea and Zimbabwe. TNF-α (-857) polymorphism TT genotype was found higher than that of other populations. NOS3 (+894) polymorphism was found to different than the others. NOS3 (intron 4 VNTR), MIF (-173), TNF-α (-238) and MPO (-463) polymorphisms were similar to the other populations. **Conclusion:** This is the first study in Southeastern Anatolian healthy population and the results show that deviations occur due to the fact that Southeastern Anatolian is the transition region of migrations. The data can be used for antropological comparisons, as well as for association studies with different diseases and for use in transplant stuation involving acute and chronic rejection.

1495/T

Pairwise sequence differences among private and shared haplotypes in a two-population model. *Z.A. Szpiech[1], N.A. Rosenberg[1,2].* 1) Center for Computational Biology and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

When one population is selected over another as a basis for genetic variation discovery, it is of interest to consider the properties of haplotypes that go undiscovered because they are private to an unsampled population. To consider a scenario in which only one of a pair of populations is sampled, we develop a modeling approach for examining the properties of private and shared haplotypes in two populations descended from a common ancestral population. In particular, in a coalescent model, assuming the infinite alleles model as the mode of mutation in a non-recombining region, we examine the smallest nontrivial case, with sample size four. In this case, two haplotypes are drawn from each population and three distinct haplotypes are observed, one of which is common to both populations, one of which is private to one population, and the third of which is private to the other population. Given this configuration, we calculate the probability that the pairwise sequence difference between the two private haplotypes is greater than either pairwise sequence difference between a private haplotype and the shared haplotype. Although we find that regardless of the mutation rate and divergence time between populations, the pair most likely to have the greatest sequence difference is the pair of private haplotypes, the largest difference often occurs between one of the private haplotypes and the shared haplotype, especially for closely related populations. Thus, if only one population is used for discovery of haplotypes in this simple scenario, a region of the parameter space exists where there is a reasonable probability that undiscovered haplotypes will be quite distinct from the shared haplotypes that can be identified without using both populations in variation discovery.

Teo[2,3,11].* 1) NUS Graduate School for Integrative Science and Engineering, National University of Singapore, Singapore; 2) Centre for Molecular Epidemiology, National University of Singapore, Singapore; 3) Department of Epidemiology and Public Health, National University of Singapore, Singapore; 4) Department of Medicine, National University of Singapore, Singapore; 5) Immunology Division, Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia; 6) Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore; 7) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore; 8) Centre for Eye Research Australia, University of Melbourne, Australia; 9) Korea National Institute of Health, Seoul, Korea; 10) Wellcome Trust Major Overseas Program, Oxford University Clinical Research Unit, Vietnam; 11) Department of Statistics and Applied Probability, National University of Singapore, Singapore.

Through the use of commercial genotyping platforms with incomplete genome coverage, long stretches of linkage disequilibrium (LD) have been critical to the success of many genome-wide association studies in enabling the detection of statistical signals of phenotypic variation. The detected polymorphisms in these studies are often not the causal variant, but markers in LD with the casual variant, making the success of replication and meta-analysis dependent on the similarity of LD patterns in the different human populations used. Regions of high LD however confound fine-mapping studies as it becomes difficult to distinguish between the causal variant and neighboring markers in high or perfect LD with the causal variant. Here, we describe the results of assessing LD variations with the varLD metric across 17 population groups; consisting of 11 populations from Hapmap Phase 3, 3 populations from the Singapore Genome Variation Project, and populations from Korea, Sweden and Vietnam. Our findings indicate that the integration of LD differences between populations could be used to refine the boundary of region containing the causal variant, narrowing the search space and thus reducing the cost of genotyping and sequencing during fine-mapping studies. In addition, regions with strong LD differences between populations are associated with genomic regions with copy number variations, differential signals of selection and variations in recombination rates due to evolutionary and migration history of these populations. These results are relevant to the design and analysis of fine-mapping studies, where candidate gene regions from genome-wide association studies could be ranked and identified to maximize the likelihood of finding the common causal variants of disease.

1497/T

Estimating the ages of two founder mutations that increase the risk of colorectal cancer in the Spanish population. *E.M. Jewett[1], N.A. Rosenberg[1,2,3], S. Gruber[4,5,2], G. Capellá[6,7,8,9].* 1) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) The Life Science Institute, University of Michigan, Ann Arbor, MI; 4) Department of Internal Medicine, University of Michigan, Ann Arbor, MI; 5) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 6) Laboratori de Recera Translacional, Hospitalet de Llobregat, Spain; 7) Institut Català d'Oncologia, Hospitalet de Llobregat, Spain; 8) Institut d'Investigació Biomèdica de Bellvitge, Hospitalet de Llobregat, Spain; 9) Programa de Consell Genètic en Càncer, Institut Català d'Oncologia, Spain.

Estimating the ages of alleles provides a basis for learning about the history of disease mutations. Here we apply a version of the allele age estimation method of Schroeder et al. (Mol Biol Evol 26:995-1016, 2009) to estimate the ages of two disease alleles of the *MLH1* mismatch repair gene that have recently been discovered in the Spanish population. The method first obtains a count of the number of recombination events that have occurred on a genealogy in the region surrounding a disease mutation. This count is used to estimate the length of the genealogical tree for the set of haplotypes on which the mutation has been observed. Coalescent simulations that evaluate the relationship between genealogy length and genealogy height are then used to determine the most likely height of the gene tree, which is taken as an estimate of the age of the mutation. We estimate that the two *MLH1* mutations arose 75 and 15 generations ago (95% confidence intervals 53-122 and 12-22 generations, respectively). The recent ages estimated for both mutations are consistent with their localized distributions within two distinct geographical regions of Spain.

Aplication of authenticity criteria in mitochondrial studies on archaic bone remains from a prehispanic muisca population. *N.P. Jara[1,2], M. Díaz[1], V. Villegas[2], C. Lopez[1], D. Torres[2], J. Bernal[2], A. Gómez[2], I. Briceño[1,2].* 1) Universidad de La Sabana, Bogotá. Campus Universitario del Puente del Común, Km. 7, Autopista Norte de Bogotá; 2) Laboratorio de Genética Pontificia Universidad Javeriana.

Introduction: Ancient DNA studies can support hypotheses regarding ancient populations; molecular studies can analyze the local population's genetic composition, minimizing biases introduced by later migrations, demographic expansions, mutations, and bottleneck effects. These analyses must be performed with special care due to the low DNA concentrations and contamination risk; therefore it is necessary to establish protocols to guarantee reproducibility and veracity of results. Objective: The present study aims to establish a protocol to obtain ancient DNA from 16 pre-columbian bone samples found in an excavation performed in the area "Candelaria La Nueva", Bogota, Colombia, dated in the period "Muisca Tardìo". Methods: Four founder mitochondrial DNA Amerindian haplotypes were analyzed by high resolution restriction enzyme analyses, obtaining fragments between 121 and 186 base pairs (bp). Different analyses were performed following a strict control of authenticity criteria regarding laboratory conditions, including: positive and negative controls, reproducibility of results and verification of particular characteristics present in ancient DNA. Results: Results obtained from the bone samples showed the exclusive presence of haplogroup A in the studied population. This data support the statement of the archaeologists of a single biological population in space and time. The distribution of this haplogroup in a 100% frequency supports the hypothesis of Chibcha genetic affiliation. Conclusion: The present study is a contribution to the study of genetic diversity in archaic American populations, allowing the integration of geographic and historic data with genetic characterization techniques associated with linguistic, ethnographic and glottochronology patterns. Following the protocol proposed in the present study allows the fulfillment of authenticity criteria for ancient samples, with the avalaible techniques, with the avalaible techniques Key words: Mitochondrial DNA, Archaic DNA, Muisca, Chibcha.

The Initial Peopling Of The Americas: An Ever-Growing Number Of Founding Mitochondrial Genomes From Beringia. *U.A. Perego[1,2], N. Angerhofer[1], M. Pala[2], A. Olivieri[2], H. Lancioni[3], B.H. Kashani[2], V. Carossa[2], J.E. Ekins[1], A. Gómez-Carballa[4], G. Huber[5], B. Zimmermann[5], D. Corach[6], N. Babudri[3], F. Panara[3], N.M. Myres[1], W. Parson[4], O. Semino[2], A. Salas[5], S.R. Woodward[1], A. Achilli[2,3], A. Torroni[2].* 1) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT, USA; 2) Dip. Genetica e Microbiologia, Università di Pavia, Pavia, Italy; 3) Dip. Biologia Cellulare e Ambientale, Università di Perugia, Perugia, Italy; 4) Unidade de Xenética, Departamento de Anatomía Patolóxica e Ciencias Forenses; and Instituto de Medicina Legal, Facultade de Medicina, Universidade de Santiago de Compostela, Santiago de Compostela, Galicia, Spain; 5) Institute of Legal Medicine, Innsbruck Medical University, Innsbruck, Austria; 6) Servicio de Huellas Digitales Genéticas, Facultad de Farmacia y Bioquímica, Universidad de Buenos Aires, Buenos Aires, Argentina.

Genetic evidence based on mitochondrial DNA (mtDNA) has recently revealed the existence of additional founding lineages that have contributed to the first peopling of America's double-continent in addition to the more popular five Native American haplogroups (A2, B2, C1, D1 and X2a), and has demonstrated as well the need for additional sampling and analysis to be performed for some of the already known but poorly characterized lineages. One paradigmatic example is represented by the pan-American haplogroup C1. Two of its sub-branches (C1b and C1c) harbor ages and geographical distributions that are indicative of an early arrival from Beringia about 15-17,000 years ago, concomitantly with the other currently accepted Paleo-Indian founders. However, the estimated age of C1d - the third Native American subset of C1 - is only 8-10,000 years, which is suggestive of a much later entry and spread in the Americas. In this study, we shed light on the origin of this enigmatic Native American branch of C1 by completely sequencing a large number of C1d mitochondrial genomes from a wide range of geographically diverse, mixed and indigenous American populations. The revised phylogeny shows that the age previously reported for C1d was heavily underestimated and indicate that C1d is ancient enough to be among the founding Paleo-Indian mtDNA lineages. Moreover, our results reveal that there were two C1d founder genomes for Paleo-Indians that most likely arose early (~16kya), either in the dynamic Beringian gene pool, or at a very initial stage of the Paleo-Indian southward migration. This brings the recognized maternal founding lineages of Native Americans to the unexpected number of 15, and indicates that the overall number of Beringian or Asian founder mitochondrial genomes will probably continue to increase as more Native American haplogroups reach the same level of phylogenetic resolution as we obtained here for C1d. Additionally, we have confirmed a nearly identical geographic distribution pattern for haplogroup C1d when comparing samples collected in the general mixed population with those from native tribal groups, as it was also reported previously for haplogroups X2a and D4h3. This substantiates the validity of searching large public mtDNA databases (such as the one available through the Sorenson Molecular Genealogy Foundation, www.SMGF.org) for novel founder candidates able to reveal unknown details concerning the ancient human history of the Americas.

1500/T

Detecting heteroplasmy from high-throughput sequencing of complete human mtDNA genomes. *M. Stoneking, M. Li, A. Schoenberg, I. Nasidze.* Evolutionary Genetics, MPI-EVA, Leipzig, Germany.

Heteroplasmy, the existence of multiple mtDNA types within an individual, has been previously detected using mostly indirect methods (e.g., multiple peaks in Sanger sequencing electropherograms) and focusing on just the hypervariable segments of the control region. High-throughput (HT) sequencing should enable studies of heteroplasmy across the entire mtDNA genome at much higher resolution, as many independent reads are generated for each position. However, the higher error rate associated with the HT platforms must be taken into consideration, to avoid false detection of heteroplasmy. We used simulations and control phiX174 sequence data to design criteria for accurate detection of heteroplasmy with the Illumina GA platform, and replicate data and artificial mixtures to test the criteria. We then applied these criteria to a dataset of 131 complete mtDNA genome sequences from five Eurasian populations that had been generated using a parallel tagged approach and sequenced to an average coverage of 67-168X. Based on simulations with this amount of coverage we have good power with our criteria to detect heteroplasmies at a frequency of 10% or higher with no false positives expected. We identified 37 heteroplasmies at 10% frequency or higher at 34 sites in 32 individuals, or 24% of the individuals studied. Three sites were heteroplasmic in two different individuals, which is significantly more than expected ($p<0.001$) if heteroplasmies are occurring randomly. The mutational spectrum does not differ between heteroplasmic mutations and polymorphisms in the same individuals, but the relative rate of mutation at heteroplasmic mutations is 24.95, which is significantly higher than the average relative rate of mutation of 2.72 estimated for all mutable sites in the human mtDNA genome ($p<0.001$). Finally, the ratio of nonsynonymous to synonymous (N:S) changes for heteroplasmies in the protein-coding genes was significantly greater than the N:S ratio for polymorphisms in the same individuals ($p<0.05$). Overall, the increased relative rate of mutation for heteroplasmies suggests that they play a role in generating neutral diversity in human mtDNA, whereas the elevated N:S ratio for heteroplasmies suggests that they are also subject to negative selection. Our results indicate that with appropriate criteria for avoiding false positives due to sequencing errors, HT platforms can provide novel insights into genome-wide aspects of mtDNA heteroplasmy.

Mitochondrial DNA Control Region Mutational Events Based on Empirical Data. *S.R. Woodward[1], T.T. Steele[1], B.C. Burdett[1], R. Hughes[1], U.A. Perego[1,2], N. Angerhofer[1], A. Achilli[2,3], N.M. Myres[1].* 1) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT, USA; 2) Dip. Genetica e Microbiologia, Università di Pavia, Pavia, Italy; 3) Dip. Biologia Cellulare e Ambientale, Università di Perugia, Perugia, Italy.

Two peculiar features of mitochondrial DNA (mtDNA) make it a very informative and widely employed instrument in studying human migrations and evolution: it is inherited exclusively along the maternal line and it lacks recombination. While it is difficult to determine the ancestral origin of mutations that occur on various locations of diploid nuclear DNA, the sequence variation observed in any mtDNA genome is the result of the sequential accumulation of new mutations along the radiating maternal lineages. Therefore, present-day molecules stand as a literal biological record of the mutational events that took place through the evolutionary history of mankind across the world. Numerous studies during the past two decades have proposed different mutation rates based on either a phylogenetic approach or on empirical data, based on control region, coding region, or complete genome sequences. However, disagreement persists on the accuracy of effective rates. One of the major limitations with a phylogenetic approach is the unavailability of actual genealogies to accurately quantify a mutation fixation rate. With regard to studies utilizing empirical data, the major limitation has been the limited size of the datasets used for such analyses. In the current study, we tried to address this issue by using data extrapolated from the Sorenson Molecular Genealogy Foundation (SMGF, www.SMGF.org) correlated database of genealogical and genetic data. As of June 2010, the publicly accessible portion of the SMGF database includes 73342 mtDNA control region haplotypes which are linked to 313121 maternal ancestors, showing a total of 140827 insertions, 39120 deletions, and 584216 substitutions. Extension and correlation of the pedigree data associated with each mtDNA sequences revealed the presence of approximately 25000 generational events characterized by nearly 1000 mutational events. An accurate analysis of these data allowed us to discuss differences/matches on the calibrations of the mtDNA molecular clock obtained from "pedigree or near-time" and "phylogenetic or distant" approaches.

Molecular characterization of abnormal hemoglobin chromatograms detected by the Bio Rad Variant II Turbo HPLC systems in Korean. *E. Cho, S.G. Lee, E.H. Lee, E.J. Kim, I.H. Yu.* Laboratory Medical Genetics, Greencross reference laboratory, Yongin, Korea.

Background: Patients with hemoglobin (Hb) variants may produce false HbA1c measurement. This study aimed to detect the common Hb variants in Korean population, to evaluate their effect on the determination of HbA1c and to characterize them by molecular methods. Methods: A total of 20,000 samples referred to Greencross reference laboratory from June 2009 to July 2009 were submitted for Hb variant analysis by the Bio-Rad Variant II Turbo (VII) which uses high-performance liquid chromatography (HPLC) method. Patients identified with Hb variants were re-tested by the Bio-Rad Variant II in thalassemia mode (VII-TM). We carried out DNA studies of the β and α1 globin genes by PCR and sequencing of all the coding exons. In the cases with high Hb F (>10%) and normal results by β globin gene sequencing, we performed the α and β globin gene dosage analyses using multiplex ligation-dependent probe amplification (MLPA, MRC-Holland) method. Results: Among the 20,000 cases, 20 cases (0.1%) had variant peaks and 31 cases (0.16%) had increased Hb F (>5%). Eight cases had variant peaks between the A1c and A0 peaks. Among them, five cases were identified as Hb G-Coushatta (β22Glu®Ala), (mean retention time, 0.71 min at VII , 2.74 min at VII-TM) and three cases were identified as Hb Ingelwood (β142Ala®Thr) (mean retention time, 0.82 min at VII, 2.05 min at VII-TM). One case had peaks between the Hb LA1c and A1c (retention time: 0.52 at VII, 1.04 at VII-TM) which were identified as Hb North Manchester (β51Pro®His) and one case had a very high peak at Hb F (46.3%), which were identified as Hb Beckman (β135Ala®Asp). Eight cases had peaks at S-window, two cases had peaks at variant window and P3, respectively. One case with high Hb F(>10%) were revealed to have heterozygous deletion of the total β-globin gene and partial δ gene deletion spanning about 9.4Kb. In patients with Hb variants, HbA1c was measured lower at the VII than VII-TM. Conclusion:In conclusion, the incidences of Hb variant and high Hb F concentrations were estimated to be 0.1% and 0.16%, respectively. The most common Hb β variants in Koreans were Hb G Coushatta and Hb Ingelwood.

Genetic Characterization of Indigenous Populations in Mexico, Mazahua and Zapotecs, with reference to phylogenetic relationships among indigenous North- and Meso-American populations. *S. Ueda[1], F. Mizuno[1], J. Gojobori[2], L. Wang[3], K. Ohnishi[1], S. Sugiyama[4], V. Acuna[5].* 1) Dept Biological Sci, Univ Tokyo, Grad Schl Sci, Tokyo, Japan; 2) Hayama Center for Advanced Studies, Graduate University for Advanced Studies, Hayama, Japan; 3) Institute of Genetics and Developmental Biology, Chinese Academy of Science, Beijing, China; 4) School of Foreign Studies, Aichi Prefectural University, Aichi, Japan; 5) Instituto Nacional de Antropología e Historia, Mexico City, Mexico.

Most indigenous American people share common mitochondrial DNA lineages that define four primary haplogroups (A, B, C, and D), now further characterized as A2, B2, C1, and D1. Mesoamerica is a region extending approximately from central Mexico to Honduras and Nicaragua, and indigenous American populations in Mesoamerica are characterized by high frequencies of haplogroup A with moderate to low frequencies of haplogroup B. To the contrary, southwest indigenous populations in North America exhibit high frequencies of haplogroup B and very low frequencies or the complete absence of haplogroup A. We here investigated the genetic structure of two indigenous American populations in Mexico, Mazahua and Zapotecs. The Mazahua inhabit the northwestern portion of the State of Mexico and northeastern area of Michoacán, while the Zapotecs do the southern state of Oaxaca and its neighboring states. We determined mitochondrial DNA sequences for 25 and 88 individuals of Mazahua and Zapotecs, respectively. All individuals examined belong to any of haplogroup A, B, C, or D. We compared their haplogroup frequencies for all pairs of populations including other indigenous American populations around Mesoamerica previously examined. In addition, we also calculated the nucleotide diversity (the mean of pairwise nucleotide differences per site) within each population and the genetic distances (net values of nucleotide substitutions) between the populations using nucleotide sequences of the mtDNA hyper-variable regions (HVR). Phylogenetic network was constructed for the mtDNA haplogroups obtained, while a neighbor-joining phylogenetic tree and principle component analysis was conducted using the HVR sequence. Based on these molecular phylogenetic indices, we discuss genetic structure of indigenous Mazahua and Zapotecs populations and genetic similarity to other indigenous populations in Meso- and North- America.

Adaptations to high altitude in Ethiopia. *G. Alkorta-Aranburu[1], D. Witonsky[1], C. Beall[2], A. Di Rienzo[1].* 1) Human Genetics , University of Chicago, Chicago, IL; 2) Anthropology Department, Case Western Reserve University, Cleveland, OH.

High-altitude (HA) resident human populations differ biologically from lowlanders; however, the biological bases of their differences are not well understood. The possibility of genetic adaptation to HA is supported by the high heritability of hemoglobin (Hb) concentration in Andean and Tibetan highlanders; a locus associated with higher oxygen saturation in Tibetans and positively selected haplotypes of EGLN1, PPARA and EPAS1 associated with lower Hb concentration in Tibetans. Epigenetic adaptation can also be hypothesized since invasive cancer clones show both genetic and epigenetic modifications due to hypoxia and nutrient deprivation.

To learn more about human adaptations to HA, we extended genomic analysis to two Ethiopian ethnic groups: the Amhara and the Oromo with, respectively, thousands of years and 500 years of residence at HA. Amhara populations at 3500-4000 and 1500 meters, and Oromo populations at 4000 and 1500 meters were sampled. HA samples show lower oxygen saturation and higher Hb concentration; but when ethnic groups are compared, Oromos show greater altitudinal differences. Then, methylation levels at ~27000 CpG sites in 17 HA and 17 low-altitude (LA) Oromos and Amharas were collected using Illumina's HumanMethylation27 BeadChips. While methylation levels differ significantly between Amharas and Oromos, no evidence for epigenetic differences between HA and LA within the same ethnic group is observed. Next, genome-wide genotype data were collected in 48 HA and 48 LA Amharas, and 24 HA and 24 LA Oromos using Illumina's 650Y or 1M SNP arrays. When allele frequency differences between HA and LA Ethiopians are compared to expectations, the Amharas and, especially, the Oromos show a significant excess of high-FST values. Interestingly, some of the genes with high-FST SNPs are good candidates for hypoxia driven adaptation based on their biological function; e.g., the Parkinson's disease gene SEMA5A that promotes angiogenesis by increasing endothelial cell proliferation, migration, and decreasing apoptosis. In addition, these data allow us to test whether the variants and genes associated with Hb concentration and/or signals of adaptation to HA in Tibetans also play a role in Ethiopian adaptations to HA. We replicate in the Oromo one EPAS1 SNP significantly associated with Hb concentration in two Tibetan cohorts.

A cross-population comparison extended haplotype-based homozygosity score test to detect positive selection in genome-wide scans. *R. Fan[1], M. Zhong[2], K. Lange[3].* 1) Dept of Statistics, Texas A&M Univ, College Station, TX; 2) Dept of R436, GPRD, Abbott Laboratories, Abbott Park, IL; 3) Dept of Human Genetics, David Geffen School of Medicine, Univ of California, Los Angeles, CA.

Positive selection may shed on complex disease and human evolution. Previously we proposed a powerful score test, Extended Haplotype-based Homozygosity Score Test (EHHST), to detect positive selection in genome-wide scans. We adopted extended stretches of homozygosity as a surrogate indicator of recent positive selection and tested the haplotype version of Hardy-Weinberg equilibrium (HWE). In this article, we developed a cross-population comparison test (xp-EHHST) to detect chromosome regions in which there is no significant excess homozygosity in one population but homozygosity remains high in another population, i.e., the HWE is roughly true in one population but hardly valid in the other. We assumed that every population has a random sample of unrelated individuals, each typed on a large number of single nucleotide polymorphisms (SNPs). A pooled t-test statistic was constructed to compare the measurements of homozygosity of the two samples around a core SNP. The detected strong signals highlighted the candidate regions that undergo positive selection in one of the two populations. We conducted the simulation study to evaluate the performance of the new test in terms of type I error and power, and then applied it to HapMap Phase II data.

Increased risk of Crohn's disease resulting from genetic hitchhiking at IBD5. *C.D. Huff[1], D. Witherspoon[1], Y. Zhang[1], C. Gatenbee[1], S. Kugathasan[2], H. Hakonarson[3,4,5], A. Whiting[1], C. Davis[1], W. Wu[1], J. Xing[1], W.S. Watkins[1], M. Bamshad[6], K. Bulayeva[7], T. Simonson[1], L.B. Jorde[1], S.L. Guthery[8].* 1) Department of Human Genetics, Eccles Institute of Human Genetics, University of Utah, Salt Lake City, UT, U.S.A; 2) Department of Pediatrics, Emory University School of Medicine and Children's Health Care of Atlanta, Atlanta, GA, USA; 3) Center for Applied Genomics, Children's Hospital of Pennsylvania,Philadelphia, Pennsylvania, United States of America; 4) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, United States of America; 5) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, United States of America; 6) Department of Pediatrics, University of Washington, Seattle, WA 98195; 7) Vavilov Institute of General Genetics, Russian Academy of Sciences, Moscow, Russia; 8) Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, Utah, USA.

We present genetic evidence that adaptation to an agricultural diet may have increased the risk of Crohn's disease in Europeans. IBD5 is a 250 kb haplotype on chromosome 5 that is associated with an increased risk of Crohn's disease in Europeans. The OCTN1 gene is centrally located on IBD5 and encodes a transporter of the antioxidant ergothioneine (ET). The 503F variant of OCTN1 is strongly associated with IBD5 and is a gain-of-function mutation that increases absorption of ET. Here, we present several lines of evidence supporting the hypothesis that 503F is a dietary adaptation to early farming in the Fertile Crescent. The decay of linkage disequilibrium (LD) around 503F indicates that the mutation originated approximately 12,500 years ago, which corresponds with the origin of agriculture in the Fertile Crescent. The iHS test for recent positive selection yielded statistically significant results for 503F in the European CEU HapMap population (p= 0.0007) and European HGDP populations (p£0.01). Evidence of a strong selective sweep among Europeans has important implications for understanding the nature of disease association with IBD5. Our simulation studies demonstrate that selective sweeps in the nuclear genome often increase the frequency of mildly deleterious alleles via genetic hitchhiking. This process results in disease association with a favorable allele, even when the favorable allele has no direct influence on disease risk. In a sample of 836 Crohn's disease cases and 1262 controls, we identified signals of disease association on the IBD5 haplotype that are consistent with genetic hitchhiking. These results suggest that genetic hitchhiking increased the frequency of disease-causing alleles at a location distal to OCTN1, accounting for the association between 503F and Crohn's disease.

Characterization of deleterious variation by using allelic age. *A. Kiezun, I. Adzhubei, S. Pulit, P. de Bakker, S. Sunyaev.* Division of Genetics, Brigham & Women's Hospital, Harvard Medical School, Boston, MA.

Characterization of deleterious genetic variation is important for evolutionary and medical genetics. Medical sequencing studies aim at detecting the direct effect of functional allelic variants on phenotypes. Most functional variants are expected to be evolutionary deleterious but identification of these alleles is challenging. Current approaches to analyze deleterious variation use site frequency spectrum, polymorphism-to-divergence ratio, evolutionary conservation and protein structure. We present a new method to characterize deleterious variation. The method uses allelic age conditioned on frequency. The effect described by Maruyama in 1974 predicts that, at a given frequency, neutral variants are older than either deleterious or advantageous variants. Because low frequency non-synonymous variation is expected to be enriched in deleterious alleles, the effect predicts that non-synonymous variants are, on average, younger than synonymous or non-coding variants of the same frequency. Our analysis of simulations and real data supports this prediction. Allelic age can be estimated from frequency, intra-allelic variability, LD, or shared haplotypes. The data from the 1000 Genomes Project enables new approaches for estimating relative allelic age: mutation and recombination "clocks". The mutation clock estimates, for each variant, the number of likely younger (less frequent and completely linked) variants. The recombination clock estimates the length of the haplotype block on which the variant exists. The two clocks can be combined to improve power. Analysis of the 1000 Genomes Project pilot dataset agrees with theory and simulations. The mutation and recombination clocks show that non-synonymous alleles are younger than synonymous alleles. Consistently with simulations, the mutation clock is more sensitive, and the effect is stronger for damaging variants than for benign non-synonymous variants. The effect disappears at higher frequencies, because few deleterious variants reach higher frequencies. Consistently with the Maruyama effect, population-specific variants are more damaging than variants shared between populations (thus older), when conditioned on frequency. As expected, however, benign variants are not significantly more population specific than synonymous variants. We will present characterization of deleterious variation using the Maruyama effect as seen in 1000 Genomes data and discuss its potential applications.

1508/T

Contrasting patterns of sequence variation in pigmentation and neutral loci indicate population-level effects of selection. *H. Norton[1], M. Hammer[2].* 1) ARL-Biotech, Univ Arizona, Tucson, AZ; 2) Department of Ecology and Evolutionary Biology.

While demographic processes affect all regions of the genome in a similar manner, selection should preferentially affect levels of diversity and the site frequency spectrum (SFS) in genic regions relative to neutral regions. Here we compare patterns of variation in ten pigmentation candidate loci to a neutral dataset comprised of 61 loci located in regions of high recombination and far from genes. Both the genic and neutral loci were sequenced in the same panel of 72 African (Biaka, Mandenka, and San) and 80 Non-African (Han Chinese, French Basque, and PNG Highlander) chromosomes. As expected, mean levels of diversity are significantly lower in genic relative to neutral regions (π_{genic} = 0.00072; $\pi_{neutral}$ = 0.00113; p < 0.01). Because it is often assumed that pigmentation loci have been affected by purifying selection within Africa and by positive directional selection outside of Africa, we compared the SFS of pigmentation and neutral loci in these regions. We observe a trend towards an excess of rare or singleton alleles (exhibited as negative Tajima's D and Fu and Li's D values) consistent with either purifying or directional selection in the genic regions. However, as a class pigmentation loci do not significantly differ from the neutral loci in either Africans ($TD_{pigmentation}$ = -0.80, $TD_{neutral}$ = -0.82, p = 0.92; $FLD_{pigmentation}$ = -1.08, $FLD_{neutral}$ =-1.03 p = 0.90) or non-Africans ($TD_{pigmentation}$ = -0.38, $TD_{neutral}$ = -0.04, p = 0.16; $FLD_{pigmentation}$ = -1.00, $FLD_{neutral}$ =-0.60 p = 0.36). At the population level, only the French Basque showed a significant difference between pigmentation loci and the neutral regions for Tajima's D ($TD_{pigmentation}$ = -0.30, $TD_{neutral}$ = 0.35, p < 0.05). However, despite the failure of pigmentation loci as class to appear distinct from neutral loci, several individual loci stood out from the neutral regions in population-level comparisons. The gene MATP exhibits an excess of high frequency derived alleles in the French Basque (FWH = -4.11, p < 0.01) consistent with expectations under positive directional selection, while the gene MITF exhibits an excess of rare alleles in the Mandenka population (TD = -1.46, p < 0.05) indicating a role for purifying selection. These results suggest that while selection pressure on pigmentation loci may differ between Africans and non-Africans, the effects of selection on individual genes may have varied among populations within broader geographic regions.

1509/T

Resequencing of the catechol-O-methyltransferase gene, *COMT* revealed non-neutral processes associated with schizophrenia. *H. Shibata[1], M. Uchida[1], H. Goto[2], S. Mano[3], O. Takenaka[4], Y. Fukumaki[1].* 1) Medical Inst Bioregulation, Kyushu Univ, Fukuoka, Japan; 2) Center for Comparative Genomics and Bioinformatics, Pennsylvania State Univ, State College, PA; 3) The Inst of Statistical Mathematics, Tokyo, Japan; 4) Primate Research Inst, Kyoto Univ, Aichi, Japan.

Schizophrenia is a common psychiatric disease with the relatively strong genetic background (λ_s = 10). Because of the early onset and the loss of sociality in patients, the susceptibility alleles of schizophrenia are expected to be selected out through generations. However, the lifetime prevalence is stably high at ~1% in any of the populations surveyed. To explain this paradox, we hypothesized that the schizophrenia susceptibility alleles are maintained by the non-neutral process such as balancing selection. In this study, we analyzed the nucleotide diversity in the *COMT* (catechol-O-methyltransferase) gene as a schizophrenia susceptibility gene. We resequenced the entire coding regions and the upstream regions of > 6 kb potentially affecting the gene expression in 72 humans (24 Japanese, 24 Caucasians, 24 African Americans) and 24 chimpanzees. Using the dataset, we examined neutrality in the evolution by the summary statistics approach such as Tajima's method. In sliding window analysis, we identified two subregions consistently showing signatures of balancing selection in different human populations. One is the subregion surrounding a common nonsynonymous SNP, rs4680 of which significant association has been frequently reported with schizophrenia (*TD* = + 2.10, *p* < 0.05, Caucasians; *TD* = + 1.46, Japanese; *TD* = +1.75, African Americans) and the other is intron 5, approximately 2 kb downstream from rs4680 (*TD* = + 2.14, *p* < 0.05, African Americans; *TD* = + 1.98, Japanese; *TD* = + 1.48, Caucasians). There is another common SNP, rs4818, of which highly significant association has been reported with schizophrenia, located in the same window with rs4680. We conclude that haplotypes defined by the two SNPs in the *COMT* gene, has been maintained by balancing selection shared by different human populations and that the balancing selection may be associated with schizophrenia as well as human brain functions.

1510/T

Signals of local adaptation in human populations. *T.S. Simonson[1], C.D. Huff[1], Y. Zhang[1], W.S. Watkins[1], D.J. Witherspoon[1], J. Xing[1], S.R. Woodward[2], L.B. Jorde[1].* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT.

Humans have adapted to various environmental conditions. Genome-wide scans of positive selection have provided a first glimpse into locally adapted regions of the genome. It is possible that many more examples of positive natural selection exist in populations that have not yet been surveyed. In order to enhance the current understanding of population-specific adaptation, we performed genome-wide selection scans for 14 previously unstudied world-wide populations from Africa, Europe, Asia, and the Americas using the iHS statistic. Five of the seven selection candidates previously reported in the HapMap populations (Sabeti 2007) were identified in at least one additional population in our sample at the 0.02 significance level. Two of the previously reported regions were found in three or more of the populations we sampled: 1) the genic region containing *PDE11A* (phosphodiesterase 11A), first identified in Europe, Japan, and China, was also significant in Bolivia, Mongolia, Thailand, and Tibet; 2) the genic region containing *SLC30A9* (solute carrier family member 9), first identified in Japan and China, was significant in India, Pakistan, and Iraq. In contrast to finding many HapMap selection candidates in our additional populations, more than two-thirds of our selection candidate regions were not significant at the 0.05 level in any of the HapMap populations. We find that positive selection candidates vary considerably among these populations, highlighting novel signals of natural selection. These results suggest that distinct human populations sampled here have differentially adapted to specific environments.

1511/T

A Genome-Wide Search for Signals of High Altitude Adaptation in Tibetans. *S. Xu[1,2], S. Li[3], Y. Yang[3], J. Tan[3], H. Lou[1], W. Jin[1], L. Yang[1], X. Pan[3], J. Wang[1], Y. Shen[4], B. Wu[3,4], H. Wang[1], L. Jin[1,2,3].* 1) Computational Genomics, CAS-MPG Partner Institute for Computational Biology, Shanghai, Shanghai, China; 2) Key Laboratory of Computational Biology, CAS-MPG Partner Institute for Computational Biology, Chinese Academy of Sciences, Shanghai 200031, China; 3) State Key Laboratory of Genetic Engineering and Ministry of Education (MOE) Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai 200433, China; 4) Children's Hospital Boston, Harvard Medical School, Boston, MA 02115, USA.

The Tibetan Plateau, known as "the roof of the world" and with an average elevation of over 4,500 meters, is the highest plateau in the world. It is almost certain that biological adaptability has contributed to the success of Tibetans in occupying the Tibetan Plateau, because traditional technology could not buffer them from the unavoidable environmental stress of severe lifelong high-altitude hypoxia. However, efforts so far have not been successful to identify specific genetic loci contributing to high-altitude adaptation. We conducted a genome-wide study of 1,000,000 genetic variants in 46 Tibetans (TBN) and 92 Han Chinese (HAN) for identifying the signals of high altitude adaptations (HAA) in Tibetan genomes. We discovered the most differentiated variants between TBN and HAN at chromosome 1q42.2 and 2p21. HIF2A and HIFPH2, both related to hypoxia-inducible factor (HIF), were found most differentiated in the two regions, respectively. Strong positive correlations were also observed between the frequency of TBN dominant haplotypes in the two gene regions and altitude in East Asian populations. Linkage disequilibrium and further haplotype network analyses of world-wide populations suggested the antiquity of the TBN dominan haplotypes and long-term persistence of the natural selection. Finally, a "dominant haplotype carrier" hypothesis could describe the role of the two genes in HAA. Our results indicate that HIF2A and HIFPH2 are most likely responsible for HAA of Tibetans. We suggest that the natural selection on the two genes should be ancient, long-term persistant and ongoing.

1512/T

Research into Association between Periodontal Diseases and Mannose-Binding Lectin Gene Polymorphisms. *K. Erciyas[1], T. Sever[2], K. Ustun[1], S. Pehlivan[2].* 1) Gaziantep University, Faculty of Dentistry, Department of Periodontology,Gaziantep, Turkey; 2) Gaziantep University, Faculty of Medicine, Department of Medical Biology, Gaziantep, Turkey.

Mannose-Binding Lectin (MBL) is an acute phase reactant with an important duty in activating the classical complement pathway and phagocytes in natural immunity. This study aimed to investigate whether there was any difference in the MBL gene polymorphisms between individuals with different periodontal diseases and healthy individuals and to evaluate its relationship with periodontal clinical parameters. This study was conducted on 167 voluntary individuals in total, individuals diagnosed with Gingivitis (39), Aggressive (37) and Chronic (57) Periodontitis as well as periodontally healthy individuals (34). Periodontal conditions of all individuals in the study were detected by measuring probing depth, clinical attachment level, plaque index, and gingival index. MBL gene in the DNA samples isolated from peripheral blood was investigated using the PCR-RFLP method. The results were analyzed comparing both patient groups and the control group and clinical parameters. When the MBL gene polymorphism was compared in terms of allele and genotype frequencies in control and patient groups, no significant association was observed, whereas when compared in terms of Hardy-Weinberg Equilibrium (HWE), a deviation was observed in the Aggressive Periodontitis group only. Moreover, no significant association of the MBL polymorphism could be detected in terms of age, sex and clinical parameters. In conclusion, it was detected that there was no significant association between MBL gene polymorphism and Periodontal diseases in terms of allele and genotype frequencies or clinical parameters but it was necessary to work on more samples in Control and Aggressive Periodontitis groups as presence of some deviation from HWE was detected in Aggressive Periodontitis patient group.

Mexican Republic is a country with diverse historical, cultural and linguistic characteristics, due to the pluriethnic legacy from a large number of native Amerindian groups, the Spaniard colonization (1519), the arrival of African slaves, and many other historical events such as the French intervention (1861-1867). The application of DNA fingerprinting in forensic/criminal cases and paternity testing is increasing worldwide. Most DNA typing applications have legal and ethic implications. Therefore there is a particular need to generate descriptive population statistics as well as forensic and paternity parameters, in order to have a reliable database. A Mexican mestizo population study (n=1640), was performed on the loci D8S1179, D21S11, D7S820, CSF1PO, D3S1358, TH01, D13S317, D16S539, D2S1338, D19S433, vWA, TPOX, D18S51, D5S818, FGA and a portion of the X-Y homologous gene Amelogenin for gender determination using AmpFISTR Identifiler® kit and capillary electrophoresis. We determine allele and genetic frequencies, and evaluate STR technology for developing a Mexican DNA database with forensic and paternity aims using Genètix, Arlequin, Fstat, and Powerstat (Promega corporation) softwares. We found that D2S1338, D18S51, and FGA are the most polymorphic and informative loci. In summary, overall 15 loci show a high forensic efficiency with a power of discrimination close to 1, with the capacity to genetically discriminate one individual in one quintillion (1/1018). We observed an important Hardy-Weinberg departure, only 3 out of the 15 loci are in equilibrium, with a high inbreeding coefficient. The Mexican mestizo population analyzed data appears significantly different (p=0 in each one of the 15 loci) to a previously published Spaniard population data. In conclusion, this database potentially validate the use of these 15 STR loci to established the forensic identity and parentage testing for legal purposes, and offers a powerful tool for genetic variation analysis.

Comparison of TPH2 sequence variability among Taiwan aboriginal populations: Application on association study of schizophrenia. *Y.M.J. Lin[1], S.C. Chao[2], C.H. Chen[3], H.S. Sun[4].* 1) Institute of Biomedical Sciences, National Chung Hsing University, Taichung Taiwan; 2) Department of Obstetrics and Gynecology, National Cheng Kung University Hospital, Douliou Branch, Yunlin, Taiwan; 3) Institute of Human Genetics, Tzu-Chi University, Hualien, Taiwan; 4) Institute of Molecular Medicine, National Cheng Kung University Medical College, Tainan, Taiwan.

Genetic differences exist among human ethnic populations address an important issue in biomedical studies, and has been considered to be a distinct problem for evaluating risk factors and the prognosis/treatment of various diseases. Taiwan has heterogeneous groups of people including several aboriginal populations that account for 1.5% of present Taiwan's population. Aborigines in Taiwan suffer from the disparity of health behavior and medical access with the major Chinese Han population. For example, higher prevalence of some psychiatric diseases, like alcoholism, drug abuse and suicide have been reported in aborigines. Therefore, the well characterized genetic feature of candidate target gene in particular ethnic group is very important for genetic studies of these diseases in Taiwan aboriginal groups. Tryptophan Hydroxylase 2 (TPH2), the rate-limiting enzyme for the biosynthesis of serotonin in the central nervous system, is the most promising candidate gene in CNS-related diseases including psychiatric disorders. This study was designed to characterize genetic information of TPH2 in Taiwan aboriginal groups. Five Single Nucleotide Polymorphisms (SNPs) of TPH2 that were previously identified in Taiwan's Han Chinese population are selected to be characterized in three aboriginal populations, Ataya, Amis and Bunun. Our results showed that most of the SNPs exist in all populations with different allelic frequencies except the functional C2755A was only observed in Amis. Based on the TPH2 genetic information, we further revealed that Ataya individuals are more distant from Amis and Bunun, and this result is consistent with previous studies of genetic relationship between Taiwan aboriginal groups. Take advantage of profiled TPH2 genetic information and based on the potential role of serotonin in schizophrenia etiology, we also pretest the association between TPH2 gene and schizophrenia in Amis and Ataya. Preliminary result showed significantly haplotypic association between TPH2 and schizophrenia in Ataya, but not in Amis. Results from this study provide an essential profile that will be useful for further genetic studies related to TPH2 in Taiwan aboriginal groups.

MEFV, TNFRSF1A and CARD15 mutation analysis in Behcet's Disease. *A. Mory[1], Y. Baruch[2], E. Dagan[1,3], M. Rozenbaum[4,5], F. Massimo[2], R. Gershoni-Baruch[1,5], I. Rosner[4,5].* 1) Inst of Human Genetics, Rambam HealthCare Campus, Haifa, Israel; 2) Dept of Clinical Medicine, University of 'La Sapienza', Rome, Italy; 3) Dept of Nursing, University of Haifa, Haifa, Israel; 4) Dept of Rheumatology, Bnei-Zion Medical Center, Haifa, Israel; 5) The Ruth and Bruce Rappaport Faculty of Medicine, Technion-Institute of Technology, Haifa, Israel.

Given the pathological similarities between Behcet's disease (BD), Familial Mediterranean fever (FMF), TNF receptor-associated periodic syndrome (TRAPS) and Crohn's disease (CD) we studied the rate of mutations and polymorphisms in MEFV, TNFRSF1A and CARD15 in Israeli BD patients compared to an ethnically matched control population. Fifty-four BD patients (11 Jews and 43 Arabs), evaluated with respect to the entire spectrum of BD disease manifestations, were granted a systemic severity score for BD. An association between BD manifestations and MEFV, TNFRSF1A and CARD15 variants was analyzed. Twelve patients (20.7%) displayed a single MEFV mutation and four patients (7.4%) had two mutated FMF alleles. Two patients (3.8%) carried a CARD15 variation and none carried a TNFRSF1A polymorphism. The frequency and distribution of mutated alleles between patients and controls was comparable (p=0.27). No statistically significant differences between carriers and non-carriers with respect to disease manifestations and severity score were calculated. Arab patients were diagnosed earlier than Jewish patients (25.8±11.6 and 37.2±10.7, respectively, p= 0.06). The overall MEFV high carrier frequency in our cohort of BD patients seems to be attributed to their Mediterranean extraction rather than related to BD. The propensity of Arab patients (79.6%) in a cohort of BD patients from Northern Israel is highlighted in face of their proportion (20%) in the general population lending further support to arguments that favor a genetic component for BD.

1516/T

Analysis of 17 Y-chromosomal STR loci in the Iranian population. *N. Amini[1], M. Sharafi Farzad[1], M. Tavallaie[2], S. Zeinali[1,3].* 1) Kowsar Human Genetic Research Center, Tehran, Iran; 2) Genetic Research Center, Baqiyatallah Medical Science University, Tehran, Iran; 3) Dept of Mol. Med. Biotech Research Center, Pasteur Institute of Iran, Tehran.

Introduction One of the smallest human chromosomes is the Y chromosome with an average size of 60 Mb. Exchanges is limited to small pseudoautosomal regions of the X-Y pair between X and Y chromosomes in the meiosis. The Y chromosome in most of its length is male-specific and effectively haploid and is transmitted from father to his son unchanged unless a mutational event takes place. Y chromosome-specific STRs have proved to be an important tool in paternity cases, especially when the alleged father is deceased, as well as forensic and non-forensic fields. Materials and methods Blood samples were collected from 129 randomly selected, unrelated Iranian males, following procedures that are in accordance with Promega kit and FTA Cards. All 17 (DYS19, DYS389I, DYS389II, DYS390, DYS391, DYS392, DYS393, DYS385a/b, DYS438, DYS439, DYS437, DYS448, DYS458, DYS456, DYS635, and Y-GATA-H4) markers were co-amplified using the AmpFlSTR Y-filerTM PCR Amplification kit(Applied Biosystems, USA).The amplified products were separated by capillary electrophoresis on ABI Prism 3130 XL Genetic Analyzer. The sample run data were analyzed by GeneMapper IDX Software V. 1.0. Allelic frequencies were estimated by direct counting. To determine of haplotype diversity and the other parameters we use Arlequin software ver 3.1 and also the online AMOVA tool from YHRD.org3.0 for y-STR haplotyping. Results Allele frequencies in our study are similar to reported allele frequencies in Iranian population on Y-STR haplotype databases. We observed 123 different haplotypes. Total haplotype diversity was 0.9996. In this study we found some new mutation as off-ladder which most of them are located on DYS458 marker and tow duplication in DYS392 and DYS393 markers. Among the 17 markers analyzed, DYS385 and DYS389II were calculated to be the highest and DYS448 lowest values for allelic range. Conclusion we used 17Y-STR markers and providing further population data for Iranian men.The Y-chromosome structure in men from Iran is very diverse. Combination of Y chromosome 17 STR loci may be used as a powerful tool for individual identification and parentage analysis in the Iran male population.

1517/T

Signatures of founder effects, admixture and selection in the Ashkenazi Jewish population. *S. Bray[1], J. Mulle[1], A. Dodd[1], A. Pulver[2], S. Wooding[3], S. Warren[1].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD; 3) The McDermott Center for Human Growth and Development, University of Texas Southwestern Medical Center, Dallas, Texas.

The Ashkenazi Jewish (AJ) population has long been viewed as a genetic isolate, yet despite decades of population genetic studies, we still lack definitive evidence of founder events or positive selection. Here we analyzed a large AJ cohort and found higher linkage disequilibrium (LD) and identity-by-descent, as expected for an isolate. However, paradoxically we also found higher genetic diversity relative to Europeans, a sign of an older or more admixed population but not of a long-term isolate. Further analysis indeed revealed higher than expected levels of admixture with Europeans, likely accounting for the increased genetic variation. Moreover, we demonstrate that admixture also correlates with high LD, suggesting that the AJ population has undergone gradual admixture with neighboring populations, increasing both its genetic diversity and LD, yet still maintaining some shared haplotypes from founding events. Additionally, we applied extended haplotype tests to determine whether positive selection can account for the level of AJ-prevelant diseases. We identified genomic regions under selection that account for lactose and alcohol tolerance in the AJ population, and while we found evidence for positive selection of some loci responsible for AJ-prevalent genetic diseases, the higher incidence of the majority of these loci is likely the result of genetic drift. Thus, the AJ population shows some evidence of past founding events, however, admixture and selection have also strongly influenced its current genetic structure.

Effective Prediction of HLA Alleles Using SNP Data for a Han Chinese Population. *S.W. Chang[1], P.L. Chen[2,3], T.C. Chang[3,4], C.S.J. Fann[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 3) Division of Endocrinology & Metabolism, Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 4) Department of Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan.

Genetic variation at classical human leukocyte antigen (HLA) loci has played an important role in the regulation of fundamental molecular or cellular processes and susceptibility to various diseases. Direct typing of HLA alleles can provide insights into complex associations among genomic structure, SNP variation and variation at respective alleles. However, the excessive cost has compelled researchers to adopt more economical approaches. A new statistical methodology developed by Leslie et al. (2008), along with HapMap individuals typed at classical HLA loci and SNPs within the MHC region, was shown to successfully predict allelic status with up to 95% accuracy. It was claimed that by utilizing a database of 300 haplotypes from African and Caucasian family trios, a set of ~100 SNPs was satisfactory for predicting HLA alleles at all loci in any population. In this study, we modified Leslie et al.'s algorithm and reshaped the models to allow for more flexibility in SNP selection and for more efficient prediction. We used Illumina HumanHap550K and Affymetrix 500K SNP data within the MHC region and predicted alleles at 6 HLA loci (HLA-A, -B, -C, -DPB1, -DQB1 and -DRB1) for the sample of 210 unrelated Han Chinese individuals residing in Taiwan. Our results indicated that a single panel of 164 SNPs typed across the region was sufficient for predicting HLA alleles at 6 loci with up to 98% accuracy at 4-digit resolution in the Han Chinese population. In comparison to previous findings, we observed that different sets of prediction SNPs were specific for different populations. We validated the methodology with a cohort of 227 unrelated Han Chinese individuals. Sensitivity, specificity, and the false discovery rate were evaluated. In conclusion, with a small number of SNPs genotyped in a population, the effective prediction algorithm provides a low-cost alternative to direct typing of HLA alleles. Moreover, the specific prediction SNP sets in different populations may aid in future medical diagnosis and drug prescription when HLA allele information is essential.

Population differentiation as a test for soft sweeps on standing genetic variation. *H. Chen[1,2], N. Patterson[2], D. Reich[1,2].* 1) Dept Gen, Havard Med Sch, Boston, MA; 2) Broad Institute of MIT and Harvard, Boston MA.

Recent studies have suggested that adaptations to environmental change in human populations in the past 10,000 years may have occurred in part as a "soft sweep", that is selection on standing genetic variation. A number of statistical methods have been developed for detecting selective sweeps on newly arising genetic variants but a concern is that almost all have low power for soft sweeps. This is because the population genetic model for selective sweeps underlying these methods assumes that causal mutants under selection started from a single copy ("hard sweeps"), and soft sweeps generate a genetic polymorphism pattern that is strikingly different from classical signatures of hard sweeps. We propose a method that can detect soft sweeps efficiently, which is based on analysis of the haplotype differentiation patterns across populations. We incorporate haplotype patterns from reference populations (which presumably did not experience selection) as an approximation of the haplotype structure around the selected standing variant before selection. We then use population genetic theory to explicitly model the effect of a soft sweep on the allele frequencies of the nearby SNPs (single nucleotide polymorphisms). This approach can capture the characteristic genetic polymorphism patterns caused by soft sweeps and it achieves much better power compared with existing methods. We apply our method to several genome-wide SNP array data sets, including comparisons of Africans to non-Africans, and also northern to southern Europeans. Our method assumes that the selected variants are genotyped in the data set and thus can be expected to work substantially better on resequencing data. In addition to providing a new method for scanning for soft sweeps, our work also demonstrates that investigating the impact of natural selection in multiple populations simultaneously can provide insights about selection that would not be accessible in any one population.

Collection of peripheral blood mononuclear cells obtained from Amerindians and other Mongoloid minority groups. *I. Danjoh[1], K. Saijo[1], S. Oota[2], K. Fukami-Kobayashi[2], Y. Nakamura[1].* 1) Cell Engineering Division, RIKEN BioResouce Center, Tsukuba, Ibaraki, Japan; 2) Bioresource Information Division, RIKEN BioResource Center, Tsukuba, Ibaraki, Japan.

<Objectives>

Ancestors of Amerindians migrated from Eurasian continent to North American continent via Bering Strait, and then migrated to South American continent over 10 thousand years ago. If human geneticists tried to find out their origin in Eurasia and to trace their migration path(s) with genetic methods, it has been difficult to obtain sufficient number of tissue or cell samples. Dr. Sonoda who has been a professor at Kagoshima University in Japan and Dr. Tajima who is the director of Aichi Cancer Center Institute in Japan had spent nearly 30 years to collect blood samples from more than 3,000 individuals of Mongoloid minority groups around the world, mainly the individuals living in South America. This cell collection was donated to RIKEN BioResource Center. No other cell banks in the world possess such a collection.

We are establishing B lymphoblastoid cell lines (BLCL) by Epstein-Barr virus (EBV) infection using the donated samples. We have recently started to provide with the BLCL together with the information such as age, gender, tribes, and localities of the individuals who each BLCL was derived from, and also relationship between individuals.

To evaluate how Amerindian populations diverse with each other, we analyzed genetic similarities between tribes and localities using this collection.

<Methods>

We analyzed short tandem repeat (STR) polymorphism regarding 8 different loci using PowerPlex 1.2 Systems (Promega). The BLCL derived from 200 Amerindians and 152 Japanese were subjected to the analysis. Allele frequencies were compared between Amerindians and Japanese, and among Amerindian groups.

<Results and Conclusion>

Significant differences of allele frequency were observed between Amerindians and Japanese. In addition, difference was observed among Amerindians such as between individuals in the Andes and Amazon area. Japanese group showed similarities with Amazon area. These data provide basic information on genetic bias for each tribe among Amerindian populations.

Human genetic differentiation from HapMap data. *E. Elhaik, A. Chakravarti.* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Apportionment of human genetic variation has long established that most human variation is within groups and that the additional variation between groups is small but greatest when comparing continental populations. These studies have used Wright's F_{ST} that apportions the standardized variance in allele frequencies within and between groups in a hierarchical manner. High values of F_{ST} are unlikely in humans due to genetic drift and migration and are consequently used to identify genes undergoing directional or heterotic selection. The availability of the HapMap data from phases I - III now allows us to reexamine these questions. We analyzed data on ~3 million autosomal, X-linked, Y-linked, and mitochondrial SNPs from the HapMap database on 602 samples from 8 populations and a common subset of ~1 million autosomal and X-linked SNPs that have been genotyped in all populations. We identified two major features of the data. First, only a paucity (12%) of the total genetic variation is among populations of different continents and even a lesser (1%) amount among populations of the same continent. These data are remarkably consistent with the early observations of Lewontin in 1972. Second, we demonstrate that, although the overall distribution is similarly shaped (inverse J), the distribution of F_{ST} varies significantly by mean allele frequency. Since the mean allele frequency is a crude indicator of allele age, these distributions mark the time-dependent change in genetic differentiation. The change in mean F_{ST} of these distributions is linear in mean allele frequency suggesting the nature of allele frequency dynamics. These observations are true for autosomal, X-linked, and mitochondrial SNPs, but not Y-linked SNPs. These results suggest that investigating the extremes of the F_{ST} distribution for each allele frequency class may be more efficient for detection of selection. Consequently, we demonstrate that such extreme SNPs are more clustered that that expected from linkage disequilibrium for each allele frequency class. These genomic regions are likely candidates for natural selection.

1522/T

Demography and History Shape Risk Factors in a Large Genome-Wide Study of U.S. Hispanics. *C. Gignoux, M. Via, D. Hu, C. Eng, D. Torgerson, E. Gonzalez Burchard.* UCSF, San Francisco, CA.

In the U.S., asthma prevalence, morbidity and mortality are highest in Puerto Ricans and lowest in Mexicans, although both are considered part of the same ethnic group - "Hispanic" or "Latino." Although there are many potential explanations for disease discrepancies between ethnic groups, including social and environmental factors, the genetic diversity of Latino populations provides the intrinsic variability necessary to untangle the genetic component of disease susceptibility. Here we demonstrate the importance of demography and the heterogeneous process of admixture in the Genetics of Asthma in Latino Americans (GALA) study, which includes 700 parent-child trios and 500 controls from both Mexico and Puerto Rico genotyped on the Affymetrix 6.0 platform. For each individual, we leveraged genome-wide polymorphism data to estimate ancestry at each locus to infer ancestry, and increase the genetic information beyond simply genotypes. Genomic admixture mapping yielded a unique association between locus-specific European ancestry and disease risk for each population within GALA. Specifically, Puerto Ricans with European ancestry at 16p12 are protected against asthma, while Mexicans with European ancestry at 7q31 are at increased risk for asthma (both $p<5x10^{-4}$). In order to further characterize these loci, and to understand why European ancestry confers varying risk in Puerto Ricans and Mexicans, we extend beyond traditional continental admixture models to investigate the distribution of ancestral European haplotypes in modern-day Hispanic/Latinos. Moreover, we investigated the biogeographical origins of population-specific risk variants in the Americas giving rise to modern-day Hispanic/Latino populations, and in doing demonstrated the importance of incorporating demographic inference in a genome-wide association studies of diverse human populations. .

1523/T

Genetic Admixture and Population Substructure Patterns in Hispanic Populations: Implications for Disease-Gene Association Studies in Schizophrenia. *S. Gonzalez[1, 2], A. Compean[3], A. Figueroa[3], L. Morales Smith[4], B. Cheng[2], R. Leach[2], J. Ge[5], R. Chakraborty[5], A. Ontiveros[6], H. Nicolini[7], M. Escamilla[1].* 1) Dept. of Psychiatry, Texas Tech University Health Science Center, El Paso, TX; 2) Dept. of Cellular and Structural Genetics, University of Texas Health Science Center, San Antonio, TX; 3) Department of Computer Science, University of Texas-Pan American, Edinburg, TX; 4) UT-Health Science Center at San Antonio, Regional Academic Health Center, Edinburg, TX; 5) Institute of Investigative Genetics, University of North Texas Health Science Center, Fort Worth, TX; 6) Instituto de Informacion de Investigacion en Salud Mental, Monterrey, Mexico; 7) Medical and Family Research Group, Caracci S.C., Mexico City, Mexico.

Genetic admixture and population substructure patterns were examined among three distinct geographical Hispanic populations to determine if sample sets from them could be combined for future population-based disease-gene association studies of schizophrenia. A panel of 75 ancestral informative markers (AIMs) was used to genotype unrelated control samples from the Lower Rio Grande Valley of Texas, USA (N=110), Mexico City, Mexico (N=25) and Monterrey, Mexico (N=21). Genetic structure was evaluated via AMOVA. F_{ST} analysis revealed no significant differences among the three Hispanic control groups (F_{ST}=0.0027, P-value = 0.088) or at any individual AIM locus after adjustment for multiple testing. A subset of 55 AIMs was used to compare genotypes between the control samples and schizophrenia subjects. Sample sizes for affected subjects were 38, 55, and 42, respectively for the three populations. Significant differences were detected among cases vs controls within each Hispanic population (F_{SC}=0.0099, P-value < 0.05) and among affected subjects across the three population groups (F_{ST}= 0.0128, P-value < 0.05). These results can be explained by significant differences in six of the 55 AIMs, after multiple testing adjustments. This implies that there is an ancestral contribution to the schizophrenia subgroups within as well as between these three Hispanic populations. All of these observations were consistent with the STUCTURE analysis of the data. Together, these imply that the three populations can be merged to investigate disease-gene association for schizophrenia because of no significant differences of genetic variation between the control samples of these populations. However, since significant ancestry differences were noticed between cases and controls as well as between populations within the cases, any disease-gene association statistic should be adjusted for ancestry specific admixture differences of each subject of these populations.

1524/T

Population Genetic Analysis of a Large Ashkenazi Jewish Cohort. *S. Guha[1], J. Rosenfeld[1], I. Pe'er[2], A. Darvasi[3], A. Malhotra[1], T. Lencz[1].* 1) Division of Psychiatry Research, The Zucker Hillside Hospital, The Feinstein Institute for Medical Research, North Shore - Long Island Jewish Health System, New York, NY; 2) Department of Computer Science, Columbia University, New York, NY; 3) Department of Genetics Institute of Life Sciences, Hebrew University of Jerusalem, Givat Ram, Jerusalem, Israel.

The abundance of high resolution, genome wide SNP data has provided novel insights in to the origin and structure of many population isolates. Traditionally these isolated populations with less genetic diversity have been considered ideal for whole genome association mapping in disease genetics. The Ashkenazi Jewish population represents a unique population for study based on its recent (<1000 year) history of a limited number of founders, population bottlenecks, and tradition of endogamy. While population history has been inferred from examination of Y chromosome and mitochondrial DNA, few population genetic studies in Ashkenazim have utilized genome-wide autosomal markers. Utilizing a large sample (n>1000) of Ashkenazi healthy controls from the Hebrew University Genetic Resource (HUGR), genotyped with the Illumina 1M platform, we compared Ashkenazi subjects to other neighboring populations (European and Asian), and sought to identify fine-scale population structure within this cohort. Analysis in STRUCTURE was conducted using 810 European substructure ancestry informative markers (ESAIMs) to compare the Ashkenazi subjects with European, Middle Eastern and Central Asian populations derived from HGDP-CEPH database. The optimal solution (k=5) separated the Ashkenazi Jewish cohort from European, Central Asian, and Middle Eastern populations, and revealed a cline within the Ashkenazi population. The principal component analysis with ~ one million markers only for Ashkenazi subjects suggest strong correlation with the diversity at Major Histocompatibility Complex (MHC) locus (6p22.1 - 6p21.3) at the top 5 principal components. Other than MHC locus, a region on chromosome 4p16.1 also emerged. Findings are relevant for understanding Ashkenazi population history, as well as for the interpretation of disease mapping studies conducted in this population.

1525/T

An unbiased SNP array for population genetics using the Axiom™ Genotyping Solution. *E. Hubbell[1], S. Mallick[2,3], N. Patterson[3], D. Reich[2,3].* 1) Affymetrix, Santa Clara, CA. 95051; 2) Harvard Medical School Department of genetics, Boston, MA 02115; 3) Broad Institute of Harvard and MIT, Cambridge, MA 02142.

A major goal in analyzing human genetic variation is to use the data to learn about human history: population expansions, contractions and migrations. While array genotyping of hundreds of thousands of SNPs simultaneously is in theory a powerful tool for these studies, a limitation is that arrays to date have also been designed for medical genetics, with the SNPs chosen in a very complicated way that results in bias in inferences about history.

Following the Keinan et al. Nature Genetics 2007 paper, a clean ascertainment strategy is to discover SNPs in a comparison of two chromosomes from the same individual of known ancestry. This should produce a panel of SNPs whose false-negative rate is unaffected by their frequency in the population, so that allele frequency spectrum analysis can be carried out simply after making a simple correction for discovery in two chromosomes. We are screening a set of such panels for validation in the Axiom genotyping assay to produce markers that achieve good genotyping performance. The validated set, from which we expect to have a commercially available array by early 2011, will be a union of such panels of SNPs, one for each individual of diverse ancestry used in discovering SNPs. We aim to obtain at least one hundred thousand SNPs from each ascertainment to produce powerful inferences about history.

An important feature of the array is that we are extraordinarily careful regarding the technical details of validating SNP performance. The validation procedure we use is blinded to prior knowledge about which probes have worked well in previous Axiom screening assays, as using this information would result in a higher success rate for probes that have been previously tried on SNP arrays, re-introducing complex biases into the ascertainment. Similarly, the oligonucleotide probes are designed based entirely on flanking sequence from the same individual, to avoid bias due to the ancestry of the human reference sequence. Finally, to avoid ascertainment bias based on population frequency, we only use information from replication of the sample in which a SNP was discovered and samples outside the human population (chimp and gorilla) to verify acceptable separation of genotype clusters.

The Genetic Canvas of European Roma. *M. Karmin[1], M. Baldovi[2], N. Jeran[3], S. Cvjetan[4], M. Reidla[1], T. šaric[3], J. šarac[3], M. Cenanovic[6], A. Leskovac[5], D. Marjanovic[6], H.D. AuguŽtin[3], A. Ficek[2], G. Chaubey[1], S. Rootsi[1], V. Ferak[2], R. Pavao[3], E. Metspalu[1], D.M. Behar[1], R. Villems[1].* 1) Estonian Biocenter and Department of Evolutionary Biology, University of Tartu, Tartu, Estonia; 2) Comenius University, Bratislava, Slovakia; 3) Institute for Anthropological Research, Zagreb, Croatia; 4) Mediterranean Institute for Life Sciences, Split, Croatia; 5) Vinca Institute of Nuclear Sciences, Belgrade, Serbia; 6) Institute for Genetic Engineering and Biotechnology, Sarajevo, Bosnia.

According to linguistic evidence, the Indian exodus of the ancestors of the European Roma took place most probably around the end of the first millennium. By 13th - 15th centuries, different groups of Roma had spread throughout Europe. Virtual lack of written records prior to their arrival to Europe has left us with scarce knowledge about their historical migratory routes. Therefore, valuable insight may come from archaeogenetic studies. Here we report the results of a combined mtDNA, NRY and autosomal study of the genetic variation of Roma (Gypsies). We have studied variation of close to 600 Roma mtDNAs from six European countries, including 60 complete mitochondrial genomes from various populations of European Roma, India and the Near East. The most common Indian-specific maternal lineage among Roma is M5a1b1. Reaching from 5% to 35% in different Roma communities, it is, at the same time, present in various linguistically, socially and geographically different populations of India. The analysis of complete mitochondrial genomes shows that U3b1 and X2e1 lineages found in Roma have their closest relatives in the Near East and X2d1 lineages in the Caucasus, suggesting that at least a part of their West Eurasian-specific matrilineages has been picked up by the Roma *en route* before reaching Europe. We have analyzed over 250 Y-chromosomes from different Roma communities for their Y-STR and Y-SNP variation. Our results confirm previous studies, identifying NRY hg H1a as a clear sign of the Indian-specific contribution within the Y-chromosomal pool of Roma. Whole genome analysis of Roma, carried out using Illumina BeadArrays in the context of Eurasian and North African populations, revealed that Roma individuals exhibit varied levels of shared South Asian - West Eurasian ancestry. Taken together, our mtDNA, Y-chromosomal and GW analysis of European Roma populations in the context of Indian, Middle Eastern and European populations offers new insights into the demographic history of Roma populations.

1527/T

Detecting Ethnic Differences in DNA Using Inter-chromosomal Paralogous Regions. *R. McCullough[1], R. Tim[1], Å.O.H. Nygren[1], C. Deciu[1], D. van den Boom[2], M. Ehrich[2].* 1) 1Sequenom Center for Molecular Medicine, San Diego, CA; 2) 1Sequenom, San Diego, CA.

The identification of genetic markers that are able to distinguish different ethnic groups is of ongoing interest. While ethnic differences have recently been characterized using single nucleotide polymorphisms (SNPs) and copy number variations (CNVs), no current method is accepted for ethnic classification of DNA. We previously studied the allelic stability of inter-chromosomal paralogous regions and identified over 12,000 paralogous regions in the genome that have high sequence similarity between two different chromosomal loci. We used single base extension in combination with MALDI TOF mass spectrometry analysis to determine the allelic ratios of these loci. Each resulting mass spectrum displays two mass signals representing the two chromosomal locations. The intensity ratio of the two mass signals reflects the ratio between the two chromosomes. Hence we expect a 50/50 ratio when analyzing a normal genome. We analyzed a total of 1862 of such inter-chromosomal paralogous regions in a set of nearly 400 genomic DNA samples. Upon analysis, the resulting data from some regions showed variable degrees of bias between the chromosomes. An unsupervised cluster analysis found that the samples clustered into groups according to their ethnic origin. The subset of markers (n=12) which exhibited the strongest ability to discriminate between ethnic groups was confirmed in a larger population of close to 800 samples in four self-declared ethnic groups. We used next generation sequencing to explore the potential underlying mechanisms which could lead to this ethnic bias. We found in this analysis previously uncharacterized SNPs that were located in the primer binding regions. In addition we explored another potential cause for the observed ethnicity related allelic bias. We performed copy number variation analysis in the regions, since if only one of the regions is duplicated, this could also lead to the observed effect. Although we did detect some new sequence polymorphisms, we did not identify any SNPs that are strongly correlated to the ethnicity of the sample. In the analysis of copy number variations we did find that the regions we are interrogating are subject to copy number changes, which are also strongly correlated with ethnicity. Our data suggests that using paralogous regions located at least partially in CNV regions is a promising tool for developing a simple and cost effective assay for the exploration of the ethnic background of a DNA sample.

A genome-wide survey of the history of the Roma people. *P. Moorjani[1], N. Patterson[2], M. Bonin[3], O. Riess[3], D. Reich[1,2,4], B. Melegh[5].* 1) Dept Gen, Harvard Medical School, Boston, MA; 2) Broad Institute, Cambridge, MA; 3) Department of Medical Genetics, University Tuebingen, Tübingen, Germany; 4) Harvard School of Public Health, Boston, MA; 5) Department of Medical Genetics, University of Pécs, Pécs, Hungary.

Previous linguistic studies, as well as studies of mitochondrial DNA and the Y chromosome, have suggested that the European Roma or Romani people are a group of endogamous founder populations that have inherited genetic material from South Asians. However, no previous studies have been able to characterize the date and proportion of mixture. To understand the origin and population history of the Roma, we have analyzed data for about a million single nucleotide polymorphisms (SNPs) and confirm evidence for their South Asian origin. We prove that the Roma, like other Indian populations, inherit ancestry from both 'Ancestral South Indians' (ASI) and 'Ancestral North Indians' (ANI) that are closely related to West Eurasians. To estimate the date of the mixture, we develop a novel method that uses summary statistics of admixture linkage disequilibrium. We estimate that the average number of generations since mixture is 29 ± 2 generations or about 800 years ago. In addition, we characterize the effect of founder events by calculating a genomic measure of individual homozygosity. We observe that the Roma have significantly higher autozygosity compared to other European populations, which likely contributes to the higher prevalence of recessive disorders seen in this population.

Brazilian Afro-derived communities: genetics and history reconstruction. *S. Oliveira[1], CC. Gontijo[1], CEG. Amorim[1,2], GGBL. Ribeiro[1], G. Falcão-Alencar[1], MAF. Pedrosa[1], RCP. Toledo[1], MR. Luizon[3], RW. Pereira[1], RM. Neto[1], LB. Ferreira[4], AL. Simões[3], CT. Mendes Júnior[3], MN. Klautau-Guimarães[1].* 1) Laboratório de Genética, Universidade de Brasília, Brazil; 2) Programa de Pós-graduação em Genética e Biologia Molecular, UFRGS, Brazil; 3) Universidade de São Paulo, Campus Ribeirão Preto, Brazil; 4) Cátedra Unesco de Bioética, Universidade de Brasília, Brazil.

During the slavery period in South America, fugitive or freed slaves founded rural semi-isolated Afro-derived communities as a form of resistance against slavery. Some of these communities still exist in South America, nourishing the same traditions from their foundation time, and in Brazil they are known as Remanescentes de Quilombo. Yet, the genetic constitution of these Brazilian Afro-derived communities is barely known. The aim of this study was to obtain an overview of the current genetic composition, especially concerning African, European and Amerindian parental contributions, in four Brazilian Afro-derived communities - Mocambo, Rio das Rãs, Kalunga and Riacho de Sacutiaba. We investigated biparental markers - 16 autosomal Ancestry Informative Markers (AIMs) and 8 STRs - and uniparental markers - 12 Y-STRs, mtDNA and Y haplogroups, and 6 X-linked Indels - in over 280 individuals from the four communities listed. African parental contribution based on autosomal AIMs was the highest for all the communities evaluated herein, although Amerindian and European contributions were also present. Regarding autosomal STRs, some differences were observed in comparison to AIMs, but no clear pattern was noticeable. Data from the Y chromosome, both STRs and haplogroups, indicate a high European contribution and a virtually absent contribution from the Amerindian parental group. Differently, data from the female profile (mtDNA) showed a high African contribution and an absence of European lineages in our samples. This result was further confirmed by the data from the X chromosome, which showed an absence of European contribution and a high African contribution in these four populations. The data presented herein indicate that, despite years of contact, these communities still maintain a higher African ancestry than urban and rural Brazilian populations of admixed descent. Yet, our data has strongly suggested that the admixture process has indeed occurred over generations. We could also observe that men were the major responsible for the insertion of European alleles, and women for the insertion of Amerindian ones. This is supported by historical data of asymmetrical matings among the parental groups in Brazil. This study was funded by CNPq, CAPES and Finatec.

Inference of Recent Demographic Events Based On Haplotype Sharing. *P.F. Palamara, G. Aponte, I. Pe'er.* Department of Computer Science, Columbia University, New York, NY.

Much progress in Population Genetics has been achieved under the assumption of unlinked markers. While this assumption is reasonable for ancient demography, relationship between contiguous markers can assist investigation of recent demographic changes. Furthermore, models for the modern diversification of a population are currently motivated by large-scale sequencing projects, where the decision of sequencing a small set of representative individuals may significantly reduce the costs. Patterns of Linkage Disequilibrium and, more recently, shared long-range haplotypes identical-by-descent (IBD), have been recognized as a signature of recent demographic events. We use these to reconstruct population parameters of the extremely recent demographic history. We develop a model to quantify the expectation on IBD sharing for different demographic scenarios. Specifically, we estimate the proportion of the Genome expected to be spanned by IBD segments in a particular length interval in the coalescent process, as a function of a population's demographic parameters. The expectation has a closed form in a Wright Fisher model, and an infinite (approximable) sum in more complex models. We use this expectation for several length intervals to guide the inference of a population's demographic parameters. Formally, we employ a hill climbing procedure in order to minimize the deviation between expected and observed levels of IBD sharing across multiple intervals of segment lengths. The accuracy of our method is confirmed using realistic coalescent simulations, where the model is used to recover a population's demographic history such as recent effective population size or bottleneck parameters (e.g. bottleneck timing, size of current and ancestral populations under exponential expansion). We apply our method to two real data sets of densely typed individuals: 1,200 Ashkenazi Jewish (AJ) subjects from the US and 56 Maasai subjects from Kenya. We reconstruct a severe bottleneck event in the AJ population about 23 generations before present, followed by the fast expansion of few hundred ancestral individuals to hundreds of thousands of contemporary N_e. This is consistent with both historical records and estimates of sample sizes for population sequencing in AJ. An opposite trend is observed in the Massai samples, for which our model suggests a very large ancestral population quickly decreasing to current few hundreds.

Evaluation of the HapMap dataset as reference for the Greek population. *P. Paschou[1], I. Karagiannidis[1], A. Tsirigoti[1], A. Stampoliou[1], V. Papadopoulou[1], V.G. Manolopoulos[2], J.R. Kidd[3], K.K. Kidd[3], P. Drineas[4].* 1) Dept. of Molecular Biology & Genetics, Democritus University of Thrace, Alexandroupoli, Greece; 2) Laboratory of Pharmacology, Medical School, Democritus University of Thrace, Alexandroupoli, Greece; 3) Dept. of Genetics, School of Medicine, Yale University, New Haven CT, USA; 4) Dept. of Computer Science, Rensselaer Polytechnic Inistitute, Troy NY, USA.

The HapMap project has provided a unique tool for the analysis of human genetic variation, providing reference information for allele frequency and genotype distributions as well as linkage disequilibrium patterns of Single Nucleotide Polymorphisms (SNPs) across the entire genome. The latest release of HapMap phase 3 data provides genotypes for millions of SNPs in 11 populations from around the world, with Europe being represented by the CEU (originating from Northwestern Europe) and the TSI populations (Tuscan Italians from Southern Europe). Although initial studies support the fact that the CEU can be used as reference for the selection of tagging SNPs in other European populations, a critical step in the design of genetic association studies, this hypothesis has not been extensively studied across Europe and in particular in Southern Europe. We set out to explore the extent to which the HapMap populations can be used as reference for a previously unstudied population of South-Eastern Europe, the Greek population. To do so we studied genomic variation in 1,813 SNPs, genotyped by our group in 56 individuals of Greek origin, and compared them to the CEU and TSI genotypes (1,813 SNPs from the CEU HapMap dataset and 1,205 from the TSI dataset). The studied SNPs are spread over 13 autosomal chromosomes and 26 regions, ranging in size from 120Kb to more than 4Mb. Genotype, allele frequency, and pairwise LD measures were compared across all three populations. PCA was used in order to identify those markers that are responsible for the observed inter-sample variance. Tagging SNPs were selected in the CEU and TSI samples and their transferability to the Greek population was tested, using both the r2 metric as well as the efficiency of genotype imputation of the non-selected SNPs. Our results demonstrate that, although the CEU population can to some extent be used as reference for the Greek population, it is preferable to use as reference a European population of closer genetic ancestry, like the TSI. These results are applicable in medical genetics, in order to inform the design of genetic association studies, as well as in studies of evolutionary relationships of Southern European populations.

1532/T

Inference of unexpected genetic relatedness among HapMap Phase 3 individuals. *T.J. Pemberton[1], C. Wang[2], J.Z. Li[1], N.A. Rosenberg[1,2].* 1) Department of Human Genetics, University of Michigan, 100 Washtenaw Avenue, Ann Arbor, Michigan 48109 USA; 2) Center for Computational Medicine and Bioinformatics, University of Michigan, 100 Washtenaw Avenue, Ann Arbor, Michigan 48109 USA.

The International Haplotype Map Project ("HapMap") has provided a widely used resource on human genetic variation. Phase I and Phase II of the HapMap project generated genotype data across >3 million SNP loci in 270 individuals representing four populations. Phase III provides dense genotype data generated by the Illumina Human 1M and the Affymetrix SNP 6.0 platforms on ~1.5 million SNPs. Release 3 of Phase III of the HapMap is comprised of 1,397 individuals from 11 populations, including 250 of the original 270 Phase I and Phase II individuals and an additional 1,127 individuals. While some known relationships among the Phase III individuals have been described in the data release, the genotype data that are currently available provide an opportunity to empirically ascertain previously unknown relationships. We performed a systematic analysis of genetic relatedness and were able to not only confirm previously described relationships, but also to detect additional, previously unidentified pairs of close relatives in Release 3 of Phase III of the HapMap. The inferred relative pairs make it possible to propose standardized subsets of unrelated individuals for use in future studies in which relatedness needs to be clearly defined.

Using community-based participatory research methods to link gene discovery and translation in a large founder population in rural mid-Michigan. *D.L. Schutte[1,4,6], J.D. Bonner[4], R.A. Fisher[3], J. Rivard[2], C. Wei[5], Q. Lu[5], K.H. Friderici[2,3,6], J.L. Elfenbein[7], E. Wilch[6], B.C. Schutte[2,3,4,6].* 1) College of Nursing, Michigan State Univ, East Lansing, MI; 2) Microbiology and Molecular Genetics, Michigan State Univ, East Lansing, MI; 3) Pediatrics and Human Development, Michigan State Univ, East Lansing, MI; 4) Comparative Medicine and Integrative Biology, Michigan State Univ, East Lansing, MI; 5) Epidemiology, Michigan State Univ, East Lansing, MI; 6) Genetics PhD Program, Michigan State Univ, East Lansing, MI; 7) Communicative Sciences and Disorders, Michigan State Univ, East Lansing, MI.

Common health conditions result from the combined effects of genetic and environmental factors. The contributing genetic factors may be discovered more easily in founder populations due to their relative genetic homogeneity. The purpose of this report is to describe an academic-community research partnership, using community-based participatory methods, between our institution and a German Catholic community in rural mid-Michigan. Our long-term goal is to foster gene discovery in a way that promotes wellness for community partners and that fosters scholarship for academic partners. Previously, we identified individuals in this community with an autosomal recessive form of hearing loss and found known and novel causative mutations in the *GJB2* gene. Since the community was isolated by language and religion, we hypothesized that they were highly related. We built a genealogical database (N= 28,256 records) that includes the descendants and ancestors of persons who are deaf from the region, including the community founders, to estimate kinship. We used Pedhunter to cluster individuals into 310 discreet family units. However, 27,747 individuals (98%) were assigned to a single remarkable pedigree. Kinship was estimated using F(ped) and F(isonymy). We observed that, in the contemporary generation, 44% of offspring occurred from parents who share a common relative. The F(ped) value was 0.0043, and the matings within the community share a common ancestor 8 generations past. The F(isonomy) value was two-fold higher than F(ped), as has been observed in other studies. This degree of kinship is comparable to other isolated populations in North America. Given this evidence for high kinship, we are extending the research partnership beyond hearing loss to examine genetic and environmental factors involved in Alzheimer disease, age-related hearing loss, and other common chronic conditions. A community-wide health needs assessment and recruitment into a research participant registry is currently underway. The infrastructure, processes and implementation phases of this community-based, translational genomics project will be further described.

Relative Risk Score of Genetic Markers for Ancestry Inference. *R. Siburian[1], J. Fagerness[1,3], S. Haddad[1], A. Kirby[1], J. Lerner-Ellis[1], D. Pauls[1,2,3], J. Smoller[1,2,3].* 1) PNGU, Massachusetts General Hospital, Cambridge, MA; 2) Harvard Medical School, Boston, MA; 3) Broad Institute of Massachusetts Institute of Technology and Harvard University, Cambridge, MA.

Ancestry informative marker (AIMS) panels are used to differentiate and cluster individuals in a dataset and to detect population structure caused by genetic drift and natural selection. In genetic association studies, understanding the population structure and assigning individuals in a genetic dataset to their subpopulations is important in the prevention of false-positive and false-negative associations caused by population stratification. Many statistical methods, each using their own inferential algorithms, have been used to ascertain markers for ancestral informativeness. However, these inferential algorithms may be computationally intensive to calculate and lack predictive measurements. Using Principal Component Analysis (PCA) on the HapMap Phase 3 dataset, we determined that the 11 populations grouped into 4 clusters: a cluster containing 4 African populations, a cluster containing 3 Asian populations, a cluster containing 2 European populations and an admixed cluster consisting of an Indian and Mexican population. These 4 clusters were defined as “continental blocks.” We developed a method of selection for the most informative markers by calculating a SNP’s relative risk (RR) for a specific continental block. RR scores were computed by converting the odds ratio from Fisher’s exact-test into a relative risk score. We ran PCA in the HapMap dataset using our top 100 unlinked RR markers and found that it clustered the 11 populations similarly to the PCA data using all markers. We developed a method for ancestry prediction by using a marker’s relative risk score in an allelic scoring system; this provided us a quantitative measurement of genetic load for a known continental population. To validate our panel’s ability to detect population structure, predict ancestry and prevent bias, we ran PCA on an independent dataset, the Human Genome Diversity Project (HGDP). We found that our panel clustered the individuals in the HGDP dataset very well in comparison to the data’s complete marker set and provided an accurate predictive score for continental ancestry. Our results suggests the relative risk method can select a small set of markers for ancestral informativeness to detect for population sub-structure and also provide an intuitive method for ancestry prediction.

Global Distribution and Haplotype-Directed Resequencing of a High-Activity ACN9 Allele. *W.C. Speed, E. Straka, J.R. Kidd, K.K. Kidd.* Genetics, Yale University School of Medicine, New Haven, CT.

ACN9 has been implicated in predisposition to alcohol dependence (PMID: 18163977). While functionally uncharacterized in humans, a yeast Acn9 phenotype implicates a role for the ACN9 protein in acetate metabolism, downstream of ADH and ALDH2 in the alcohol metabolic pathway. Using public data on ACN9 expression for the HapMap samples (PMID: 17873874), 12 SNPs at ACN9 showed significant cis associations with higher expression at the population level. We have selected 11 SNPs distributed across 90.7kb encompassing ACN9, including 5 of the SNPs implicated in alcohol dependence and 4 of the SNPs associated with higher mRNA levels. All 11 SNPs were genotyped on 2465 individuals of a global set of 47 populations. Only one haplotype, very divergent from the ancestral, is associated with high expression levels and reaches high frequencies in SE Asia and the Americas. To find cryptic variation which might be responsible for the higher expression, we selected individuals for next-generation sequencing based on their haplotypic phenotype. 8.2kb PCR amplicons upstream of and including exon 1 were resequenced at greater than 30x coverage for four haplotypes: 20 chromosomes carrying the high expression haplotype (found at 1.6% in Europe, but 37.9% in the Americas); 10 chromosomes of the ancestral haplotype (found at 17% in Africa and negligible levels elsewhere); and 10 chromosomes each of the two remaining globally common haplotypes. These 4 haplotypes represent 90% of the global haplotype variation. All 5 SNPs in this region with reported frequencies in dbSNP were seen; 7 SNPs in dbSNP which had no frequency information were confirmed. 16 novel SNPs were identified, as well as 6 insertion/deletion polymorphisms; our targeted resequencing strategy doubled the known variation at this gene promoter. Two of the SNPs located in the 5’ UTR were chosen for genotyping on the complete population set. A variant allele 204bp upstream of the ATG was seen almost exclusively in North and South American populations, where it reaches an allele frequency of up to 30%. The haplotype carrying this allele has average frequencies of 16.3% in North American and 6.2% in South American populations; in all other regions the haplotype frequency falls below 1%. These data suggest the hypothesis that selection involving this allele may be responsible for the high frequency in Native Americans. Funded in part by USPHS AA009379 (KKK).

1536/T

Ethnic differences in allele distribution of the Androgen Receptor (*AR*) $(CAG)_n$ repeat in the Hyperglycemia and Adverse Pregnancy Outcome (HAPO) cohort. *M. Urbanek[1], L.P. Lowe[2], H. Lee[1], A.R. Dyer[2], M.G. Hayes[1], B.E. Metzger[1], W.L. Lowe[1], C. Ackerman[1], HAPO Study Cooperative Research Group.* 1) Dept Med, Div Endocrinol, Northwestern Univ, Chicago, IL; 2) Department of Preventive Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL.

The androgen receptor (AR) is important in reproductive organ development and homeostasis of the pancreas, liver and skeletal muscle in adulthood. The *AR* gene contains a highly polymorphic $(CAG)_n$ repeat in exon 1 that codes for a glutamine tract in the protein’s N-terminal transactivation domain. Expansion of the *AR* $(CAG)_n$ repeat (>38 repeats) beyond the normal range causes spinal and bulbar muscular atrophy (SBMA), also known as Kennedy disease, which is an X-linked form of spinal muscular atrophy. Features of SBMA include gynecomastia, infertility, androgen insensitivity, and increased incidence of type 2 diabetes. The *AR* $(CAG)_n$ repeat within the normal range (10-36 repeats) is associated with body fat, insulin levels, and leptin in healthy men, and with obesity and leptin in diabetic men. The $(CAG)_n$ repeat has been suggested to regulate AR activity, with longer alleles conferring reduced receptor activity. Therefore, the evaluation of the allelic distribution of this polymorphism in populations of various ethnic origins is crucial in understanding the interindividual variability in AR activity. We evaluated the ethnic variation of this polymorphism by genotyping 4424 Caucasian mothers and 3347 offspring of Northern European ancestry, 1957 Thai mothers and 2089 offspring, 1208 Afro-Caribbean mothers and 1209 offspring; and 774 Hispanic mothers and 762 offspring from the multi-ethnic Hyperglycemia and Adverse Pregnancy Outcome cohort.

Allele distributions of maternal genotypes were compared using Pearson’s chi-squared and Monte Carlo tests. The distribution of $(CAG)_n$ alleles between all four ethnicities is significantly different ($P<0.0001$). These highly significant differences were confirmed using the Monte Carlo test ($P<0.001$). Separate chi-squared analyses were used for pairwise comparisons of ethnicities. These analyses confirmed that there are significant differences between each pair of ethnicities tested ($P<10^{-28}$), even after adjustment for multiple testing. The Afro-Caribbean group had the shortest repeat lengths, and the repeat length increases from Afro-Caribbeans, to Caucasians, to Hispanics, and then Thais. Using this large dataset, we found significant interethnic differences in the allele frequencies of the *AR* exon 1 $(CAG)_n$ polymorphism. Our results suggest that there may be underlying ethnic differences in androgenic pathway activity and androgen sensitivity.

1537/T

Constructing haplotype trees from genome-wide SNP genotypes. *S. Vattathil[1,2], J. Novembre[3], P. Scheet[2,1].* 1) Graduate School of Biomedical Sciences, Univ of Texas at Houston, Houston, TX; 2) Dept of Epidemiology, Univ of Texas M.D. Anderson Cancer Center, Houston, TX; 3) Dept of Ecology and Evolutionary Biology, Univ of California - Los Angeles, Los Angeles, CA.

Multiple approaches exist for modeling population haplotype variation from unphased genotypes, often for the purposes of prediction, e.g. imputing missing genotypes or reconstructing haplotypes. In certain settings, however, inference from such models may also be useful. For example, the topology of the genealogy for the haplotypes in a sample provides a natural way to group the haplotypes. Although heuristic methods exist for estimating the genealogy that describes a non-recombining haplotype segment, they are computationally intractable for whole-genome data from a large number of samples. Here we propose an algorithm for constructing local genealogies -- or trees -- for haplotypes sampled in the form of unphased genotype data. Our method is fast, since it leaves the most recent branches of the tree unresolved, and may be applied pointwise to data from whole-genome scans of thousands of individuals.

Our tree-building algorithm is applied to the clusters of a statistical model for haplotype variation (P. Scheet & M. Stephens, AJHG 78:629-644, 2006), thus generating trees of consensus haplotypes. The consensus haplotypes summarize the variation in the sample, and can be interpreted as ancestral haplotypes from which the sample-level haplotypes descended. We use the summary haplotypes as the external nodes for the genealogy and define relationships among the upper, or earlier, branches of the tree, but represent the lower branches by star-shaped genealogies. We construct trees by using PHYLIP (J. Felsenstein, 2004) to apply a neighbor-joining algorithm. We build a tree at every marker in the dataset, using information from flanking loci to calculate pairwise differences between segments. Since a tree is most interpretable for haplotype segments containing markers in tight linkage disequilibrium, which have experienced little recombination, the flanking loci for each target marker are chosen by sampling adjacent loci using a parameter analogous to a population recombination rate. We apply the method to data collected for a GWA study for lung cancer risk to explore features of the model and interrogate association signals. Our method is reminiscent of that of Minichiello & Durbin (AJHG, 79:910-922, 2006), who applied their method to disease mapping. Our approach can augment methods that utilize haplotypes for inference of population genetic phenomena.

1538/T

A general model for admixture histories in hybrid populations. *P. Verdu, N.A. Rosenberg.* Human Genetics, University of Michigan, Ann Arbor, MI.

Admixed human populations have previously been used for inferring human migrations, detecting natural selection, and finding disease genes. However, these applications often use a simple statistical model of admixture rather than a modeling perspective that incorporates the history of the admixture process. We have developed a general new model of admixture that mechanistically accounts for complex historical admixture processes. We consider M source populations contributing to the ancestry of a hybrid population, potentially with variable contributions across generations. For a random individual in the hybrid population at generation g, we study the fraction of genetic ancestry originating from one of the source populations by computing its moments as functions of time and of introgression parameters. We show how very different admixture processes can produce identical mean admixture proportions but different variances. In a case with two source populations, we also show that when introgression parameters for each source population are constant over time, the long-term limit of the expectation of admixture proportions depends only on the ratio of the introgression parameters. Further, in this constant admixture process, we show that the variance of the admixture proportion can reach a maximum before decreasing to its long-term limit. Our approach will facilitate the inference of admixture mechanisms, illustrating how higher moments of the distribution of admixture proportions can be informative about the admixture processes contributing to the genetic diversity of hybrid populations.

1539/T

Genetic distinctiveness of Spanish Basque population with other surrounding Spanish populations revealed by genome wide high density SNP genotype data. *W. Wang[1,2], L. Rodriguez[4], B. Henn[3], J. Bertranpetit[4], D. Comas[4], C. Bustamante[1,3].* 1) Department of Biological Statistics and Computation Biology, Cornell University, Ithaca, NY; 2) Life Sciences Core Laboratories Center, Cornell University, Ithaca, NY; 3) Department of Genetics, Stanford University, Palo Alto, CA; 4) Institute of Evolutionary Biology (UPF-CSIC), CEXS-UPF-PRBB, 08003 Barcelona, Catalonia, Spain.

Basque is generally considered a culture isolate, while their genetic distinctiveness with surrounding populations is controversial. Varying extent of genetic differentiation of Basques has been reported in a number of studies using different types of markers, which include mtDNA and Y chromosome markers, small sets of candidate SNP, genome-wide SNP, STR and other classical genetic markers. In this study, we investigated the genome wide genetic differentiation using high density SNP markers in 4 populations within Spain: Basques, southern Spain, northwestern Spain, and Canary Islands. Principle component analysis revealed that Basque could be effectively separated from the other 3 Spanish populations, and it was more similar to the HapMap CEU population of western European origin. The southern and northwestern Spanish populations were indistinguishable from each other and from the HapMap TSI population of southern European origin. Canary Islands population demonstrated more similarity to African population than the other 3 Spanish populations. The overall homozygosity rate of Basque (75.9%) was slightly higher than those of the other 3 Spanish populations (74.8% to 75.2%), which were similar to CEU and TSI (75.4%). However, the total length of extended runs of homozygosity in Basque was significantly larger than those of the other 3 Spanish populations, as well as CEU and TSI. This suggests the Basque are a more genetically isolated population than the others, presumably due to a combination of geographic factors and cultural practices. Taken together, the present study using genome wide high density SNP genotypes suggests that Basque are genetically distinct from neighboring Spanish populations, as well as from other western and southern European populations, although the magnitude of differentiation is subtle.

1540/T

Admixture in New World populations: an analysis of Y-chromosome, mtDNA, and genome-wide microarray data. *W.S. Watkins[1], J. Xing[1], D.J. Witherspoon[1], Y. Zhang[1], S.R. Woodward[2], L.B. Jorde[1].* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Sorenson Molecular Genealogy Foundation, Salt Lake City Utah.

The first major interaction between Native Americans and Europeans is documented historically and occurred less than 550 years ago. This recent time frame provides an excellent opportunity to investigate the effects of admixture between two populations that were previously separated for hundreds of generations. To characterize European admixture in Native American populations, we sampled and analyzed a group of isolated Totonac agriculturists from tropical Mexico near Veracruz and a group of native Bolivians predominantly from the mountainous region near La Paz, Boliva. Mitochondrial sequencing of HVS1 showed that all samples had pre-Columbian mtDNA haplogroups (A, B, C, and D). Using a panel of 48 STRs or 12 Y-chromosome SNPs, Totonac Y-chromosomes lineages were all assigned to the pre-Columbian haplogroup Q1a3a, and Bolivian Y-chromosome lineages were assigned to haplogroups Q1a3a, R1, and J2. Haplogroups R1 and J2 are common in European populations. Principal components analysis (PCA) using >800K autosomal SNPs typed in 24 Totonacs and 23 Bolivians showed that all Totonacs and 14 Bolivians clustered distinctly from Eurasian individuals. Nine Bolivians, however, were positioned between the New World and European PCA clusters. Admixture analysis showed that these nine samples had 21 - 33% European admixture using a European reference population. All three observed Y-chromosome haplogroups, including the well-studied pre-Columbian haplogroup Q1a3a, occurred in the admixed individuals. Two of the nine admixed individuals had pre-Columbian mtDNA and Y-chromosome haplogroups but 21-23% European ancestry. This result demonstrates that Y-chromosome and mtDNA haplogroups are only partial indicators of an individual's complete ancestry.

1541/T

Inference of human expansion in Eurasia and genetic diversity in India. *J. Xing[1], W.S. Watkins[1], Y. Hu[2], C.D. Huff[1], A. Sabo[2], D.M. Muzny[2], R.A. Gibbs[2], L.B. Jorde[1], F. Yu[2].* 1) Dept of Human Genetics, Eccles Institute of Human Genetics, University of Utah, Salt Lake City, UT; 2) Human Genome Sequencing Center, Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Genetic studies of populations from the Indian subcontinent are of great interest for many reasons, including India's large population size, its complex demographic history, and its unique social structure. Despite recent large-scale efforts in discovering human genetic variation, India's vast reservoir of genetic diversity remains largely unexplored. To address this issue and to study human migration history in Eurasia, we resequenced one of the 100 kb ENCODE regions in 92 samples collected from four groups - representing three castes and one tribal group - from the state of Andhra Pradesh in south India. By comparing the four south Indian populations with eight HapMap populations that are sequenced for the same region, we found that more than 15% of the total SNPs in the twelve populations in this region are Indian-specific (including HapMap GIH), and 30% of all SNPs in the south Indian populations are not seen in any HapMap population. For this 100 kb region, several Indian population samples, such as middle-caste Yadava, and lower-caste Mala/Madiga, have nucleotide diversity as high as HapMap African populations. In contrast to many other Eurasian populations, the diversity levels in the Indian samples are not correlated with their geographic distances from eastern Africa. Using the unbiased allele-frequency spectrum from twelve Old World populations, we were also able to investigate the divergence and expansion of human populations in Eurasia. The divergence time estimates among continental groups suggest that all Eurasian populations in this study diverged from Africans during the same time frame (~100-120 thousand years ago). The divergence times among the individual Eurasian populations were more than 40 thousand years later than their divergence with Africans, supporting the long-term existence of an ancestral Eurasian founding population after the out-of-Africa diaspora.

1542/T

Selecting genetic marker panels to detect population stratification using a multidimensional principal components and hierarchical clustering approaches. *K. Cho[1,2], J.R. Kidd[1], K.K. Kidd[1].* 1) Department of Genetics, Yale School of Medicine, New Haven, CT; 2) Division of Biostatistics, Yale School of Public Health, New Haven, CT.

Identifying population stratification is essential in case-control studies designed to elucidate the genetics of complex human diseases. Self-reported ethnicity cannot fully capture the underlying genetic population stratification and can confound results, even involving European populations, which are very similar overall. Several panels of ancestry informative markers (AIMs) have been proposed to address this issue. Selection of AIMs depends on the populations and the biostatistical methods used. Many such studies have used only a few very distantly related populations. In contrast, we are studying 34 Eurasian populations, excluding African and Native American populations. We investigate general dimension reduction algorithms using correlations of markers to multiple principal components and the heatmap hierarchical clustering approach and apply these algorithms to select AIMs from a pool of 104 single nucleotide polymorphisms (SNPs) with a globally high Fst genotyped in this geographically restricted set of populations. Using multidimensional principal components and hierarchically evaluating the dendrogram from the heatmap, we examine several subsets of SNPs to capture a wide range of ancestry information minimizing redundancy. We then use the STRUCTURE program to evaluate the performance of panels and derived subsets. From our set of SNPs with varying levels of Fst for the Eurasian populations, we have selected three subsets of 50 SNPs using the two approaches described and by selecting the top 50 highest Fst SNPs. These three panels contain 10 overlapping SNPs and have been compared to the initial panel of SNPs. Overall among the three panels, the multidimensional principal components SNPs panel shows the best clustering using K=2 to 6, followed by the panel using hierarchical clustering. Further investigation of a general approach combining these two methods may help identify an AIMs panel for the underlying populations. These dimension reduction algorithms are useful in selection of AIMs panels with the minimum number of SNPs that retain most information from any given set of SNPs from any platforms already typed. Such SNP panels have a wide range of applications both in genetic studies and forensic studies.

1543/T

Using EuroAIMs to measure admixture proportions in atypical European populations: the case of Canary Islanders. *C. Flores[1,2], M. Pino-Yanes[1,2], A. Corrales[1,2], A. Hernandez[3], S. Basaldua[1], L. Guerra[4], J. Villar[2,5,6].* 1) Research Unit, Hospital Universitario N.S. de Candelaria, Tenerife, Spain; 2) CIBER de Enfermedades Respiratorias, Instituto de Salud Carlos III, Madrid, Spain; 3) Instituto Nacional de Toxicologia y Ciencias Forenses, Delegación de Canarias, Tenerife, Spain; 4) Hematology Service, Hospital Universitario Dr. Negrin, Las Palmas de Gran Canaria, Spain; 5) Multidisciplinary Organ Dysfunction Evaluation Research Network, Research Unit, Hospital Universitario Dr. Negrin, Las Palmas de Gran Canaria, Spain; 6) Keenan Research Center, St. Michael's Hospital, Toronto, ON, Canada.

Using ancestry informative markers (AIMs) allows reducing the number of makers needed for population stratification adjustments in association studies. As few as 100 AIMs are sufficient to adjust for the largest European axis of differentiation (i.e. EuroAIMs). However, their use for ancestry inference and adjustment in association studies in atypical European populations such as the Canary Islanders, a recently African-admixed population from Spain, needs to be addressed. We aimed to explore whether EuroAIMs were suitable both for the inference of Spanish and Northwest African admixture proportions and for ancestry adjustments in association studies including samples from Canary Islanders. We analyzed samples from Canary Islanders, mainland Spanish (IBE) and Northwest Africans (NWA) for 93 EuroAIMs and compared the data with CEU and YRI from HapMap, Basques and Mozabite from HGDP, as well as from previously analyzed European samples. The major genetic difference was observed between NWA and all European populations, preserving the northwest-to-southeast differentiation of European populations in the second axis. Analyses revealed that Canary Islanders were intermediate between IBE and NWA, and that direct sub-Saharan African influences were negligible. Assessment of individual admixtures without prior population information clearly identified two subpopulations corresponding to NWA and IBE, while Canary Islanders were admixed with an average of 17.4% Northwest African contribution varying largely among individuals (range 0-95.7%). As few as 23 EuroAIMs correctly estimated population membership to IBE and NWA, while 69 EuroAIMs were required to accurately estimate individual admixture proportions in Canary Islanders. Ancestry estimates based on a subset of 69 EuroAIMs also controlled significant allele frequency differences between IBE and Canary Islanders. These data suggest that a handful of EuroAIMs would be useful to control false-positives in association studies performed in Spanish populations. Supported by FUNCIS 23/07 and grants from the Spanish Ministry of Science and Innovation PI081383 and EMER07/001 to CF.

Effects of incompatibility selection on genomic patterns of neutral variation. *D. Fusco[1], M.K. Uyenoyama[2].* 1) Computational Biology and Bioinformatics Program, Duke University, Durham, NC; 2) Dept of Biological Sciences, Duke University, Durham, NC.

Geography has emerged as a major determinant of the pattern of genetic variation in global samples of human genomes. Extreme values of Fst have been interpreted as prima facie evidence of strong directional selection (selective sweeps) confined to certain geographical regions. We present a theoretical analysis of a distinct form of selection under which the well-functioning wild-type allele of a given deme may reduce fitness upon placement on the genomic background of a different deme. We call this process incompatibility selection - local selective neutrality balanced by negative selection in other demes. We address the consequences of incompatibility selection on patterns of variation at globally neutral sites (marker loci) throughout the genome. These patterns differ from expectations under recent selective sweeps. We show that genealogical histories at marker loci can be modeled as a neutral process with an appropriately scaled backward migration rate. We examine the effects of sex-specific selection and sex-specific rates of crossing-over on the backward migration rate at neutral marker loci. Under sex-specificity of this kind, the barrier to introgression at markers departs in general from multiplicativity even in the absence of multiplicative epistasis among incompatibility loci. This departure reflects linkage disequilibrium (LD) between incompatibility loci conditional on transmission of the marker allele. Positive LD reduces and negative LD increases the barrier relative to the multiplicative expectation. Negative LD arises, for example, between an incompatibility allele that induces a greater reduction in the fitness of male than female carriers and an incompatibility allele at another locus that induces greater harm to female than male carriers. LD of this kind arises even between unlinked incompatibility loci, implying that the presence of incompatibility loci anywhere in the genome can affect introgression rates at neutral marker loci. Results from forward-in-time simulations of sex-specific selection, recombination, and migration confirm that a neutral process with our expression for the backward migration rate provides a useful approximation of the full complex process. In particular, values of Fst and other summary statistics observed in the simulations conform to expectation under our neutral approximation. We also extracted from the simulations the distribution of waiting times between ancestral migration events along lineages.

CoAIMs: A Cost-Effective Panel of Ancestry Informative Markers for Determining Continental Origins. *E.R. Londin[1], M.A. Keller[1], C. Maista[1], G. Smith[1], L.A. Mamounas[2], R. Zhang[2], S.J. Madore[1], K. Gwinn[2], R.A. Corriveau[1].* 1) NINDS Repository, Coriell Inst Med Res, Camden, NJ; 2) National Institute for Neurological Disorders and Stroke, Bethesda, MD.

Genetic ancestry is known to impact outcomes of genotype-phenotype studies that are designed to identify risk for common diseases in human populations. Failure to control for population stratification due to genetic ancestry is a significant confounder of disease association studies. Self-identified race is the most common method used to track and control for population stratification; however, social constructs of race are not necessarily informative for genetic applications. The use of ancestry informative markers (AIMs) is a more accurate method for determining genetic ancestry for the purposes of population stratification. Here we use a panel of 36 microsatellite (MSAT) AIMs to determine continental admixture proportions in the context of a biorepository collection. This panel, named CoAIMs, consists of MSAT AIMs chosen based upon their measure of genetic variance (Fst), allele frequencies and their suitability for efficient genotyping. Genotype analysis with a Bayesian clustering method (STRUCTURE) is able to discern continental origins including Europe/Middle East (Caucasians), East Asia, Africa, Native America, and Oceania in reference populations. In addition to determining continental ancestry for such individuals without significant admixture, we applied CoAIMs to ascertain admixture proportions of a large collection of individuals of self-declared race. CoAIMs was used to efficiently and effectively determine continental admixture proportions in a sample set from the NINDS Human Genetics DNA and Cell Line Repository. Individuals of self-declared Caucasian (N=92), African-American (N=200), and Hispanic (N=200) race were analyzed. African American individuals displayed admixture of both African and European ancestry, with 2/200 (1%) of the samples having nearly 100% Caucasian Ancestry, suggesting discordance between self-declared and genetic race. Caucasian and Native American represented the highest ancestral proportions in self-reported Hispanic populations. The determination of genetic ancestry in biorepository collections can increase the utility of these samples for gene discovery. The CoAIMs panel used here has potential for broad applicability as a cost effective tool for determining admixture proportions.

The genetic structure of South Asian populations as revealed by 650 000 SNPs. *M. Metspalu[1], G. Chaubey[1], B. Yunusbayev[1,2], I. Gallego Romero[4], M. Karmin[1], C. Basu Mallick[1], E. Metspalu[1], K. Thangaraj[3], L. Singh[3], S. Shanmugalakshmi[6], K. Balakrishnan[6], R. Pitchappan[5], T. Kivisild[4,1], R. Villems[1].* 1) Dept. of Evolutionary Biology, Estonian Biocentre and Tartu University, Tartu, Estonia; 2) Institute of Biochemistry and Genetics, Ufa Research Center, Russian Academy of Sciences, Ufa 450054, Russia; 3) Centre for Cellular and Molecular Biology, Hyderabad, India; 4) Leverhulme Centre of Human Evolutionary Studies, The Henry Wellcome Building, University of Cambridge, Fitzwilliam Street, Cambridge, CB2 1QH, UK; 5) Department of Immunology, School of Biological Sciences, Madurai Kamaraj University, India; 6) School of Biotechnology, Bharathidasan University, Trichirappalli, India.

The onset of the era of analyses of dense marker sets covering the whole genome has revolutionised the field of (human) population genetics. Driven largely by the needs of biomedical research the new data is helping to unveil our demographic past outlined by the study of mtDNA and Y-chromosome variation during the past ca. 20 years. Here we have analysed (Illumina 650K SNPs) over 320 new samples from South and Central Asia and the Caucasus together with the publicly available databases (HGDP panel and our published dataset of ca. 600 Eurasian samples) and illustrate the power of full genome analyses by addressing two specific questions: i) the nature of genetic continuity and discontinuity between South Asia, Middle East and Central Asia, and ii) genetic origins of the Munda speakers of India. We use principal component and structure-like analyses to reveal the structure in the genome wide SNP data. The most striking feature of the genetic structure of South Asian populations is the clear separation of the Indus valley and southern India populations. The genetic component prevalent in the latter region is marginal in the former and absent outside South Asia. The component ubiquitous to Indus valley is, in contrast, also present (ca. 30 - 40%) among Indo-European speakers of Ganges valley and Dravidic speakers in southern India. Furthermore this component can also be found in Central Asia and the Caucasus as well as in Middle East. We explore possibilities to identify the source region for this genetic component. Alternative models put the origins of Munda languages speakers either in South Asia (the Munda speakers sport exclusively autochthonous South Asian mtDNA variants) or to Southeast Asia where the other Austro Asiatic languages are spread. Y-chromosome variation supports the latter model through sharing of hg O2a in both regions. We show that in addition to the dominant ancestry component shared between the Indian Dravidic and Munda speakers the latter retain (up to 30%) an ancestry component otherwise prevalent in East Asia. There is no widespread sign of South Asian ancestry component in Southeast Asia. This provides genomic support to the model by which Indian Austro-Asiatic populations derive from dispersal from Southeast/East Asia followed by an extensive admixture with local Indian populations.

The History in our Genes: the Complex Structure of the South African Coloured Population. *M. Möller[1], L. Quintana-Murci[2,3], E. de Wit[1], W. Delport[4,5], C. Harmant[2,3], C.E. Rugamika[4], H. Quach[2,3], A. Meintjes[4], O. Balanovsky[6], V. Zaporozhchenko[6], C. Bormans[7], P.D. van Helden[1], C. Seoighe[8], D.M. Behar[2,9], E.G. Hoal[1].* 1) Molecular Biology and Human Genetics, MRC Centre for Molecular and Cellular Biology, DST/NRF Centre of Excellence for Biomedical TB Research, Stellenbosch University, Tygerberg, Western Cape, South Africa; 2) Institut Pasteur, Human Evolutionary Genetics, Department of Genomes and Genetics, Paris, France; 3) Centre National de la Récherche Scièntifique, Paris, France; 4) Institute of Infectious Disease and Molecular Medicine, University of Cape Town, Cape Town, Western Cape, South Africa; 5) Department of Pathology, Antiviral Research Center,University of California, San Diego, USA; 6) Research Centre for Medical Genetics, Russian Academy of Medical Sciences, Moscow, Russia; 7) Genomics Research Center, Family Tree DNA, Houston, Texas, USA; 8) School of Mathematics, Statistics and Applied Mathematics, National University of Ireland, Galway, Ireland; 9) Molecular Medicine Laboratory, Rambam Health Care Campus, Haifa, Israel.

The study of recently admixed populations provides unique tools for understanding recent population dynamics, socio-cultural factors associated with the founding of emerging populations, and the genetic basis of disease by means of admixture mapping. The geographical position and complex history of South Africa has led to the establishment of the unique admixed population known as the South African Coloured. We performed a Genome-Wide Analysis of the genetic make-up of this population. We genotyped 959 self-identified individuals from the Western Cape area, using the Affymetrix 500k genotyping platform. This resulted in nearly 75 000 autosomal SNPs that could be compared with populations represented in the International HapMap Project and the Human Genome Diversity Project. Analysis in STRUCTURE revealed that the major ancestral components of this population are predominantly Khoesan (32-43%), Bantu-speaking Africans (20-36%), European (21-28%), and a smaller Asian contribution (9-11%), depending on the model used. However, the autosomal data provides little evidence about the mode in which this admixed population was founded. We went on to show, through detailed phylogeographic analyses of mitochondrial DNA and Y-chromosome variation in a large sample of South African Coloured individuals, that this population derives from at least five different parental populations (Khoisan, Bantus, Europeans, Indians and Southeast Asians), who have differently contributed to the foundation of the South African Coloured. Our analyses reveal extraordinarily unbalanced gender-specific contributions of the various population genetic components, the most striking being the massive maternal contribution of Khoisan peoples (more than 60%) and the almost negligible maternal contribution of Europeans with respect to their paternal counterparts. The overall picture of gender-biased admixture depicted in this study indicates that the modern South African Coloured population results to a large degree from the early encounter of European and African males with autochthonous Khoisan females of the Western Cape of Good Hope hundreds of years ago.

The geographic structure of rare variant diversity. *J. Novembre[1], D. Wegmann[1], S. Gopalakrishnan[2], M. Zawistowski[2], P. St. Jean[3], L. Li[3], M.G. Ehm[3], J. Li[3], Y. Li[3], G. Abecasis[2], J.C. Whittaker[3], S.L. Chissoe[3], V.E. Mooser[3], M.R. Nelson[3], S. Zöllner[2].* 1) Dept Eco & Evo Biol, Univ California, Los Angeles, Los Angeles, CA; 2) Biostatistics Department, School of Public Health, University of Michigan; 3) GlaxoSmithKline, Research Triangle Park, North Carolina 27709, USA.

The challenges of population stratification for common variant association tests are well understood, but it is less clear how population stratification affects rare variant mapping techniques and how often rare variants discovered in one population are shared in closely related populations. To investigate these questions we analyze patterns of rare variant diversity amongst 15,000 subjects who have been re-sequenced with average depth >20x across 202 genes as part of the GSK QPOC DeepSeq project (see abstract by Nelson et al). The scale of the study allows us to document rare variants in multiple populations. Specifically, the sample includes >275 individuals from 4 globally distributed populations (African-American, Chinese, European, and Indian). Within Europe, the sample contains >500 individuals from each of more than 6 geographically defined populations. We quantify whether rare variant diversity differs among populations and the extent to which rare variants at different frequencies and functional categories are structured at global and local scales. The results underscore the importance of considering population stratification when performing rare variant mapping techniques.

1549/T

Autosomal African admixture in Yemeni populations. *R.L. Raaum[1], A.M. Al-Meeri[2], C.J. Mulligan[3].* 1) Anthropology, Lehman College & The Graduate Center, CUNY, New York, NY; 2) Biochemistry, Faculty of Medicine, Sana'a University, Sana'a, Yemen; 3) Anthropology, University of Florida, Gainesville, FL.

Approximately 30% of mtDNA lineages in South Arabian samples are African L haplotypes, whose origin has usually been attributed to migration and assimilation of African females into the Arabian population over approximately the last 2,500 years. Few In contrast, few Y chromosome lineages of clear recent sub-Saharan African origin have been found in Southern Arabian populations. This bias in maternal and paternal lineages is in accord with historical accounts of the female bias in the Middle Eastern slave trade. In order to evaluate autosomal African ancestry, we collected high-resolution SNP genotype data from a geographically representative set of 62 Yemenis selected from a collection of 552 samples acquired in the Spring of 2007. The ancestry of chromosomal segments in the Yemeni population was estimated using a haplotype-based local ancestry estimation method, HAPMIX. The HAPMIX method is based on a two way admixture model that requires two phased reference populations; we used the HapMap Yoruba in Ibadan, Nigeria (YRI), Luhya in Webuye, Kenya (LWK), Maasai in Kinyawa, Kenya (MKK), and CEPH US residents with ancestry from northern and western Europe (CEU) samples. The three African reference populations include two Bantu-speaking groups (YRI and LWK) and one Nilotic-speaking group (MKK). We estimated local ancestry in the Yemeni sample with all three European-African reference population combinations (CEU-YRI, CEU-LWK, CEU-MKK). The correlations among African ancestry calculated using all three reference population combinations are high ($r > 0.98$ in all pairwise correlations). Furthermore, there is no significant difference between the average proportion of African ancestry in Yemenis calculated using either of the two Bantu-speaking reference populations: CEU-YRI (mean 0.062, sd 0.044) and CEU-LWK (mean 0.076, sd 0.049) ($p=0.13$, two-tailed Welch two sample t-test). However, the average African ancestry calculated using the Maasai reference population (CEU-MKK, mean 0.148, sd 0.060) is significantly greater from that calculated using either the Yoruba or Luhya reference populations ($p < 0.0001$ in both comparison, two-tailed Welch two sample t-test). These data suggest that the source population for the African ancestry of the Yemeni population is more similar to the contemporary Maasai population than either the Luhya or Yoruba.

1550/T

Admixture in Ashkenazi Jewish cohorts and implications for association studies. *V. Vacic[1], E.E. Kenny[1,2], A. Gusev[1], I. Peter[3], J. Cho[4], G. Atzmon[5], H. Ostrer[6], S.B. Bressman[5], I. Ozelius[3], I. Pe'er[1].* 1) Columbia University, New York, NY; 2) The Rockefeller University, New York, NY; 3) Mount Sinai School of Medicine, New York, NY; 4) Yale University, New Haven, CT; 5) Albert Einstein College of Medcine, Yeshiva University, New York, NY; 6) Langone Medical Center, New York University, New York, NY.

Studies of complex genetic disorders may benefit from focusing on population isolates, such as Ashkenazi Jews (AJ). However, in order to truly exploit the advantages of reduced genetic diversity the self-declared AJ ancestry of study participants should be independently confirmed with available genetic data. We investigate whether the AJ cohorts display genetic heterogeneity, such as e.g. different rate of admixing in cases and controls, which could potentially confound disease association studies. We applied principal component analysis (PCA) to AJ cohorts ascertained in Israel and the US East Coast with the goal of characterizing population structure. As described previously, when compared to the HapMap samples with CEU, YRI and CHB/JPT ancestry, virtually all AJ samples cluster with the CEU. Similar analysis done on CEU and Jewish HapMap samples from Ashkenazi, Sephardic and Middle Eastern Jewish communities revealed that 97.8% of AJ samples cluster along the AJ-CEU axis, with modes at AJ and CEU cluster centers and at approximately quartile distances between them. We postulate that these groups correspond to 100-0, 75-25, 50-50, 25-75, and 0-100% AJ-CEU admixtures. Notably, only 91.7% of self-reported AJ individuals fall into the reference JHapMap panel AJ cluster, with 1.6, 3.3, 0.5 and 0.7% in the admixed modes ordered by decreasing fraction of AJ ancestry. We also observe admixing with the non-AJ Jewish communities: 0.7% of samples fall within the non-AJ clusters and 1.4% at a subgroup approximately halfway between the AJ and non-AJ cluster centers. In our dataset we found that when compared to the sample as a whole or only to controls, individuals with Crohn's disease (CD) show significantly more admixing: 78.1, 3.1, 8.5, 2.0 and 0.9% in the 100, 75, 50, 25 and 0% AJ subgroups respectively. Also, CD samples show more admixing with non-AJ groups (2.8 and 1.0% in the 50-50 and 0-100 AJ-non-AJ subgroups). Isolates typically exhibit a greater amount of cryptic relatedness compared to outbred populations, which motivates an orthogonal method for verifying AJ ancestry based on identity-by-descent (IBD). The high background level of IBD within the Ashkenazi Jewish community can be used to estimate degree of AJ ancestry by averaging the IBD between a sample under study and the AJ individuals in the JHapMap panel. Our preliminary results show that this method recapitulates the high-level results from the PCA analysis and provides better resolution.

1551/T

Balancing ethics and genetics: classifying individuals by their ancestry groups. *R. Zuvich[1,2], E.W. Clayton[3], M. Basford[4], J. Denny[5,6], D.M. Roden[6,7], J.L. Haines[1,2], M.D. Ritchie[1,2].* 1) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Center for Biomedical Ethics and Society, Vanderbilt University, Nashville, TN; 4) Office of Personalized Medicine, Vanderbilt University, Nashville, TN; 5) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 6) Department of Medicine, Vanderbilt University, Nashville, TN; 7) Department of Pharmacology, Vanderbilt University, Nashville, TN.

Individuals with different genetic ancestry differ in allele frequencies of various single nucleotide polymorphisms (SNPs), linkage disequilibrium patterns, and disease susceptibility, all of which affect analysis of the data and interpretation of the results. Therefore, characterization of an individual's genetic ancestry is imperative to minimize spurious association results. The Vanderbilt DNA Databank (BioVU) is a DNA repository of >85,000 DNA samples (both adult and pediatric), which are de-identified and linked to electronic medical records. In a preliminary study, we genotyped 360 SNPs using the Illumina DNA Test Panel, which contains ancestry informative markers (AIMs) on ~1,500 DNA samples from patients whose race/ethnicity was identified by hospital personnel ("observer-reported"). Using an ancestry proportion threshold of 90%, there was 95.7% concordance in people of European ancestry between the observer-reported race/ethnicity and the ancestry group identified by the AIMs; while people of African ancestry had far less concordance (22%). However, lowering the ancestry proportion threshold to 75% increases African ancestry concordance to 74%. This is due to the expected proportion of admixture in African American individuals. About 20% of samples in BioVU do not have a race/ethnicity noted in the EMR and characterization of these samples using AIMs would be of great utility. We genotyped an additional ~7,900 DNA samples from BioVU using the DNA Test Panel to characterize genetic ancestry and determine whether using a smaller subset of AIMs yields the same classifications as the full set of AIMs. While characterizing genetic ancestry is important for association studies, this process raises many ethical and social implications about "labeling" patients based on genetic markers. Additionally, with admixed populations, such as those in the United States, the utility of AIMs are limited in their ability to explore genetic ancestry and provide no data to describe socially defined categories of race and ethnicity. We suggest that including AIMs in the EMR will be important to interpret and apply the results of genetics research in the clinic, but that it will be critical to declare that these markers of genetic ancestry do not necessarily correspond to a particular race or ethnicity.

1552/T

W. African recessive *LEPRE1* allele (c.1080+1G>T) in Trinidad and Tobago - Does perinatal lethal Osteogenesis Imperfecta (OI) influence the high neonatal death rate? *M.G. Pepin[1], U. Schwarze[1], V. Singh[2], M. Romana[3], A. Jones-LeCointe[2], S. Paray[2], P.H. Byers[1].* 1) Dept Pathology, Univ Washington, Seattle, WA; 2) Mt. Hope Hospital, University of West Indies Medical School, Trinidad and Tobago; 3) Inserm/Université des Antilles et de la Guyane, Centre Hospitalier Universitaire de Pointe-à-Pitre, Guadeloupe.

Almost all African American (AA) infants with *LEPRE1*-related perinatal lethal OI are homozygous for a single mutation (c.1080+1G>T, IVS5+1G>T). Carrier frequency in AA populations is between 1/100 and 1/241 depending upon geographic region. Studies of DNA samples from W. Africa, particularly from tribes originating near Ghana and Nigeria, found carrier frequencies between 2% and 5%. To determine the carrier frequency of the *LEPRE1* W. African allele in Tobago we purified 200 DNA samples and sequenced the exon and surrounding intron sequence of the c.1080+1G>T region of the gene. We reviewed all neonatal death records (n=172) at the Mt. Hope Hospital in St Augustine Trinidad between 2006 and 2009 to assess cause of death and prevalence of neonatal lethal skeletal dysplasias, including OI. Three neonatal deaths with possible skeletal dysplasia were identified although OI was an unlikely cause. The carrier frequency of the W. African allele in Tobago was identical to the reported frequency in the US (0.5%). Our data does not support the hypothesis that *LEPRE1* related neonatal lethal OI contributes to the perinatal mortality rate in Trinidad and Tobago. The expected rate of lethal OI due to homozygous *LEPRE1* mutation based on present birth rates is predicted to be one case every 15-17 years. The *LEPRE1* sequencing data from Tobago samples revealed 11 intron and exon variants in the 440 bp fragment sequenced. Each characterized a unique allele with a frequency in the population studied that ranged from 50% to less than 1%. The *LEPRE1* lethal mutation occurred on the background of the most common allele. Data from slave trade logs of port of departure in Africa and disembarkation in Tobago and the *LEPRE1* allele variation data suggest that the African descendants of Tobago lived in relatively close proximity in W. Africa, between the Gold Coast to the northern regions of Congo consistent with studies of globin allele origins.

Health Insurance Society General Ohta Hospital, Ohta, Japan; 14) Department of Cardiology, Boston Children's Hospital, Boston, MA; 15) Department of Pediatrics, Feinberg School of Medicine Northwestern University, Children's Memorial Hospital, Chicago, IL; 16) Department of Public Health, Jichi Medical School, Minamikawachi, Japan; 17) Department of Preventive Medicine, Shinshu University School of Medicine, Matsumoto, Japan; 18) Department of Surgery, National Center for Child Health and Development, Tokyo, Japan; 19) Laboratory for Medical Informatics, Ctr Genomic Medicine, RIKEN, Yokohama, Japan; 20) Japan Kawasaki Disease Research Center, Tokyo, Japan; 21) Laboratory for Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan; 22) U. S. KD Genetics Consortium.

Kawasaki disease (KD; OMIM 611775) is an acute systemic vasculitis syndrome of infants and young children. Previously we conducted a genome-wide sibpair study for KD and found ten candidate loci with positive linkage signals. From one candidate region in 19q13.2, we have identified a SNP of *ITPKC* gene which is significantly associated with KD and the risk for IVIG unresponsiveness both in Japanese and European American populations. In an attempt to identify a novel susceptibility gene we performed a positional candidate gene study for 4q35 region. We found that multiple common variants in *caspase-3* (*CASP3*) gene were significantly associated with KD both in Japanese and in European American populations and a G to A substitution of one commonly associated SNP located in the 5' UTR of *CASP3* (rs72689236; $P = 4.2 \times 10^{-8}$ in the Japanese and $P = 3.7 \times 10^{-3}$ in the European Americans) abolished binding of NFATc2 to the DNA sequence surrounding the SNP. Allele specific transcript quantification analysis showed a consistent result that the amount of the transcripts from the A allele of *CASP3* was less than that from the G allele in PBMCs. Interestingly, the GGAA motif of which the first G nucleotide is substituted by the SNP in human is seen in a similar position within the first non-coding exon of rodent *Casp3* genes, suggesting that the enhancer element might be evolutionarily conserved. CASP3 is one of the key molecules of apoptosis and it has been reported that apoptosis of neutrophils and lymphocytes is delayed in the acute phase of KD. Our data indicates that reduced expression of CASP3 might be involved in the pathogenesis of KD possibly through affecting apoptosis of immune cells.

Identification of Novel Sequence Variants in Neuroligin Genes Contributing Autism Susceptibility. *D. Ramachandran[1], K.M. Steinberg[1,2], A.C. Shetty[1], V. Patel[1], M.E. Zwick[1].* 1) Human Genetics, Emory University, Atlanta, GA; 2) Graduate Program in Population Biology, Ecology and Evolution, Emory University, Atlanta, GA.

Autism Spectrum Disorders (ASDs) exhibit high heritability and affect four times as many males as females, yet the genetic risk factors remain largely unidentified. Several mutations in the neuroligin pathway have recently been implicated in the pathogenesis of ASD. We explored the hypothesis that other rare genetic variants found in neuroligin genes may contribute to ASD susceptibility. We performed paired end multiplexed sequencing of the genomic regions containing NLGN4X, NLGN3 and NRXN1β using the Illumina GAII platform on 144 male ASD probands from the Autism Genetic Resource Exchange (AGRE) collection. We observed a total of 314 single nucleotide variants (SNVs) and 139 insertion/deletion (indels) from these three loci. Of this, 167 variants are reported in either dbSNP130 or 1000 genomes project Pilot 1 data. We focused our attention on novel, rare variants found at highly conserved sites. In NLGN4X, we discovered one 3' UTR SNV, one 5'UTR SNV, and a novel 2-base 3'UTR indel. In NLGN3X, we found three 3'UTR variants, of which two are present in a single case. In NRXN1β, we observed two exonic heterozygous missense replacements (V193G; E357V) and five rare 3'UTR variants. The functional effects of the missense variants in NRXN1β were predicted to be damaging using SIFT, PolyPhen and Panther. We also identified one heterozygous exonic indel and 25 UTR indels that are highly conserved and not previously reported. All the rare and highly conserved single nucleotide variants and indels have been validated by Sanger sequencing. We will present results from functional assays to directly assess the effects of these rare variants. Our results suggest that rare variants in NLGN pathway genes may influence ASD susceptibility and demonstrates a study paradigm required to fully characterize the contribution of rare genetic variation to complex disorders like ASD.

Greater than three-fold variation in mean leukocyte telomere length in young men living in eleven European countries: variation is not obviously related to population genetic structure or ecological variation in infectious exposures. *D.T.A. Eisenberg[1,2], K.D. Salpea[3], C.W. Kuzawa[1,2], M.G. Hayes[1,4,5], S.E. Humphries[3], European Atherosclerosis Research Study II group.* 1) Department of Anthropology, Northwestern University, Evanston, Illinois, 60208, USA; 2) Cells 2 Society: the Center for Social Disparities and Health, Institute for Policy Research, Northwestern University, Evanston, IL 60208; 3) Centre for Cardiovascular Genetics, Department of Medicine, Royal Free and University College Medical School, London, UK; 4) Division of Endocrinology, Metabolism and Molecular Medicine, Department of Medicine, Northwestern University Medical School, Chicago, Illinois, 60611, USA; 5) Center for Genetic Medicine, Northwestern University, Chicago, Illinois, 60611, U.S.A.

Telomeres are repetitive DNA sequences (5'-TTAGGG-3' in vertebrates) found at the ends of chromosomes. These telomere sequences shorten with age in proliferating human tissues, and with cell replications in vitro; and are therefore implicated in senescence. Previous studies suggest that shorter telomeres impair immune and cardiovascular function and result in increased mortality. Although few, prior studies have documented ethnic/population differences in human telomere lengths. In the US, African-American samples have tended to show longer leukocyte telomere lengths (LTLs) than European-Americans. Further, Salpea and colleagues (2008) demonstrated that LTLs vary across regions of Europe by over 25%. The causes of these population differences remain poorly understood. Here we extend the work of Salpea and colleagues by reporting variation in mean leukocyte telomere length (LTL) from 765 individuals from 14 study centers across 11 European countries (N from each study centers ranges from 32-71). Subjects are male students (ages 18-28), half of whom had fathers with myocardial infarction(s) before 55 and the remainder age-matched controls. Controlling for age and case/control status, telomere lengths averaged 10.20 kilobases (interpolated from qPCR measures) across study centers and ranged from 5.10 kilobases in Naples, Italy to 18.64 kilobases in Ghent, Belgium—a greater than three-fold difference across populations. These population level differences in LTLs were not explained by population genetic structure as measured by the eigenvalues from the first two principal components of a previous analysis of the genetic structure of European populations (Novembre and colleagues 2008), nor by national level ecological analysis of an index of infection/economic status (United Nations Infant Mortality Rates). In sum, we show considerable population variation in LTL in Europe that is not obviously a result of broad measures of population structure or infection/economic exposure measured in early life or in adulthood. Studying telomere dynamics in a wider variety of populations, and with greater attention to lifecycle dynamics, will be important to help elucidate the causes and possible consequences of human population variation in telomere length. This work was supported by the British Heart Foundation [KDS (FS/06/053) and SEH (RG2005/014)] and by the EC Concerted Action BMH1 CT92-0206. The VNTR polymorphism of the dopamine D4 receptor (*DRD4*) gene in Oceanic populations. *I. Naka[1], N. Nishida[2], R. Kimura[3], T. Furusawa[4], K. Natsuhara[5], T. Yamauchi[6], M. Nakazawa[7], Y. Ataka[8], T. Ishida[9], T. Inaoka[10], Y. Matsumura[11], R. Ohtsuka[12], N. Tsuchiya[1], J. Ohashi[1].* 1) Doctoral Program in Life System Medical Sciences, Graduate School of Comprehensive Human Sciences, University of Tsukuba, Ibaraki, Japan; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 3) Transdisciplinary Research Organization for Subtropics and Island Studies, University of the Ryukyus, Okinawa, Japan; 4) ASNET Promotion Office, Division for International Relations, The University of Tokyo, Tokyo, Japan; 5) School of Nursing, Fukuoka Prefectural University, Fukuoka, Japan; 6) Department of Health Sciences, Hokkaido University School of Medicine, Hokkaido, Japan; 7) Department of Public Health, Graduate School of Medicine, Gunma University, Gunma, Japan; 8) School of Policy Studies, Kwansei Gakuin University, Hyogo, Japan; 9) Department of Biological Sciences, Graduate School of Science, The University of Tokyo, Tokyo, Japan; 10) Department of Environmental Sociology, Faculty of Agriculture, Saga University, Saga, Japan; 11) Faculty of Healthcare, Kiryu University, Gunma, Japan; 12) Japan Wildlife Research Center, Tokyo, Japan.

The dopamine D4 receptor (*DRD4*) gene contains a 48-base pair variable number of tandem repeat (VNTR) in exon 3, encoding the third intracellular loop of this D2-like receptor. The lengths of VNTR vary from 2 to 11 repeats (2R to 11R), and alleles with 2R, 4R, and 7R are commonly observed in human populations. The *DRD4* VNTR has been suggested to be associated with behavioral and psychiatric phenotypes including novelty seeing, drinking behavior, and attention deficit/hyperactivity disorder, although there are conflicting reports. Further, the 7R allele has been suggested to be subjected to positive selection since the linkage disequilibrium from 7R is more extended than those from the other common VNTR alleles (i.e., 2R and 4R). In this study, the VNTR polymorphism of *DRD4* was investigated in 7 Oceanic populations (4 Melanesians, 1 Micronesian, and 2 Polynesians). In the studied populations, only alleles with 2 to 7 repeats were observed. The 7R allele was frequent in non-Austronesian speaking Melanesian population (Gidra), whereas rare in Micronesian (Rawaki) and Polynesian (Ha'apai and Nuku'alofa of Tonga) populations. Interestingly, the 5R allele was frequently found in Micronesian population (Rawaki), but nearly absent in the other Oceanic populations. These observations are considered to reflect their evolutionary history. Our results will provide useful information for association studies of the *DRD4* gene in Oceanic populations.

1557/F

Molecular Confirmation of Hemophilia A Through RNA Analysis. *H. Best, T. Lewis, P. Bayrak-Toydemir.* ARUP Institute for Clinical and Experimental Patho, Salt Lake City, UT.

BACKGROUND: Hemophilia A is a hereditary bleeding disorder caused by mutations in the F8 gene (Xq28). A subset of patients, 5-10%, with mild or moderate hemophilia has no detectable mutation in the coding regions of the F8 gene. For these patients it is feasible that intronic mutations affecting splicing are responsible for the disorder. Here we describe a 9 year old male with a clinical diagnosis of hemophilia A based on Factor VIII activity levels reported to be between 5-12% (consistent with mild to moderate disease) that was referred for F8 gene sequencing. Previous testing for F8 gene inversions was negative and DNA sequencing revealed no mutations within the coding regions of the gene. METHODS AND RESULTS: The proband's genomic DNA was sequenced for the F8 gene and a c.602-9_602-7delCTT variant was detected. Based on splice prediction software, this variant was predicted to be a splice site mutation. To verify that the variant led to alternative splicing, RNA was collected from the patient and cDNA synthesized using the protocol described in El-Maarri et al., 2005. PCR across exons 4-8 yielded an abnormal sized PCR product of 542 bp rather than the expected 611 bp product. Sequencing of the cDNA amplicon product showed a read through straight from exon 4 to exon 6, with exon 5 missing. Exon 5 is 69 bp in length accounting for the size difference observed in the PCR product. The same variant, c.602-9_602-7delCTT, was observed by genomic sequencing in the proband's affected half-brother whose Factor VIII activity levels were reported to be between 3-13%. cDNA analysis of the sibling showed the same aberrant band pattern for the amplicon spanning exons 4-8. CONCLUSIONS: Analysis of cDNA is a useful way of investigating predicted splicing mutations in hemophilia A patients. Our analysis of a proband and an affected sibling with presumed splice site mutations demonstrated that the mRNA transcript produced skips exon 5 of the F8 gene with no full-length wild type transcript detected.

Evaluating the alternative splicing of interleukin 7 receptor alpha chain (IL7Rα) and its role in multiple sclerosis. *S. Gregory[1, 2], I. Evsyukova[3,4], M. Garcia-Blanco[2, 4, 5].* 1) Duke Center for Human Genetics; 2) Duke University Department of Medicine; 3) Duke University Department of Biochemistry; 4) Duke University Center for RNA Biology; 5) Department of Molecular Genetics and Microbiology, Duke University.

Multiple sclerosis (MS) is a debilitating neurodegenerative disorder of the central nervous system that is thought to be mediated by T-cell autoimmunity. The pathophysiology of MS, which affects 400,000 individuals in the US, causes chronic inflammation, myelin loss and progressive neurological dysfunction. Recently we identified genetic association (p-val 2.9x10-7) of a non-synonymous SNP, rs6897932 (C®T, Thr244Ile), within exon 6 of the interleukin 7 receptor gene (IL7Rα) with MS. IL7Rα is an attractive candidate in the etiology of the disease because it facilitates interleukin 7 (IL7) signaling at specific stages during T cell development in the thymus, and also during naïve and memory T cells maintenance in the periphery.

Functional analysis of the associated SNP revealed that the "C" risk allele results in increased skipping of exon 6. Previous studies have shown that alternative splicing of exon 6 leads to in vitro production of either membrane-bound (exon 6 included) or soluble (exon 6 skipped) isoforms of IL7Rα. To address our hypothesis that increased skipping of exon 6 alters the ratio of the membrane-bound to soluble isoforms of IL7Rα and negatively affects IL7 signaling, we sought to identify the cis-acting motifs and transacting factors that regulate IL7Rα splicing.

Our data show that the "C" risk allele, which results in a two fold increase in the soluble isoform of IL7Rα, augments a weak exon splice silencer (ESS). Mutation analysis also reveals that exon 6 contains two exon splice enhancers (ESE) and that weak 5' and 3' splice accepter and splice donor sequences surround exon 6 in the human most likely account for the fact that exon 6 is not alternatively spliced in the mouse. We have successfully recapitulated the ESE and ESS sequence motifs within a splicing vector in a heterologous context and in vitro. Together with RNA affinity chromatography, these constructs will facilitate the identification of the trans-acting protein factors regulating exon 6 splicing. In addition to helping define the complex mechanisms of IL7Rα splicing, identifying the proteins that regulate IL7Rα will provide additional candidates genes that contribute to the genetic risk of developing MS.

FLJ Human cDNA Database and tissue specific expressed alternative splicing variants. *T. Isogai, A. Wakamatsu.* Grad Sch Pharmaceutical Sci, Univ Tokyo, Tokyo, Japan.

Human gene number was predicted to be about 20 thousand. But the number of the mRNA was predicted to be several times of gene number. Those varieties were thought to be caused by alternative splicing. In our NEDO human cDNA project, we sequenced 55,402 of human full-length cDNAs (FLJ cDNAs) covered 14,959 genome loci, and also obtained about 1.5 million of 5'-end sequences (5'-EST), about 500 base length, of full-length cDNAs covered 17,287 genome loci from about 100 kinds of cDNA libraries consist of human tissues and cells constructed by oligo-capping method. The majority of the insert size of those was over 2 kb and the full-length rate of 5'-end of those was 90%. Then we constructed FLJ Human cDNA Database ver. 3.0, http://flj.lifesciencedb.jp/. In those 11,769 of full-length sequenced FLJ cDNAs covered 7,025 genome loci, which were obtained as new ORFs at that time by mainly focusing on variations of splicing and transcription start site (TSS) from our cDNA resources described above, were included. Those ORFs were consisted in 3,403 cDNAs, 3,105 genome loci, of alternative N-terminus variants by different TSSs, 8,277 cDNAs, 3,815 genome loci, of alternative splicing variants except for TSSs, and 89 cDNAs of new genome loci. In the selection process we used ATGpr, http://atgpr.dbcls.jp/, the program for identifying the initiation codons and predicting the coding potential in cDNA sequences, for effective cDNA selection from protein coding mRNAs. Elimination efficiency of cDNAs from non-coding RNAs was increased to three fold using ATGpr. In addition, we found some alternative splicing variations which showed specific expression patterns from 11,769 cDNAs. We analyzed gene expression profiles with the about 1.5 million of 5'-ESTs by oligo-capping method described above. Then we selected variant cDNAs shown both characters, a specific expression profile of exons and a variation of motifs and/or domains in coding regions. Obtained cDNAs of each cluster were further analyzed expression patterns of each exon by realtime PCR. As a result, we obtained cDNAs shown tumor tissue specific expressions (FLJ57068, FLJ57884, FLJ52319 etc.), synovial and osteoclast specific expressions (FLJ55256, FLJ55661 etc.) and so on. In conclusion combination of high full-length rate cDNA resources, about 500 base of 5'-ESTs of those and ATGpr was effective for cloning of protein coding alternative splicing variant mRNAs.

Evolutionary acquired alternative splicing in the 5'-UTR of retinal dystrophin transcript is a default pathway with weaker translational activity than non-spliced retina specific form. *I. Kubokawa, M. Yagi, H. Awano, M. Ota, A. Nishida, E.K. Dwianingsih, R.G. Malueka, Y. Takeshima, M. Matsuo.* Pediatrics, Graduate School of Medicine Kobe University, Kobe, Japan.

Background The dystrophin gene, which mutations cause Duchnne or Becker muscular dystrophy (DMD/BMD), has been reported to have a retina specific promoter in intron 29. The R-dystrophin transcript has retina-specific exon 1(R1) joining to exon 30 of the dystrophin gene and has been claimed responsible for ophthalmological problems observed in DMD/BMD. However, the structure of the 5'- untranslated region (5'-UTR) of R-dystrophin is not well elucidated. **Materials and Methods** Retina-promoter derived transcript spanning exon R1 to exon 32 of the dystrophin gene was RT-PCR amplified from total RNA of human retina and other tissues. The translational activity of 5`-UTR was analyzed by the dual-luciferase reporter assay system. **Results and Discussion** RT-PCR amplification of the R-dytrophin transcript in human retina using a conventional primer set revealed a clear product consisting of exon R1 and exon 30, 31 and 32. In contrast, three amplified products were obtained using outer forward primer. Two main products were found the longer form with exons R1, 30, 31 and 32, and the shorter form with deletion of 98bp from exon R1. However, they encoded the identical open reading frame. The deleted 98bp sequence within exon R1 was disclosed a cryptic intron that was evolutionally acquired. The shorter form without the cryptic intron was ubiquitously expressed with wide expression ranges, while the longer form was retina specific expressed. Splicing of the cryptic intron was considered a default splicing pathway. To clarify the physiological difference between two main variants, their 5'-UTRs were examined for translational activity. Remarkably, the shorter ubiquitously expressed form showed lower translational activity than the longer one. The lower activity was supposed due to the removal of internal ribosome entry sites by the cryptic intron splicing. This splicing seemed a molecular switch that regulates translation of the R-dystrophin transcript. Here, an evolutionary acquired alternative splicing was first identified in the 5'- UTR of the retinal dystrophin transcript and considered a default splicing pathway with weaker translational activity than non-spliced retina specific form.

1561/F

Novel FADS1 transcripts generated by alternative polyadenylation, alternative transcription initiation and alternative splicing. *W.J. Park, K.S.D. Kothapalli, J.T. Brenna.* Division of Nutritional Sciences, Cornell University, Ithaca, New York.

Omega-3 (ω3 or n-3) and omega-6 (ω6 or n-6) long chain polyunsaturated fatty acids (LCPUFA) are nutrients and bioactive metabolites associated with most of the human diseases, specifically cardiovascular (CVD), neurological, metabolic syndrome, and are also critical for growth and development. The nonheme, iron-containing, oxygen-dependent fatty acid desaturase enzymes (coded by FADS1 and FADS2, and hypothetically by FADS3) introduce double bonds between two carbon atoms and are of key importance in LCPUFA biosynthesis. Twenty carbon PUFA are the direct precursors for the biosynthesis of physiologically active eicosanoids. FADS1 protein products catalyze the desaturation of 20 carbon PUFA dihomo-gamma-linolenic acid (20:3n-6) to arachidonic acid (20:4n-6) and eicosatetraenoic acid (20:4n-3) to eicosapentaenoic acid (20:5n-3). It is presently assumed that both n-3 and n-6 families of fatty acids, share and compete for the same enzymes, and only a single transcript has been identified for FADS1. The enormous diversity that can be generated at the RNA level is gaining importance as a significant mechanism in the regulation of gene expression and in expanding the diversity of proteome. Recently, we have shown for the first time the existence of alternative transcripts (ATs) for FADS2 and FADS3 genes in a primate (neonate baboon) generated by alternative splicing events. We have also shown the expression of these transcripts in baboon tissues, their conservation in several vertebrate species and reciprocal changes in expression in response to human neuronal cell differentiation. To investigate whether FADS1 is also subjected to alternative splicing, we performed both 5' and 3' rapid amplification of cDNA ends (RACE) using gene specific primers for FADS1. Multiple products were detected on 2% agarose gels. Cloning and sequencing of these products show at least seven alternative transcripts for FADS1. The identified transcripts are generated by alternative selection of Poly A sites, different 5' UTRs, and by internal exon deletions resulting from alternative splicing. These data show, for the first time, that FADS1 produces several mRNA isoforms, and thus that all three FADS genes do so. Our results indicate that these ATs might play critical roles either as mediators of LCPUFA biosynthesis and/or regulation. Thus, consideration of ATs represents possible conceptual change for FADS and in general for diet-gene interaction studies.

1562/F

A Study of PMP22 Localization in Mouse Cochlea Throughout Postnatal Development of the Inner Ear. *T. Carver, M. Kovach.* Biol & Enviro Sci/ 2653, Univ TN at Chattanooga, Chattanooga, TN.

Peripheral myelin protein-22, referred to as PMP22, is a 22 kD glycoprotein associated with the Gas (Growth arrest specific) gene family. PMP22 is largely expressed in Schwann cells and appears to play a role in myelination of neural tissues. However, it has also been found expressed at lower levels in non-neural tissues such as lungs and intestines throughout development. The non-neural pattern of PMP22 gene expression is more akin to the expression pattern characteristic of Gas genes, which are induced during periods of growth arrest, but down regulated at terminal differentiation and cell senescence. Thus, in non-neural tissues, PMP22 may be involved more with cell growth regulation. This dual expression pattern is consistent with the description of both neural and cochlear components to hearing loss in patients with the disorder Charcot-Marie-Tooth (CMT). CMT1E is an autosomal dominant, genetic variant of CMT disease in which patients present with profound sensori-neural deafness in addition to progressive peripheral neuropathy. Since its initial description, several other independent cases of CMT1E have been reported, the majority of which are due to point mutations in the PMP22 gene. This study was designed to gain a better understanding of PMP22 expression in the cochlea throughout development of the inner ear and its role in deafness. The Trembler-J (TrJ) mouse was chosen as a model for PMP22-associated auditory dysfunction with B6 (Wt) being the control. Cochlea were extracted from the mice at various postnatal developmental time points (Days: 1, 7, 14, 21 and 42) and prepared for examination by Immunohistochemistry (IHC) with anti-PMP22 antibody. IHC reveals the presence of PMP22 protein in non-neural tissues of the cochlear chamber in addition to high levels of protein localization in the cochlear nerve. In the neural tissue of Wt, the level of PMP22 increases through D21, while TrJ shows little PMP22 presence. However, this pattern is reversed in the non-neural cells in the organ of corti. At D7, PMP22 is detected in the inner and outer hair cells of both Wt and TrJ. By D21, PMP22 becomes more intense and widespread in TrJ including the inner hair cell, Claudius', Hensen's and Deiters' cells. In comparison, Wt becomes less intense and more localized to the Hensen's and Deiters' cells. This divergence in protein localization patterns between Wt and TrJ mirrors expression levels of non-neural PMP22 transcripts as determined by qRT-PCR.

Regulation of expression of chitinase genes in mouse tissues. *F. Oyama, K. Tsuda, M. Ohno, M. Sakaguchi, Y. Sugahara.* Dept Applied Chemistry, Kogakuin Univ, Hachioji, Tokyo, Japan.

Chitin, an integral component of the fungal cell walls, the exoskeletons of crustaceans and insects, and the microfilarial sheaths of parasites, is the second abundant polysaccharide in nature. Although mammals do not have chitin and chitin synthase, two major chitinases, chitotriosidase and acidic mammalian chitinase (AMCase), have been identified in both human and mouse. Marked elevation of plasma chitotriosidase activity was reported in Gaucher disease, an autosomal recessive lysosomal storage disorder. In addition, significant increases in AMCase mRNA and protein were detected in an induced asthma mouse model and patients. Little is known, however, about the regulation and physiological functions of the chitinases in mammals. We studied expression of both chitinases in mouse tissues by quantitative RT-PCR. Clear tissue specificities were observed in the expression patterns in both chitinases mRNA levels. High levels of chitotriosidase mRNA were identified in testis, stomach, spleen and lung. AMCase mRNA was predominantly expressed in stomach and moderately in testis, spleen and lung. These results indicate that expression of chitinases is regulated in a tissue-type specific manner in mouse tissues.

Development of bioinformatics strategies to predict the functionnal impact of polymorphisms in regulatory regions. *P. Beaulieu[1], M. Ouimet[1], V. Gagné[1], T. Pastinen[3], D. Sinnett[1,2].* 1) Centre de recherche, Hopital Ste-Justine, Montréal, QC, Canada; 2) Departement de Pédiatrie, Université de Montréal, Montreal, QC, Canada; 3) McGill University and Genome Quebec Innovation Center, Montreal, QC, Canada.

Previous efforts to identify functional disease-causing DNA variants were essentially oriented towards the coding regions of candidate genes since these variants have a direct impact on the structure and function of the affected proteins. However, abnormal expression of finely regulated genes can also lead to disequilibria in different metabolic pathways and/or biological processes. Thus, investigation of the functional impact of polymorphisms as well as the determination of the importance of evolutionary conservation in the regulatory regions of candidate genes should improve our knowledge of complex disease aetiologies. As part of an ongoing regulatory genomics initiative, we have integrated several layers of information such as gene structure, SNP content, and probability of transcription factors binding to DNA according to genomic patterns together with experimental results from electrophoretic mobility shift assays (EMSA) and several types of in vitro/vivo promoter activity assays. This information is integrated in web-based environment that can be used to combine and analyse regulatory genomics data (www.regulatorygenomics.org). Here we present a detailed computational analysis of regulatory regions and attempt to improve their functional annotation. This allows us to establish criterias and parameters usable for better predictions of active regulatory regions as well as improved prediction of regulatory SNPs with impact on gene expression. Such functional annotation provide a more effective selection of regulatory targets and thereby facilitates our efforts understand human complex diseases.

1565/F

Rheumatoid arthritis (RA) associated-gene, CD244 expressed in RA synovial tissue. *A. Suzuki[1], R. Yamada[1,2], Y. Kochi[1], Y. Okada[1,3], T. Sawada[4], K. Matsuda[5], Y. Kamatani[5], M. Mori[3], K. Shimane[1,3], A. Takahashi[1], Y. Nakamura[1,5], K. Yamamoto[1,3].* 1) Center for Genomic medicine, Kanagawa, RIKEN, Yokohama City, Japan; 2) Center for Genomic Medicine, Kyoto University, Tokyo, Japan; 3) Department of Allergy and Rheumatology, Graduate School of Medicine, University of Tokyo, Japan; 4) Tokyo Medical University, Tokyo, Japan; 5) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

RA is well-known as an autoimmune disease and is a chronic inflammatory disorder characterized by the destruction of multiple joints. Many genome wide association studies were performed and multiple RA-susceptibility loci and autoimmune-susceptibility loci have been identified. These studies suggested that multiple genes and its functions were related with disease causing and development. These studies also indicated an important factor regarding genetic factors of RA and autoimmune diseases; some of the RA-susceptible polymorphisms also increase the risks of other autoimmune diseases as reported for e.g., STAT4 (ref1) and FCRL3 (ref2) with RA and SLE. One of the mechanisms of the inflammation in autoimmune diseases associated with signal transduction via signaling lymphocytic activation molecule (SLAM). It was reported that SLAM family gene, e.g., Ly108 is also associated with systemic lupus erythematosus (SLE). We studied whether variants of the SLAM family gene in the chromosome 1q region are associated with susceptibility to RA. The association peak in the block was observed at two functional SNPs (rs3766379 and rs6682654) in CD244 in two independent RA cohorts from Japan (P= 3.23 x 10-8 and P=7.45 x 10-8). We found a Japanese cohort of systemic lupus erythematosus (SLE) that had the similar genotype distribution with RA cohorts. These disease-associated SNPs, rs3766379 and rs6682654 also have been shown as functional SNPs(ref3). Furthermore, we indicated that CD244 also expressed in synovial tissues of CIA mice and RA patients. We supposed that up-regulation of CD244 affect on RA and other autoimmune diseases, including SLE. Thus, CD244 is a genetic risk factor for RA and may have a role for autoimmunity in RA. 1) Remmers, E.F. et al. N Engl J Med 357, 977-86 (2007). 2) Kochi, Y. et al. Nat Genet 37, 478-85 (2005). 3) Suzuki, A. et al. Nat Genet 40, 1224-1229 (2008).

Neto2 is a novel regulator of the potassium chloride co-transporter KCC2 and GABA-mediated synaptic inhibition. *E.A. Ivakine[1], B.A. Acton[2], M.A. Woodin[2], R.R. McInnes[1,3].* 1) Program in Stem Cell and Developmental Biology, Hospital for Sick Children Research Institute, Toronto, M5G1L7,; 2) Department of Cell & Systems Biology, University of Toronto, 25 Harbord Street, Toronto, M5S 3G5; 3) The Lady Davis Institute, Jewish General Hospital, McGill University, Montreal, H3T1E2.

Neto1 and Neto2 are two related neuronal single pass transmembrane proteins, expressed highly in the developing and adult brain. Recently, we and others reported that the Neto proteins are important regulators of synaptic strength and excitatory neurotransmission (Ng et al. PLoS Biol. 2009; 7(2):e41; Zhang et al. Neuron. 2009; 12;61(3):385-96). The objective of the current study was to define the role of Neto2 in GABA-mediated synaptic inhibition. Using a GST pulldown approach followed by LC-MS/MS we identified KCC2 as a putative Neto2 interactor. KCC2 is a K^+-Cl^- cotransporter required for synaptic inhibition in the mature CNS, where it establishes a Cl^- ion gradient. We validated the Neto2:KCC2 interaction by co-immunoprecipitating them from both hippocampal protein lysates and HEK-293 cells. Using a series of Neto2 deletion constructs we determined that the Neto2:KCC2 interaction was mediated by the Neto2 ectodomain. To define the functional consequences of this interaction, we measured the strength of synaptic inhibition, as determined by the Cl^- equilibrium potential (E_{Cl} = membrane potential where net flow of chloride ions is zero). We found that in *Neto2-/-* neurons E_{Cl} was significantly depolarized vs. wild type neurons (-53.74 ± 2.43 mV vs. -75.22 ± 2.05 mV; $p < 0.001$), demonstrating a highly significant increase in the intracellular Cl^- concentration, and suggesting a decrease in KCC2 activity. This depolarized E_{Cl} can be completely rescued by reintroducing a full length *Neto2* into *Neto2-/-* neurons; E_{Cl} = -73.12 ± 3.07 mV ($p < 0.001$). Importantly, shRNA-mediated knock-down of Neto2 in mature wild type cultured neurons also causes a depolarization of E_{Cl} (-54.43 ± 2.12 mV; $p = 0.016$), indicating that maturation of *Neto2-/-* and *wt* neurons occurs at similar rate. To define the consequences of *Neto2* deficiency on KCC2 function, we first analyzed KCC2 levels in wild type and *Neto2*-deficient mice: the lack of Neto2 had no effect on KCC2 abundance, either on the cell surface or in total hippocampal lysates. We conclude that Neto2 is a novel regulator of neuronal Cl^- homeostasis through its interaction with KCC2, thereby profoundly influencing GABA-mediated synaptic inhibition. Through its ectodomain Neto2 directly binds to KCC2 and regulates KCC2 activity without affecting either total or cell surface levels of the transporter.

Neuron-specific enhanced expression of TAF1 and its isoform. *S. Makino[1], G. Tamiya[2], I. Tooyama[1].* 1) Molecular Neuroscience Research Center, Shiga University of Medical Science; 2) Advanced Molecular Epidemiology Research Institute, Yamagata University School of Medicine.

We previously found a neuron-specific isoform of the *TAF1* (TATA box binding protein-associated factor 1), which is the disease causative gene of X-linked recessive dystonia-parkinsonism showing severe neurodegeneration in striatum (XDP/DYT3; MIM314250). The *TAF1* gene encodes the largest component of the TFIID complex involved in RNA polymerase II-mediated expression of many genes related cell division. The neuron-specific isoform of the *TAF1* gene, named *N-TAF1*, may have an essential role in neuronal survival in the striatum through transcriptional regulation of many neuron-specific genes. To investigate the detailed function of the neuron-specific isoform of the *TAF1* gene, we carried out over-expression of *N-TAF1* in several mice cell lines. First, we established the stable N2a-TetR cells with an inducible mouse N-TAF1/TAF1 expression vector. The doxycycline treatment of N-TAF1/TAF1 inducible cells allowed a substantial expression of its products. We subsequently performed MTS assay, which could easily be interpreted as cellular mitochondria activities, to examine if the over-expression of N-TAF1/TAF1 affect cell proliferation in Neuro-2a. The MTS assay showed that the N-TAF1 induction for 7 days significantly inhibited N2a proliferation whereas the TAF1 induction elevated cell proliferation. Second, we compared the intracellular localizations of GFP-tagged N-TAF1 and TAF1 protein during the cell cycle and mitosis between mice neuroblastoma, hepatoma and renal carcinoma cell lines. These experiments would reveal the neuron-specific role of *N-TAF1* gene and shed light on the molecular pathogenesis of disease caused by transcriptional dysregulation as well as XDP.

Targeted Integration of Fluorescent Reporter Genes Utilizing Zinc Finger Nucleases. *D. Vassar, N. Zenser, H. Zhang, F. Zhang, D. Malkov, G. Davis.* Sigma-Aldrich Biotechnology, 2909 Laclede Avenue, St. Louis, MO 63139.

Zinc finger nucleases (ZFNs) are synthetic proteins engineered to bind DNA at a sequence-specific location and create a double strand break. The cell's natural machinery repairs the break in one of two ways: non-homologous end joining or homologous recombination. We relied on the homologous recombination pathway to insert a transgene into a desired location. ZFNs were customized/designed to cut near the near the desired site of integration for the three organelle specific genes. These ZFNs were nucleofected along with a donor construct containing a fluorescent reporter gene flanked by sequences homologous to the target integration site into U2OS cells. Integration resulted in endogenous expression of fluorescent fusion proteins that labeled a particular organelle. Three gene loci were tagged: TUBA1B (α-tubulin 1b, microtubule), ACTB (β-actin, actin stress fibers), LMNB1 (lamin B1, nucleus). Fluorescent proteins were used as reporters. The fluorescent reporters were stably integrated into the genome of the cells. Preservation of protein function and gene regulation was observed. Additionally, due to the specificity of the targeted integration process, multiple reporter genes can be integrated into a cell's genome for further study of cellular processes.

THE ATM PROTEIN DISPLAYS DISTINCT SPATIAL AND TEMPORAL DYNAMICS AT SITES OF INDUCED DNA DAMAGE. *P.S Bradshaw[1, 2], M.S Meyn[1, 2].* 1) Program in Genetics and Genome Biology, Sick Kids Research Institute, Toronto, ON, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada.

Human cells use complex signaling networks to detect and respond to DNA damage in genomic DNA. ATM, the protein kinase inactivated in the cancer syndrome Ataxia-Telangiectasia, controls the major human DNA Double Strand Break (DSB) response pathway. Current models assume that ATM is a critical component of the megabase-sized chromatin complexes that develop around induced DSBs and serve as a platform for DSB repair. To better understand the behavior of ATM at DNA breaks we use UVA light and Hoechst dye to introduce spatially-defined DNA breaks within nuclear chromatin in human fibroblasts. Photo-induction of DNA damage, equivalent to ~10 Gy γ-radiation, causes rapid recruitment of endogenous ATM to damage sites. This recruitment occurs after MRN complex recruitment and prior to DNA damage response factors γH2AX, 53BP1 and MDC1. ATM accumulation peaks 10-30 minutes post damage, then declines with kinetics paralleling those of DSB rejoining. We find the induced foci of many DSB response proteins enlarge and diffuse with time. Mre11 and Nbs1, for example, display both MDC1-dependent diffuse staining and localized MDC1-independent foci 1 hr post DNA break induction. The latter co-localize with foci of the homologous recombination (HR) proteins RPA and Rad51. In contrast, ATM forms localized, non-diffusible foci that are MRN-dependent, MDC1-independent and spatially separate from HR foci. The non-diffusible nature of DNA damage-associated foci of endogenous ATM is confirmed by FRAP analysis of GFP-tagged ATM. Further, mutating the ATM serine 1981 phosphorylation site to alanine impairs but does not completely block accumulation of GFP-ATM. Over-expression of the telomeric protein TRF2, an ATM kinase inhibitor whose binding spans the S1981 residue, also attenuates GFP-ATM accumulation DNA damage sites. Our results demonstrate the dynamic nature of protein complexes formed at DNA damage sites and document three types of complexes: chromatin-associated megabase complexes; discrete foci of HR proteins; and discrete foci of ATM. The spatial and temporal dynamics of ATM foci suggest ATM is not a major component of chromatin-associated megabase complexes and does not directly facilitate HR-mediated repair. Rather, our findings are consistent with ATM rapidly accumulating at localized sites of damage in an MRN-dependent manner, then being displaced as DNA breaks are either rejoined or processed for recombinational repair.

VSXl mutational analysis in Indian patients affected by keratoconus: identification of a novel mutation. *I. Goyal[1], M. Kumar[1], D. Pathak[1], M. Tanwar[1], N. Sharma[2], J.S. Titiyal[2], R. Dada[1].* 1) Laboratory for Molecular Reproduction and Genetics, Department of Anatomy, All India Institute of Medical Sciences, New Delhi; 2) Dr R.P. Centre for Ophthalmic Sciences, All India Institute of Medical Sciences, New Delhi.

Keratoconus is the most common of noninflammatory ectatic disorders of cornea, with an estimated incidence between 1 in 500 and 1 in 2000 persons. Although most cases of keratoconus are sporadic, 5% to 10% of patients have a positive family history. The pathogenesis of keratoconus is unknown. The only identified molecular cause for keratoconus involves mutations in VSXl gene. This study was aimed to analyze keratoconus patients for mutations in VSXl gene. All participants had a comprehensive eye examination. DNA was extracted from whole blood samples (5 ml) of all Keratoconus patients and controls using phenol chloroform method. The coding regions of VSXl and exon-intron junctions were amplified using five sets of oligonucleotide primers. Sequencing analysis showed 4 mutations in VSXl gene. R217H, P237P, A182A changes in amino acids were already reported in the literature. We found a novel C>T intronic polymorphism between exon 2-3. As this novel variation is in proximity to the intron-exon junction, it possibly interference with splicing mechanism. Various studies have shown that role of VSXl gene in the pathogenesis of corneal disease is controversial. The lack of evidence to support that VSXl mutations are pathogenic, failure to demonstrate corneal expression of VSXl gene and identification of presumed pathogenic mutations in VSXl gene in less than 5% of keratoconus patients suggested that VSXl gene does not play a major role in the pathogenesis of keratoconus. In conclusion, our study reports a new VSXl mutation and shows no significant correlation between VSXl and keratoconus.

1571/F

Effects of TNF-α and IL-1β on the activation of genes related to inflammatory, immune responses and cell death in immortalized human keratinocytes HaCat. *S. Nistico[1], N. Paolillo[2], D. Minella[3], S. Piccirilli[4], G. Emiliano[3], M. Biancolella[5], S. Chimenti[1], G. Novelli[3], G. Nistico[4].* 1) . Department of Dermatology, School of Medicine, University of Rome Tor Vergata, Italy; 2) IRCCS "C. Mondino Institute of Neurology" Foundation, Pavia, Italy; 3) Department of Biopathology and Diagnostic Imaging, School of Medicine, Tor Vergata University, Rome, Italy; 4) Center of Pharmaceutical Biotechnology, University of Rome Tor Vergata, Italy; 5) Department of Preventive Medicine University of Southern California,Los Angeles, CA, USA.

The epidermis is implicated in allergic and severe skin adverse reactions to drugs such as toxic epidermal necrolysis (TEN; OMIM #608579) and Stevens-Johnson syndrome (SJS; OMIM #608579) both characterized morphologically by the rapid onset of keratinocyte cell death by apoptosis. To date, the precise sequence of molecular and cellular events that lead to the development of SJS and TEN is only partially understood. A large body of evidence exists in the literature involving some cytokines of the tumor necrosis factor (TNF) family and interleukins (ILs) in the pathogenesis of cell death in epidermal keratinocytes.By controlling gene expression, TNF-α orchestrates the cutaneous response to environmental damage and inflammation. Interleukin 1 (IL-1) often referred to as prototypic inflammatory cytokine is a family of three closely related proteins that are the products of separate genes.In particular it has been reported that IL-1 treatment causes profound morphological changes of keratinocytes. Several reports of microarrays analysis investigated the transcriptional changes in cells induced by treatment with TNF-α and IL-1β.Important changes in gene expression profiles of human epidermal keratinocytes were reported with TNF-α as well as with the treatment with IL-1α showing that both cytokines are able to activate many genes involved in the inflammatory and immune responses as well as in cell death. To our aims, we applied microarray technology to characterize the modification of gene expression in HaCat cells treated with TNF-α, and IL-1β given alone or in combination. We focused our attention on gene expression changes evoked by both cytokines specifically analyzing up or down-regulation of genes related to inflammatory, immune response, cell death as well as cell differentiation, growth and repair mechanisms, in order to disclose specific genomic markers of pathological responses to inflammatory injuries. Significant differences in the percentage and quality of genes dysregulated by TNF-α and IL-1β were shown. Both cytokines activated a series of genes involved in inflammatory, immune response as well as in cell death. In our experimental conditions, TNF-α, in contrast to IL-1β, did not induce a significant level of apoptosis in keratinocytes. Given together both cytokines produced a synergistic transcriptional response which was due to the activation of several specific genes occurring after application of each cytokine.

1572/F

Elevated levels of oxdatively damaged DNA in patients with heterozygous defects in the selenocysteine insertion sequence-binding protein 2 gene (SECISBP2). *M. Karbaschi[1], E. Schoenmakers[2], M.D. Evand[1], K. Chatterjee[2], M.S Cooke[1].* 1) University of Leicester, Leicester, United Kingdom; 2) Institute of Metabolic Science, Cambridge, United Kingdom.

Selenium (Se) is a vital dietary element for eukaryote and prokaryotic cells. In humans, its biological role is mediated principally by incorporation of selenocysteine, into selenium containing proteins. About 30 different selenoproteins have so far been observed in human cells and tissues, performing a variety of different functions including removal of cellular reactive oxygen species, reduction of oxidised methionines in proteins, metabolism of thyroid hormones, transport and delivery of selenium to peripheral tissues, protein folding and ER stress, plus proteins whose precise function is unknown. One of the best-known functions of selenoproteins is displayed by the family of selenium-dependent glutathione peroxidases which reduces hydrogen peroxide, and damaging lipid and phospholipid hydroperoxides to harmless products such as water and alcohols. This function helps to reduce the risk of induction of further oxdatively generated damage to biomolecules and accordingly reduces risk of a variety of damage-related pathological conditions. In this study, we examined the baseline levels of oxdatively damaged DNA in two individuals, one adult and one child with compound heterozygous defects in the selenocysteine insertion sequence-binding protein 2 (SECISBP2) gene. As part of a complex phenotype, using hOGG1-modified comet assay, we noted a significantly elevated baseline levels of 8-oxoguanine and alkali labile sites in dermal fibroblasts versus age/gender match controls in the presence and absence of exogenous H_2O_2 (50 μM, 30 min). Using the same assay, we demonstrated that whilst DNA repair processes were unaffected, antioxidant defences were impaired, the likely source of the elevated baseline levels. Similarly, there was a significant increase in the level of 8-oxoguanine following exposure to 10 J/cm^2 UVA in affected adult, accounting for the pronounced photosensitivity seen in this subject. These results demonstrate the central role of selenoprotein in cellular antioxidant defence.

CHD7 promotes transcription of ribosomal RNA: evidence for mechanistic overlap between CHARGE syndrome and disorders of ribosome biogenesis. *G.E. Zentner[1], E.A. Hurd[2], D.M. Martin[2,3], P.C. Scacheri[1,4].* 1) Department of Genetics, Case Western Reserve University, Cleveland, OH; 2) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 4) Case Comprehensive Cancer Center, Case Western Reserve University, Cleveland, OH.

De novo mutation of the *CHD7* gene, encoding a member of the chromodomain helicase DNA binding protein family, is responsible for approximately two-thirds of cases of CHARGE syndrome, a developmental disorder characterized by a complex constellation of birth defects. Recent studies have defined functions for CHD7 in enhancer-mediated transcriptional regulation and neural crest cell development. Despite these advances, very few genes have been found to be dysregulated by CHD7 haploinsufficiency, and it is not clear if their dysregulation contributes to the phenotypes of CHARGE syndrome. Here we report results of immunofluorescence, subcellular fractionation, and ChIP-seq experiments which show that CHD7 localizes to the nucleolus and associates with rDNA. Consistent with a role for CHD7 as an activator of rDNA transcription, transient overexpression of CHD7 increases the levels of 45S pre-rRNA, the primary transcript of rDNA that is ultimately processed into the mature 18S, 5.8S, and 28S rRNA species. Likewise, siRNA-mediated depletion of CHD7 results in hypermethylation of the rDNA promoter and a concomitant reduction in levels of 45S pre-rRNA. Depletion of CHD7 also reduces cell proliferation, a process linked to rRNA synthesis which is defective in the olfactory epithelium of Chd7 mutant mouse embryos. Consistent with this embryonic olfactory proliferation defect and further supporting a role for CHD7 in rRNA transcription, CHARGE-relevant tissues from Chd7 mutant mouse embryos show reduced levels of 45S pre-rRNA. These results raise the possibility that the pathogenesis of CHARGE syndrome shares common mechanisms with well-defined "ribopathies" such as Treacher Collins syndrome and Diamond-Blackfan anemia, which are caused by deficiencies in ribosome biogenesis.

Tandem repeat sequences as causative cis eQTLs for protein-coding gene expression variation: the case of CSTB. *C. Borel[1], E. Migliavacca[1], E.T. Dermitzakis[1], M. Gagnebin[1], A.J. Sharp[1,2], S.E. Antonarakis[1].* 1) Dept Genetic Medicine, Univ Geneva Medical Sch, Geneva, Switzerland; 2) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York.

Individual variation of gene expression contributes to phenotypic variability. Thus the understanding of the genetic control of gene expression is important to decipher the etiology of genetic traits and disorders. Genetic analysis in cells and tissues from different individuals has revealed both cis and trans eQTLs for many genes; cis eQTL effect is relatively strong since they have been discovered and replicated with relatively small sample sizes. Recent studies have revealed that the majority of the discovered eQTLs are tissue specific (Dimas et al. Science 2009), a finding compatible with the tissue specificity of the phenotypic characteristics of genetic disorders. The challenging question for each eQTL is to identify the functional variant that controls the gene expression variation. We hypothesize that CNV of short sequence repeats in the human genome contributes to the gene expression variation of some genes. Our laboratory has previously identified that rare expansions of a dodecamer repeat (CG4C G4CG) in the promoter region of the CSTB gene on chromosome 21q lead to silencing of the gene, resulting in progressive myoclonus epilepsy (Lalioti et al Nature 1997). The majority of alleles in the human population contain either 2 or 3 copies of this dodecamer repeat. Since the large expansion to more than 200 repeat copies results in silencing of the CSTB gene, we hypothesized that the common 2 or 3 copy variation may be a causative cis-eQTL for CSTB expression variation. We used PCR to genotype the repeat length and quantified CSTB expression by TaqMan qRT-PCR in 170 lymphoblast and fibroblast samples from the GenCord collection. Although there is considerable variation in expression of this gene in the normal population, we observed that in lymphoblasts repeat length is strongly correlated with CSTB expression (p=3x10-11), with individuals homozygous for the 3-repeat allele showing ~2-fold higher expression than individuals homozygous for the 2-repeat allele. In fibroblasts a weaker effect was observed (p=0.03), showing that this effect is cell-type specific. Examination of both genotyped and imputed SNPs within 1Mb of CSTB revealed none that were significantly correlated with CSTB expression. Therefore, the dodecamer repeat represents the strongest cis eQTL for CSTB in lymphoblasts, explaining 23% of expression variation. We conclude that polymorphic tandem repeats likely represent the causative variation of a fraction of eQTLs in the genome.

The functional effects of *CCL3L1* copy number. *D. Carpenter, R.I. McIntosh, R. Pleass, J.A.L. Armour.* Genetics, University of Nottingham, Nottingham, Notts, United Kingdom.

Copy number variation (CNV) is a frequent form of variation throughout the human genome. It is now apparent that CNVs contribute to the variation observed between individuals and can influence both gene expression[1] and human disease progression.

CCL3L1 encodes the chemokine MIP-1α isoform LD78β which functions as a chemotactic mediator of the immune system, and is the most potent known ligand for the CCR5 receptor. Furthermore copy number variation of *CCL3L1* has been implicated in HIV progression and has the potential to influence other immune disorders.

This study examines the functional consequences of copy number variation of *CCL3L1*. Monocytes were isolated from 53 independent UK samples with no known clinical phenotypes and, after stimulation with LPS, secreted protein and cellular mRNA were isolated. Genomic DNA extracted from remaining leukocytes was used for determination of *CCL3L1* copy number by the paralogue ratio test (PRT)[2]. A time trial assessment was performed to optimise the time point for protein and mRNA collection.

Levels of MIP-1α protein were determined by sandwich ELISAs of the cell supernatants and real time PCR was used to determine transcripts levels of mRNA. The protein and mRNA results suggest that there is some influence of copy number on gene expression but only at higher copy numbers, and that there may be other factors influencing gene expression of *CCL3L1*.

Transcriptional Regulation of ERBB3, a gene essential in neural crest development. *M.K. Prasad[1], J. Cronin[2], S.K. Loftus[2], W.J. Pavan[2], A.S. McCallion[1].* 1) Johns Hopkins University, Baltimore, MD; 2) National Institutes of Health, National Human Genome Research Institute, Bethesda, MD.

The neural crest (NC) is a transient multipotent population of cells in vertebrate development that give rise to a variety of cell types including peripheral neurons and glia, melanocytes, craniofacial skeleton and smooth muscle. The molecular pathways governing neural crest development are of immense interest due to the large number of neurocristopathies seen in patient populations. ERBB3 is one many genes that are essential for normal NC development. Studies in mouse knockouts and zebrafish mutants have established a role for ERBB3 in Schwann cell development. However, recent studies have also suggested a role for ERBB3 in melanocyte development. Although not required for their specification, it is required for later stages of development in culture. ERBB3 is also required for maintaining the proliferative and migratory properties of melanocyte precursors, and is activated in melanomas. In order to better understand the regulation of ERBB3 during melanocyte development and melanoma progression, we have begun a comprehensive analysis of the regulatory landscape at this locus. To date, we have tested the regulatory activity of eight evolutionarily conserved sequences in vitro in 2 human melanoma cell lines (UACC-1022 and BLA) and a mouse melanocyte cell line (melan-A). Five of eight sequences showed greater than 3-fold luciferase activity relative to a promoter only construct. We then tested regulatory activity of these sequences in vivo using a Tol2 based transgenic zebrafish assay. Preliminary results from mosaic embryos indicate that most (7/8) sequences have regulatory activity, of which two direct expression in a manner consistent with ERBB3 expression in peripheral glia and epidermal cells. We will describe the progress in our efforts confirming the regulatory activity of these and other sequences at ERBB3 in germline transmitted transgenic fish. Our long-term goal is to determine key factors involved in regulating the expression of these sequences in the melanocyte lineage.

The role of the transcription factor TCF7L2 in type 2 diabetes. *J.L. Hall[1], L. Prokunina-Olsson[2], V. Weaver[1], J.A. Wood[3], B. LaCroix[1], N.T. Turner[1], M. Rolfe[1], D. Delaney[1], D. Bloom[1], M.K. Thomas[3].* 1) Department of Medicine, University of Minnesota, Minneapolis, MN; 2) Lab of Translational Genomics, Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Bethesda MD; 3) Lab of Molecular Endocrinology, Massachusetts General Hospital, Boston, MA.

Genetic variants within the TCF7L2 gene have been identified as the strongest common risk factors for the development of type 2 diabetes (T2D). Using a systems biology approach, we identified a neuroendocrine specific isoform of TCF7L2 that was associated with the T2D risk alleles (Prokunina-Olsson et al, 2009). This unique neuroendocrine isoform was found in human thalamus, hypothalamus, occipital lobe, gut, pancreas, and pancreatic islets. RTQPCR and in situ hybridization confirmed the neuroendocrine expression pattern for this TCF7L2 isoform in mice. To further test the biological mechanisms through which TCF7L2 regulates metabolic homeostasis, we utilized the TCF7L2 heterozygous mouse model, as the TCF7L2 -/- mouse dies at birth. TCF7L2 heterozygous mice exhibited an impaired glucose tolerance phenotype on a low fat diet in response to an intraperitoneal glucose test ($n= 5$, $p < 0.015$). These findings align with a previously identified association in non-diabetic individuals harboring the TCF7L2 risk allele and impaired glucose tolerance. Circulating ghrelin levels were also decreased in the TCF7L2 heterozygous mice ($n = 3$, $p < 0.03$), similar to individuals harboring the TCF7L2 T2D risk allele. Expression of the neuroendocrine specific isoform of TCF7L2 was decreased in TCF7L2 heterozygous mice, and correlated with decreased ghrelin mRNA levels in the gut (n=4-5 TCF7L2 heterozyous and wild type mice per group, $p < 0.037$). The neuroendocrine specific TCF7L2 isoform also correlated with expression of additional metabolic regulation genes CART ($r = 0.45$, $n = 41$, $p <0.0032$) and glucagon ($r = -0.4$, $n=41$, $p <0.0096$) in the gut of TCF7L2 heterozygous and wild type mice. In addition, this TCF7L2 isoform correlated with expression of cell proliferation and survival regulators in the gut including cyclinD1 ($r = 0.5$, $n = 41$, $p < 0.00087$), bcl-2 ($r= 0.74$, $n = 41$, $p < 0.0001$), and c-myc ($r = 0.41$, $n=41$, $p < 0.0077$). In conclusion, TCF7L2 deficiency results in impaired glucose tolerance and decreased circulating ghrelin levels in mice. These findings are similar to humans with the T2D risk alleles. Moreover, loss of the neuroendocrine specific isoform of TCF7L2 is associated with decreased mRNA expression of ghrelin, cyclin D1, bcl-2, and c-myc in the gut. Taken together, these findings may have important implications for a newly identified isoform of TCF7L2 in regulating metabolism through a neuroendocrine specific axis.

RFX6, a novel gene necessary for the β-cell phenotype. *N. Taleb, D. Levi, H. Zouk, C. Polychronakos.* Departments of Pediatrics and Human Genetics, McGill University, Montreal, Québec, Canada.

Introduction: Our group has recently identified RFX6 as a novel gene necessary for the development of the endocrine pancreas, using homozygosity mapping and high throughput sequencing on several probands with neonatal diabetes mellitus (Nature, Feb 2010). Interestingly, many family members, obligatory or potential heterozygous carriers of RFX6 mutations, have been diagnosed with diabetes (type 1, 2 or gestational, glucose intolerant). This, added to its sustained specific expression in the adult pancreatic islets, implies a role for RFX6 as a phenotype-maintaining gene in the insulin producing beta-cells. Methods and results: To examine the role of RFX6, a transcription factor, in the post-natal pancreas two different hypotheses have been tested. Hypothesis 1- RFX6 expression is modulated by glucose concentration. In vivo glucose stimulation effect on the expression of RFX6 was studied in C57 mice. We treated mice with intraperitoneal glucose (Dextrose 50%) injection at 3 g/kg body weight and euthanased them at one hour. In four different pairs, the expression of RFX6, tested by real-time PCR, significantly increased in the stimulated versus unstimulated mice (2.3 ± 0.5 fold increase, $p = 0.03$). Hypothesis 2- RFX6 determines insulin synthesis and/or release. We knocked RFX6 down in Min6 cells, an established mouse β-cell cell line model for glucose stimulated insulin secretion (GSIS) using si-RNA. A static glucose stimulation experiment (0.5 vs 25 mM Glucose for half an hour) was carried out at 48 hours post-transfection. Insulin peptide levels were measured by ELISA kit. GSIS percentage from baseline was significantly reduced in the knock-down samples compared to negative controls ($292.0\pm48.7\%$ vs $192.5\pm52.1\%$, $p=0.008$). There was no significant difference in the total insulin content between the two groups. RNA-microarray is generated from the knock-down cells and will be analysed for the effect of RFX6 as a transcription factor on other genes in beta-cells. Conclusion: According to our data, RFX6 plays a role in GSIS, a main function of beta-cells. More experiments are being carried to characterize the interaction of RFX6 with other genes. Our study will hopefully add to our genetic understanding of the function of beta-cells and the pathophysiology of diabetes mellitus.

1579/F

Individual variation in insulin response. *I.X. Wang[1,2], V.G. Cheung[1,2].* 1) Howard Hughes Medical Institute; 2) Departments of Pediatrics & Genetics, University of Pennsylvania.

Insulin sensitivity varies greatly among individuals, which underlies susceptibility to diseases including metabolic and polycystic ovary syndromes. In this study, we measured the extent of natural variation in insulin response, and investigated the molecular mechanisms of how human cells respond to insulin at the signal transduction and gene expression levels. Insulin induces intracellular kinase signaling that mediates diverse cellular processes, such as gene expression. Using primary fibroblasts from 35 unrelated and age-matched healthy individuals, we measured insulin-induced 1) phosphorylation of signaling factors; and 2) changes in gene expression. We identified signaling factors and nearly 3,000 genes (ANOVA, $p<10\text{-}6$) that are involved in insulin response. Signal transduction initiates insulin response pathways; however, despite their importance, the levels of induction of key factors including ERK and AKT vary greatly among individuals. For example, following insulin treatment, the phosphorylation of ERK1/2 differs by >20 fold among our subjects. We further showed that the variability of signal transduction is functional; it leads to variation in downstream gene expression. The level of ERK1/2 phosphorylation is correlated with induction of about 500 genes ($r>0.4$, $p<0.01$). We confirmed that these genes are targets of ERK by pharmacologic inhibition studies using U0126. Annotations of these ERK target genes showed that they are involved in primary metabolism and cell cycle regulation. In this presentation, I will describe results from our study and discuss the implications for insulin resistance and associated human diseases.

1580/F

Length of GT repeats in intron 2 of the JME-associated gene BRD2 affects alternative splicing. *Q. Cui[1], E. Shang[2], D. Greenberg[2, 3], D. Wolgemuth[1, 4, 5].* 1) Departments of Genetics and Development and Obstetrics and Gynecology, Columbia University Medical Center, NEW York, NY; 2) Division of Statistical Genetics, Department of Biostatistics, Mailman School of Public Health, Columbia University Medical Center, NEW York, NY; 3) Department of Psychiatry, Columbia University Medical Center and New York State Psychiatric Institute, NEW York, NY; 4) The Herbert Irving Comprehensive Cancer Center, Columbia University Medical Center, NEW York, NY; 5) The Institute of Human Nutrition, Columbia University Medical Center, New York, NY.

Juvenile Myoclonic Epilepsy (JME) is among the most common types of Idiopathic Generalized Epilepsy and has a complex genetic inheritance. Linkage and association analysis led us to the double- bromodomain-containing gene BRD2, which is implicated in a variety of cellular processes, including regulating gene expression. Our gene-targeting studies showed that homozygous Brd2-/- mice are embryonic lethal, importantly, with profound abnormalities in neural development. Heterozygous Brd2+/- mice exhibit enhanced sensitivity to chemically-induced seizures and abnormal neural architecture. We also discovered that intron 2 of BRD2 contains a highly conserved, alternatively spliced exon, which introduces a premature termination codon in the resulting mRNA. Further, we identified polymorphisms in the lengths of GT-repeats in intron 2 of BRD2 that are associated with JME. Variation in the length of GT-repeats has been shown to affect alternative splicing events in other experimental models. We now test the hypothesis that the polymorphisms in intron 2, in particular JME-associated variants in GT repeat-length identified in patient DNA, affect alternative exon splicing and the levels of the corresponding transcripts, and hence, the production of functional BRD2 products. We have generated 10 mini-gene constructs containing exon2-intron2-exon3 of BRD2, incorporating different GT dinucleotide repeat lengths (13, 4, 3, 2 and 1) in the presence or absence of GTAA (another polymorphism located 22 bp upstream of the GT repeats). These mini-genes were transiently transfected into 293T cells (embryonic kidney) and SH-SY5Y cells (neuroblastoma). Splicing activity was detected by RT-PCR analysis using primers that discriminate between the regularly spliced mRNA and the exon 2a-containing alternatively spliced mRNA. In 293T cells, shortening of the GT repeats significantly increased the proportion of the alternatively spliced BRD2 mRNA product. In SH-SY5Y cells, this phenomenon only exists in mini-genes lacking the GTAA. We therefore conclude that the length of the GT repeats in intron 2 of BRD2, which is polymorphic in the human population and associated with JME, affects the alternative splicing event, and hence, the production of functional BRD2 protein. The data suggest that aberrant expression of BRD2 in neuronal populations contributes to seizure susceptibility, likely through mechanisms involving haplo-insufficiency.

Identification of a novel transcript of ARMS2 gene in human retina. *G. Wang[1], W.K. Scott[1], P. Whitehead[1], B.L. Court[1], S.G. Schwartz[3], J.L. Kovach[3], K.L. Spencer[2], A. Agarwal[4], J.L. Haines[2], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Bascom Palmer Eye Institute, university of Miami Miller School of Medicine, Miami, FL; 4) Department of Ophthalmology, Vanderbilt, Nashville, TN.

Variations in gene ARMS2 (Age-related macular degeneration susceptibility 2, also known as LOC387715, MIM 611313) at the chromosome 10q26 locus is strongly associated with risk of age-related macular degeneration (AMD). However, it remains unclear of what the basic function of ARMS2 is in human eye. We recently systematically analyzed ARMS2 transcription in human retina. We first performed 5'RACE (Rapid amplification of cDNA ends) and 3'RACE assays to characterize ARMS2 transcripts. The 5'RACE found that the transcription start site (TSS) of ARMS2 in human retina is 220bp upstream compared to the annotation in public database (NCBI GRCh37). And 3'RACE confirmed that the polyadenylation site in retina matches the annotation in the database (NCBI GRCh37). Whether the extended 5'UTR contains any local cis-acting regulatory elements need more studies. We validated this 5' end extended transcripts by RT-PCR and sequencing. We then conducted quantitative PCR to measure ARMS2 mRNA level in dissected retina and choroid/retinal pigment epithelium (RPE) samples. The preliminary data show that ARMS2 transcript is preferentially and significantly expressed in choroid/RPE compared to retina (fold change»11, P<0.05). In conclusion, the transcription start site of the ARMS2 gene in human eyes is 220bp upstream from the annotated TSS. ARMS2 is preferentially expressed in the choroid/RPE than in the retina, suggesting a potential function of ARMS2 in the RPE and choroid. The results of this study are critical to further analyze the function of ARMS2 in AMD pathogenesis in the future.

Genetic variants and monoallelic expression of surfactant protein D in inflammatory bowel disease. *Z. Lin[1], G. John[1], J.P. Hegarty[1], A. Berg[2], W. Yu[1], Y. Wang[1,3], A. Kelly[1], B.Z. Peterson[3], L.S. Poritz[1,3], J. Floros[4,5], W.A. Koltun[1].* 1) Surgery, Pennsylvania State University College of Medicine, Hershey, PA; 2) Public Health Sciences, Pennsylvania State University College of Medicine, Hershey, PA; 3) Cellular and Molecular Physiology, Pennsylvania State University College of Medicine, Hershey, PA; 4) Pediatrics, Pennsylvania State University College of Medicine, Hershey, PA; 5) Obstetrics and Gynecology, Pennsylvania State University College of Medicine, Hershey, PA.

Surfactant protein-D (SP-D) belongs to the collagen-containing C-type (calcium dependent) lectins. It plays an important role in linking adaptive and innate immune cell functions in the first line of the host defense. SP-D primarily studied in the lung is widely distributed on mucosal surfaces of various tissues. It is most likely involved in extra-pulmonary host defenses. SP-D is expressed in the gastrointestinal tract, and SP-D polymorphisms have been associated to inflammatory bowel disease (IBD) recently. IBD comprised of two main forms of Crohn's disease (CD) and ulcerative colitis (UC) is a chronic and often debilitating disorder of the gastrointestinal tract. Although more than 32 genes have been associated with IBD, but only account for 20% of genetic risky factors. Here we studied the genetic association and allele expression of the two non-synonymous SP-D SNPs rs721917 (C/T Met11Thr) and rs2243639 (G/A Ala160Thr) in 256 IBD cases (123 CD and 133 UC) and 376 unrelated healthy individuals from an IBD population from Central PA. Case-control analysis revealed a significant association of rs2243639 with susceptibility to CD (OR=1.5531, 95% CI= 1.14992-2.0983, p=0.003570), but not UC (OR=1.0300, 95% CI=0.7645-1.3845, p= 0.8836), and no association of rs721917 with CD (p=0.328) or UC (p=0.218). Using intestinal tissues from 19 individuals heterozygous for each SNP, we compared allele expression of these two SNPs between diseased and matched normal tissues. The SNP rs2243639 exhibited balanced biallele expression while rs721917 exhibited a differential allele expression (balanced biallelic 37%, imbalanced biallelic 45%, and dominant monoallelic 18%). Monoallelic expression is widely observed in human, it was assessed that more than 5% of genes were subjected to random monoallelic expression. Monoallelic expression can lead to differences in expression level of gene and alleles. Different expression of mutated allele may affect gene function and phenotype outcome. Comparison of allelic expression pattern between diseased and matched normal tissues, 13 out 19 individuals (14 UC, 5 CD) showed a similar pattern. The six patients exhibiting a different pattern were all UC patients. From the present study we suggest that factors determining the incomplete penetrance of a genetic mutation should be addressed in genetic association studies, especially for complex human diseases such as IBD.

Fine mapping and expression studies implicate *KIF5A* as the gene responsible for association of the 12q13 locus with Rheumatoid Arthritis. *A. McClure, S. Eyre, W. Thomson, J. Worthington, A. Barton, UKRAG Consortium.* Arthritis Research UK , The University of Manchester, Manchester, United Kingdom.

Background: Association of the chromosome 12q13 region with rheumatoid arthritis (RA) has now been confirmed in two independent studies and a meta analysis ($p=3.6x10^{-9}$). The associated variant is located in intron 15 of the *KIF5A* gene, a surprising candidate for RA as the expression of KIF5A has been reported to be confined to neurons.

Objective: The aim of this study was to investigate the 12q13 region further to identify the most likely RA susceptibility gene within the region.

Methods: Fine mapping of the 12q13 region surrounding the associated variant (~400kb) was carried out by genotyping tag SNPs, capturing all of the known variation across the region (r2>0.8) in 1076 RA cases and 890 controls. SNPs showing greater effect sizes than rs1678542 were then genotyped in a larger independent validation cohort consisting of 3633 RA cases and 2908 controls. The expression of KIF5A and two other candidate genes in the region (PIP4K2C and CYP27B1) was investigated by QRT-PCR. RNA was extracted from whole blood collected from 52 RA patients (genotype at rs1678542: major allele homozygous n=20, heterozygous n= 19, minor allele homozygous n=13) and cDNA was synthesised.

Results: Fine-mapping identified 5 SNPs exhibiting greater effect sizes than rs1678542. However only rs1678542 was significantly associated (p= 0.004, OR 0.90, 95% CI 0.84-0.97) in the validation cohort. Expression studies confirm the expression of KIF5A in whole blood. Gene expression levels were then analysed according to genotype at the most associated SNP (rs1678542). Expression of KIF5A was significantly associated with genotype (p=0.001) whereas expression of two other candidate genes in the region was not.

Conclusion: We have confirmed that the strongest association with RA at 12q13 is tagged by rs1678542 in intron 15 of KIF5A. We have confirmed expression of KIF5A in whole blood of RA cases and have shown for the first time that expression of KIF5A, but not other genes in the region, is influenced by genotype at rs1678542. Although validation is required the findings suggest that KIF5A may be the RA susceptibility gene in the region as all other SNPs tagged by rs1678542 map within the gene.

1584/F

A novel role for hMSH5 (MutS Homolog 5) which localizes into mitochondria after oxidative stress and stimulates mitochondrial DNA repair. *S. Bannwarth[1,2], A. Figueroa[1,2], K. Fragaki[1,2], L. Destroismaisons[3], F. Lespinasse[1], M. Abbassi[1], F. Vandenbos[4], L.A. Pradelli[5], J-E. Ricci[5], A. Rötig[6], J-F. Michiels[4], S. de Vries[7], C. Vande Velde[3], V. Paquis-Flucklinger[1,2].* 1) LBPG, CNRS UMR 6267/Inserm U998/UNS, Medicine School, Nice; 2) Department of Medical School, CHU Nice, Nice; 3) Center of Excellence in Neuromics (CENUM), University of Montreal, Montreal; 4) Department of Neuropathology, CHU Nice, Nice; 5) Inserm, U895, C3M, Nice; 6) Inserm U781, Paris; 7) Division of Molecular Biology, The Netherlands Cancer Institute, Amsterdam.

MutS Homolog 5 (MSH5) does not participate in mismatch repair but is essential for meiotic recombination in germ cells. MSH5 and MSH4, another MutS homolog, form a heterodimeric complex that is likely involved in the processing and/or the stabilization of meiotic recombination intermediates. We report a novel function for human MSH5 that may have a fondamental role in protecting the mitochondrial genome (mtDNA) from oxidative damage. We show that hMSH5 is mainly associated with the outer mitochondrial membrane in basal conditions and that Msh5 deficiency causes respiratory chain defect in knock-out mice. However, the role of the MSH5 protein is particularly important under conditions of oxidative stress. Reactive oxygen species (ROS) production is decreased in rotenone-treated HeLa cells over-expressing *hMSH5* gene. And in response to DNA damage induced by H2O2, a fraction of hMSH5 localizes inside mitochondria and stimulates mtDNA repair. The hMSH5 protein physically interacts with mitochondrial helicase Twinkle and DNA polymerase gamma, two proteins involved in mtDNA replication and repair. Therefore, *hMSH5* is a new candidate gene for mitochondrial diseases linked to mtDNA instability. Furthermore, we observed subsarcolemmal accumulation of hMSH5 in cytochrome c oxidase-negative muscle fibers of patients carrying mtDNA deletions, suggesting that this protein may accumulate into mitochondria in response to mitochondrial dysfunction in vivo. Our data indicate a novel role for MSH5 in protecting mitochondrial genome by supporting mtDNA repair with polymerase γ and Twinkle and providing a mechanism to suppress ROS amplification vicious circle.

1585/F

Variants controlling expression of multiple genes in the insulin/IGF1 signaling pathway. *D. Hu, S. Huntsman, E. Ziv.* Dept Medicine, Institute for Human Genetics, Univ of California, San Francisco, San Francisco, CA.

The insulin/IGF1 signaling pathway is involved in the aging process in several model organisms. Common variants of genes in this pathway have been associated with human longevity in some studies. Studies of expression as a Quantitative Trait Locus (eQTL) may help identify genetic variations that control expression and may be candidates for association with more complex traits. We performed an association analysis for 35 genes in the insulin/IGF1 signaling pathway in order to identify loci affecting expressions of these genes. Gene expression and genotype data for 58 European samples were used from previously published studies (Cheung et al, Nature, vol 437, 2005). The association of a genetic variant with gene expression was tested by linear regression. The p value cutoffs for cis effect (+/- 5kb of a gene) and trans effect are 0.01 and 1E-7, respectively. Once we identified one transcript controlled by a SNP at a genome wide significance level, we evaluated significance for other transcripts using a permutation procedure. We found evidence for trans-regulation for IGF1, AKT1, IGFBP2, and IGFBP6. Among these trans effects, a genetic variant (rs10243691) for MAGI2 on chromosome 7 is associated with the expression of AKT1. A SNP (rs873078) for DOK5 (IRS6) on chromosome 20 is strongly associated with IGFBP2 (p<1E-10) and more weakly with IGFBP5 (p=0.009). Two SNPs (rs9470112 and rs11967333) that are associated with IGFBP6 (p<1E-9) also show association with IGF1 and PIK3CA (p=0.003 and p=0.001). SNPs rs651825, rs678957, rs11216795, and rs12282334 that are associated with KL (p<1E-7) might be associated with GH1 (p=0.002) and INSR (p=0.008). In addition to trans effects, we have observed weak evidence for cis-regulation for INSR, IRS1, PI3KR3, PI3KCB, and SHC1. Our results suggest that several loci, acting in trans, control multiple transcripts in the insulin/IGF-1 pathway and are good candidates for biological processes controlled by this pathway.

An evaluation of Limp-2 in patients with Gaucher disease and myoclonic epilepsy. *N. Gupta, A. Velayati, JH. Choi, W. Westbrook, J. Depaolo, BK. Stubblefield, E. Sidransky, N. Tayebi.* Section on Molecular Neurogenetics, Medical Genetics Branch/NHGRI, NIH, Bethesda, MD.

Lysosomal integral membrane protein type 2 (LIMP-2) is responsible for the proper sorting of glucocerebrosidase, the enzyme deficient in Gaucher disease (GD), to the lysosome. Mutations in LIMP-2 were identified in patients with some forms of myoclonic epilepsy (ME). A subgroup of patients with neuronopathic Gaucher disease develop myoclonic epilepsy. We investigated whether development of ME in type 3 GD is related to alterations in Limp-2, studying two groups of patients with GD,13 patients with myoclonic epilepsy and 18 without myoclonic epilepsy, as well as 40 normal controls. The promoter region, all 12 exons and the flanking intronic regions of the Limp-2 gene (Scarb2) were sequenced in each of the patients and controls. One patient with GD/ME was found to have a heterozygous mutation in exon 12. Two other GD/ME patients had intronic mutations, although no effect on splicing was demonstrated using RT-PCR and cDNA sequencing. Furthermore, one polymorphism in exon 1 and 21 polymorphisms in introns were identified among patients and controls. Two polymorphisms are also present in the promoter region of Scarb2. The frequency of these polymorphic changes did not differ significantly between patients with GD with or without ME or controls. We also studied glucocerebrosidase and Limp-2 RNA expression in fibroblasts from patients with GD/ME, 20 with GD and 20 controls using real-time. The results demonstrated down-regulation of Limp-2 in the patient with the exonic mutation and up-regulation in individuals carrying an intronic mutation 1100bp upstream of exon 4 as compared to controls. Protein expression studies, cell-based assays and the confocal microscopy are being employed to evaluate the functional significance of the exonic and intronic mutations identified. These studies should clarify to what extent Limp-2 is associated with myoclonic epilepsy in patients with neuronopathic Gaucher disease.

1587/F

***Drosophila* deficient for porin provide a model to identify and dissect functions of VDAC.** *R. Masand, Z. Li, Y. Huang, B.H. Graham.* Department of Moleular and Human Genetics, Baylor College of Medicine, Houston, TX.

The voltage-dependent anion channel (VDAC or porin) is an integral membrane protein present in the mitochondrial outer membrane (MOM). VDACs are the predominant determinant of MOM permeability but also integrate mitochondrial function and other cellular pathways by interacting with various mitochondrial and cytoplasmic proteins; however, many details of these functions as well as the interacting pathways remain poorly understood. VDACs have also been implicated to play a pathogenic role in several human diseases including cancer, diabetes, Alzheimer's and cardiac ischemia-reperfusion injury. Flies mutant for *porin* (the predominant VDAC in *Drosophila*) demonstrate energy metabolism defects, neurologic dysfunction with abnormal mitochondrial distribution in motor neurons and male infertility. The ultimate goal of this project is to exploit the genetic versatility of *Drosophila* to dissect and identify VDAC functions and interacting pathways by identifying modifiers of *porin* mutant phenotypes using both candidate genes and unbiased genetic screens.

Aconitase activity analysis from isolated mutant mitochondria suggests that porin deficiency deficiency results in increased mitochondrial reactive oxygen species (ROS). A microarray analysis of gene expression has identified significant altered expression of a subset of cytochrome P450 genes in *porin* mutants. As cytochrome P450 monooxygenases can produce ROS through NADPH dependent oxidation reactions and as *porin* mutants have increased ROS,these P450 genes are potential candidate modifiers of *porin* mutant phenotypes. To evaluate their potential as genetic modifiers of *porin*,-cytochrome P450 genes with confirmed altered expression in *porin* mutants are being screened through systematic overexpression and knockdown in the *porin* mutant background to observe potential modifying effects on *porin* mutant phenotypes. In addition,a pilot deficiency screen has identified multiple deletions that suppress male infertility in *porin* mutants,including one deletion that also suppresses neuronal dysfunction. A chemical mutagenesis screen designed to identify suppressors of *porin*-deficient male infertility has been initiated with two confirmed suppressors recovered to date. Identification of suppressors of *porin* mutant phenotypes will provide insight into VDAC functions as well as identify potential novel therapeutic targets and strategies for multiple human diseases.

1588/F

Ribosomal stress and the p53 network: Impaired ribosome biogenesis due to ribosomal protein deficiency leads to p53 induction in zebrafish. *N. Kenmochi, A. Chakraborty, H. Torihara, T. Uechi.* Frontier Sci Res Ctr, Univ Miyazaki, Miyazaki, Japan.

Ribosomes, the molecular factories that carry out protein synthesis, are essential for every living cell and ribosomal proteins (RPs) play important roles in the formation of a functional ribosome. Recent findings indicate that disruption of ribosome biogenesis, induced either by decrease of an RP or mutations in rRNA processing factors, activates the p53 pathway presumably through a nucleolar stress. Studies in cell lines have identified several RPs as key mediators of this new ribosomal stress-p53 signaling pathway because of their ability to directly bind to MDM2, thus inhibiting the MDM2-p53 regulatory loop. RPL11 has been identified to be the most important among these MDM2-interacting RPs. To investigate the consequences of L11 depletion in vivo, and its physiological relevance to p53 activity, we knocked down the *rpl11* gene in zebrafish and analyzed the p53 response. Contrary to the cell line-based results, our data indicate that L11 deficiency activates the p53 pathway in zebrafish. The L11-deficient embryos (morphants) displayed morphological defects mainly in the developing brain and died within 6-7 days post-fertilization. TUNEL assay indicated that these developmental defects are due to increased cellular apoptosis, which was p53 dependent, as revealed by increased transcript level of *p53* and its down stream target genes in the morphants. We also observed upregulation of ccng1 (encoding cyclin G1), a p53-responsive gene involved in G1-S cell-cycle transition, in the morphants indicating that a cell-cycle arrest precedes the apoptotic pathway. In addition, *in situ* analysis revealed enhanced expression of *p53* and its target genes specifically in the head region of the morphants. The morphants displayed altered rRNA levels and upregulation of several ribosome-associated nucleolar proteins, indicating an impaired ribosome biogenesis. Interestingly, these nucleolar proteins were also enriched in the head region of the morphants that displayed morphological abnormalities and high levels of *p53* expression. These results suggest that ribosomal dysfunction due to the loss of L11 activates p53 to prevent improper embryonic development. Deficiency of any RP could lead to p53 induction, suggesting a general response of a cell against ribosomal stress.

1589/F

Interactive expressions of HtrA1 and VEGF in human vitreous and retinal pigment epithelial cells through a NFκB-related mechanism. *C.P. Pang[1], T.K. Ng[1], G.H.F. Yam[1], D.T.L. Liu[2], S.W.Y. Chiang[1], L.J. Chen[1], P.O.S. Tam[1], T.Y.Y. Lai[1].* 1) Department of Ophthalmology & Visual Sciences, The Chinese University of Hong Kong, Hong Kong, HKSAR, China; 2) Hong Kong Eye Hospital, Hong Kong, HKSAR, China.

Purpose: High temperature requirement factor A1 (HtrA1) is associated with exudative age-related macular degeneration (AMD), which is an angiogenic retinal disease related to vascular endothelial growth factor (VEGF) and a leading cause of serious visual impairment affecting the elder populations in developed countries. In this study, we investigated the interactions of HtrA1 and VEGF. **Methods:** The vitreous levels of HtrA1, VEGF and PEDF were determined in vitreous samples of 55 unrelated Chinese patients who underwent ocular surgeries. Expressions of HtrA1 and VEGF were studied interactively and under stress conditions in cultured human fetal retinal pigment epithelial (RPE) cells. **Results:** Significant association of vitreous humor levels of HtrA1 with VEGF was found (Pearson's correlation coefficient test; r = 0.650, $p = 7.91 \times 10^{-8}$). Vitreous levels of HtrA1 were higher in patients with retinal vascular and inflammatory diseases than those with traumatic injury ($p < 0.04$). However, neither HtrA1 nor VEGF regulated each other's expressions in the incremental analysis. Like HtrA2, HtrA1 was involved in cellular stress response, which also induced VEGFA expression. Meanwhile, HTRA1 expression was substantially reduced in the presence of MG132, a proteasome and NFκB inhibitor. **Conclusions:** Our results revealed an association between the vitreous humor levels of HtrA1 and VEGF. They are both involved in cellular stress response and modulated by a NFκB-related mechanism. There is therefore a direct role of HtrA1 in the pathogenesis of angiogenic diseases.

Functional analysis of *BBS3* and *BBS3L*, a novel *BBS3* transcript, in syndromic and non-syndromic retinal degeneration in animal models and humans. *P.R. Pretorius[1, 2, 3], M.A. Aldahmesh[4], Q. Zhang[1, 3], C.C. Searby[1, 3], D.Y. Nishimura[1, 3], F.S. Alkuraya[4, 5, 6], E.M. Stone[3, 7], K. Rahmouni[8], D.C. Slusarski[2], V.C. Sheffield[1, 3].* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Dept Biology, University of Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute; 4) Dept Genetics, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia; 5) Dept Pediatrics, King Khalid University Hospital and College of Medicine, King Saud University, Riyadh, Saudi Arabia; 6) Dept Anatomy and Cell Biology, College of Medicine, Alfaisal University, Riyadh, Saudi Arabia; 7) Dept Ophthalmology and Visual Sciences, University of Iowa, Iowa City, IA; 8) Dept Internal Medicine, University of Iowa, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a heterogeneous, autosomal recessive disorder characterized by retinal degeneration, obesity, learning disabilities, congenital anomalies, and an increased incidence of hypertension and diabetes. Seven BBS proteins form a stable complex known as the BBSome that promotes ciliary membrane elongation. Other BBS proteins have chaperonin homology and play a role in BBSome formation. BBS3, an ADP-ribosylation factor (ARF)-like small GTPase (ARL6), is not part of the BBSome complex. We identified a second longer transcript of *BBS3*, designated *BBS3L*, which is expressed primarily in the eye. To gain insight into BBS3 disease mechanisms, we created mouse and zebrafish models of both *BBS3* and *BBS3L*. *Bbs3*$^{-/-}$ mice have retinal degeneration, increased body fat, elevated blood pressure and severe hydrocephalus, whereas *Bbs3L*$^{-/-}$ mice have only a retina phenotype. These models were used to demonstrate that *BBS3L* is specifically required for retinal organization and function in both mouse and zebrafish. To extend this work to humans, genetic mapping and DNA sequencing identified a homozygous missense mutation (A89V) in *BBS3* that results in non-syndromic retinal degeneration. To evaluate the *in vivo* function of the A89V missense mutation in non-syndromic retinal degeneration and BBS, rescue experiments were performed in the zebrafish. Unlike wild-type *BBS3L* RNA, *BBS3L A89V* RNA does not rescue the vision defect seen with loss of *bbs3* in zebrafish; however, *BBS3 A89V* RNA is able to suppress the cardinal zebrafish BBS phenotype of melanosome transport, similar to wild-type *BBS3* RNA. These data demonstrate that the *BBS3L A89V* mutation identified in patients with non-syndromic retinal degeneration is critical and specific for the vision defect. To investigate the function of BBS3, we used *Bbs3*$^{-/-}$ mice to determine whether BBS3 is required for BBSome formation. Loss of Bbs3 does not affect BBSome protein levels or BBSome formation; however, loss of Bbs3 disrupts localization of BBSome proteins to cilia. Our results demonstrate that one of the functions of BBS3 is to target the BBSome to cilia, explaining the phenotypic similarity between Bbs3 knockout mice and BBSome subunit knockout mice. Phenotypic differences between patients can, in some instances, be explained by mutations affecting tissue specific BBS protein isoforms and tissue specific BBSome functions.

1591/F

The Role of SRY Mutations in the Etiology of Gonadal Dysgenesis in Patients with 45,X/46,XY Disorder of Sex Development and Variants. *M.Y. Nishi, E.M.F. Costa, S.B. Oliveira, B.B. Mendonca, S. Domenice.* Div Endocr. Lab Horm LIM42, Faculdade de Medicina da Univ Sao Paulo, Sao Paulo, Brazil.

Background- The potential involvement of SRY in abnormal gonadal development in 45,X/46,X,der(Y) patients was proposed following the identification of SRY mutations in a few patients with Turner syndrome (TS). However, its exact etiological role in gonadal dysgenesis in patients with Y chromosome mosaicisms has not yet been clarified. Aims- To screen for allelic variation in SRY in a large cohort of patients with disorders of sex development (DSD) due to chromosomal abnormalities with 45,X/46,X,der(Y) karyotype. Patients- 27 patients [14 with TS and 13 with mixed gonadal dysgenesis (MGD)] harboring 45,X/46,X,der(Y) karyotypes were selected. Methods- Genomic DNA was extracted from peripheral blood leukocytes of all patients and from gonadal tissue in four cases. SRY coding region was PCR-amplified and sequenced. Results- We identified only one polymorphism (c.561C>T) in a 45,X/46,XY MGD patient, which was detected in blood and in gonadal tissue. Conclusion- Our results indicate that mutations in SRY are rare findings in patients with Y chromosome mosaicisms. Therefore, a significant role of mutated SRY in the etiology of gonadal dysgenesis in patients harboring 45,X/46,XY karyotype and variants seems very unlikely.

1592/F

ATP7B variants in Wilson disease: impact on protein function. *J.R. Pon, G. Macintyre, L. Davies, D.W. Cox.* Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Wilson disease (WND) is an autosomal recessive disorder caused by mutations in *ATP7B*, a gene encoding an integral membrane copper transporting ATPase. Copper accumulation ultimately results in life-threatening liver and/or neurological impairment. Treatment is essential, and consists of copper chelation and inhibition of copper uptake. Mutation detection facilitates early diagnosis and treatment, reducing symptoms and the need for liver transplant. Since our discovery of the *ATP7B* gene in 1993, more than 590 potential WND-causing *ATP7B* variants have been identified worldwide (www.wilsondisease.med.ualberta.ca). However, due to incomplete gene sequencing and lack of population control data, some variants may be ethnic group specific SNPs or rare normal variants. Functional testing is necessary to confirm designation as disease-causing (DV). ATP7B contains several functional domains and DVs have been identified in each domain. We have tested eighteen variants, using a stable transfectant mammalian cell system. The tested variants are located within either the ATP binding domain for autophosphorylation (N-D) or the transmembrane domains (TM), required for membrane integration and copper transport. Full length *ATP7B* variant cDNAs were stably transfected into Chinese hamster ovary (CHO) cells. Wild type (WT) human ATP7B protects CHO cells from copper toxicity and each variant cell line was assayed for copper resistance. The five N-D variants exhibited reduced copper resistance: P1052L, G1149A, I1184T, V1262F, and P1273Q. Nine of thirteen TM variants tested were also impaired: G710S, A727D, A874V, R969Q, A971V, L1305P, Y1331S, I1336T and L1371P. The deficits of G1149A and L1371P were severe. The remaining TM variants, P840L, D918N, R919G and T974M, exhibited normal copper resistance. In response to excess copper, WT ATP7B is trafficked in copper-loaded vesicles for copper extrusion at the plasma membrane. Using immunofluorescent microscopy, trafficking defects were observed for P840L, P1052L, G1149A, I1184T, V1262F, L1305P, I1336T, and L1371P. On Western blots, variants with trafficking defects showed reduced ATP7B levels. T974M, D918N and R919G confer WT ATP7B protection and traffic normally, and are designated suspected non-disease causing variants. All other tested variants likely contribute to the WND phenotype. Our studies aid in the designation of variant status and enhance our understanding of ATP7B function.

1593/F

Functional impact of the RAI1 missense and polyQ length mutations identified in Smith-Magenis syndrome patients. *W. Gu[1], M. Heney[1], W. Bi[1], J.R. Lupski[1, 2, 3].* 1) Molecular and Human Genetics, Baylor College Med, Houston, TX; 2) Department of Pediatrics, Baylor College Med, Houston, TX; 3) Texas Children's Hospital.

Genetic variations involving RAI1 (Retinoic acid induced gene 1), including copy number variation (CNV), single nucleotide variation (SNV) and trinucleotide expansion, have been associated with common disease traits. The decrease (1n) in gene dosage of RAI1 (per deletion or point mutation) causes Smith-Magenis syndrome (SMS, MIM 182290), characterized by mental retardation, circadian rhythm distortion, self-aggression and obesity. The increase (3n) of RAI1 dosage results in Potocki-Lupski syndrome (PTLS, MIM610883), which manifests autism. Furthermore, the length of a polyQ repeat in RAI1 protein is associated with phenotypic manifestation of ataxia and drug response in schizophrenia; abnormally increased poly Q length was also reported in one patient with SMS phenotypes. Little is known about the function of RAI1 protein and the pathomechanisms of RAI1 mutations except that RAI1 is a nuclear protein and can act as a transcriptional co-activator. So far, twelve heterozygous point mutations and one poly Q length variation in RAI1 have been reported in SMS patients who did not have a heterozygous deletion of 17p11.2. Nine of the twelve point mutations are frameshift or nonsense alleles, and thus likely loss of function mutations; the functional consequences of the three missense alleles and poly Q variation have not been examined prior to this study. We cloned the full length human RAI into the expression vector pEGFP-C (Clontech) and pCMV-BD (Stratagene). Similar to the mouse Rai1, human RAI1 is localized in the nucleus and it can activate transcription. The three disease-related missense mutations of RAI1 (c.4685A>G [Q1562R], c.5423G>A [S1808N] and c.3634A>G [G1212S]) and the 18Q (instead of 14Q in wild type allele) variant were engineered into the constructs using the Quick-change site-directed mutagenesis kit (Stratagene). These mutations do not change the nuclear localization of RAI1 but appear to affect its transcription activity.

1594/F

Molecular characterization of phenotypes associated with PEX7 deficiency: Rhizomelic Chondrodysplasia Punctata type 1 (RCDP1) and adult Refsum disease (ARD). *S. Jiralerspong[1], A. Moser[2], S. Steinberg[2], N. Braverman[1].* 1) Dept. of Human Genetics, McGill University-Montreal Childrens Hospital Research Institute, Montreal, Quebec, Canada; 2) Dept. of Neurogenetics and Neurology, Kennedy Krieger Institute, Johns Hopkins Med. Ctr., Baltimore, Maryland, USA.

RCDP1 is a peroxisome biogenesis disorder caused by defects in PEX7, the peroxisome receptor for PTS2 targeted matrix proteins: thiolase, phytanoyl-CoA hydroxylase (PhyH) and alkylglycerone-phosphate synthase (AGPS). PEX7 defects mislocalize these enzymes to the cytosol where they are inactive. The severity of the clinical phenotype directly correlates to tissue plasmalogen levels and therefore, amounts of AGPS transported into the peroxisome. We previously reported 3 phenotype groups, severe, intermediate and mild, based on residual plasmalogen levels. In the mild group, plasmalogens are near normal and the phenotype no longer resembles RCDP, but instead resembles ARD, due to a deficiency of PhyH. We used protein modeling to show that mutations predicted to disrupt the β-propeller organization of PEX7 were associated with severe phenotypes, whereas mutations with less structural impact were associated with milder phenotypes. In the present study, we evaluated amounts of AGPS, PhyH and PEX7 proteins in 24 RCDP1 fibroblast lines, covering all 3 phenotypic groups, by immunoblotting methods. PTS2 proteins undergo N-terminal peptide removal inside the peroxisome to generate a smaller protein distinguishable by size. We show that 30-60% of AGPS is correctly targeted inside the peroxisome in the mild patient group, whereas AGPS import appeared absent in the severe and intermediate groups. We suggest that AGPS import in the intermediate group is below the sensitivity of western analysis, but accounts for residual tissue plasmalogen levels in this group. For PhyH, 10-20% is imported into the peroxisome in both mild and intermediate groups, but negligible in the severe group. We found reduced amounts of PEX7 protein generated by the majority of alleles in each group. The highest recovery of AGPS and PhyH import occurred in an ARD patient, shown to express residual amounts of wild type PEX7 transcript from a 'leaky' splice site mutation. To determine if conformational correction of the PEX7 missense proteins could be encouraged by chemical chaperones, we treated the cell lines with trimethylamines but did not find any improvement in PTS2 protein import. We conclude that certain PEX7 missense alleles as well as residual amounts of wild type PEX7 can rescue the RCDP phenotype by restoring sufficient (≥30%) AGPS import. These same PEX7 alleles, however, although associated with some PhyH import, cannot prevent the development of ARD over time.

1595/F

***Rai1* haploinsufficiency causes reduced *Bdnf* expression resulting in hyperphagia, obesity, and altered fat distribution in mice and humans with no evidence of metabolic syndrome.** *S.H. Elsea[1,2], B. Burns[2], K. Schmidt[2], S.R. Williams[2], S. Kim[2], S. Girirajan[2,3].* 1) Department of Pediatrics, Virginia Commonwealth University, Richmond, VA; 2) Department of Human & Molecular Genetics, Virginia Commonwealth University, Richmond, VA; 3) Department of Genome Sciences, University of Washington, Seattle, WA.

Smith-Magenis syndrome (SMS) is a genetic disorder caused by haploinsufficiency of the *retinoic acid induced 1 gene* (*RAI1*). In addition to intellectual disabilities, behavioral abnormalities, and sleep disturbances, a majority of children with SMS also have significant early-onset obesity. To study the role of RAI1 in obesity, we investigated the growth and obesity phenotype in a mouse model haploinsufficient for *Rai1*. Data show that *Rai1*$^{+/-}$ mice are hyperphagic, have an impaired satiety response, and have altered abdominal and subcutaneous fat distribution, with *Rai1*$^{+/-}$ female mice having a higher proportion of abdominal fat when compared to wild type female mice. Expression analyses revealed that *Bdnf*, a gene previously associated with hyperphagia and obesity, is downregulated in the *Rai1*$^{+/-}$ mouse hypothalamus, and reporter studies that show RAI1 directly regulates the expression of *BDNF*. Even though the *Rai1*$^{+/-}$ mice are significantly obese, serum analyses do not reveal any evidence of metabolic syndrome. Supporting these findings, a caregiver survey revealed that even though a high incidence of abdominal obesity is observed in females with SMS, they did not exhibit a higher incidence of metabolic syndrome compared to that in the general population. We conclude that *Rai1* haploinsufficiency represents a single gene model of obesity with hyperphagia, abnormal fat distribution, and altered hypothalamic gene expression associated with satiety, food intake, behavior, and obesity. Linking RAI1 and BDNF provides a thorough understanding of the role of RAI1 in growth and obesity and insight into the complex pathogenicity of obesity, behavior, and sex-specific differences in adiposity.

1596/F

Looping Interactions and Anatomical Specificity of Distant *Bmp2* Enhancers. *E.M. Broeckelmann, S. Pregizer, D.P. Mortlock*. Vanderbilt University, Nashville, TN.

Bone Morphogenic Proteins (BMPs) are members of the TGF-β superfamily of secreted signaling molecules that are not only vital factors in pattern formation and morphogenesis during early embryonic development but also play critical roles in the maintenance of health throughout all stages of adult life. For example, both *Bmp2* and *Bmp4* are among top GWAS hits on colorectal cancer, and *Bmp2* polymorphisms have been implicated in the pathogenesis of bone disorders such as osteoporosis and osteoarthritis. The osteogenic properties of BMP2 have been studied extensively and are highlighted by the fact that *Bmp2* conditional knockout mice exhibit reduced bone density and suffer spontaneous fractures that are unable to heal, indicating that BMP2 is indispensable for the endogenous repair process in bone. We have previously shown that *Bmp2* gene expression is controlled by numerous distant cis-regulatory elements in a tissue- and time- specific manner. Specifically, transgenic analyses in mice have identified a 656bp evolutionarily conserved element (ECR1) 156kb downstream of the promoter, which functions as *Bmp2* enhancer in osteoblasts. However, while ECR1 drives robust transgene expression in most endochondral bones, it exhibits remarkable anatomical specificity in that it is inactive in cranial intramembranous bones, suggesting the existence of (an) additional osteoblast enhancer(s). In order to further elucidate the role of ECR1 in various osteoblast cell populations *in vivo*, we deleted ECR1 from a *Bmp2*-containing BAC transgene, whose expression is analyzed in transient transgenic mouse embryos. Preliminary data suggest that ECR1 is essential for transgene expression in all bones, although in isolation it is only sufficient to drive expression in a specific subset of osteoblasts. Further evidence for the involvement of multiple enhancers in osteoblast-specific *Bmp2* expression was obtained in a Chromosome Conformation Capture (3C) assay, which demonstrated direct looping interactions of the *Bmp2* promoter with not only ECR1 but also with two additional candidate loci in the large gene desert surrounding *Bmp2*. Ultimately, a detailed understanding of both the regulatory elements governing *Bmp2* expression in bone and the molecular mechanisms underlying their function will be essential for the development of new therapies for the treatment of various human bone disorders.

1597/F

Promoter-enhancer interaction is responsible for tissue specific expression of OTC, the disruption may cause the manifestation of ornithine carbamoyltransferase deficiency. *O. Luksan[1], M. Jirsa[1], M. Hrebicek[2], L. Dvorakova[2].* 1) Laboratory of Experimental Hepatology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic; 2) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague, and General University Hospital in Prague, Czech Republic.

Ornithine carbamoyltransferase (OTC, EC 2.1.3.3) is a homotrimeric enzyme catalyzing the synthesis of citrulline in the second step of the urea cycle. The OTC is expressed exclusively in the liver and the gene is located on Xp21.1. OTC deficiency (OTCD; OMIM 311250) is the most common inherited urea cycle disorder manifesting in a spectrum of severity ranging from neonatal hyperammonemic coma followed by death to later onset of milder symptoms or asymptomatic course. The published data bring evidence that mutation analysis fails in 20-25% of cases. The reason for the disease manifestation in these cases may be a genetic defect in regulatory regions of the gene.

We predicted the human promoter and enhancer elements from homology with rat and mouse and performed functional studies of both regulatory regions using dual luciferase reporter assay. The transcriptional activity of the promoter and the promoter - enhancer interaction was tested in three human hepatocellular lines (Hep-G2, HuH-7, PLC/PRF/5) and in the human embryonic kidney cells HEK293. Functional studies showed that the presence of the promoter increases the expression of the reporter gene significantly, but with no difference in both liver and kidney cells. The interaction promoter - enhancer contributed to high tissue specific expression of *OTC* in the liver while no increase of luciferase expression was observed in the HEK293 cells. We studied the effect of a single nucleotide substitution c.-366A>G located in the promoter of a female patient with mild symtoms of OTCD. The promoter variation did not affect the function of the promoter alone but it disrupted the interaction of the promoter with the enhancer, which was observed as 50% decrease of the transcriptional activity.

Our data indicate that full transcriptional activity of human *OTC* promoter depends on an upstream enhancer. The promoter - enhancer interaction contribute to tissue specific expression of *OTC* in the liver and the disruption can lead to the manifestation of OTCD. Therefore the regulatory regions should be included in genetic testing of OTC deficiency.

Specific interactions of the Williams-Beuren syndrome-associated protein GTF2IRD1 suggest a role in chromatin reorganization. *S.J. Palmer[1], J. Widagdo[1], K.M. Taylor[1], S. Bontempo[2], P.W. Gunning[3], E.C. Hardeman[1].* 1) School of Medical Science, Neuromuscular and Regenerative Medicine Unit, University of New South Wales, Sydney, NSW, Australia; 2) Muscle Development Unit, Children's Medical Research Institute, Westmead, NSW, Australia; 3) School of Medical Sciences, Oncology Research Unit, University of New South Wales, Sydney, NSW, Australia.

Williams-Beuren syndrome (WBS) results from a hemizygous microdeletion within chromosome 7q11.23 involving 28 genes. Its features typically involve characteristic physical abnormalities and a set of cognitive and behavioural symptoms that are collectively called the Williams syndrome cognitive profile (WSCP). Haploinsufficiency of elastin (encoded by *ELN*) causes the supravalvular aortic stenosis. The remaining physical and neurological symptoms have not yet been attributed to specific genes, but it is assumed that they are due to haploinsufficiency for a subset of the remaining 27. Genotype/phenotype correlations in patients with smaller deletions have mapped the typical craniofacial dysmorphology and WSCP to a pair of evolutionarily-related DNA-binding proteins, GTF2IRD1 and GTF2I. We have generated *Gtf2ird1* knockout mouse lines by deletion of exon 2 and replacement with a LacZ reporter allowing us to map expression and examine the consequences of gene inactivation. These mice show developmental abnormalities and cognitive impairments that reflect aspects of the disease. In an effort to understand the underlying biochemistry of these features, we have developed studies that focus on GTF2IRD1 function. We have demonstrated that GTF2IRD1 undergoes post-translational modification through attachment of SUMO to identified lysine residues. SUMOylation is catalysed via interactions with the E3 SUMO ligase PIASX and the E2 ligase UBC9, which occurs at separate well-conserved domains of the protein. In addition, we have identified a series of nuclear proteins that are capable of interacting with GTF2IRD1 using yeast 2-hybrid screening. Several of these novel target proteins have been implicated in chromatin reorganization via histone methylation, acetylation or ubiquitination. We propose that GTF2IRD1 nucleates a complex of proteins that are targeted to specific regions of the genome in order to repress gene expression via specific modifications of the underlying histones. Homology between GTF2I and GTF2IRD1 and adjacent chromosomal locations of the encoding genes clearly indicate a common ancestral origin. Therefore, it is highly probable that they share functional similarities. We are currently investigating whether this includes sharing similar protein-protein interactions.

In utero knockdown of FlnA leads to periventricular nodular heterotopia in rats. *A. Carabalona[1,2], S. Beguin[1,2], E. Pallesi-Pocachard[1,2], C. Quere[4], A. Allain[4], E. Buhler[2,3], N. Dagoneau[4], I. Coupry[4], A. Gelot[5], C. Goizet[4], A. Represa[1,2], C. Cardoso[1,2].* 1) INMED, INSERM, Faculté des Sciences de Luminy, Marseille, France; 2) University de la Mediterranee, Marseille, France; 3) INSERM, Plateforme Postgenomics-INMED, Marseille, France; 4) Laboratoire de Génétique Humaine, Université Victor Segalen Bordeaux 2, Bordeaux, France; 5) Département de Neuropathologie, Service d'Anatomie et Cytologie Pathologiques, Hopital A. Trousseau, Paris, France.

Cortical malformations are important causes of mental retardation and account for 20-40% of drug-resistant epilepsy in childhood. The advancement of high-resolution imaging has facilitated the in vivo identification of a large number of brain malformation phenotypes. Periventricular Nodular Heterotopia (PNH) is one of these cortical malformations caused by defective neuronal migration resulting in abnormal positioning of post-mitotic neurons. These ectopic neurons remain in the periventricular zone, close to their birth place, and form nodules of heterotopic grey matter. Clinical manifestations range from asymptomatic to intractable epilepsy and mental retardation. To date, two genes have been identified to cause PNH. Mutations in FLNA (Xq28) and ARFGEF2 (20q13) are responsible for X-linked bilateral PNH (Fox et al. 1998) and a rare autosomal recessive form of PNH is associated with microcephaly (Sheen et al. 2004). Although the link between PNH and epilepsy has been well established, the physio-pathological mechanism responsible for epileptogenesis remains obscure. In addition, the limited availability of human samples and the lack of genetic animal models that mimic PNH have both delayed our understanding of the underlying pathological mechanism. Thus, It is unclear whether the epileptogenic foci involve ectopic neurons or normotopic cortex or both. To address this issue, we have developed an animal model that reproduces a FlnA gene-driven PNH phenotype. Ectopic masses of grey matter lining the lateral ventricle are obtained by knocking-down FlnA in the rat developing neocortex using in utero RNA interference. The reliability of this genetic model in reproducing a PNH phenotype allows us, to study nodular formation and intrinsic cellular organization during development.

1600/F

Disruptions of spatacsin and/or spastizin functions lead to motor neuron axonal outgrowth defects in the Danio rerio. *E. Martin, C. Yanicostas, A. Maouedj, A. Brice, N. Soussi-Yanicostas, G. Stevanin.* CR-icm, INSERM / UPMC UMR_S 975, NEB, Paris, France.

The hereditary spastic paraplegias (HSP) are characterized by the degeneration of the cortico-spinal tracts leading to a progressive spasticity of lower limbs. A common autosomal recessive HSP associates various additional signs to this spasticity: mental retardation and/or cognitive deficits, neuropathy, cerebellar ataxia and an abnormal brain MRI with thin corpus callosum (TCC) and white matter hyperintensities. Two genes, SPG11 and SPG15, coding for the spatacsin and the spastizin proteins, respectively, have been identified as responsible for the majority of these complex HSPs. All, except one, mutations found in both genes result in an abnormally truncated protein, suggesting that both diseases are due to loss of protein functions. Furthermore, SPG11 and SPG15 have similar expression profiles, shown by in situ hybridization in adult rat brain and an identical associated phenotype, suggesting that both proteins are involved in a common pathway. However, the spatacsin and spastizin functions are still unknown. Here we used the Danio rerio (zebrafish) to explore these functions during development. We first demonstrated that the expression profiles of both genes established by RT-PCR and in situ hybridization are similar and that their mRNA are ubiquitously expressed from the first developmental stages to adulthood but at a higher levels in the brain. We then used a morpholino-based gene knockdown approach. The down regulation of spatacsin or spastizin resulted in a frequent curly tail phenotype in injected embryos leading to reduced or abolished motility of morphant animals. Morpholino injections in zebrafish strains expressing GFP in motorneurons or oligodendrocytes demonstrated that the phenotype was due to aberrant motor neuron axonal outgrowth. To test whether the spatacsin and spastizin proteins are involved in a common pathway, we co-injected SPG11 and SPG15 morpholino oligonucleotides at doses that did not markedly perturb locomotor activity and tail phenotype when either morpholino was injected individually. The co-injected embryos presented with curly tails and reduced locomotor activity. Together, these data suggest that SPG11 and SPG15 are acting in a common pathway involved in development of the spinal motor neurons. These models should help us to decipher both spatacsin and spastizin functions and may represent powerful tools for therapeutic trials.

Functional characterization of a conserved intronic element in hypertension- associated gene, STK39. *J. Chen, S. Dorff, Y. Chang.* Division of Endocrinology, U. of Maryland, SOM, Baltimore, MD.

The WNK-SPAK-NCC signaling pathway has recently been appreciated for its essential role in maintaining ion and osmotic homeostasis, as well as blood pressure (BP). SPAK is a key kinase in this signaling pathway, responding to activation by upstream WNK kinases and activating downstream cation-chloride cotransporters. Using a genome-wide association scan approach, we previously reported that common variants in STK39, the gene encoding SPAK, are associated with baseline BP. The most promising functional candidate among the BP-associated SNPs in STK39 is located in an intronic conserved element, CE5. In this study, we examined the potential role of CE5 in regulating SPAK expression. We demonstrate that CE5 binds nuclear protein(s) from multiple cell-lines in an allele-specific manner. Mass Spectrometry sequencing of these proteins revealed that multiple components of the splicing machinery interact either directly or indirectly with CE5. How CE5 functions in splicing was tested by insertion of CE5 into the second intron of human beta-globin minigene. We found a novel alternate splice form of mRNA in which CE5 is partially integrated into the mature mRNA. This novel mRNA represents approximately 15% of total mature mRNA, with an increase in abundance when additional splicing regulatory elements are present in the same intron. Tissue-specific alternate splicing of STK39 has been previously reported, although the underlying regulatory mechanism has not been identified. Studies to determine if CE5 is involved in tissue-specific splicing of SPAK in vivo, and if this function is altered by the sequence variant associated with higher BP, are underway to provide insight on how SPAK expression can influence BP.

1602/F

Frequency and function of a common IgE heavy chain (IGHE) variant. *J.M. Reynolds[1], D.B. Lloyd[2], K.G. Spink[3], J.F. Zobel[4], G.I. Johnston[5].* 1) DNA and BioFluids RCoE , Pfizer, Inc., Groton, CT, USA; 2) CVMED Research Unit, Pfizer, Inc., Groton, CT, USA; 3) Research Enabling Group, Pfizer, Inc., Sandwich, Kent, UK; 4) Bioprocess Analytic, Pfizer, Inc., Chesterfiled, MO, USA; 5) Molecular Medicine, Pfizer, Inc., Sandwich, Kent, UK.

Amino acid changing polymorphisms have the potential to alter the structure and function of a protein as well as influence sensitivity to targeted therapies. In the quest for the treatment of severe asthma, blocking the activity of IgE using a monoclonal antibody has been identified as a targeted therapy. A search of the public data revealed several SNPs located in the heavy chain of IgE (IGHE). However, when the IGHE sequence was aligned to one of it's pseudogenes, IGHEP1, it was observed that most of the putative SNPs were located at a position of sequence disagreement between IGHE and IGHEP1. To determine the true variation in the CH3 and CH4 domains of IGHE , we resequenced these regions in DNA from an ethnically diverse panel of 102 individuals using primers specific for IGHE. Our findings suggest that many of the amino acid changing SNPs for these regions reported in public databases were misidentified due to co-amplification of non-conserved alleles of IGHE and IGHEP1. In addition, we have identified novel amino acid changing SNPs not previously reported. The most common of these SNPs was analyzed for its ability to be bound by a marketed IgE therapy and it was found to have binding properties similar to wild-type IgE. Despite this observation, development of other novel antibodies should be tested against this variant to avoid finding a potential pharmacogenetic effect in the clinic.

SplicePort: Analysis of Genetic Variation Affecting the Splicing of Precursors to Messenger RNA. *S. Mount[1, 2].* 1) Dept. Cell Biology and Molecular Genetics, University of Maryland, College Park, MD; 2) Center for Bioinformatics and Compuational Biology, University of Maryland, College Park, MD.

SplicePort (see spliceport.org) is a splice-site analysis tool that makes splice-site predictions for submitted sequences, and which allows browsing of predictive signals and motif exploration. The SplicePort algorithm is based on a feature generation algorithm that produces accurate splice site prediction on human pre-mRNA sequence data using predictive features selected from a large space of sequence based features (1). We are using SplicePort to systematically examine human sequence variants, primarily single nucleotide polymorphisms, for their effect, or potential effect, on the splicing of precursors to messenger RNA. The goal of this analysis is to assess the contribution of these variants to genetic disease susceptibility. SplicePort score changes due to sequence variants of potential significance are compared with the distribution of score changes associated with high frequency variants. Preliminary data indicate that a surprising fraction of minor alleles at polymorphic sites have the potential to affect splicing. Candidate variants will be assessed experimentally by reverse transcription, polymerase chain reaction and sequencing, or by mining publicly available human RNA sequence data. 1. Dogan RI, L Getoor, WJ Wilbur and SM Mount. 2007. SplicePort -- An interactive splice site analysis tool. Nucleic Acids Research. PMID 17576680.

Expression of chitin binding domain of mouse chitinase in Escherichia coli and characterization of its properties. *A. Kashimura, M. Kojima, M. Sakaguchi, Y. Sugahara, F. Oyama.* Applied Chemistr, Faculty of Engineering, Kogakuin University, Hachioji, Tokyo, Japan.

Chitinases hydrolyze chitin, a polymer of N-acetyl-D-glucosamine, which is present in a wide range of organisms, including fungi, insects, and parasites. Although chitin is not present in mammals, chitinase genes were found in both human and mouse genomes. It has been known that chitinase activity is significantly increased in plasma from patients with Gaucher disease, an autosomal recessive lysosomal storage disorder. Recent researches have shown that elevated expression of chitinases is closely associated with progression of allergy and asthma. The pathophysiological role for the mammalian chitinases remains unproven. To understand how chitinase interacts with chitin and their derivatives, we expressed the chitin binding domain (CBD, the C-terminal ~80 amino acids) of chitinase in Escherichia coli as a fusion protein. The recombinant fusion protein with the CBD domain bound to chitin beads, whereas fusion protein without it did not, indicating that the recombinant CBD bound to chitin. Thus, this recombinant protein can be used to elucidate detailed biological functions of the chitinases.

Molecular Genetics Study on HCMV Clinical Isolates from Guangzhou: the Gene Structure and Function of UL136 and UL145. *B. Wang, JJ. Hu, HH. Su, JC. Ding, YY. Guo, CA. Zhao, XZ. Zhang.* Paediatrics Dept., Maternal and Children's Hospital of Guangdong, Guangzhou, Guangdong, China.

BACKGROUND Human cytomegalovirus (HCMV) is the most important cause of congenital infection. It will develop to neonate anomaly, deafness, mental retardation and hydrocephalus. When it occur to immunosuppression children or adults, will lead to severe disease. The clinical low-passage isolate which is capable of pathogenesis, comparing with avirulent high-passage laboratory strain, it contains the UL/b' area. This unique structure, including at least 19 open reading frames (ORF): UL133 to UL151, is supposed to be a crucial area for HCMV pathogenicity. Now we know litter about two of the ORFs, UL145 and UL136. PURPOSE To investigate the genetic characterization and gene function of human cytomegalovirus UL145 and UL136 genes in low passage clinical isolates from Guangzhou China. METHOD The clinical isolates of HCMV were segregated from the urine sample collected from those infants with intra-uterus HCMV infection from Guangzhou. Using Multiplex PCR, we identify HCMV. After cloning UL145 and UL136 genes, amplifying the genes and sequencing, we analyzed its genetic characterization. Finally, we predict their post-translation modified site entering ProtParam web site. RESULT Two strains of low-passage isolate have been obtained. The completed sequence of UL145 and UL136 gene have submitted to GenBank, and gained GenBank accessions (No.: DQ180367, DQ180381, DQ180377, DQ180389). The aberration rate of DNA and amino acid sequences of UL145 is 0.7-1.5% and 0.7-2.2% respectively, and the UL136 is 2.9% and 1.7-3.6% respectively. And UL145 is predicted to have 1 PKC phosphorylation site, 2 CK II phosphorylation site and a zinc finger analogic structure, and is identified has mRNA expression. UL136 is predicted to exist PKC phosphorylation site, N-Myristoylation site, cAMP- and cGMP-dependent protein kinase phosphorylation site and Tyrosine kinaseII phosphorylation site. CONCLUSION The DNA and deduced amino acid sequences of the two genes show great conservation, regardless its polymorphism. UL145 protein is predicted to be a intranuclear cell factor. While UL136 protein is predicted to act as a factor related to membrane receptor mediated signal transduction.

1606/F

The Fanconi anemia pathway regulates telomeric recombination and telomere DNA synthesis in ALT-immortalized human cells. *M. Komosa[1, 2], H.A. Root[1, 2], A. Larsen[1, 3], D. Bazett-Jones[1, 3], M.S. Meyn[1,2,4].* 1) Program in Genetics & Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Dept of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 3) Dept of Biochemistry, University of Toronto, Toronto, ON, Canada; 4) Dept of Paediatrics, University of Toronto, Toronto, ON, Canada.

Fanconi anemia (FA) is an inherited disorder characterized by bone marrow failure, congenital malformations and cancer. A core complex of FA proteins is required to promote FANCD2 monoubiquitination and foci formation during S-phase and in response to DNA damage. Other FA proteins, including the FANCJ ATP-dependent DNA helicase, function independently of FANCD2. To understand the role(s) of FA proteins in DNA replication and recombination, we study the involvement of FA proteins in ALT, the recombination-dependent telomere maintenance pathway used by telomerase-negative immortalized human cells. We find that FANCD2, FA core complex proteins, and FANCJ form nuclear foci that colocalize with telomeric foci in ALT-dependent, but not telomerase-positive or primary cells. FA protein colocalization with telomeric DNA occurs primarily within ALT-associated PML bodies (APBs). Electron spectroscopic imaging of APBs suggests that they contain extrachromosomal telomeric repeat DNA (ECTR) and that FANCD2 depletion leads to chromatin intrusions within APBs that may represent dysfunctional telomeres. FANCD2 depletion also results in ALT-specific increases in ECTR DNA synthesis, telomere dysfunction induced foci, telomere entanglements, and recombination events between sister telomeres, as well as decreased cell viability. We previously found that telomere abnormalities in FANCD2-depleted ALT cells occur via a BLM-dependent, RAD51-independent mechanism. We now report co-depletion of BLM with FANCD2 partially rescues cell viability, suggesting that the induced telomere abnormalities trigger increased cell death. In addition, telomeres in ALT, but not telomerase-positive cells, can display a FISH staining pattern characteristic of expressed fragile sites. FANCD2 depletion results in an ALT-specific increase in “fragile” telomeres, suggesting that FANCD2-associated telomere abnormalities arise during replication of ALT telomeric DNA. In contrast to FANCD2, depletion of FANCJ results in a significant decrease in the number and intensity of detectable foci of telomeric DNA, telomeric binding proteins, and BRCA1. Additionally, co-depletion of FANCJ with FANCD2 partially suppresses amplification of ECTR DNA in FANCD2-depleted cells. Together our results suggest regulation of ALT telomeric DNA replication/recombination by the FA pathway is complex, with FANCJ and BLM required to promote replication/recombination, while FANCD2 and the core complex restrain these events.

1607/F

***Gtf2ird1*$^{-/-}$ mice do not show genotype-specific changes in gene expression during brain development.** *J. O'Leary, L.R. Osborne.* Departments of Molecular Genetics and Medicine, University of Toronto, Toronto, ON, Canada.

Williams-Beuren Syndrome (WBS) is an autosomal dominant neurodevelopmental disorder caused by hemizygous deletion of a 1.5 Mb region on chromosome 7q11.23. The clinical symptoms are numerous and include behavioural and cognitive components. One of the deleted genes, *GTF2IRD1*, shows widespread expression during development and genotype-phenotype studies in patients with atypical deletions of 7q11.23 implicate this gene in the neurological features of WBS. *Gtf2ird1*-targeted mice have features consistent with the WBS phenotype, namely reduced innate fear and increased sociability so to identify neural targets of GTF2IRD1, microarray analyses were performed comparing gene expression in the whole brains of *Gtf2ird1*$^{-/-}$ and wildtype (WT) mice at embryonic day 15.5 and at birth. Overall, the changes in gene expression in the mutant mice were not striking, with most changes falling in the range of 0.3 to 2 fold. Real-Time PCR was used to verify the expression levels of candidate genes identified as altered in the *Gtf2ird1*$^{-/-}$ mice and examination of verified genes revealed that they were all located on chromosome 5, within 50 Mb of *Gtf2ird1*. Since gene targeting may have affected local gene expression, we used siRNA to knock-down *Gtf2ird1* in two mouse neuronal cell lines (Neuro2A and N1E-115) and analyzed the genes identified from the microarray, but none were altered. The initial targeting of the Gtf2ird1 locus was done in R1 ES cells, which are derived from 129 strains, and the mice were backcrossed onto CD1. As the region around the targeted locus will retain a 129 genotype, we hypothesized that the gene expression differences in the *Gtf2ird1*$^{-/-}$ mice were actually the result of differential expression between mouse strains. Expression of the altered genes in *Gtf2ird1*$^{-/-}$ mice was found to be the same as in WT 129S1/SvImJ mice, and significantly different from CD1 WT mice. In addition, analysis of strain-specific SNPs within genes that showed altered expression, demonstrated that the *Gtf2ird1*$^{-/-}$ mice were homozygous for 129 alleles within this region of chromosome 5. In summary, we have been unable to find any in vivo neuronal targets of this putative transcription factor, despite its widespread and robust expression in the developing rodent brain. It seems likely, therefore, that GTF2IRD1, like its protein family member GTF2I which regulates calcium entry, may have an alternate role in the cells of the developing brain.

1608/F

The C-Terminus of P/Q type Voltage Gated Calcium Channel Alpha1A subunit (Cav2.1) modulates the transcription of other neuronal genes. *L. Veneziano[1], E. Mantuano[1], G. Maresca[1], I. Arisi[2], R. Brandi[2], M. D'Onofrio[2], P. Imbrici[3], M. Frontali[1], A. Felsani[1].* 1) Institute of Neurobiology and Molecular Medicine, National Council of Research. Rome, Italy; 2) European Brain Research Institute (EBRI). Rome, Italy; 3) Department of Internal Medicine. Section of Human Physiology. University of Perugia, Italy.

The CACNA1A gene on chromosome 19p13 encodes the α1A subunit of P/Q type voltage-gated Ca2+ channels (Cav2.1) expressed mainly in the cerebellum (particularly in cerebellar Purkinje and granule cells) and (presynaptically) at the neuromuscular junction. Mutations in this gene are responsible for three rare autosomal dominant neurological disorders: Episodic Ataxia type 2 (EA2), Familial Hemiplegic Migraine type 1 (FHM1) and Spinocerebellar Ataxia type 6 (SCA6) due to the expansion of a CAG repeat at the 3'end of the gene. The Cav2.1 α1A subunit is a four domain transmembrane protein of about 280KDa with cytoplasmic N- and C-terminal tails. The cytoplasmic C-terminus plays regulatory roles in the gating and trafficking of many ion channels. The C-terminus of the Cav2.1 α1A subunit, which represent the 25% of the entire protein (about 700 aminoacids) and contains the CAG repeat expanded in SCA6, plays a regulatory role in gating and trafficking and contains residues involved in channel inactivation and modulation induced by intracellular signalling proteins. Recently, the C-terminal tail was shown to be cleaved in vivo and conveyed into the nucleus, suggesting its involvement in regulating some transcriptional processes. In order to elucidate the role of the Cav2.1 C-terminal tail as possible transcription factor, gene expression arrays were carried out in HEK293 cell line wild type and over-expressing Cav2.1 C-terminal tail. Total RNA, extracted from these cells, was analyzed using Agilent 44K whole human genome oligo microarray system. Gene expression in HEK293 cells wild type and over-expressing Cav2.1 C-terminal tail was compared and for genes resulted up or down-regulated more than 5 folds, the expression profile was checked by using standard qRT-PCR analysis. These results, for the first time, provide evidence that Cav2.1 C-terminus, beside modulating channel activity, regulates the expression of genes important for the neuronal excitability such as gap junctions, ion channels, signalling proteins.

1609/F

TP63, TFAP2A, and ADH1C are potential transcriptional targets of interferon response factor 6 (IRF6). *D. Zemke, B. Schutte.* Michigan State University, East Lansing, MI.

Variation in the interferon response factor 6 (IRF6) gene has been shown to cause and contribute risk for cleft lip and palate. IRF6 is a member of the IRF family of transcription factors, however the genes regulated by IRF6 are currently unknown. In this study we used a candidate gene approach to identify genes that are direct transcriptional targets of IRF6. Potential target genes were selected based upon multiple criteria, including expression in relevant tissues, mutant phenotype resembling that of mice lacking Irf6, altered expression in tissues lacking Irf6, and the presence of an IRF6 DNA binding site. Additional candidates were selected based upon the results of genome wide association studies for nonsyndromic cleft lip and/or palate. Among the candidate genes, TP63, TFAP2A, and ADH1C were found to contain sequences bound by the IRF6 DNA binding domain in vitro, as determined by electrophoretic mobility shift assays. Since previous studies demonstrated that p63 and AP2α regulate expression of Irf6, our data suggests a potential transcriptional feedback loop between these transcription factors. The investigation of IRF6 and its targets may lead to a greater understanding of the mechanisms by which the palate is formed. In addition, the targets of IRF6 may be potential candidates for the cause of other clefting syndromes or isolated cleft of the lip and/or palate.

1610/F

A multi-species conserved sequence located 9.7 kb upstream of *IRF6* is sufficient to recapitulate endogenous expression in epidermis, limb and craniofacial tissues. *W.D. Fakhouri[1], L. Rhea[2], M.M. Dunnwald[2], B.C. Schutte[3].* 1) Microbiology and Molecular Gen, Michigan State University, East Lansing, MI; 2) The University of Iowa, Department of Pediatrics, Iowa City, Iowa; 3) Microbiology and Molecular Gen, Department of Pediatrics, Michigan State University, East Lansing, MI.

DNA variation in interferon regulatory factor 6 (*IRF6*) causes, and contributes risk for, orofacial clefting, including a common DNA variant (rs642961) that is located in MCS9.7, a multi-species conserved sequence (MCS) that is 9.7 kb upstream from the *IRF6* transcription start site. MCS9.7 possesses enhancer activity. We hypothesized that the MCS9.7 is sufficient to recapitulate the endogenous expression of *IRF6* during embryo development. We generated three independent stable transgenic lines of mice that contain a *lacZ* reporter gene under the control of MCS9.7. Expression of *lacZ* was determined at E9.5 to E17.5 of embryonic development using X-gal staining of whole embryos and of cryosectioned tissues. In E9.5 embryos, we detected *lacZ* expression in the periderm cells. At E10.5 and E11.5, *lacZ* was expressed in the epithelium of lateral and medial nasal prominences, in the epithelium of the maxillary and mandibular prominences, and in the apical ectodermal ridge of fore- and hind-limbs. At E13.5 and E14.5, *lacZ* expression was detected in the nasal pit, hair follicles, eyelid, corneal ectoderm, epithelial tongue, incisor tooth germ, submandibular gland and secondary palatal shelves. OCT transverse sections showed that *lacZ* is also expressed in the medulla and shaft of hair follicles and the sebaceous glands. In E17.5 skin, MCS9.7 was expressed in the spinous, granular, and cornified layers of the epidermis. In adult ear and footpad, we observed *lacZ* expression in the granular and cornified layers of the epidermis, and occasionally in spinous cells. A similar pattern was also observed in the footpad. In both the tongue and the palate, *lacZ* expression was detected in the suprabasal layers, however, only in patches. In conclusion, our results indicate that MSC9.7 element is sufficient to recapitulate endogenous expression of IRF6 in epidermis, limb and craniofacial tissues during embryonic development between E9.5-E17.5. However, we also observed *lacZ* expression in the neuroepithelium of hindbrain, the 3rd branchial arch, the somites and corneal ectoderm. Further studies are needed to determine whether endogenous *IRF6* is expressed in these latter tissues.

1611/F

Characterization of a LINE-1 retrotransposition intermediate. *P. Mandal, J. Goodier, H. Kazazian.* Gen, Univ Pennsylvania, Philadelphia, PA.

Long Interspersed Nucleotide Element-1s (LINEs1 or L1s) are the most active human retrotransposons, occupying, 17% of the human genome. Although most L1s are not able to retrotranspose, about 100 remain potentially active. A potentially active L1 is 6.0 kb in length and contains a 5' UTR, two open reading frames (ORF1 and ORF2) and a 3' UTR. ORF1 encodes a 40 kDa nucleic acid binding protein, whereas ORF2 encodes a 150 kDa protein with endonuclease (EN) and reverse transcriptase (RT) activities. Although the function of the ORFs is not completely understood, both are critical for the retrotransposition process. A model of L1 retrotransposition proposes that L1 ORF1p and ORF2p bind in cis with L1 RNA and form an L1 ribonucleoprotein particle (L1-RNP) in the cytoplasm. The L1-RNP then enters the nucleus and finds its target site where the L1 RNA is converted to a new genomic DNA copy. Previous studies to characterize human L1-RNPs relied on differential centrifugation of extracts from HeLa cells transfected with an active epitope-tagged L1. Although informative, these studies probably examined L1-RNPs in association with co-concentrating molecules not involved in the retrotransposition process. Here we have developed a quick and efficient way to purify L1RNPs by affinity purification. We have fused a Flag epitope at the C-terminus of ORF1p of a wild type active L1. Cell culture based retrotransposition assays show that this epitope-tagged L1 retrotransposes at the same frequency as wild type L1. We transfected this epitope-tagged L1 into 293T cells and prepared cytoplasmic lysate after 72 hours. The cytoplasmic lysate was incubated with anti Flag-agarose beads for 2 hrs and washed extensively with 500 mM NaCl before eluting L1-RNPs by Flag peptide competition. We have detected the 40 kDa ORF1p by Flag Ab and the 150 kDa ORF2p either by using an ORF2p N-terminal Ab or C-terminal Ab. We have also detected the 6kb L1 RNA in the L1-RNPs. We also demonstrated ORF2p RT activity in these same RNPs. We made another construct in which the C-terminus of ORF2p was fused with Flag epitope and repeated the same experiments. We demonstrated the presence of ORF1p, ORF2p, L1RNA and ORF2p RT activity in the RNPs pulled down via the ORF2p Flag-tag. Our ability to efficiently purify L1-RNPs using either an epitope-tagged ORF1p or ORF2p now makes it possible to identify cis-acting cellular factors involved in L1 RNP assembly and the complex process of retrotransposition.

1612/F

Detection and characterization of microsatellite variation in the human genome from 1,000 genomes Pilots 1 & 2. *D.R. Murdock, F. Yu, R.A. Gibbs, P.E. Bonnen, 1000 Genomes Project.* Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

Variation in microsatellites contributes to the spectrum of human phenotypic diversity ranging from non-pathogenic traits to causing devastating diseases. There is also evidence in non-human species for a role for microsatellites as a mechanism of rapid evolution. We have developed a methodology for extracting genotypes for microsatellites from next-generation sequence data and applied this method to data from the 1000 Genomes Project. Using low coverage whole genome sequence data pooled across 22 individuals (Pilot 1) we developed high confidence genotypes for 110,769 microsatellites in the human genome. Additionally, we computed microsatellite genotypes for two high coverage individuals (Pilot 2). Using these data we assess the extent of heterozygosity among microsatellites genome-wide and the factors that contribute to this variability. Our method and analyses demonstrate the ability to genotype highly polymorphic, multiallelic variants such as microsatellites and provide insight into the basis for this variability. In addition, we expand the repertoire of variants available for human studies beyond bi-allelic markers and provide a rich substrate for studies into phenotypic variability and disease investigations.

1613/F

Structural-Functional Analysis of *cep290* in Zebrafish Vision. *L.M. Baye[1], X. Patrinostro[1], J.S. Beck[2,4], S. Swaminathan[1], Y. Zhang[2], E. Stone[3,4], V.C. Sheffield[2,4], D.C. Slusarski[1].* 1) Dept of Biology, University of Iowa, Iowa City, IA; 2) Dept of Pediatrics, University of Iowa, Iowa City, IA; 3) Dept of Ophthalmology,University of Iowa, Iowa City, IA; 4) Howard Hughes Medical Institute.

CEP290 is a large, multi-domain gene implicated in several cilia related syndromic disorders including Meckel-Gruber, Joubert, Senor-Loken and Bardet-Biedl Syndrome (BBS). Moreover, *CEP290* is the most frequently mutated gene underlying the non-syndromic blinding disorder Leber's congenital amaurosis (LCA). Using the zebrafish model system, we characterized the developmental role of *cep290* and used a functional assay to identify a region of the CEP290 protein that is required for vision. In the zebrafish embryo the *cep290* transcript is expressed throughout development and localizes to the ganglion, inner nuclear layer and the photoreceptor cells of the retina. To determine the *in vivo* function of *cep290* in the zebrafish, we examined the effects of gene knockdown using an antisense oligonucleotide (Morpholino, MO) designed to generate an altered *cep290* splice product that models a common LCA mutation. We have previously demonstrated that knockdown of *bbs1-12* results in reduction of a ciliated vesicle, the Kupffer's Vesicle (KV) and delays in intracellular transport of zebrafish melanosomes. Consistent with a role in BBS, *cep290* morpholino-injected embryos exhibited defects in the size of the KV and statistically significant delays melanosome transport. Morphologically, the embryos exhibited a curved body axis at increased doses of MO consistent with additional roles of *cep290* in cilia function. Histological analysis of the retina revealed no gross morphological defects; however, knockdown of *cep290* resulted in a statistically significant reduction in visual function. We next examined the function of CEP290 protein domains by co-injection of RNA with the *cep290* MO and then evaluated suppression of morpholino-induced phenotypes. We demonstrate that vision impairment caused by disruption of *cep290* can be rescued by expressing only a portion of the protein; however, the KV and melanosome transport delays were not rescued. Together, these data illuminate a specific region of the CEP290 protein that is functioning in vision and identify a potential gene therapy target for LCA patients with mutations in *CEP290*.

1614/F

The Role of *Robo1* in Retinal Vascular Disorders. *N. Haider[1,2], A. Yang[1], Y. Yuan[1], M. DeAngelis[3].* 1) Dept Gen, Univ Nebraska Med Ctr, Omaha, NE; 2) Dept. Ophthalmology & Visual Sciences, Univ Nebraska Med. Ctr, Omaha NE; 3) Ocular Molecular Genetics Institute and Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary Boston, Massachusetts.

Pathological ocular angiogenesis occurs in many vision-debilitating diseases such as retinopathy of prematurity, diabetic retinopathy, and age-related macular degeneration (AMD). The Slit/Roundabout (Robo) system, originally discovered in Drosophila neurons for its role in axon guidance, has been well studied in the brain and other parts of the central nervous system. Although there is some evidence that *Robo1* plays a role in retinal angiogenesis, its exact role in the normal retina is still unknown. We previously reported that SNPs and haplotypes in RAR-related orphan receptor alpha, *RORA*, are significantly associated with neovascular AMD in three diverse populations and furthermore that ROBO1 likely functions in the same pathway with RORA. Using ChIP assays in the normal mouse retina, we report that Robo1 gene expression is modulated by *Rora*. Further, in order to better understand the role of *Robo1* in retinal angiogenesis, we have examined the temporal and spatial expression profile of *Robo1* in the mouse retina and have determined the retinal pathology of the *Robo1* knockout mouse model. Our results demonstrate that *Robo1* is expressed in several layers of the retina including the inner segments of the photoreceptor cells, inner and outer plexiform layers, ganglion cell layer, nerve fiber layer, as well as retinal blood vessels. Our studies suggest a novel role for *Robo1* in retinal angiogenesis and studies using the *Robo1* knockout mouse will allow us to better understand the role of *Robo1* in common blinding retinal diseases such as neovascular AMD and diabetic retinopathy.

Human Kir7.1 Channel Mutation (R162W), Associated With Snowflake Vitreoretinal Degeneration (SVD), Disrupts the Lipid Binding Pocket and Results in a Non-Functional Channel. *D.M. Pillers[1, 2], S. Tokarz[1], M. Asuma[1], T. Schoeder[1], A. Sharma[3], A.O. Edwards[4], B. Pattnaik[1, 2, 5].* 1) Dept Pediatrics-Neonatology, University Wisconsin, Madison, WI; 2) Eye Research Institute, University Wisconsin, Madison, WI; 3) Experimental Pathology, Mayo Clinic, Rochester, MN; 4) Institute for Molecular Biology, Univ. of Oregon, Eugene; 5) Ophthalmology, University Wisconsin, Madison, WI.

Background: Hereditary snowflake vitreoretinal degeneration (SVD) is an autosomal dominant disorder that causes degeneration of multiple ocular tissues. SVD is linked to a mutation R162W in the Kir7.1 inwardly rectifying potassium channel. The Kir7.1 channel is located in the apical membrane of retinal pigment epithelium (RPE) and facilitates potassium homeostasis around the photoreceptor outer segment and also facilitates directional fluid flow across the RPE. A similar mutation in rat Kir7.1 forms functional but non-selective channels in CHO cells. Purpose: To understand the cellular physiology phenotype associated with the R162W mutation in human Kir7.1 expressed in mammalian cells. Methods: Wild-type (hKir7.1WT) and mutant (hKir7.1M) were co-transfected into CHO cells along with GFP. Kir channel currents were studied by whole-cell electrophysiology. Bath solution (in mM): 135 NaCl, 5 KCl, 10 HEPES, 10 glucose, 1.8 CaCl2 and 1 MgCl2 pH 7.4. For selectivity bath Na+ was replaced with either K+ or Rb+. Recording electrodes (in mM): 30 KCl, 83 K-gluconate, 10 HEPES, 5.5 EGTA, 0.5 CaCl2, 4 Mg-ATP, and 0.5 GTP adjusted to pH 7.2. Total protein from transfected CHO cells was isolated, subjected to electrophoresis and Western blot analysis using Kir7.1 and βactin antibodies.The blot was visualized using the Odyssey IR system.Results: Cells expressing hKir7.1WT had a resting membrane potential of -45 ± 4.6 mV (n=10) compared to -3.2 ± 1.8 mV (n=15) for the hKir7.1M transfected cells ($p<0.005$). Current-voltage curves for the hKir7.1WT showed typical inward rectification. The inward current of hKir7.1WT had preference for Rb+ over K+ as expected. The hKir7.1M exhibited no current over the whole voltage range in which hKir7.1WT is active. Protein analysis showed that mutant Kir7.1 expression was decreased compared to wild-type. Conclusions: Wild-type Kir7.1 expression in CHO cells results in a highly selective current while the human mutant Kir7.1 did not exhibit any current proving that the mutant fails to form functional channels. This mutation also results in reduced Kir7.1 expression in transfected cells. The R162W mutation lies within the Kir7.1 cytoplasmic lipid-binding pocket. A similar mutation in Kir2.1 results in cardiac electrical instability causing cardiodysrhythmic periodic paralysis. This non-functional Kir7.1 channel may contribute to the classic phenotype of SVD, by distorting RPE transport function and altering RPE physiology.

1616/W

Rapid and Sensitive by Capillary Electrophoresis for Expanded Allele in Friedreich Ataxia Type 1. *P. YESCAS[1], N. MONROY[1], M. LOPEZ[2], E. ALONSO[1].* 1) Department of Neurogenetics, National Institute of Neurology and Neurosurgery Mexico City, Mexico; 2) Biological Systems UAM-Xochimilco, Mexico City, Mexico.

Friedreich's ataxia (FA) is an autosomal recessive disease. FA type 1 is caused by mutations in the gene encoding frataxin (FXN). The most common molecular alteration is the expansion of a GAA trinucleotide repeat in intron 1 of FXN gene. Normal subjects have 5 to 30 GAA repeats, while 98% of affected individuals may have from 70 to more than 1000 repeats. In general the clinical diagnosis of ataxias is difficult, often the FA phenotype is atypical and the techniques used for detection are laborious and require enormous amounts of DNA sample. To implement a screening technique that allows fast and simple detection of expanded FXN alleles. The sample consisted of 18 patients positive for AF type 1, previously confirmed by other techniques, and negative controls. The region flanking the GAA repeat of intron 1 of FXN was amplified triple-primer PCR 100 ng of DNA, where one of them is fluorescent. The amplicons were separated in a capillary electrophoresis genetic analyzer. Each sample was analyzed by triplicate. The technique used allows to distinguish healthy individuals, as well as heterozygous and homozygous FA patients. The results of the 18 cases of AF were consistent with those previously obtained by Southern blot The implemented technique allows rapid screening of expanded alleles in individuals with suspected type 1 FA. We propose that the expansion by triplet repeat in the FXN gene should be investigated in all patients with sporadic ataxia and age of onset before 40 years even though the phenotype is atypical FA. This technique could be used for other types of ataxias. CONACYT 69210.

Analysis of the performance of prediction algorithms for the evaluation of missense and splicing variants in a clinical diagnostics context. *C.D. Elzinga, C.D. Braastad, I.D. Karbassi, C. DiVincenzo, C. Moffitt, J.G. Jones, S.D. Batish, E.J. Couchon.* Athena Diagnostics, Worcester, MA.

Missense variants and variants that may have an effect on splicing are commonly encountered by clinical diagnostic labs. Often little or no information is available in the scientific literature to assist in classifying these variants as normal or as pathogenic. Predictive algorithms (i.e. SIFT, PolyPhen, and various splicing algorithms) are commonly used as part of the analysis of these variants of unknown clinical significance. However, the sensitivities and specificities of different algorithms vary, and the performance of individual prediction algorithms vary across genes as well. In order to evaluate the performance of prediction algorithms intended for missense variants (including SIFT and PolyPhen), missense disease variants and known missense polymorphisms (normal variants) from a variety of genes were used as a test pool. Each algorithm was used to produce predictions for these selected variants. Concordance of the predicted effect on normal protein function with the actual effect was used to assess sensitivity, specificity, and other test performance metrics for individual genes and for the algorithm as a whole. Similarly, to evaluate selected splicing algorithms, variants known to have an effect on splicing and known polymorphisms occurring very near known splice sites were used as a splicing test pool. Splicing algorithms were used to produce predictions for variants in the splicing test pool. Where possible, ROC curves were generated to assist in selecting optimal significance thresholds for algorithms tested, and test performance metrics were calculated for each splicing algorithm.

Deciphering the Molecular Basis of Neurological Diseases: Screening Tests in the Bedouin Population. *S. Khateeb, O. Barel, G. Narkis, O.S Birk.* Soroka Medical Center and NIBN, Ben Gurion University, Beer-Sheva, Israel.

Our Bedouin community of ~170,000 is characterized by ~60% consanguineous marriages and 8-9 children per couple, leading to a high incidence of autosomal recessive diseases. A comprehensive organization of community education, molecular research and clinical implementation has been set up. We have generated effective novel software that facilitates finding disease-associated loci using Affymetrix SNP arrays, and a unique bioinformatics tool (S2G = Syndrome to Gene) to identify the disease genes within the defined loci. Using these tools, we recently identified 14 novel disease genes, 5 of them for severe neurological diseases: infantile neuroaxonal dystrophy (INAD) is a storage disease caused by mutations in phopholipase PLA2G6; a severe recessive phenotype of mental retardation and cerebral palsy is due to a mutation in UQCRQ of mitochondrial complex 3; Birk Barel genomic imprinting mental retardation syndrome is due to mutation in potassium channel KCNK9; Lethal congenital arthrogryposis can be caused by mutations in either ERBB3 or PIP5K1C, which directs ERBB3 internalization. These findings, with dozens of novel mutations we found in known disease genes, are being implemented as free carrier testing, prenatal diagnoses and pre-implantation genetic diagnoses, leading to a dramatic two-fold reduction in infant mortality in our Bedouin community over the past 4 years.

MutaDATABASE, a standardised, centralised, open access database of mutations leading to human genetic disease. *P.J. Willems[1], F. Decouttere[2], S. Bale[3], M. Devisscher[2], W. Van Criekinge[4], R.L. Nussbaum[5].* 1) GENDIA, Antwerp, Belgium; 2) GENOHM, Zwijnaarde, Belgium; 3) GENEDX, Gaithersburg , USA; 4) BIOBIX, University Ghent, Belgium; 5) Department of Medicine, UCSF, San Francisco, USA.

A small fraction of the mutations causing genetic disease have been published in the literature or listed in public mutation databases, as most novel disease mutations identified over the last decade have been identified in clinical diagnostic laboratories. International journals have published individual or lists of mutations without accompanying detailed clinical and/or functional data, which is generally not available to the diagnostic laboratory. Many mutations are not introduced into mutation databases because at present there is no easy or efficient way for a busy diagnostic laboratory to submit novel mutations into a standardized database platform. Furthermore, there is only limited exchange of information about mutations between different diagnostic laboratories. Consequently, the clinical significance of many novel mutations remains undetermined. Furthermore, no standardized, centralized, and open access database of mutations exists that includes well-vetted information on the common disease genes and mutations implicated in human genetic diseases. To address these problems we have developed MutaDATABASE, a standardized, centralized, and free open access database that addresses this need. Included for each disease gene is : i) general information on the disease gene, including genomic sequence, cDNA sequence, amino acid sequence, genomic structure, intron-exon boundaries, functional domains, and function, ii) general information on the diseases associated with mutations in that gene, iii) tables of exon-intron sequences and disease-causing mutations, and iv) figures of the cytogenetic position, genomic structure of the gene, and disease-causing mutations, v) lists of MutaCIRCLES -- labs working on the same disease gene that are linked in community groups. MutaDATABASE has real-time bidirectional communication with a new software interface, MutaREPORTER, which is designed to define, characterize and archive variations in human disease genes. MutaDATABASE currently is supported by hundreds of gene curators and genetic labs.

1620/W

Mitochondrial Genome Sequence Analysis: A custom bioinformatics pipeline substantially improves Affymetrix MitoChip call rate and accuracy. *H.M. Xie[1], J.C. Perin[1], T.G. Schurr[2], J. Baur[2], M. King[3], E. Place[1], C. Clarke[1], M. Grauer[1], J. Schug[2], A. Santani[1], A. Albano[1], C. Kim[1], H. Hakonarson[1,2], X. Gai[1], M.J. Falk[1,2].* 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, Philadelphia, PA; 3) Thomas Jefferson University, Philadelphia, PA.

Mitochondrial genome sequence analysis has become highly relevant to the clinical diagnostic evaluation of mitochondrial disease. Existing methodologies widely differ in cost, complexity, and heteroplasmy detection sensitivity. Further, reports of numerous sequence variants often present a challenge to ready clinical diagnostic interpretation. Here, we report the performance of a bioinformatics software pipeline that achieves much improved mitochondrial genome sequence call rates and accuracy following Affymetrix MitoChip analysis. **METHODS:** A custom bioinformatics software pipeline was created to detect sequence variation. Results are fed into a presentation layer that incorporates a MySQL database backend with a PHP-based web front-end, "MitoSNP", which facilitate rapid SNP presentation and visualization. MitoSNP annotates variants based on gene content, known pathogenicity, and haplogroup-determining SNPs. Gbrowse integration permits visual interpretation in the context of all other publicly available genome annotations. 24 samples were genotyped by Affymetrix MitoChip (v2) and analyzed with this custom pipeline. For comparison purposes, samples included 7 previously analyzed with Sanger sequencing in a clinical laboratory, 1 analyzed by NGS, 1 with a 2 base pair deletion, 1 with a 5 Kb deletion, 2 harboring known heteroplasmic mutations, and 1 from a rare haplogroup. **RESULTS:** An average call rate of 99.97% was achieved with our pipeline. In comparison, Affymetrix GSEQ software provided an average call rate of 98.63% for the same data set. We successfully identified 2 known heteroplasmic mutations and an additional 21 potential heteroplasmic mutations from all samples. GSEQ software could not detect 1 of the 2 heteroplasmic mutations despite overcalling other potential heteroplasmic mutations that we confirmed were not present by NGS analysis. As expected, the 2 base pair deletion was not detected but the 5 Kb deletion was clearly illustrated. Comparison of calls for 7 samples previously sequenced in a clinical laboratory revealed a total of 19 discordant calls, which translates to an upper bound of 0.016% for the estimated error rate. **CONCLUSIONS:** Affymetrix MitoChip analysis using a revised bioinformatics pipeline offers desirable sensitivity and accuracy for whole genome mitochondrial sequencing at a very low cost. This pipeline provides an attractive alternative to classic Sanger and other whole genome mitochondrial sequencing technologies.

Can genetic-guided screening help the prevention of lung cancer? *B. Peng[1], J. Su[1], M. Foy[2], O. Gorlova[1], C. Amos[1].* 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Brown Foundation Institute of Molecular Medicine, University of Texas Health Science Center at Houston, Houston, TX 77030.

Because of concerns about the unknown degree of over-diagnosis, risks associated with radiation exposure, and follow-up of very small indeterminate nodule, early detection of lung cancer using chest X-ray, computed tomography, and sputum cytology screening of high-risk individuals is currently not recommended. However, with the identification of a number of risk factors associated with this disease, it is possible that the benefit of screening in high-risk populations, defined by those with strong family history or presence of specific biomarkers and a heavy smoking history, could outweigh the cost and make screening a useful tool in the prevention of cancer among these individuals. Using a microsimulation model that simulates populations with realistic smoking histories and individual lung cancer risk models, we introduced explicit genetic risk factors to a two-stage clonal expansion model and simulated populations with realistic individual, familial and population level properties. Hypothetical genetic risk factors following different disease models are used to compensate for the missing heritability of lung cancer. We applied different cancer screening strategies to various high-risk populations defined by smoking patterns and individual genotype profile and compared the benefits, harms and costs of these strategies using a cost model.

1622/W

Copy Number Analysis of the FH Gene is a Valuable Tool in Diagnosing Hereditary Leiomyomatosis and Renal Cell Cancer Syndrome and Fumarate Hydratase Deficiency. *J. Higgs[1], J. Boyle[2], A. Mroch[2], J. Flanagan[2], S. Suchy[1].* 1) GeneDx, Gaithersburg, MD; 2) Sanford Health, Sioux Falls, SD.

Germline mutations in the FH gene, encoding the TCA cycle enzyme fumarate hydratase, are associated with both an autosomal dominant syndrome that includes skin and uterine tumors and/or renal cell cancer: hereditary leiomyomatosis and renal cell cancer (HLRCC), and with an extremely rare autosomal recessive inborn error of metabolism: fumarate hydratase deficiency (FHD). Identification of FH mutations completes the search for a diagnosis, enables accurate risk assessment and genetic counseling, allows for prenatal diagnosis and carrier testing, and for HLRCC permits the identification of additional family members and establishment of cancer surveillance programs prior to the onset of symptoms. While most disease-associated mutations are identified by sequence analysis of the FH gene, large intragenic deletion/duplications of one or more exons that have been reported in HLRCC and FHD will not be detected by sequencing. Copy number analysis of the FH gene was performed on 15 individuals at GeneDx by quantitative PCR, custom oligonucleotide array with exon-level resolution (ExonArrayDx), or by multiplex ligation-dependent probe amplification, and 4 deletions of one or more exons were identified (27%). These included a novel deletion of exon 6 found in a single patient via array CGH. In one family with a previous child with FHD and an apparently homozygous missense mutation in the FH gene, a second pregnancy presented with ventriculomegaly and agenesis of the corpus callosum. Parental testing revealed that one parent did not have the missense mutation present in the proband but instead had a large deletion in the FH gene. Identification of the deletion allowed for prenatal diagnosis and establishment of carrier status in the siblings. Enzymatic testing performed after delivery confirmed the diagnosis of FHD. Deletion/duplication testing has a high detection rate for FH-related disorders particularly after sequence analysis fails to identify the mutation(s), enables the accurate diagnosis of individuals affected with HLRCC and FHD, and establishes carrier status in individuals at risk for HLRCC-related tumors prior to the onset of symptoms.

1623/W

Longitudinal Changes in Patient Distress following Interactive Decision Aid Use among BRCA1/2 Carriers. *G.W. Hooker[1], K.G. Leventhal[1], T. DeMarco[1], B. Peshkin[1], C. Finch[1], E. Wahl[2], J. Rispoli-Joines[3], K. Brown[4], H. Valdimarsdottir[5], M.D. Schwartz[1].* 1) Cancer Control ,Lombardi Comprehensive Cancer Center, Georgetown University, Washington, DC; 2) Section of Genetics and Metabolism, Albany Medical Center; 3) University of Maryland, Greenebaum Cancer Center; 4) Department of Genetic and Genomic Sciences, Mount Sinai School of Medicine; 5) Department of Oncological Sciences, Mount Sinai School of Medicine.

Background: Increasingly, women with a strong family history of breast cancer are seeking genetic testing as a starting point to making significant decisions regarding management of their cancer risks. Individuals who are found to be carriers of a BRCA1 or BRCA2 mutation have a substantially elevated risk for breast cancer and are frequently faced with the decision of whether or not to undergo risk reducing mastectomy. **Objective:** In order to provide BRCA1/2 carriers with ongoing decision support for breast cancer risk management, a computer-based interactive decision aid was developed and tested against usual care in a randomized controlled trial. **Design:** Following genetic counseling, 214 female (aged 21-75) BRCA1/2 mutation carriers were randomized to Usual Care (UC; N=114) or Usual Care plus Decision Aid (DA; N=100) arms. UC participants received no further intervention; DA participants were sent the CD-ROM based decision aid to view at home. **Main Outcome Measures:** The authors measured general distress, cancer specific distress and genetic testing specific distress at 1-, 6- and 12-month follow up time points, post-randomization. **Results:** Longitudinal analyses revealed a significant longitudinal impact of the DA on cancer specific distress (B= 5.54, z = 2.74, p = 0.006) which varied over time (DA group by time; B = -2.19, z = -2.45, p = 0.01) and on genetic testing specific distress (B = 5.38, z = 2.38, p = 0.02) which also varied over time (DA group by time; B= -2.38, z = -2.43, p = 0.02). Individuals randomized to UC reported significantly decreased distress in the month following randomization, whereas individuals randomized to the DA maintained their post-disclosure distress over the short-term. By 12-months, the overall decrease in distress between the two groups was similar. **Conclusion:** This report provides new insight into the long-term longitudinal effects of DAs, and raises possibilities for mechanisms of deliberative decision making.

VUS Predict, a web based tool for classifying *BRCA* variants of uncertain significance. *A. Toland[1,4,5], L. Senter-Jamieson[2,4,5], K. Sweet[2,4,5], S. Gnanadesikan[3,5], D. Newman[3,5].* 1) Human Cancer Genetics; 2) Cancer Genetics Program; 3) Information Warehouse; 4) Comprehensive Cancer Center; 5) The Ohio State University, Columbus, OH.

Approximately 7% of individuals who undergo genetic testing of *BRCA1* and *BRCA2* are found to carry a variant of uncertain significance (VUS). There are a number of different algorithms used to classify these variants, many of which require intensive statistical analysis and the availability of genetic test results for the *BRCA* VUS for multiple family members. We developed a user-friendly algorithm to classify *BRCA1* and *BRCA2* variants in individuals with breast and/or ovarian cancer which utilizes readily available tumor histopathology and evolutionary conservation data. We tested our algorithm using 50 deleterious *BRCA1* and *BRCA2* mutations and 21 neutral polymorphisms. We had 98% sensitivity and 76% specificity to predict classified BRCA sequence changes. (It is important to note that the majority of deleterious mutations tested using the model were nonsense or truncating.) To make this algorithm widely available, we developed a web-based tool called VUS Predict, which genetic counselors and other genetic professionals can use to obtain evidence that a *BRCA* VUS may be deleterious or neutral. VUS Predict requires VUS sequence information; histopathological data from the patient who has the variant as well as breast and/or ovarian cancer; and age of diagnosis in order to estimate the odds of a VUS being deleterious. Information from only one patient is necessary to estimate odds but the ability of the program to classify an uncertain variant as neutral or deleterious improves with the number of unique individuals entered with the particular VUS. On-going studies will further evaluate the predictive power of this tool. Our goal is to continue to enhance VUS Predict so that all types of *BRCA* variants might be evaluated, including putative splice variants, which are likely to be an important class of variants.

Arginine Missense Mutation Concentration in the Ig Loop of SCN1B: Epilepsy Testing Results from a Clinical Reference Laboratory. *I.D. Karbassi, S.D. Batish, J.G. Jones, C.D. Elzinga, C. DiVincenzo, C.D. Braastad.* Athena Diagnostics/Thermo Fisher Scientific 377 Plantation Street Worcester, MA 01605.

SCN1B is a voltage-gated ion channel auxiliary beta subunit that associates non-covalently with the alpha subunit. Beta subunits have been shown to regulate channel kinetics and cell surface expression of alpha subunits and mutations in SCN1B may result in generalized epilepsy with febrile seizures plus, Brugada syndrome 5, and other defects in cardiac conduction. Providing a differential diagnosis through genetic testing of SCN1B (available since 2007 from Athena Diagnostics as a single test or within a panel) in a young patient guides proper treatment, given that anticonvulsant drugs exacerbate seizures in these patients. SCN1B, a 218 amino acid protein, contains a signal peptide, one transmembrane domain, an intracellular C-terminus and an extracellular Ig-like domain. Within the Ig-like domain there is an Ig loop region that is thought to be defined by a disulfide linkage between C40 and C121. This loop has been shown to be involved in critical interactions with cell-adhesion molecules and also with other SCN1B molecules. There are currently five published disease-associated variants and all are found within, or just outside, the Ig- loop: R85C, R85H, IVS2-2A>C (causes a deletion of I70 to E74), C121W (abolishes the disulfide bond), and R125C (associated with Dravet if seen as homozygous). The majority of these variants affect arginine residues (the deletion caused by IVS2-2AC encompasses R72). Since the extracellular portion of SCN1B is structured into beta-sheets, arginines may play a role in maintaining beta-sheet integrity through hydrogen bonding or even in stabilizing protein interactions occurring in this region. There are a total of seven arginines contained within the Ig-loop (with the eighth, R125, located just outside). These arginines are highly conserved among 12 species (from human to zebrafish), with R46 and R89 being completely conserved. We at Athena have observed each of these arginines (with the exception of R60) changed to another amino acid in individuals whose physicians have referred them for febrile seizures evaluation. Interestingly, the majority of these changes have been from an arginine to a cysteine or histidine. This pattern suggests pathogenicity, but there is limited published data available on the variants that affect SCN1B and cause disease. As a leader in genetic testing for epilepsy, Athena is in a unique position to collaborate with researchers to better assess clinical pathogenicity of SCN1B sequence variants.

Rapid detection of the 22q11.2 deletion by Pyrosequencing. *D. Koontz, S. Nikolova, M. Gallagher.* Centers for Disease Control, Newborn Screening and Molecular Biology Branch, Atlanta, GA.

Identification of microdeletions of the chromosome 22q11.2 region is important to the diagnosis of DiGeorge (DGS) and Velocardiofacial (VCFS) syndrome, also referred to as 22q11.2 deletion syndrome (22q11DS). Much clinical heterogeneity is associated with deletions in this region, which can be variable in size. Most individuals (~90%) with 22q11DS have a common 3.0Mb deletion that contains more than 45 known genes, and another 8% carry a 1.5Mb nested deletion. A minority of cases contain smaller atypical deletions. The conventional method for 22q11.2 deletion detection is fluorescence in situ hybridization (FISH) with commercial probes. Molecular-based methods include microsatellite typing, microarray-based comparative genomic hybridization, multiplex ligation-dependent probe amplification (MLPA), and TaqMan real-time quantitative PCR. However, most of these methods require a minimum of 20-100ng of high quality DNA. We developed a Pyrosequencing assay suitable for lower quantity DNA from buccal swabs that requires as little as 1.0ng input DNA. Results can be obtained in a single run with one set of PCR and Pyrosequencing primers. PCR primers target the human ubiquitin fusion-degradation gene (UFD1L) within the commonly deleted 3.0 Mb region and nested 1.5 Mb region. Determination of relative copy number of the deletion was obtained by co-amplification of an intergenic region on chromosome 18 with 97% sequence homology to the 22q11 target. Two sequence differences in the co-amplified amplicons were used to distinguish chromosome 18 (Chr18) from chromosome 22 (Chr22) sequence. The Chr18-specific peak heights were used as two copy references, and genotype calls are derived from quantitative peak height ratios between Chr18-specific and Chr22-specific peak heights. Assay optimization was performed on Coriell DNA from clinically diagnosed and FISH-confirmed DGS (n=2) and VCFS (n=1) patients and on multi-ethnic DNA samples from the Coriell Variation Collection (n=186). Further assay validation was performed on paired blood and buccal specimens from patients with FISH-confirmed 22q11.2 deletion (n=20) and buccal samples from normal subjects who presumably lack the deletion (n=118). Pyrosequencing results showed 100% concordance with FISH data, and reproducibility was high. This method represents a reliable and low-cost alternative to other methods for the detection of 22q11.2 microdeletions, especially when DNA quality and quantity is limited.

Identification of Loss of Function *SPRED1* copy number changes using RT-PCR, Multiplex Ligation-dependent Probe Amplification and Quantitative PCR. *E. Spencer[1], J. Ramsey[1], F.M. Mikhail[1], C. Fu[1], R. Vijzelaar[2], H. Feret[3], E. Zackai[3], A. Shugar[4], M.S. Meyn[4], G. Bellus[5], S. Kivirikko[6], M. Pöyhönen[7,8], L. Messiaen[1].* 1) Genetics, University of Alabama, Birmingham, Birmingham, AL; 2) MRC-Holland, Amsterdam, The Netherlands; 3) Division of Human Genetics, Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA; 4) Division of Clinical & Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 5) Department of Genetics, Children's Hospital, Aurora, CO; 6) Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, FInland; 7) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 8) Dept of Clinical Genetics, HUSLAB, Helsinki, Finland.

Legius syndrome, is a recently identified autosomal dominant disorder caused by Loss of Function (LOF) mutations in the *SPRED1* gene, with individuals mainly presenting with multiple café-au-lait macules (CALM), freckling and macrocephaly. So far, only minor lesion LOF *SPRED1* mutations have been identified as the cause of this syndrome. To determine if Copy Number Changes (CNCs) are a cause of Legius syndrome, we have used a Multiplex Ligation-dependent Probe Amplification (MLPA) assay covering all *SPRED1* exons in a cohort of 320 NF1-negative patients presenting with multiple CALM in whom no minor lesion LOF *SPRED1* mutation had been found by cDNA sequence analysis of the entire *SPRED1* coding region. Four different deletions were identified by MLPA and confirmed by quantitative PCR, reverse transcriptase PCR and/or Array CGH: a deletion of exon 1 and the *SPRED1* promoter region in a proband and two first-degree relatives; a deletion of the entire *SPRED1* gene in a sporadic patient; a deletion of exon 2-6 in a proband and her father; and a deletion of ~6MB of chromosome 15 in a sporadic patient. Patients presented with multiple CALM with or without freckling, but fulfilled no other NF1 diagnostic criteria. These results indicate the need for dosage analysis to complement sequencing-based *SPRED1* mutation analyses.

1628/W

Genetic Laboratory Testing Without Clinical Correlation: A Recipe for Misdiagnosis. *H. Welsh[1], L. Zhang[2], S. Yu[2], H. Ardinger[1].* 1) Section of Genetics, Children's Mercy Hospitals and Clinics, Kansas City, MO; 2) Cytogenetics Laboratory, Children's Mercy Hospitals and Clinics, Kansas City, MO.

A chromosome analysis was ordered by an endocrinologist to rule out Turner syndrome in a 12-year-old girl with short stature. This testing revealed a 46,XX,del(11)(q24q25) karyotype, consistent with the diagnosis of the Jacobsen Syndrome. The phenotype of Jacobsen Syndrome includes growth deficiency, microcephaly, mental retardation, craniofacial anomalies, joint contractures and cardiac defects. The family was advised of the cytogenetic findings and referred for a genetics evaluation and counseling for Jacobsen syndrome. On physical examination, the patient was found to be at the <3rd percentile for height and at the 40th percentile for head circumference. The remainder of her physical exam was normal, with the exception of an inability to pronate or supinate her forearms and difficulty with fine motor skills. There were no dysmorphic features. There was no developmental delay and the family reported her to be a straight A student. Because of the inconsistency between her phenotype and her cytogenetic findings we obtained a skeletal survey, a second chromosome analysis with FISH studies and a microarray analysis. The skeletal survey was suggestive of the diagnosis of Leri-Weil Dyschondrosteosis (LWD), which is typically associated with a mutation or deletion of the SHOX gene located on Xp. With this information in mind, we asked the Cytogenetics Lab to carefully study the X chromosome. The studies in our laboratory revealed a nonrciprocal, unbalanced translocation between one chromosome X short arm and one chromosome 11 long arm. The karyotype is 46,X,der(X)t(X;11)(p22.32;q24.2),del(11)(q24.2).ish der(X)t(X;11)(DXYS129-,SHOX-,DXZ1+,D11S2071+), del(11) (D11Z1+,D11S2071-,DXYS129-,SHOX-), which indicates a genetic imbalance for monosomy of Xp22.32-Xpter with loss of one copy of the SHOX gene. Microarray analysis confirmed a 4.33 Mb terminal deletion of one chromosome X short arm and identified an additional 1.11 Mb deletion at the 11q24.2 breakpoint. SHOX haploinsufficiency is associated with LWD, which is the diagnosis most consistent with her clinical presentation. The translocation of the segment of 11qter to Xp masked the deleted segment of Xp and led to an erroneous initial diagnosis that was quite concerning to the family. This case demonstrates the need for clinical correlation with laboratory results prior to devising treatment and management plans.

1629/W

Perceived Risk, Anxiety and Sharing Behavior in Response to Personalized Risk Information in a Cohort Study. *E.S. Gordon, C.B. Stack, N. Gharani, T.J. Schmidlen, M.F. Christman, M.A. Keller.* Coriell Institute for Medical Research, Camden, NJ.

In the new era of direct-to-consumer testing (DTC), risk perception may influence the patient's decision to share their genomic results with their health care provider (HCP) thus influencing not only lifestyle decisions but direct medical care as well. In the present study, we delivered personalized risk results for coronary artery disease (CAD) based on a validated genetic risk variant (rs1333049 on 9p21.3), family history, smoking status, and diabetes status through a secure web based portal to participants in the Coriell Personalized Medicine Collaborative. Participants reported perceived risk and decision to share results with a HCP in a follow up survey distributed to participants 90 days after they had viewed their result. Thirty-three percent (472 of 1437) of eligible participants completed the follow up survey. The majority of respondents were Caucasian (95%), female (69%), with a bachelors degree or higher (72%), high incomes (50% >$100,000) and an average age of 51 years. Overall, survey respondents closely mirrored non-responders with respect to demographics, though responders were older (mean age 51 vs. 48, p<0.001) and a larger proportion of responders were female (69% vs. 62%, p<0.001). Each of the factors included in the CPMC risk report for CAD were associated with overall perceived risk of CAD: genotype (p<0.001), family history (p<0.001), diabetes status (p=0.007) and smoking status (p=0.026). Participants with zero copies of the genetic risk variant rated their overall risk of CAD higher if they also had a family history of CAD (p-interaction = 0.0076). The decision or intention to share results was associated with perceived risk (p<0.001); 51%, 62%, and 74% of participants who rated their risk of CAD as low, average, and high, respectively, reported that they had shared or planned to share results. Older age (p=0.001) and higher BMI (p=0.009) were also associated with increased rates of sharing. No association was found between the decision to share results with a HCP and having 0, 1, or 2 copies of the genetic risk variant (p=0.73). These findings suggest that participants are making behavioral decisions, specifically related to sharing results with a HCP, based on their perception of their risk. Autonomous decisions regarding sharing have the potential to lead to missed medical intervention for those who underestimate their risk and elect not to share and overuse of the health care system among the worried well.

1630/W

Comprehensive variant analysis using the Variant Analysis Tool. *R.K. Hart[1], S.E. Brenner[2].* 1) Center for Computational Biology, 324G Stanley Hall, University of California, Berkeley, CA 94720; 2) 461 Koshland Hall, University of California, Berkeley, CA 94720.

The analysis of genomic variants in clinical settings frequently involves entering variants into multiple tools and manually integrating results. This process is time-consuming and error-prone. We are developing the Genome Commons Variant Analysis Tool (VAT), an open source, open access portal that facilitates the analysis of variants by clinical geneticists and genetic counselors. With the VAT, clinicians will be able to enter a variant once and obtain up-to-date data from public sources and tools.

Given a single nucleotide or protein variant specified in standard Human Genome Variation Society mutation syntax, the current VAT prototype aggregates disparate publicly accessible data and tools. Data sources presently referenced include UniGene, PubMed, dbSNP, RefSeq, Homologene, GeneTests and GeneReviews. Links to expression data, genome browsers, LSDBs, and pathogenicity assessment tools will be available. Additional facilities will be added to accommodate requests from users and to keep up with the evolution of tools for genome interpretation.

The VAT improves the reliability, accuracy, completeness, and currency of information used to assess the pathogenicity and pathogenic mechanisms of clinical variants by using up-to-date data and eliminating the need to manually enter variation specifications. The VAT is an initial tool being developed by the Genome Commons, a project that aims to provide open source and open access interoperable tools for the interpretation of individuals' genomes.

Expanding access to cardiovascular genetic counseling through integration of services within cardiology specialty clinics. *P.L. Arscott, C.M. Rigelsky, R.T. Moran.* Genomic Medicine Institute, Cleveland Clinic Foundation, Cleveland, OH.

As the genetic basis for a growing number of cardiovascular (CV) conditions is revealed and genetic testing becomes increasingly available, the demand for genetic counseling (GC) for inherited CV conditions will increase. Traditionally, this was accomplished through referral to genetic centers where a patient may be seen by both a genetic counselor and a geneticist. In order to respond to increasing demand for these services, we developed a model for integrating GC services into various CV practices within a large health center. Patients were referred for GC by a managing physician. Testing, referrals, and clinical follow up were based on collaboration between the referring physician and genetic counselor. Clinical oversight was provided by a clinical geneticist. The appointment with a genetic counselor was billed using the 96040 reimbursement code, or self-paid. Evaluation of the clinical services was performed using information collected for clinical operations for CV GC outpatient appointments between September 2009 and May 2010. A total of 160 patients were seen within the 9-month period. Patients were referred for personal or family history of aneurysms or connective tissue disorder (55%), cardiomyopathy (34%), arrhythmia (4%), or other CV condition (6%). Genetic counselors collaborated with 57 referring physicians from multiple departments. Nearly half of the patients (n=76) were referred by seven physicians. Referring physicians were predominantly cardiologists (81%) and referrals from non-cardiologists tended to be for a familial mutation. Fifty-eight percent of patients with HCM and 41% of patients with aneurysms had genetic testing as a result of the appointment. GC Services provided in direct collaboration with managing physicians facilitate access to genetic risk assessment and genetic testing for a wide variety of CV conditions. A small group of specialists consistently referred for GC services, while others referred few patients even though their patient population includes those with high genetic risk. These findings highlight areas for growth such as increasing awareness and education about our services. Systematic approaches to increase referrals for specific CV indications are being explored. The direct collaboration with physicians in multiple specialty areas is expected to increase recognition of available services and to facilitate the use of genetic information in the management of heritable CV conditions.

1632/W

Level of risk and change in risk are determining factors in patient decisions regarding prenatal diagnosis following positive first or second trimester maternal serum screening for Down syndrome. *K. Borsack, A. Vimb, H. Lichtenstein, V. Fudulu, N. Nakata.* Genzyme Genetics, Los Angeles, CA.

OBJECTIVE: Prenatal maternal serum screening (MSS) provides patients with individualized risks for Down syndrome as well as other fetal conditions. This allows patients to make informed decisions regarding prenatal diagnosis (PNDx) via chorionic villus sampling (CVS) or amniocentesis. The purpose of our study was to determine if numeric risk, magnitude of change in numeric risk (from a priori age related risk), and/or other maternal factors correlate with patients' decisions to undergo PNDx. **STUDY DESIGN:** We conducted a retrospective study of singleton pregnancies referred to Genzyme Genetics for genetic counseling services from 2007 through 2008 with an indication of MSS results (including first trimester combined screening, Sequential 1 and 2 screening, and integrated screening) positive for Down syndrome. We compared numeric risk determined by screening, the magnitude of change in risk compared to a priori age related risk, and maternal factors including maternal age and pregnancy history (gravidity, parity, pregnancy loss and termination) for patients who elected to undergo invasive testing and for patients who declined invasive testing. **RESULTS:** The study population included 1,794 patients. Both post-screening risk and magnitude of change in risk were noted to be significant predictors of a patient's uptake of invasive testing. Also significant was a lower average maternal age for patients who had second trimester screening compared with those who had first trimester screening (34.3 years vs. 36.6 years). Other findings included: greater uptake of CVS over amniocentesis in screen positive patients (72% vs. 59%), greater uptake of PNDx in patients with screen positive first trimester results compared with second trimester results (64% vs. 56%), and little correlation with pregnancy history as a determining factor about invasive testing. **CONCLUSION:** In our study population we observed that among patients with either positive first or second trimester MSS results for Down syndrome, numeric risk and magnitude of change in risk are significant factors that influence patients' decisions to pursue PNDx. Both factors have a positive correlation with the decision to pursue PNDx. Women with greater risk and/or higher magnitude of change in risk who have had first trimester MSS screening are more likely to pursue PNDx, most commonly via CVS if testing is available.

1633/W

Where there are no genetic services: a study of patients suffering from Ushers Syndrome in Bangladesh. *E. Haque[1], S. Rozario[2].* 1) Clinical Genetics, Ferguson-Smith Centre for Clinical Genetics, Glasgow, Scotland, United Kingdom; 2) Cardiff University, Cardiff, United Kingdom.

Genetic counselling is available in the western world to support patients with genetic conditions and their families through difficult decision making processes and understanding of their condition. However, not much is known about the quality of life in countries where there are no genetic services. This study was conducted in Bangladesh as an MSc Dissertation and was designed to reach those patients and their families who suffer from genetic diseases but due to a total lack of Genetic services and appropriate genetic counselling may have difficulties in making an informed decision. Semi-structured interviews were undertaken with various members of six families with children suffering from Ushers Syndrome and thematic analysis was used to analyse the data. Family members that took part in the study had no knowledge of hereditary diseases or how they can be passed on. Most participants resorted to trying alternative therapies (e.g. homeopathy) and religious healing to try and make their children well as there was overwhelming evidence of stigma associated with disability. No psychosocial support has been provided for any of the participants or their families. The quality of life lead by these patients and their families were generally poor. It was observed that most families were facing financial troubles due to the cost of the medical care of their children. The findings are in stark contrast to the basic services and facilities taken for granted in countries like the USA and UK. They show that living with a genetic condition in a country where there are no genetic services can be distressing for patients and their families. Better services and better understanding of Genetics needs to be put in place in order to improve their quality of life and making sure they are not victims of stigmatization.

1634/W

“This is not what I was expecting...” - Revealing a personal genetic disorder throughout prenatal counseling for an affected offspring: A counseling challenge. *S. Horowitz[1], S. Shkedi[1], A. Shaag[1], J. Zlotogora[2], V. Meiner[1].* 1) Department of Human Genetics, Hadassah-Hebrew University Medical Center, Jerusalem, Israel; 2) Department of Community Genetics, Ministry of Health, Jerusalem, Israel.

Autosomal dominant disorders frequently present with variable expression and reduced penetrance. Thus, a healthy parent may learn that he carries a faulty gene only after the discovery of abnormal findings in his offspring during or after pregnancy. Oral-facial-digital (OFD) syndrome is a genetically heterogeneous condition with extensive pleiotropy. The common form is inherited as an X-linked dominant disorder with variable expression. Most of the carriers express minor variable symptoms, hence might be unaware of their risk for passing on an abnormal gene. We report a 25 year old individual that was referred for genetic counseling following termination of a multi-malformed pregnancy. Upon intake of personal history, she reported having a “short pinky” and that when being one year old “some kind of an oral operation” was performed. Following clinical examination OFD syndrome was suspected and further molecular studies were issued. OFD1 screening led to the identification of a disease causing mutation. In light of these findings this individual had not only to deal with her grief and mourning for her recent pregnancy loss, but also with feelings of guilt and uncertainty regarding her own personal health perception and future reproductive plans. This is one of many other similar genetic counseling scenarios in which the counselor is confronted by a prenatal issue of concerned parents about an offspring’s health situation which leads to diagnosing an actual clinical genetic disorder in one of the parents. Such incidence presents a critical unique challenge for the genetic counselor in helping the parents to cope with the psychosocial and personal aspects of their current circumstances. In addition, various social perceptions of the role of genetic counseling in health promotion within distinct ethnic groups will be discussed.

1635/W

Mutation Risk Associated with Paternal and Maternal Age in a Cohort of Retinoblastoma Survivors. *M.B. Mills[1], L. Hudgins[2], R.R. Balise[3], R.A. Kleinerman[4].* 1) Master’s Program in Human Genetics and Genetic Counseling, Stanford University School of Medicine, Stanford, CA; 2) Department of Pediatrics, Division of Medical Genetics, Stanford University School of Medicine, Stanford, CA; 3) Health Research and Policy, Stanford University School of Medicine, Stanford, CA; 4) Radiation Epidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Rockville, MD.

Autosomal dominant conditions such as achondroplasia are known to be associated with advanced paternal age, and it has been suggested that retinoblastoma (Rb) also exhibits a paternal age effect. Research on the relationship between advanced paternal and maternal age and risk of Rb has been reported for several countries, including the United States (U.S.), with mixed findings. To our knowledge this is the first study to look at risk of a *de novo* mutation in relation to parental age for 3 categories of Rb: Rb resulting from a *de novo* mutation, sporadic Rb, and familial Rb inherited from an affected parent.

A cohort of 262 retinoblastoma patients was retrospectively identified at one institution, and data were collected from parents of 160 patients (65.3%) via telephone interview. Mean parental ages were calculated for the general U.S. population. Two sets of hierarchical stepwise logistic regression models were built to look for increased odds of a *de novo* mutation related to older parental age compared to sporadic and familial Rb. The modeling strategy looked for effects of continuous increasing maternal and paternal age controlling for ethnicity and age of the other parent. To assess nonlinear age effects, 5-year age increases were analyzed. All differences between means were compared using either one sample t-tests or one-way ANOVAs.

Our results showed that both mean maternal and paternal ages for *de novo* mutations and sporadic Rb were similar as well as statistically significantly higher than the general U.S. population means, whereas parental ages for familial Rb were not significantly different. There were no significant differences between mean maternal and paternal ages for the comparison between each of the 3 Rb classification groups. For each 5-year increase in paternal age, we found increased odds of having a *de novo* mutation, but these findings were not statistically significant.

Our analysis suggests a weak paternal age effect for *de novo* Rb mutations, however we have insufficient data for investigating paternal age over age 40 to test this hypothesis further. The similarity of mean maternal and paternal ages for *de novo* Rb mutations and sporadic Rb was unexpected and deserves further attention.

1636/W

The future of recurrence risk counseling for complex diseases: a paradigm for counseling incorporating recent molecular findings and discussion of the challenges. *C. Nichols, A. Chakravarti.* Inst Gen Med, Johns Hopkins Univ, Baltimore, MD.

In the past, recurrence risk counseling for isolated multifactorial congenital anomalies, such as Hirschsprung disease (HSCR), involved quoting an ~3% recurrence risk for siblings, with little refinement available for individual families. Noted heterogeneity in risk based on factors such as severity, familiality, and gender has allowed more refined empiric risks, yet individualized risk assessment is often still not possible. Molecular genetic and epidemiological studies in recent years have identified chromosomal variants in ~12% of HSCR cases and rare sequence variants in 11 genes, at least 6 of which are implicated in isolated HSCR. Three common variants are implicated thus far, including a well-characterized RET enhancer variant that increases risk by 4-8 fold. While more detailed studies are needed to clarify the effects of variants, much promise for the use of these findings in risk assessment has been proposed. We consider how this new genetic information will be used in the future. Using HSCR as a complex disease model, we present a paradigm for recurrence risk counseling for complex diseases that incorporates recent findings of rare and common variants, with discussion of the advances, limitations, and counseling challenges through examples. In this paradigm, cases are categorized through phenotypic assessment and genetic testing into those due to syndromic occurrence, rare variants, or common variants. This will allow refinement of level of recurrence risk and potential for phenotypic heterogeneity by group. Limitations and counseling challenges to discuss include arduousness of categorization due to variable expressivity within and between families, highlighting the importance of careful family history and phenotypic assessment. Reports of allelic heterogeneity and pleiotropy also leave remaining uncertainty about potential manifestations that may need to be discussed with families. Interpretation of rare variants and combinations of common and rare variants will be challenging, as will decisions about which tests to offer as numerous genes and types of variation are implicated and cost effectiveness must be considered. Whether testing, particularly for common variants, provides useful information and improved counseling to families in comparison to available empiric risks based on phenotypic and family history information will need to be assessed through family perception and outcome studies.

Reflections on genetic counseling for type 2 diabetes mellitus risk in primary care. *W.M. Scott[1], L.A. Killeya-Jones[2], A. Cho[2], S. Joy[2], G. Ginsburg[2].* 1) School of Nursing, Duke University, Durham, NC, 27710; 2) Duke Institute for Genome Sciences & Policy Durham, NC 27708.

Advances in the identification of genomic makers for type 2 diabetes mellitus (t2dm) and the development of commercially available tests suggest that genomic susceptibility testing for this disease may soon be available in primary care settings. Importantly, the potential of personal genomics to increase primary prevention of t2dm relies upon patients' interest in testing. We report a very high level of interest in testing in a general clinic sample enrolled in an RCT assessing the clinical utility of genetic risk testing for t2dm. We discuss the procedure for delivering the genetic results within the scope of a 40-min counseling visit (RCV) with a trained risk counselor (RC) at one of two study sites. We report reflections on participants' responses to genetic risk information as part of their overall standard risk assessment. Participants were randomized 1:1 to receive genetic results at RCV approx. 2 mths post baseline or 12 mths post RCV. Findings reported herein are based on 157 participants' RCVs (approx 50% randomized to receive their genetic results, 1/157 not interested in genetic testing). The aim of the RCV is to inform patients' perceptions of their t2dm risk. The RC is a master's-prepared, nationally-certified family nurse practitioner (NP) with 20 yrs experience as a primary care clinician. The RC uses a semi-structured format to present an overview of diabetic pathophysiology and related risk factors, followed by a discussion of the individual patients' risk factors. To facilitate this discussion, pts receive a color-coded risk profile including FPG, family history, BMI, age, and race. A genetic risk estimate is included for pts randomized to receive genetic risk results (# high-risk alleles and combined genetic risk estimate). The RC reports genuine interest from study pts about the role of genetic testing in healthcare. Participants expressed disappointment when they discovered they would not receive their genetic results at the RCV but looked forward to receiving them at the end of the study. 100% were engaged, with none reacting with negative responses upon learning their individualized genetic risk scores. Most have expressed a willingness to engage in health modifying behaviors, because or in spite of, receiving information on personal t2dm genetic risk. This underscores the value of offering genetic testing/counseling for t2dm in primary care practices in an effort to reduce incidence and improve quality of life.

Changes in physical activity but not diet following disclosure of pleiotropic information during genetic risk assessment for Alzheimer's disease: Findings from the REVEAL Study. *K. Christensen[1], J.S. Roberts[1], W.R. Uhlmann[2], P.J. Whitehouse[3], T. Obisesan[4], D.L. Bhatt[5], L.A. Cupples[6], R.C. Green[7] on behalf of the REVEAL Study Group.* 1) Department of Health Behavior & Health Education, University of Michigan School of Public Health, Ann Arbor, MI; 2) Department of Internal Medicine & Human Genetics, University of Michigan, Ann Arbor, MI; 3) Memory & Aging Center, Case Western Reserve University/University Hospitals of Cleveland Memory & Aging, Cleveland, OH; 4) Department of Medicine, Howard University, Washington, DC; 5) VA Boston Healthcare System, Brigham & Women's Hospital, and Harvard Medical School, Boston, MA; 6) Departments of Biostatistics & Epidemiology, Boston University School of Public Health, Boston, MA; 7) Departments of Epidemiology, Neurology & Medicine (Genetics Program), Boston University Schools of Public Health & Medicine, Boston, MA.

Background: Little is known about the impact of disclosing pleiotropic information during genetic susceptibility testing for a specific disease. The ε4 allele of APOE is a risk factor for both Alzheimer's disease (AD) and coronary artery disease (CAD). As part of a series of multi-site randomized controlled clinical trials, the Risk Evaluation and Education for Alzheimer's Disease (REVEAL) Study explored how learning about this pleiotropic association during a genetic risk assessment for AD affects diet and physical activity.

Methods: Subjects randomized into a control arm received their APOE genotypes and an AD risk estimate (range: 6%-70%) based on the gender, ethnicity, family history, and APOE genotype. Subjects randomized to a 'pleiotropy' arm were also informed that APOE ε4 carriers were at increased risk for CAD. Overall physical activity and diet were assessed before and after testing using 7-item versions of the physical activity subscale of the Rapid Assessment of Physical Activity and the Dietary Risk Assessment. Logistic regression was used to determine whether subjects in the pleiotropy arm were more likely than subjects in the control arm to report improvements in physical activity and diet at the one-year follow-up compared with baseline after controlling for APOE genotype, gender, race, and family history of AD.

Results: A total of 257 subjects were enrolled at four study sites (median age 58; 55% female; 16% African American; 71% with affected first degree relatives). Of the pleiotropy arm, 35% showed improvements in physical activity compared with 24% of the control arm. Of the pleiotropy arm, 53% showed improvements in diet compared with 42% of the control arm. Logistic regression confirmed that differences were significant for physical activity (OR=1.99, p=.02), but not for diet (OR=1.50, p=.13).

Conclusions: Findings suggest that pleiotropic information shared during a genetic risk assessment for AD can motivate improvements in physical activity. Such information may not be sufficient to motivate changes in diet, although analyses did not target diets specific to CAD or AD prevention. Overall, the data suggest that pleiotropic associations shared during a genetic risk assessment for a specific condition may have power to motivate additional health behavior changes.

Use and misuse of genetic molecular testing: one institution's experience. *H. Toriello.* Gen Services, Spectrum Hlth, Grand Rapids, MI.

In 2009, the CDC published a document entitled "Good Laboratory Practices for Molecular Genetic Testing for Heritable Diseases and Conditions". In that article, it was noted that "no studies have determined the number of molecular genetic tests performed that could be considered unwarranted or unnecessary". As part of my role as consultant to the laboratory at our institution, I undertook a project whereby I kept a database of all molecular genetic tests that were sent out by our referral laboratory. I was able to access information on 135 molecular genetic tests which were sent to a reference laboratory other than Mayo Medical Laboratories (I had no access to that data). The results of my study are cause for alarm, at least for our own institution. Among this group of 135 tests, a genetic counselor was involved with the patient in only 28 cases (21%). Many of the tests in which a counselor was NOT involved included presymptomatic testing for hereditary cancer. I also sought to determine the utility of testing. Overall, 67 of this group were considered unwarranted or unnecessary, with an additional 11 considered questionably appropriate. That means that only 42% was justifiable. There were many reasons for a particular test being considered unwarranted or unnecessary, and included but were not limited to, ordering a test highly unlikely to be positive and ordering a molecular test when a diagnosis had been established biochemically. In addition, there were 29 cases which could be considered compliance issues. For example, research samples were sent without going through our IRB (with no evidence that anyone explained the consent form). Additionally, a few "shaky" situations were discovered, such as the physician stating that the results of testing were required before surgery was done, but then that surgery was done anyway before results were back; and repeat testing when a molecular mutation had previously been found. Unfortunately, this dismal state of affairs also extended to post-testing situations. There were three cases in which incorrect interpretations were provided to patients by the physician ordering the test. In conclusion, my findings provide evidence that genetics professionals clearly need to take a more central role in the provision of molecular genetic testing to patients. As a result of my study, a protocol for review will be instituted before any testing is allowed to be sent via our referral laboratory.

Carrier Screening of Recessive Genetic Disorders by Next Generation Sequencing. *C.J. Bell, D.L. Dinwiddie, N.A. Miller, S.L. Hateley, B.J. Rice, S.F. Kingsmore.* National Center for Genome Resources, Santa Fe, New Mexico.

Orphan Mendelian recessive diseases are individually rare, but collectively constitute a major healthcare burden, causing significant childhood morbidity and mortality. 20-30% of all infant deaths and 11% of pediatric hospital admissions are related to genetic disorders. In collaboration with the Beyond Batten Disease Foundation, the National Center for Genome Resources is developing a carrier screening test for a panel of more than 400 recessive genetic conditions that cause death or catastrophic illness in childhood. The intent of this screen is prevention; it is to be targeted at couples considering pregnancy—with appropriate counseling prospective parents having mutations in the same gene will be able to make informed family planning choices. The test uses enrichment of the exons, splice junctions and selected intronic segments of the genes, followed by multiplexed next-generation sequencing. Automated bioinformatic analysis is used to identify carrier status and zygosity for known and novel mutations. To identify the appropriate target enrichment technology for the carrier screening test, a total of 24 samples from carriers of 17 autosomal recessive diseases and 1 X-linked recessive disease were enriched for 437 genes using Agilent SureSelect, RainDance, febit, and Olink enrichment techniques and subjected to multiplexed deep sequencing using the Illumina GA IIx. The 24 samples contained 42 previously characterized mutations including 18 SNPs, 12 short in/dels, and 7 gross deletions impacting both coding and splicing elements. The four enrichment techniques were evaluated for % sequencing reads on target, fold enrichment and mutation detection, with a desired sequencing threshold of at least 20x coverage of at least 99% of targeted nucleotides based upon 500 Mb of aligned sequences, less than 1% of targeted nucleotides with zero coverage, and very high sensitivity and specificity for heterozygous variant detection. Based on these experiments we selected RainDance as the enrichment platform. The final choice of sequencing platform is yet to be made. Initial estimates indicate that members of the sample population carry mutations in 4-5 of our genes of interest. The next phase of the program is to determine sensitivity and specificity of the test for the major classes of mutations in a larger cohort of individuals. The panel currently contains 422 genes causing 430 such diseases. The results to date will be presented.

1641/W

Mutation Analysis of SLC26A4 for Pendred Syndrome and Non-Syndromic Hearing Loss by High Resolution Melting. *N. Chen, I. Schrijver.* Dept Pathology, Stanford Univ, Palo Alto, CA.

Pendred syndrome and DFNB4 are associated with autosomal recessive congenital hearing loss. Up to 50% of patients with Pendred syndrome/DFNB4 carry SLC26A4 mutations. Extensive allelic heterogeneity necessitates analysis of all exons and splice sites to identify mutations for individual patients and sequencing is the gold standard for clinical mutation detection. Denaturing high performance liquid chromatography (dHPLC) is more cost-effective and less time-consuming, but it cannot distinguish homozygous mutations from wild-type sequences. Such mutations require the mixing of wild-type DNA with a patient sample to form heteroduplexes. High resolution melting (HRM), a straight-forward and fast scanning method, is capable of detecting both heterozygous and homozygous mutations cost-effectively. We developed a closed-tube clinical HRM mutation detection method specific for the SLC26A4 gene. Twenty-eight amplicons were designed to cover all 21 SLC26A4 exons and splice junction sequences. Using these amplicons, HRM analysis detected every one of the 47 variants initially identified by diagnostic sequencing. Subsequently, a 384-well diagnostic plate format was designed for routine clinical testing. On each plate, 6 adjacent wells were reserved for each of the 28 amplicons. On one diagnostic plate, up to three patient samples could be tested per run. To evaluate within-run and run-to-run variations, a diagnostic plate with DNA from one patient was run 4 times to measure melting temperature (Tm) of each well. Therefore, 6 wells of each amplicon in each run were analyzed for within-run variations. Run-to-run variations of each amplicon were compared in the 4 replicated runs. Tm analysis of the results indicated that the standard deviation (SD) of within-run variation was less than 0.09°C in 26 of the 28 amplicons. For the other two amplicons, one had one run with an SD of 0.1°C and one had two runs with an SD of 0.11°C. The SD between runs was less than 0.04°C for all 28 amplicons. Subsequent blinded HRM testing of more patient samples detected all variants identified by diagnostic sequencing. Among the variants detected, there were new variants that were not included in the initial set of 47. In conclusion, HRM is a reliable, simple and cost-effective method for SLC26A4 gene mutation detection.

1642/W

A rapid closed-tube method for screening point mutations in Duchenne muscular dystrophy (DMD). *P.S. Lai[1], O.S. Yim[1], S.K.H. Tay[1], P.S. Low[1], E.P.H. Yap[2].* 1) Dept Pediatrics, National Univ Singapore, Singapore, Singapore; 2) DSO National Laboratories, Defence Medical and Environmental Research Institute, Singapore.

Duchenne Muscular Dystrophy (DMD) is an X-linked recessive disorder. Effective mutation screening for families affected with DMD will allow for genetic counseling, carrier screening and molecular diagnosis. Determination of the precise type of mutations present in patients can also contribute towards the identification of cohorts amenable for different types of genetic treatment approaches such as antisense splicing or nonsense codon suppression. However, screening of the DMD gene responsible for this disorder presents special challenges due to its large size and complexity. The most common and easily detectable mutations in DMD are gross deletions or duplications. However, point mutations account for the remaining 40% of patients. Conventional screening for point mutations utilizes PCR-based DNA sequencing and more than 100 amplification reactions are needed to analyze the entire gene coding regions. This study reports a method for rapid screening of point mutations in the DMD gene using High Resolution Melt (HRM) analysis. Amplification and screening are carried out in the same tube without any additional post-PCR steps of reagent addition or manipulation of products. HRM analysis was found to be sensitive and accurate in identifying mutations in DMD amplicons ranging from 130-200 bp. Carrier screening could be carried out in families with mutations. A patient and three female carriers were identified in a family carrying an exon 60 nonsense mutation (UGA stop codon). The HRM results were confirmed to be accurate by re-sequencing. Subsequent genetic correction assays for the nonsense codon were carried out using aminoglycoside-induced translational readthrough approach. A construct carrying this exon 60 nonsense mutation in a reporter gene vector was assayed for luciferase activity after treatment with different concentrations of gentamycin, paromomycin and tobramycin at 24, 48 and 72 hours. Highest readthroughs of about 18% was observed using 2.0 mg/ml gentamycin at 48 hours treatment indicating gene correction during translation. Our results show that HRM screening can identify point mutations, in particular nonsense mutations which are amenable for genetic correction by a drug-induced translation readthough approach. It can thus be used for rapid molecular diagnosis, carrier screening and identification of cohorts suitable for future therapeutic trials.

Rapid identification of common β-thalassemia mutations in the Chinese population using duplex or triplex amplicon genotyping by high-resolution melting analysis. *Z. Ren, X. He, M. Xu, C. Xiong.* Shanghai Inst Med Gen, Shanghai Children's Hosp, Shanghai Jiaotong Univ School of Medicine, 24/1400 West Beijing Rd, Shanghai 200040, China.

β-Thalassemia is one of the most prevalent inherited diseases in China. To date, over 20 β-thalassemia mutations have been identified in the Chinese population, and four mutations (CD41-42 (-4 bp), IVS-2-654 C®T, CD17 A®T, and -28 A®G) account for approximately 90% of the cases. Therefore, the exploration of simple, reliable, and rapid approaches for molecular detection of these common mutations is important for prevention and early diagnosis of the disease. High-resolution melting (HRM) analysis is a new technique for mutation detection that has the advantages of rapidity, accuracy, and convenience. Building on one-amplicon genotyping by HRM analysis, we developed duplex and triplex amplicon genotyping to simultaneously identify these common β-thalassemia mutations in patients or carriers. Two or three sets of primers were combined to conduct duplex or triplex amplicon genotyping that distinguished a variety of genotypes by HRM based on the melting curve shapes. 71 DNA samples from β-thalassemia traits or patients were analyzed using the described approaches and 65 were identified to carry the four common β-thalassemia alleles including 56 heterozygous mutations (23 for CD41-42 (-4 bp), 18 for IVS-2-654 C®T, 11 for CD17A®T, and 4 for -28 A®G), 3 homozygous mutations for IVS-2-654C®T, and 6 compound heterozygous mutations [CD41-42 (-4 bp)/ IVS-2-654C®T (four cases), -28 A®G /CD17A®T (one case), IVS-2-654C®T /CD17A®T (one case)]. The whole procedure for mutation detection was completed within only half an hour. The results derived from HRM analysis were fully in accordance with sequencing. We suggest this rapid and accurate method for molecular screening to detect the common β-thalassemia mutations in the Chinese population.

Preferential amplification due to DNA secondary structure - a potential cause of diagnostic error. *Y. Wang, S.J. Steinberg, B.A. Karczeski, G.R. Cutting.* DNA Diagnostic Lab, Johns Hopkins Univ, Baltimore, MD.

Molecular diagnosis based on the polymerase chain reaction (PCR) is widely used in clinical laboratories. While PCR has revolutionized diagnostics, it has some shortcomings such as preferential amplification that can lead to errors. We investigated mechanisms underlying preferential amplification of exon 3 (e3) in the α-ENAC gene (*SCNN1A*) in a Pseudohypoaldosteronism type 1A patient and her parents. Initial test results for the proband revealed apparent homozygosity for adjacent nucleotide changes (c.540_541delGCinsTT). Parental testing revealed paternal heterozygosity for the sequence variation and apparent maternal homozygosity for wildtype. Heterozygous SNPs flanking e3 in the mother excluded a maternal deletion. Re-testing revealed heterozygosity in the proband for 4 of 9 assays. Use of multiple primer pairs excluded polymorphism within the primer sequence as the cause of the inconsistency. Since this region of the *SCNN1A* gene is GC-rich, we considered whether a structural feature affected the ability of *Taq* polymerase to copy e3 bearing the wild-type sequence. G-Quadruplex and i-Motif structures predicted by QGRS Mapper and Quadfinder were excluded. However, the MFold algorithm revealed that the two mutated nucleotides reside within a predicted stem-loop structure, and sequence bearing c.540_541GC was predicted to form a more stable stem-loop structure (ΔG= -10.53) than the sequence bearing c.540_541TT (ΔG= -8.2). To test the secondary structure predictions, we altered the annealing temperature of the PCR reaction, theorizing that the higher temperature would destabilize the stem-loop structure, thereby facilitating amplification of the wild-type sequence. Indeed, increasing the annealing temperature from 62° C to 68° C resulted in consistent amplification of both alleles from the heterozygous patient and her father (n=6). Furthermore, decreasing the annealing temperature by 2° C to 60° C resulted in only mutant sequence being amplified (n=6). These observations highlight a previously unrecognized source of mis-genotyping of a rare allele due to differential amplification of mutated and wild-type sequence. For this reason, segregation analysis should be employed for any rare sequence variant that appears homozygous to exclude diagnostic error due to preferential PCR amplification.

Receiving genetic results: exploration of this experience in familial epilepsy. *D.F. Vears[1], K. Dunn[2], S.A. Wake[2,3], I.E. Scheffer[1,4].* 1) Epilepsy Research Centre, University of Melbourne, Austin Health, Melbourne, Australia; 2) Department of Paediatics, University of Melbourne, Melbourne, Australia; 3) Genetic Health Services Victoria, Royal Children's Hospital, Melbourne, Australia; 4) Department of Paediatrics, University of Melbourne, Royal Children's Hospital, Melbourne, Australia.

Statement of purpose: Rapid advances in genetic technology have lead to gene identification for many inherited disorders. There is little information, however, on the impact of gene identification for individuals and families with genetic conditions. This study explored the experience of receiving a genetic result in people with familial epilepsy in whom a genetic cause was identified. **Methods:** Using a targeted sampling strategy, individuals who had participated in a previous study identifying familial epilepsy genes and who had received a positive genetic test, were invited to participate. A wide selection of family members were invited to participate. In-depth, semi-structured interviews were conducted. Interviews were audio-taped and transcribed. The data underwent content and thematic analysis. **Results summary:** 20 individuals from 3 families with different epilepsy syndromes and different epilepsy genes were interviewed across 14 interviews. Multiple generations within families were represented. The mean time of receiving the genetic result prior to the study was 10.9 years (range 5-14 years). Three major themes were identified: (i) living with epilepsy; (ii) clinical utility of the test; and (iii) 'talking about the family genes'. How epilepsy affected the individual influences the impact of receiving genetic results and the use of genetic information for reproductive decision-making. While altruism can influence decisions to participate in studies of gene identification, people also want to know what this means for them and how this may help them and their families. It cannot be assumed that family members communicate about their epilepsy. Information that may benefit others in the family may not be shared and understanding of genetic inheritance may be limited. **Conclusions:** While this study focused on familial epilepsy, the findings are relevant to other genetic disorders. The results can inform the development of guidelines for genetic result disclosure, in the context of the research study setting, and more broadly. They also reveal important insights into the family experience of genetic conditions and communication within families, and can be used to improve genetic counselling for individuals and families.

Our Experience of Paternity Tests. *M. Korabecna[1], A. Horinek[2].* 1) Faculty of Medicine in Pilsen, Charles University, Czech Republic; 2) 1st Faculty of Medicine, Charles University, Prague, Czech Republic.

AIM: We selected randomly 100 cases from our database to demonstrate the extent of tasks they are solved by Czech laboratories involved in paternity testing. We evaluate the efficiency of our approach based on DNA profiling with PowerPlex 16 not only in classical trios but also in motherless files and deficient files in which the putative father of a person is not available and the paternity testing is dependent on the DNA analysis of his relatives. METHODS: DNA samples were isolated from buccal swabs using QIAamp DNA Blood Mini Kit (Qiagen). For STR analysis, PowerPlex16 (Promega) and AmpFlSTR Yfiler PCR (AppliedBiosystems) were used. The results of STR analysis on autosomal loci were evaluated using the program Familias (Egeland et al., For Sci Int 2000). RESULTS: We found 34 % of trios (accused man, mother and child) in which paternity was excluded, 59% trios in which paternity was practically proven, 2% of motherless files (only putative father and child were tested) and 5% of deficient files in which we tested different relatives of putative fathers - most often their parents but also their siblings and children. In cases of excluded paternity, the inconsistencies were found in 94.11% in more than seven polymorphisms using PowerPlex 16. In such cases, inconsistencies in 8 polymorphisms were detected in 26.5%, in 9 polymorphisms in 14.7%, in 10 polymorphisms in 20.6%, in 11 polymorphisms in 11.5 %, and in 12 polymorphisms in 11.8%. The exclusion was based most often on inconsistencies on loci D21S11, D18S51 and Penta E (76.5% each), vWA (70.6%), and FGA (67.6%). Inconsistencies on some loci were founded more rarely - in TPOX (38.2%),in CSF1P0 (41.2%)and D16S539 (44.1%). In cases in which paternity has been practically proven, probability of paternity reached the values W=99.999999% in 30.5%, W= 99.99999% in 27.1%. The values of paternity index (PI) over 10^{10} were obtained in 8.5%.For motherless files, we reported W= 99.999% using PowerPlex 16 only. In deficient cases, the values of posterior probability calculated using Familias and population data for Czech population (STR loci involved in PowerPlex 16) were in interval from 99.9 to 99.999%. CONCLUSION: Our combination of STR analysis together with application of the program Familias seems to be sufficient for the successful solution of all common cases. The posterior probabilities calculated for deficient cases provided evidence for or against paternity in each tested family.

Can informed decision making be measured in population carrier screening for fragile X syndrome? *S. Metcalfe[1, 2], A. Ames[1,2], A. Archibald[1,2], J. Cohen[3], J. Emery[4], M. Hill[1,5], M. Martyn[1], O. Ukoumunne[1,2].* 1) Murdoch Childrens Research Institute, Royal Children's Hospital, Melbourne, Australia; 2) Dept Paediatrics, The University of Melbourne, Melbourne, Australia; 3) Fragile X Alliance Inc, and Centre for Developmental Disability Health Victoria, Department of General Practice, Monash University, Melbourne, Australia; 4) School of Primary, Aboriginal and Rural Health Care, University of Western Australia, Perth, Australia; 5) Clinical and Molecular Genetics, Institute of Child Health and Great Ormond St Hospital for Children, NHS Trust, London, United Kingdom.

Informed decision making (IDM) is important so that individuals can make autonomous decisions without coercion or deception. Tools have been developed to measure IDM in prenatal Down syndrome screening, eg the multidimensional measure of informed choice (MMIC), plus a deliberation (D) scale to measure weighing up of the pros and cons (ie IDM = MMIC+D). However these tools have not been applied to carrier screening. We are currently offering carrier screening for fragile X syndrome (FXS) to non-pregnant women from the general population and applying existing measures to examine IDM in this context. 156 women completed a questionnaire at the time of deciding about testing and, if tested, provided a saliva sample. The questionnaire contained measures of FXS knowledge, attitudes and deliberation, as well as other questions derived from the Health Belief Model. The MMIC and IDM models were applied to these data, including that of test uptake (the behaviour). Results of the measures used in the questionnaire were: test uptake (85%); good knowledge (79%); positive attitudes (80%); deliberated (87%). 71% of women made an 'informed choice' (defined as being tested, having good knowledge and positive attitudes or not tested, good knowledge and negative attitudes). 65% of women made an 'informed decision' (defined as being tested, having good knowledge, positive attitudes and deliberated or not tested, good knowledge, negative attitudes and deliberated). A sub-group of 28 women were also interviewed. Interview responses were coded by three independent researchers using content analysis. Responses in the semi-structured interviews were compared with corresponding responses in the questionnaires to triangulate the findings. Interview and questionnaire findings were discrepant in 12/28 cases, ie 12 women were misclassified according to the models. Interviews highlighted factors other than poor knowledge, which contributed to the apparent lack of IDM, primarily with a mismatch between attitudes and behaviour. These factors, such as not planning a family at the time or apparent lack of deliberation because of prior experiences, are not captured by applying these models. To assess IDM in contexts other than prenatal screening, alternate approaches to these models may be needed to account for these other factors.

1648/W

Design of a triplet repeat-primed PCR protocol for identification of fragile X syndrome. *R.C. Niessen, S. Bronowski, P.M. Grootscholten, R.J. Sinke.* Department of Genetics, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands.

The fragile X syndrome is a frequent cause of X-linked mental retardation and is caused by expansion of a CGG repeat in the 5'untranslated region of the fragile X mental retardation gene (*FMR1*). Repeats larger than 200 repeat units induce hypermethylation of the CpG island in the promoter region of *FMR1* which subsequently results in transcriptional silencing of the gene. To confirm or exclude the clinical diagnosis of fragile X syndrome one needs to determine the length of the CGG repeat in the *FMR1* 5'untranslated region. This usually involves PCR and analysis on automated sequencers. In cases where the outcome of the PCR or family history is suggestive for an expansion, Southern blotting is performed to detect larger expansions (>70 repeats). This technique is very labour-intensive, costly and often requires radioactive labeled probes. Currently, no technique is available which can replace Southern blotting completely. Warner et al. developed an alternative technique for Southern analysis, the triplet repeat-primed PCR (TP-PCR) to screen for presence of expanded CAG repeats in myotonic dystrophy patients (J Med genet 1996;33;1022-1026). We adapted this TP-PCR protocol for the detection of expanded CGG repeats in patients suspected for fragile X syndrome. In our protocol, a fluorescently labeled, locus-specific primer flanking the CGG repeat (P1) is used together with a non-specific primer (P4) which primes at any position within the CGG repeat in the first cycles of the PCR. This non-specific primer has a tail-sequence which is a target for a third primer (P3), which is used in the following cycles of the PCR when the non-specific primer is depleted. In this way, PCR fragments of different lengths are generated and produce a characteristic ladder on an automated sequencer. TP-PCR on DNA from carriers of an expanded CGG repeat results in significantly larger 'ladders' - in other words in broader peak patterns - than DNA from non-carriers. By use of this method presence of an expanded *FMR1* allele can be excluded in women who appear to be homozygous for a normal CGG repeat after regular *FMR1* PCR. Here we show that implementation of triplet repeat-primed PCR techniques is a robust, sensitive and cost-effective means of screening for *FMR1* expansions.

1649/W

Toward elimination of Southern blot analysis for fragile X syndrome: A rapid and sensitive PCR-based assay for accurate sizing of FMR1 alleles, and the detection of full mutation CGG expansions. *C. Stolle, T. Tischler, A. Santani.* Molecular Genetics Laboratory, Dept of Pathology & Lab Med, Children's Hosp Philadelphia, Philadelphia, PA.

In a pediatric setting, molecular diagnosis of fragile X syndrome is used to determine if a child has mental retardation or developmental delay due to an expanded, hypermethylated FMR1 allele. For this purpose, Southern blot analysis (SB) has been the only method capable of detecting both expanded alleles and methylation status. However, SB is labor intensive, time consuming, and unreliable for allele sizing. The exact size of alleles in the normal to premutation range is important for risk assessment and diagnosis of fragile X associated tremor and ataxia syndrome and premature ovarian failure. PCR methods may be used to size alleles, but some methods cannot detect expanded alleles and require SB for males with no amplified allele, females with a single allele, potential mosaics, and to determine the methylation status of large premutations. We describe validation testing of a commercially available PCR assay capable of detecting large alleles and accurately sizing alleles in the normal to premutation range. Validation samples consisting of normal, gray zone, premutation, and full mutation alleles from males, mosaics males, and females previously analyzed by SB, as well as DNA samples of known repeat size, were analyzed using the AmplideX™ Gene Specific PCR and/or CGG Repeat Primed PCR reagents (Asuragen) and resolved by capillary electrophoresis (ABI 3730). Allele sizing was performed using Gene Mapper. The observed allele size of DNAs with a known number of CGG repeats exactly matched expected values for alleles in the 20-80 repeat range. Heterozygous females with alleles differing by a single repeat were clearly resolved and accurately sized. One premutation allele exhibited a one repeat difference in size (91 vs 92), suggesting that this assay is capable of sizing alleles with an accuracy of +/- 1 repeat. Detection of full expansions was in 100% agreement with SB results in both male and female samples. As expected, the PCR method was superior to SB in sizing normal, gray zone, and premutation alleles. Differences in allele sizing resulted in reclassification of the allele designation in 6 out of 62 samples. Mosaic males, females with a full expansions, and homozygous females were also correctly identified. This assay enables detection of alleles in all size ranges and accurate allele sizing in the normal to premutation range. Reflex testing by SB may only be required to determine the methylation status of alleles in the high premutation range.

1650/W

Narrowing the approach to identifying genes and characterizing novel genotypes associated with neuromuscular diseases. *A. Ankala[1], J. Kohn[1], S. Bhide[1], C. Bonneman[2], S. Sparks[3], S. Khadilkar[4], M. Hegde[1].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Division of Neurology, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, Levine Children's Hospital at Carolinas Medical Center, Charlotte, NC; 4) Department of Neurology, Bombay Hospital and Medical Research Centre, Mumbai, India.

Inherited neuromuscular disorders (NMDs) form a large and heterogeneous group of genetic diseases that cause progressive degeneration of the muscles and/or motor nerves that control movements. Most NMDs result in chronic long-term disability placing a significant burden on patients, their families, and the health care system. Affected patients develop multiple and cumulative symptoms during disease progression which may result in premature death from cardiac and respiratory muscle impairment. NMDs are present in all populations, affecting children as well as adults and is estimated that about 1 in 1000 people may have a disabling inherited neuromuscular disorder. The precise diagnosis and treatment of NMDs require a combination of extensive clinical examination and targeted complementary tests: biological analyses, electromyography, imaging, and histological analysis of biopsies. Currently, molecular genetics analyses are performed on known implicated genes both to confirm the clinical diagnosis and to determine the precise genotype for each patient. However, owing to the several factors including frequent overlap of clinical phenotypes, the large number of affected genes, and lack of common mutations, picking the right gene for molecular diagnosis is challenging. This eventually ends in having to perform highly complex, expensive, and time-consuming analyses on several genes. Also, since many of the genes potentially responsible for these diseases are not yet known, many patients remain undiagnosed; to date, these amount to 30-40%. Therefore, in contrast to the current approach, a differential molecular genotyping is required. The new era of medical genetics focused on investigating rare disorders demands the identification of the causative genes and their mutations. We have developed a sequential, cost effective and comprehensive approach to identify new genes associated with NMDs which includes; grouping them according to phenotype, performing multiplex western blot analysis to compare protein expression, followed by gene expression analysis and high throughput next generation sequencing to identify the causative gene. We present here the effectiveness of our strategy with data from two groups; 1. Isolated cases of CMD- like phenotype; 2. A large kindred with multiple affected descendants from a common ancestor. Our ultimate goal is to create a comprehensive map of the muscle genome and proteome, which may enable development of new therapeutics.

Investigation of massively parallel targeted exome sequencing for clinical diagnostic testing and gene discovery in primary ciliary dyskinesia. *J. Berg[1,2], K. Weck[1,3], M. Leigh[4], M. Knowles[2], J. Evans[1,2], M. Zariwala[3].* 1) Department of Genetics, UNC Chapel Hill, Chapel Hill, NC; 2) Department of Medicine, UNC Chapel Hill, Chapel Hill, NC; 3) Department of Pathology and Lab Medicine, UNC Chapel Hill, Chapel Hill, NC; 4) Department of Pediatrics, UNC Chapel Hill, Chapel Hill, NC.

BACKGROUND: Primary ciliary dyskinesia (PCD) is an autosomal recessive disorder associated with impaired mucociliary clearance. Ultrastructural studies suggest a common role of molecular defects in components of the cilia, and mutations in nine different genes have been identified in PCD patients. Advances in genetic sequencing technology are revolutionizing genetic research and have the potential to enhance genetic testing for panels of genes associated with genetically heterogenous clinical syndromes. The objective of this study was to investigate the performance characteristics of exon-capture technology coupled with massively parallel sequencing in the diagnostic evaluation of a highly heterogeneous condition such as PCD. METHODS: We performed a pilot study of four individuals with known PCD mutations (three compound heterozygous and one with only a single known mutation) to determine whether we could identify different classes of mutations including missense, splice site, nonsense, small insertions/deletions, and whole exon deletions. We designed a custom exon capture array (Nimblegen) consisting of 2089 exons from 83 genes, including all genes known to be associated with PCD and a large number of candidate ciliary genes. Sequencing of the enriched material was performed using GS FLX Titanium Sequencing (Roche 454). Bioinformatics analysis was performed in a blinded fashion in an attempt to detect the known mutations and validate the process. RESULTS: Four of seven known mutations were readily identified using this methodology. A fifth known mutation was identified after adjusting the bioinformatics handling of known SNPs. A potentially deleterious mutation in a second gene was identified in a patient for whom only one mutation had been previously identified, raising the possibility of digenic inheritance. Numerous other variants were also detected, which may indicate potential genetic modifiers of the PCD phenotype. However, this process failed to detect two known mutations: a single nucleotide insertion and a whole exon deletion. Additional retrospective bioinformatics analysis revealed strong sequence-based evidence for the single nucleotide insertion but failed to detect the whole exon deletion. CONCLUSIONS: Massively parallel sequencing has great potential for both research and clinical diagnostics, but further accuracy and validation are required before widespread adoption in a clinical setting.

Molecular Genetics of Carbamoyl Phosphate Synthetase I Deficiency. *L. Chen[1], J. Wang[1], O. Shchelochkov[2], J. Häberle[3], F. Li[1], H. Zhan[1], E. Brundage[1,4], A. Pursley[1], E. Schmitt[1], L. Wong[1].* 1) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Pediatrics, Division of Genetics, University of Iowa Hospitals and Clinics, , Iowa City, IA; 3) University Children's Hospital Zurich, Division of Metabolism, 8032 Zürich, Switzerland; 4) GeneDx, Gaithersburg, MD.

The urea cycle disorders (UCD) are inherited defects in the disposal of nitrogenous waste produced from the breakdown of protein and other nitrogen-containing compounds. Carbamoyl phosphate synthetase I (CPSI) is the first enzyme and one of the rate limiting steps in the urea cycle. CPSI deficiency is an autosomal recessive disorder and usually results in severe hyperammonemia presenting in the first days of life warranting prompt diagnosis. It is often difficult to distinguish CPSI deficiency from other proximal urea cycle disorders, such as OTC and NAGS deficiencies based upon the clinical presentation and biochemical tests alone. Therefore mutation analysis of the CPS1 gene is important for diagnostic confirmation, prenatal diagnosis, and counseling. A total of 81 samples from patients suspected of having CPSI deficiency were analyzed. All 38 coding exons of the CPS1 gene and their flanking intron regions were PCR-amplified and sequenced. Only four of the 35 identified mutations were previously reported. The novel changes were either protein truncation mutations or predicted to be deleterious missense mutations by the Polyphen and SIFT computer algorithms. Among the identified mutations, 60% (21/35) were missense, 20% (7/35) were small insertion/deletion mutations, and 20% (7/35) were protein truncation mutations (nonsense and splice site changes). Four cases of CPS1 gross deletions were detected by targeted oligonucleotide microarray MitoMet®. The deletion sizes varied from 1.4 kb to 130 kb. We estimate that the incidence of gross deletions in the CPS1 gene to be approximately 2-3%. All four patients in this study presented with hyperammonemia in early infancy, suggesting that CPS1 deletion confers a risk of early-onset CPSI deficiency. We recommend using aCGH to detect gross intragenic deletion when only one mutation can be found in patients with clinical and biochemical features of CPSI deficiency or there are other indications for the presence of intragenic CPS1 deletion. Five patients negative for CPS1 mutations were subsequently found to have mutations in the OTC gene, including two female patients with large deletions involving the OTC gene were detected by MitoMet® oligonucleotide array and three male patients who had point mutations in OTC gene detected by sequencing. Our results underscore the importance of comprehensive molecular testing in order to diagnose and appropriately counsel families with urea cycle disorders.

EuroGentest Clinical Utility Gene Cards - expert documents for the evaluation of genetic tests. *A. Dierking, P. Javaher, E. Nyoungui, J. Schmidtke.* Insitute of Human Genetics, Hannover Medical School, Hannover, Germany.

Clinical utility refers to the ability of genetic test results, either positive or negative, to provide information that is of value in the clinical setting. From many different perspectives this is the most important but on the other hand also the most difficult aspect to define in the context of genetic testing. A major challenge is to balance clinical validity, clinical utility and cost-benefit issues. In some cases a test is performing superbly in the laboratory, but is not viable from the clinical or economical point of view. On the other hand some tests are limited in their validity, but nevertheless have great impact on patient and family management. It is therefore important that (1) the specific requirements for a test with regard to clinical validity are defined in the context of their impact on the clinical setting and (2) that the laboratory genetic test is only one of the components of an overall evaluation and/or intervention. EuroGentest, an EU-funded "Network of Excellence" designed a work package establishing and administering guidelines assessing the clinical utility of genetic testing: Clinical Utility Gene Cards (CUGCs). Sharing the main components analytical validity, clinical validity, clinical utility as well as ethical, legal and social issues with the CDC (Centers for Disease Control and Prevention) ACCE model project, the CUGC initiative intends to additionally cover highly context-dependent aspects such as health care system, locally available resources and set priorities. Also unique is the approach regarding guideline publication. International experts are invited, according to their field of expertise and interest, to convene multinational author teams in order to develop a CUGC. After completion all guidelines are freely available on the EuroGentest and ESHG (European Society of Human Genetics) websites and in the European Journal of Human Genetics, where they are published online and in print. As of May 2010, 17 CUGCs have been finalised. Since the beginning of the year 2010, invitations for 250 CUGCs were sent out. Within the next EuroGentest funding period (2011-2013) another 300 documents are planned to be solicited and published and previously existing ones will be revised on an annual basis. With regards to content, the focus of this work lies on Mendelian, mostly rare, disorders. Further inclusion of diseases with varying causes, e.g. chromosomal aberration, is being discussed at present.

1654/W

Molecular genetic testing of podocin (*NPHS2*) mutations in steroid-resistant nephrotic syndrome by high resolution melting curve analysis. *M. Lu[1], A. Mottl[2], K. Weck[1].* 1) Dept. of Pathology and Lab Medicine, UNC at Chapel Hill, Chapel Hill, NC; 2) Dept. of Medicine and Nephrology, UNC at Chapel Hill, Chapel Hill, NC.

Background: Steroid-resistant nephrotic syndrome(SRNS)occurs mainly in children, typically manifests histologically as focal segmental glomerulosclerosis (FSGS) and often progresses to end-stage renal failure. Mutations in NPHS2 have been associated with autosomal recessive SRNS, with important and variable correlations between genotype and clinical features such as age of onset, severity and treatment responses. The detection of NPHS2 mutations is of potential clinical utility as it could prevent unnecessary steroid treatment and allow risk stratification for post-transplant FSGS recurrence. Our goals are to: 1) develop mutation scanning by high resolution melting curve analysis (HRMA) to screen for mutations in FSGS associated genes, and 2) better characterize the spectrum, incidence and genotype-phenotype correlation of mutations in a cohort of well-characterized patients with biopsy proven primary FSGS or SRNS. **Methods:** We developed HRMA and DNA sequencing conditions for all 8 exons of NPHS2. PCR products were tested by HRMA on a LightScanner (Idaho Technologies) and by DNA sequencing on a 3130xl genetic analyzer (Applied Biosystems). The sensitivity and specificity of HRMA for detecting DNA variants were compared with DNA sequencing. **Results:** Analysis of 10 normal control DNA samples and 64 patient samples showed mutation scanning by HRMA had 100% sensitivity and 93% specificity compared to direct DNA sequencing for detection of all DNA variants. Standardized parameters were established from these analyses. Of 64 patients with biopsy proven primary FSGS, we detected NPHS2 variants in three steroid resistant patients: two patients were compound heterozygous for R229Q and another podocin mutation, which typically leads to mild SRNS in young adults. The third patient was homozygous for R138Q, which leads to early onset SRNS and rapid progression to end stage renal disease. One novel missense mutation (Arg10Thr) in an evolutionally conserved region was found in two steroid resistant patients; the clinical significance of this variant has not been established. **Conclusions:** In summary, mutation scanning by HRMA is a sensitive method for detecting variants in NPHS2. Future work includes testing of a larger sample pool of patients with SRNS, in order to further characterize the clinical features and genotype-phenotype correlation of NPHS2 mutations, and establishing standardized procedures for NPHS2 clinical testing.

Genetic Counseling and Testing for Hypertrophic and Dilated Cardiomyopathy: Uptake of genetic testing among family members. *E.M. Miller, S.M. Ware.* Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Up to 70% of adults with hypertrophic cardiomyopathy (HCM) and 30% with dilated cardiomyopathy (DCM) have positive clinical molecular genetic testing. One of the primary benefits of genetic testing is identification of at risk family members, and recent guidelines recommend increased cardiac surveillance in mutation positive, asymptomatic individuals. This study aims to identify uptake of genetic testing among first and second degree relatives of patients with mutation confirmed HCM and DCM. Thirty-seven unrelated patients (31 HCM, 6 DCM) underwent genetic testing for a personal history of HCM or DCM from October 2006-April 2010. Of 37 probands tested, 28 (76%) had positive test results; 57% of probands had a positive family history, with a disease causing mutation identified in 86% (18/21). Of 16 probands without a positive family history at presentation, 63% (10/16) had positive genetic testing results and nine (56%) subsequently had family members clinically diagnosed with cardiomyopathy as a result of their evaluation and recommendation for family screening with echocardiogram. Patients who received a positive test result were encouraged to share their results with family members and >80% received a post-testing counseling letter. Genetic testing was indicated for 132 first and second degree relatives. Forty-two first degree relatives (49%) and 9 second degree relatives (19%) underwent genetic testing. Nineteen relatives received negative results and therefore could be excluded from ongoing cardiac surveillance. Positive genetic testing results were obtained in a high percentage of probands regardless of family history of cardiomyopathy. Genetic testing and cardiac screening both identified previously unrecognized affected or at risk individuals, facilitating appropriate medical intervention. These data are the first analysis of uptake of genetic testing among first and second degree relatives of patients with mutation positive DCM and HCM and demonstrate the importance of genetic counseling and family based care in this population.

Small pathogenic copy number changes detected by whole-genome array CGH define novel dosage-sensitive regions. *L. Schmidt, S. Warren, N. Flores, G. Richard, S. Aradhya.* GeneDx, Gaithersburg, MD.

Whole-genome array CGH is a powerful new standard for chromosomal analysis. Its application has become widespread, leading to the discovery of novel genomic disorders. Several of these disorders are due to large copy number changes but some, such as the 17q21.31 or the 1q21 microdeletions, are caused by <1 Mb deletions. We have used whole-genome array CGH to analyze 7,500 cases and identified positive findings in 25% of cases. Of these, 151 cases involved copy number changes < 2 Mb and that had occurred de novo, thus offering the opportunity to define novel dosage-sensitive genomic regions at a high resolution. Of the 151 de novo cases, nearly 30% were associated with newly defined microdeletion syndromes, thereby confirming the validity of this analysis. For example, nine cases involved the Williams syndrome deletion, another nine represented the autism-linked 16p11.2 deletion, seven matched the 17q21 microdeletion, and one corresponded to the 1q21 TAR syndrome microdeletion. The remaining 70% of cases involved either single genes associated with known Mendelian disorders or novel copy number changes affecting genes that, when haploinsufficient, may be associated with a clinical outcome. Many of these genes are not associated with clinical disorders at present and may be sensitive to dosage. As might be expected of pathogenic genomic changes, particularly when affecting a few genes, most findings (~65%) in this data set involved deletions rather than duplications. These data represent an initial precursor to a high-resolution whole-genome dosage map as more cytogenetic array CGH data is accumulated in the coming years.

1657/W

An automated analysis protocol for research of KRAS/BRAF mutation detection for data generated on capillary electrophoresis instruments. *S. Sharp[1], E. Currie-Fraser[1], J. Walker[1], J. Wang[2].* 1) Life Technologies, Foster City, CA; 2) Trimgen, Sparks, MD.

Biomarker research continues to be an important focus in oncology studies, including the role of KRAS and BRAF mutations in CRC and other EGFR-associated cancers. This has lead to increased research of these genes as possible predictive markers and targets for continued study. With this increased interest comes a need for automation of data analysis and report generation to decrease bottlenecks in the research laboratory by reducing manual review time. This poster will present an automated workflow for detection of KRAS and BRAF mutations and concise report generation in sample data generated on capillary electrophoresis instruments using fragment analysis software tools. We will demonstrate how key features in the software, such as sample quality values, allele binning and report analysis, enable this workflow to be a significant improvement over visual scoring methods.

Monogenic diabetes due to mutations in 5 MODY genes: Distribution of disease-associated mutations and implications for approaches to molecular diagnostic testing. *C.M. Stanley[1], U. Geigenmuller[2], N. Leach[2], T. Love[2], S.D. Batish[1], M. Chen[1], E. Couchon[1], M. Morra[2], M. Ito[1].* 1) Athena Diagnostics, Worcester, MA; 2) Correlagen Diagnostics, Waltham, MA.

An estimated 2-5% of the 23.6 million people in the United States with diabetes have monogenic diabetes, also known as maturity onset diabetes of the young (MODY), an autosomal dominant disorder caused by a mutation in one of several MODY genes affecting the development and function of the pancreatic β cells. Patients with MODY differ clinically from those with type 1 or type 2 diabetes and genetic testing for MODY should be considered for atypical patients. MODY diagnostic criteria include a family history of diabetes with one family member having been diagnosed before age of 25, negative for autoantibodies, normal weight, noninsulin dependent 3-5 years after diagnosis, noninsulin-resistant and without acanthosis nigricans. Treatment for individuals with MODY differs from treatment for other types of diabetes mainly because many do not require insulin, responding favorably to either oral sulfonylureas or dietary restriction alone. Therefore, a diagnosis of MODY can offer the patient better prediction of disease progression and prognosis, more appropriate treatment, and identification of risks to children or other family members. We report sequencing results for five genes known to cause MODY: *HNF4A* (MODY1), *GCK* (MODY2), *TCF1/HNF1A* (MODY3), *IPF1/PDX1* (MODY4), and *TCF2/HNF1B* (MODY5), which encode transcription factors, with the exception of MODY2 (*GCK*), encoding a glucokinase. Results from 2,427 MODY panel diagnostic reports were used to estimate the positive rate and the relative distribution of the genes that cause MODY. Approximately twenty percent of reports were positive for a previously published or predicted disease-associated mutation. Of these, 59% were positive for MODY2, 32% for MODY3, 3% for MODY1, 3% for MODY4 and 2% for MODY5. Among individuals with MODY, our data support MODY2 as the most common form of monogenic diabetes and MODY3 as the most common form of transcription factor diabetes and though MODYs 1, 4 and 5 are rare, they collectively account for 8% of MODY-positive reports.

1659/W

Patient Contacts, Counseling and RYR1 Genetic Testing Results in an Academic Medical Center. *D. Steele[1], B.W. Brandom[2], J.A. Kant[3], E.E. Smith[1].* 1) Ctr Med Genetics, Magee Woman's Hosp, Pittsburgh, PA; 2) Department of Anesthesiology, University of Pittsburgh Medical Center, Pittsburgh, PA; 3) Department of Pathology, University of Pittsburgh Medical Center, Pittsburgh, PA.

The laboratory received 162 specimens for sequencing of the 19 exons of the ryanodine receptor type one gene (RYR1)in which mutations that cause malignant hyperthermia (MH) have been documented (see www.emhg.org). In those cases referred for testing because of an episode of suspected MH the yield of mutations and variants of unknown significance was 0.38. This included 3 MH deaths. In those cases referred because of positive muscle contracture tests yield was 0.26. This is not statistically significantly different from the yield in suspected episodes. In those cases referred because of a family history of MH yield was 0.29. In cases that were referred to the lab without a known reason for referral the yield was 0.11. Two thirds of the positive results were known MH mutations; one third were variants of unknown significance. However, at least 2 of these variants were found in people with significant pathology consistent with MH. The two most frequent MH mutations were Gly2434Arg and Gly341Arg. A total of 235 contacts were made regarding testing for malignant hyperthermia. 71% of these cases had contact with a board certified genetic counselor. Nineteen had face-to-face genetic counseling sessions. Fifteen families were identified. One family had 3 positive for a familial mutation and 3 negative. Another family had 3 positive for a familial mutation and 1 negative. Of the 8 cases associated with a death 3 were positive for a mutation, 1 for a variant and 1 the sample did not yield a result. One mother tested positive after her son died of a suspected MH episode. By identifying the familial mutation, families have had the opportunity to have targeted RYR1 analysis. Genetic counseling also allowed for recommendations regarding the most appropriate family member to begin testing. This helps to increase the usefulness of the information from the testing and reduce cost for the family. The access to the lab, an anesthesiologist and a genetic counselor has allowed patients and physicians to receive advice on utility of testing for MH, management of patient care and education regarding the North American MH Registry. The RYR1 gene screen with genetic counseling performed at UPMC has been of benefit to MH individuals and families.

1660/W

Experience with Carrier Screening and Prenatal Diagnosis for Sixteen Ashkenazi Jewish Genetic Diseases. *Z. Tan, S.A. Scott, L. Edelmann, L. Liu, M. Luo, R. Kornreich, R.J. Desnick.* Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY.

Prenatal carrier screening in the Ashkenazi Jewish (AJ) population has proven an effective disease prevention strategy since enzyme-based carrier detection for Tay-Sachs disease (TSD) began in the early 1970s. Since then, screening panels have expanded as prevalent disease-causing mutations have been identified in the AJ population. Here, we report the AJ carrier frequencies of over 100 mutations in the greater New York metropolitan area AJ population and our experience with the following 16 debilitating recessive disorders: Bloom syndrome (BS), Canavan disease, cystic fibrosis (CF), familial dysautonomia, familial hyperinsulinism, Fanconi anemia group C, Gaucher disease (GD), glycogen storage disease Ia, lipoamide dehydrogenase deficiency, maple syrup urine disease, mucolipidosis type IV, nemaline myopathy (NM), Niemann-Pick disease type A, TSD, and Usher types 1F and 3. Carrier frequencies were determined for individuals of 100% AJ descent and ranged from 0.066 (1 in 15.2; GD) to 0.006 (1 in 168; NM), which were ~15% higher, on average, than those for all screenees. Residual risks among the 100% AJ population ranged from 1 in 281 (GD) to 1 in 13,301 (BS), and the cumulative frequency for all 16 disorders predicted that ~1 in 3.3 AJ will be a carrier for one of these diseases and ~1 in 24 may be a carrier of more than one disease. Among the observed double-heterozygotes, GD and CF were the most commonly carried disorders (1 in 400). Importantly, panel selection among the screenees indicated that the vast majority of AJ individuals (>95%) chose the expanded disease panel, including those disorders with lower carrier frequencies and/or detectability. Carrier screening also identified rare individuals who were homozygous for disease-causing mutations with previously unrecognized clinical manifestations. These studies include prenatal testing results and experience for all 16 disorders (n = 574). Together, these data illustrate the current status, acceptance, and future directions of prenatal carrier screening in the AJ population.

1661/W

Clinical molecular testing for Neurofibromatosis type 1 (NF1)/ Legius syndrome (SPRED1): 88 novel mutations in NF1/SPRED1. *Z. Wang[1, 2], RK. Basran[1, 2], TA. Maher[1], M. Flynn[1, 2], SM. Jamal[1, 2], JM. Milunsky[1, 2, 3].* 1) Ctr Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Department of Pediatrics, Boston Univ Sch Medicine, Boston, MA; 3) Department of Genetics and Genomics, Boston Univ Sch Medicine, Boston, MA.

Neurofibromatosis Type 1 (NF1) [MIM# 162200] is one of the most common autosomal dominant disorders affecting ~ 1/ 3,000 individuals. The main clinical features are café-au-lait macules (CALM), cutaneous neurofibromas, lisch nodules, and optic glioma. Legius syndrome is caused by mutations in SPRED1. Legius syndrome is characterized by the presence of CALMs, axillary freckling and macrocephaly without neurofibromas, and is likely underdiagnosed. Accurate diagnosis of NF1 and Legius syndrome is important since NF1 requires different medical management. We describe our experience with samples submitted to our Molecular Diagnostic Laboratory for NF1 testing. Nearly 400 patients (300 probands) from around the world were tested via bidirectional sequencing of the 58 exons of the NF1 gene. Deletion and duplication analysis was performed by MLPA. Targeted prenatal diagnosis of NF1 mutations was completed in 7 families. In our cohort of 300 probands, a total of 130 (43%) were found to have a mutation or an alteration of unknown significance. A total of 120 mutations were identified, of which 87 (72%) are novel changes and the remaining 33 (28%) were previously reported in NF1 patients. The mutation spectrum included small insertions or deletions (31), splice (23), nonsense (33), and missense (34). In addition, MLPA analysis revealed whole exon or entire gene deletions in 8 patients. Mosaicism is suspected in one NF1 patient with a known termination mutation. The pathogenicity of the unreported changes was assessed using Polyphen, Sift and BDGP Splice site software tools, and correlated to the clinical findings. Testing parental samples, when possible, is undertaken to further elucidate the clinical significance of the changes. Of those patients referred for NF1 gene analysis in whom no NF1 mutations were identified, 36 were tested for mutations in the SPRED1 gene by sequencing. Three patients (8%) were found to have a mutation/alteration. The novel alterations identified here in both NF1 and SPRED1 provide a valuable addition to the currently available mutation database and will aid in better interpretation of molecular test results. This study highlights the importance of employing comprehensive sequencing coupled with MLPA in detection of mutations of various types for NF1. Further, our study demonstrates the necessity of SPRED1 testing for NF1 negative patients as a specific molecular diagnosis will allow better anticipatory guidance.

1662/W

The utility of exon targeted array CGH in the diagnosis of mitochondrial related disorders. *H. Zhan, F.Y. Li, E. Brundage, A.N. Pursley, J. Wang, L. Wong.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Background: Mitochondrial disorders constitute a group of clinically and genetically heterogeneous diseases for which molecular diagnosis has been a challenge. Currently, direct DNA sequencing of candidate genes is the primary technique for the identification of mutations. However, sequencing does not detect large deletions. Oligonucleotide array-based comparative genomic hybridization (oligo aCGH) is presently in clinical use to detect major chromosomal copy number changes. Methods: A custom oligonucleotide array-based comparative genomic hybridization (oligo aCGH) platform was developed to provide both tiled coverage of the entire 16.6-kilobase mitochondrial genome and high-density coverage of a set of nuclear genes involved in mitochondrial and metabolic related disorders, for quick evaluation of copy number changes in nuclear and mitochondrial genomes. A total of 1000 DNA samples from patients suspected of mitochondrial and metabolic disorders were evaluated using this custom exon targeted aCGH. Deletions detected were confirmed by PCR amplification of the deletion breakpoints followed by sequencing. Results: Oligo aCGH identified a total of 61 (6.1%) cases of unrelated individuals with 21 large deletions in urea cycle genes (16 OTC, 4CPS1, and 1 ASS1), 5 in genes (2 DGUOK, 1 each in POLG1, TK2, and MPV17) responsible for mitochondrial DNA (mtDNA) depletion syndromes, 9 cases with deletions in metabolic related genes (SLC25A13, ABCB11, CACT, OCTN2, ALDOB, STS, MCCC1, MECP2, and GK), and 9 cases with large deletions in mtDNA. In almost all cases, the breakpoints were confirmed and determined by PCR/sequencing and the percentage of mtDNA deletion heteroplasmy was also estimated. In addition, 9 and 8 cases, respectively, of large copy number loss and gain involving multiple genes (ranging from 10 kb to 16 Mb) believed to be pathogenic were identified. Conclusions: These examples illustrate the successful utilization of exon targeted custom oligonucleotide arrays to detect either whole gene deletions or intragenic exonic deletions, and deletions in mitochondrial genome. This technology is particularly useful as a complementary diagnostic test in the context of a recessive disease when only one mutant allele is found by sequencing. Furthermore, deletion of as small as a single exon of about 200 bp or as large as entire chromosome can be easily detected using the custom aCGH.

1663/W

Cystic Fibrosis mutation screening in a North American population. *V.V. Zvereff, K.J. Friedman.* Center for Molecular Biology and Pathology, Laboratory Corporation of America, Research Triangle Park, NC.

Cystic Fibrosis (OMIM 219700) is one of the most common autosomal recessive genetic disorders. The incidence of CF in the US is estimated to be 1: 3,300 live births (Grody et al. 2001). The disease is caused by mutations in the CFTR gene located at chromosome 7q31.2. Over 1300 CFTR mutations have been identified, but most of these mutations are rare. In April 2001, American College of Medical Genetics (ACMG) and American College of Obstetricians and Gynecologists (ACOG) recommended a panel of 25 mutations for carrier screening of the US population. Since that time, extended panels have targeted specific ethnic populations while maintaining the value of a pan-ethnic screen. To investigate the performance of extended panels in CF population-based screening, we examined data from 1,140,769 cases tested in our laboratory using two mutation screening panels. One panel included 32 of the most common CF mutations (CF32) with 1,061,764 samples tested, and a second panel consisted of 70 mutations (CF70) with 79,005 cases tested. DNA analysis of the mutations on the CF32 panel was performed using multiplex PCR and oligonucleotide ligation assay (Applied Biosystems). Mutation detection technique of the CF70 was based on the Tm Bioscience/Luminex Universal Array Platform using primer extension chemistry. Genotyping data from the CF32 panel identified deltaF508 as the most frequent mutation (69.3%), followed by R117H (12.5%), and G542X (2.34%). A majority of the mutations on the CF32 panel have exceeded the ACMG 0.1% incidence threshold. Only S549R, which is not present on the ACMG CF panel, was observed at a lower frequency (0.07%). Genotyping data from the CF70 panel demonstrated a significantly lower mutation frequency for deltaF508 (58.5%) compared to the CF32 deltaF508 mutation frequency. For the rest of the variants present on both CF32 and CF70 panels, a comparable pattern of mutation frequencies were identified. Other mutations on the CF70 panel, such as D1152H, G622D and L206W, were identified with the frequency 4%, 3.23%, and 2.47% respectively, and 19 other mutations exceeded a frequency of 0.1%. In conclusion, although the clinical utility of extended CF panels is still controversial, their use improves the mutation detection rate for specific mutations within specific target populations.

Whole Genome Sequencing: Medical and Genetic Counseling Approaches and Challenges. *FM. Facio[1], JK. Teer[1], JJ. Johnston[1], PF. Cherukuri[2], P. Cruz[2], NF. Hansen[2], DA. King[1], SC. Parker[2], HO. Abaan[2], ED. Green[2,3], EH. Margulies[2], JC. Mullikin[2,3], LG. Biesekcer[1].* 1) Genetic Disease Research Branch, Natl Human Genome Res Inst, NIH, Bethesda, MD; 2) Genome Technology Branch, Natl Human Genome Res Inst, NIH, Bethesda, MD; 3) NIH Intramural Sequencing Center, Natl Human Genome Res Inst, NIH, Bethesda, MD.

Introduction: Medical and genetic counseling at the scale of a full genome will be a major challenge of clinical research in the genomic era. The ClinSeq™ study was implemented with the goal of piloting large-scale medical sequencing (LSMS) in a clinical research setting to contribute to the research base for the development of these practices. By sequencing targeted or all regions of 1000 human genomes and returning individual relevant genotype results to research participants, the study aims to investigate the technical, medical, and genetic counseling issues that accompany the implementation of LSMS in the clinical setting. We present the findings associated with the first whole genome sequence of a ClinSeq™ participant. **Methods**: After enrollment in ClinSeq™, participants provide personal and family history of disease, and undergo clinical evaluations focused on cardiovascular health. A ClinSeq™ participant reported a remarkable personal and family history of early onset autosomal dominant atherosclerotic coronary artery disease without hyperlipidemia, and was selected to be the first participant to have his whole genome sequenced. Paired-end Illumina sequencing system was used to generate 50-fold coverage upon alignment. Upon identification of genetic variants of clinical significance the participant was contacted to decide if he wished to learn about these individual genotype results. **Results**: Initial analysis detected ~4.1 million variants including ~3.7 million single nucleotide polymorphisms and ~439 thousand copy number variations. One of the copy number variations found is a deletion of the PMP22 gene associated with Hereditary Neuropathy with Liability to Pressure Palsies. Preliminary analysis of the sequence alterations using the Human Gene Mutation Database identified >40 potential pathogenic variants. Manual curation trimmed this to four. These included variations in genes associated with carrier status for Congenital dyserythropoietic anemia type II (*SEC23B*), Ectodermal dysplasia (*WNT10A*), Pendred syndrome (*SLC26A4*), and Galactosemia (*GALT*). The participant opted to learn these genotype results and met with the team to discuss the medical and genetic meaning of these variants. **Conclusions**: Despite the challenges surrounding interpretation and disclosure of results from LSMS, our results show that this technology can generate genetic test results that are clinically significant and of interest to clinical research participants.

Whole Genome Sequencing in the Clinical Laboratory. *T.M. Hambuch[1], M. Laurent[1], B. Sickler[1], A. Liao[1], P. Cotter[1], S. Jain[1], Y. Lyan[1], J. Bernd[1], J.M. O'Daniel[1], P. Poggio[1], M.T. Ross[2], D.R. Bentley[2].* 1) Illumina Clinical Services Laboratory, San Diego, CA; 2) Illumina United Kingdom Chesterford Research Park Little Chesterford Nr Saffron Walden Essex CB10 1XL, UK.

The advent of routine whole genome sequencing creates an opportunity to provide an accurate, comprehensive and cost-effective catalogue of germline variation for an individual. The process of sequencing and delivering genomes for individual use must be driven by clinical and educational opportunities balanced by addressing ethical concerns. Using guidelines issued from professional and accrediting agencies as well as an independent ethics board, we developed and launched individual genome sequencing (IGS) as a physician-led service. A physician orders the sequence and obtains informed consent from the individual; the sample is sequenced within a CLIA certified laboratory and after a series of quality checks the sequence is returned to the physician for communication back to the individual. The sequencing platform and process were validated for accuracy and precision, and accredited following review by a College of American Pathologist (CAP) inspection team. Each individual genome is sequenced at >30 fold coverage using paired-end reads of 100 base pairs. Resulting sequence information is provided for >93% of the NCBI36 genome, the remainder being mostly recently duplicated repeats where ambiguous read alignment is not permitted in our ELAND analysis. On average, we detect over 3 million SNPs most of which are previously documented in dbSNP129. The overall accuracy of our base calling is measured as >99.99% and the accuracy for SNP calling is >99.7% based on assessments using multiple methodologies. The aim of the Illumina Clinical Services Laboratory is to make Individual Genome Sequencing accurate, accessible and clinically relevant for physicians and patients through a fully accredited process. Here we have established baseline processes, tools, and policies to maximize the benefit to patients and minimize potential misuse. Additionally, our ongoing efforts to develop clinically relevant interpretation tools for physicians are described in a separate abstract (see M. Ross). Individual Genome Sequencing has the capacity to replace current genetic testing with a near-complete description of the sequence of an individual. Considering this potential, it is essential to engage policy makers and ethicists so that appropriate policies are developed around information access and use of whole genome information.

1666/W

Next generation sequencing - applications for genetic testing. *A. Horvath, C. Wassif, C. Stratakis, F. Porter.* NICHD, NIH, Bethesda, MD.

Next generation sequencing (NGS) technologies are anticipated to have a crucial impact on genetic testing, by providing accuracy at a reasonable cost, tremendous robustness, and a relatively straightforward data analysis. So far, NGS diagnostics-related applications have been limited by the high cost of the individual tests, as well as by a high rate of false-negative and, in particular, false-positive results. Consistent advancements in technology have led to increased speed and read length, allowing for higher accuracy due to extended coverage in a cost-effective setting. We have developed an approach that allows accurate sequence analysis of one or more disease-related genes in multiple patients, and in parallel, generates data for research applications in a single run. The approach utilizes a capture enrichment protocol (Agilent) of a custom, disease-based array, and subsequent re-sequencing on a Solid 4 platform (Applied Biosystems). Thus, a high level of sequence coverage is achieved on 392,574 bp, consisting of the coding and the flanking regions of 1982 exons of 201 genes. The panel of the included genes consists of two major groups: genes related to tumors of endocrine origin, and genes linked to aberrant lipid metabolism. Extending the experience into diagnostic applications of the NGS technologies, along with their constantly improving accuracy, speed, and cost-effectiveness, are expected to bring a significant progress towards clinical applications, including sequencing of numerous genes in an individual with a complex or muti-factoral genetic disorder or complex disease predisposition.

1667/W

An approach to clinical interpretive tools for whole genome sequencing. *M.T. Ross[1], T.M. Hambuch[2], J.M. O'Daniel[2], L.J. Murray[1], D.R. Bentley[1].* 1) Seqeuncing Applications, Illumina, Chesterford, Essex, United Kingdom; 2) Illumina Clinical Services Laboratory, 9440 Carroll Park Dr., Ste. 100, San Diego, CA 92121.

The barriers to accurate human genome re-sequencing have largely been surmounted, enabling considerations of routine clinical applications. Significant challenges remain, however, for interpretation of whole genome data for diagnostic or prognostic purposes. Public data on mendelian variants are held in a disparate set of locus-specific or genomic databases, while the largest repository of human diversity data (dbSNP) currently contains limited information of clinical relevance. The significance of novel coding variants remains unknown in the absence of other medical information. Most importantly, the prediction of phenotype from genotype is complicated by variability in penetrance, expressivity, epigenetic and environmental factors. We have established a clinical service for whole genome sequencing (see abstract by T.Hambuch). To assist physicians in patient management, we explored the challenges of providing genome interpretation tools. We analyzed an individual genome, utilizing available databases. For our approach, we considered five tiers of variant information with varying degrees of immediacy in their clinical impact: (1) known monogenic variants with evidence for disease causation, (2) pharmacogenetic markers, (3) polymorphisms associated with common, complex conditions, (4) novel variants in genes in tier 1, and (5) known tissue-type variants. We focused our efforts on Tier 1, where our starting point was the Human Gene Mutation Database (HGMD). We observed 16 homozygous and 48 heterozygous variants considered by HGMD as "disease causing" in the individual genome most of which were not compatible with a reportedly healthy adult. These variants were manually assessed via literature review, locus-specific databases and function prediction algorithms. The evaluation resulted in a list of 10 variants with sufficient evidence of clinical impact to be considered pathogenic, probably pathogenic or possibly pathogenic. Whole genome sequencing holds tremendous potential for clinically important information throughout the lifespan. The development of interpretation tools is essential to assist the physician in understanding and management of the implications of genome information for the patient. Ongoing discussions of the ethical, legal and social implications around appropriate access and use of this information will guide the further development of the interpretation strategy we present here.

1668/W

Novel Approaches toward a One-Step Comprehensive Molecular Diagnosis of Mitochondrial Disorders. *L. Wong, H. Zhan.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX. 77030.

Mitochondrial disorders are a group of clinically and genetically heterogeneous diseases that may affect any individual at any age with any form of clinical manifestation. Due to the large number of genes (~1500) involved and the complexity, the disease is undoubtedly under-diagnosed. Currently, clinical molecular analysis is based on the screening of known recurrent mutations and sequencing of a limit number of nuclear genes known to cause mitochondrial disorders. However, more than 90% of patients with mitochondrial disorders are left without a definite diagnosis. In addition, sequence analysis of relevant genes one by one using Sanger's method is too costly and not practical. At the present, the molecular diagnosis of mitochondrial disorders requires the implementation of several different methods including sequencing, quantitative PCR for mtDNA heteroplasmy and depletion, as well as the detection of large deletions by various techniques. It is tedious, expensive, and often not definitive because not all the genes can be analyzed. We recently have designed a comprehensive approach by capture of all 1300 nuclear genes targeted to mitochondria plus mitochondrial genome, followed by massive parallel sequencing with deep coverage, such that point mutations and copy number changes in both mitochondrial and nuclear genomes can be detected simultaneously with the estimation of deletion breakpoints and mtDNA heteroplasmy. We used Agilent's eArray to tile coding exons of nuclear genes and the entire mitochondrial genome at an optimized ratio to a DNA array, followed by SureSelect method to pull down the targeted DNA templates, which were then sequenced at a deep coverage. Our results showed that point mutations or variants in both nuclear and mitochondrial genes were correctly identified. In-house developed algorithms similar to the analysis of oligonucleotide array CGH data were used for large deletions in both nuclear and mitochondrial genomes. Detection of mtDNA copy number changes (mtDNA depletion) requires more sophisticated analytical tools that are currently being developed. This approach will also lead to the discovery of new disease genes. In conclusion, we have developed a high throughput, one-step comprehensive molecular diagnostic approach that would allow the identification of the molecular defects in mitochondrial disorders at an affordable cost.

Use of chromosomal microarrays in the diagnosis of primary neuromuscular diseases. *L. Medne[1,2], A.R. Foley[2,5], Y. Hu[2], Y. Zou[2], M. Yang[6], M. Leach[2], E.H. Zackai[1], J. Ganesh[1,4], K. Chatfield[1,4], M. Falk[1], E. Place[1], A.M. Neumeyer[8], L. Bliss[8], B.S. Tseng[8], R.E. Schnur[9], L. Coffee[9], J. Stone[9], T. Shaikh[7], L.G. Shaffer[10], T. Winder[11], S. Mulchandani[3], B.D. Thiel[3], L.K. Conlin[3], N.B. Spinner[1,3], C.G. Bönnemann[2].* 1) Div Hum Gen, Children's Hosp Philadelphia, Philadelphia, PA; 2) Division of Neurology, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Division of Pathology, Children's Hospital of Philadelphia, Philadelphia, PA; 4) Section of Biochemical Genetics and Metabolic Disease, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Dubowitz Neuromuscular Centre, UCL Institute of Child Health and Great Ormond Street Hospital for Children, London, UK; 6) Department of Neurology, The Children's Hospital, University of Colorado, Denver, CO; 7) Department of Pediatrics, University of Colorado - Denver, Aurora, CO; 8) Department of Neurology, Massachusets General Hospital, Harvard University, Botson, MA; 9) Division of Genetics, Cooper University Hospital, Camden, NJ; 10) Signature Genomics Laboratories, Spokane, WA; 11) Prevention Genetics Laboratory, Marshfield, WI.

We report 7 patients with four different primary neuromuscular disorders - Ullrich congenital muscular dystrophy (UCMD), congenital muscular dystrophy (CMD) due to alpha-dystroglycan glycosylation defect, myotubular myopathy and Duchenne muscular dystrophy (DMD) - in whom the use of genomic microarray analysis was crucial in establishing the diagnosis, identifying the mutational mechanisms and providing appropriate genetic counseling for the family. Some patients had findings limited to the primary neuromuscular disease while other had additional systemic involvement to suggest a contiguous gene deletion. Patients 1 and 2 have Ullrich congenital muscular dystrophy (UCMD) without additional findings. Patient 1 has a 69 Kb deletion at 21q22.3 encompassing *COL6A2* gene. Sequencing of the other allele revealed an intronic splice mutation (c.1970-9) with cDNA testing showing 7 bp insertion from the used of the novel splice acceptor site leading to a downstream frameshift (G656AfsX17). Patient 2 has heterozygous deletions detected by SNP array: 1.61 Mb deletion encompassing the entire *COL6A1* and *COL6A2* and other genes; and 47 Kb deletion encompassing *COL6A2* gene. Patient 3 has 76 Kb deletion at 22q12.3 containing part of *LARGE* gene, which lead to recognition of the CMD phenotype and identification of p.Glu509Lys mutation in the other allele. This is only the 3rd report of a patient with CMD due to *LARGE* gene mutations. Patient 4 had a 2.9 Mb deletion at Xq27.3-q28 encompassing *MTM1* and other genes, which accounted for his congenital myopathy with severe respiratory distress and additional findings of Pierre-Robin and genitourinary abnormalities. Patients 5, 6 (brothers) and 7 had Xp21 microdeletions encompassing dystrophin, *MAP3K71P3*, and *GK* genes. Patient 7 had a larger deletion accounting for the additional adrenal hypoplasia phenotype. In 4 of the 7 patients presented here microarray analysis was ordered as part of first-round diagnostic work-up without a suspicion for a specific neuromuscular disease. Results showed previously known disease entities like 'DMD plus' due to Xp21 microdeletions as well as novel mutational mechanisms like *COL6A1* and/or *COL6A2* gene deletions in autosomal recessive UCMD. These cases clearly illustrate that chromosomal microarrays have a place in the diagnostic repertoire for neuromuscular disorders as phenotypes may not be clearly apparent due to age or masked by more severe or additional systemic findings.

1670/W

***COL3A1* haploinsufficiency results in EDS type IV with delayed onset of complications and longer life span when compared to missense and splice-site mutations.** *D.F. Leistritz, M.G. Pepin, U. Schwarze, P.H. Byers.* University of Washington, Seattle, WA.

Ehlers-Danlos syndrome (EDS) type IV, the vascular type, results from mutations in *COL3A1*, the gene that encodes the proα1(III) chain of type III procollagen. We have identified heterozygous *COL3A1* mutations in 508 families, about 95% of which lead to the synthesis of an abnormal type III procollagen. Mutations that result in substitutions for glycine residues in the triple helical domain of the proα1(III) chain account for two-thirds of identified mutations in *COL3A1*, and splicing mutations comprise most of the remainder. We identified frameshift or premature termination codons that result in nonsense mediated mRNA decay of the *COL3A1* mRNA encoded by that allele ("null mutations") in 19 families (about 4% of the total); cultured cells from these individuals produced about half the normal amount of type III procollagen and no abnormal molecules, as expected. We reviewed the clinical and family histories and medical complications in 53 individuals with *COL3A1* null mutations. Compared to individuals with missense or exon-skipping mutations, we found that in the cohort with *COL3A1* null mutations mean life span was extended by close to 20 years, the age of first complication was delayed by almost 15 years, and major complications were limited to vascular events. The families were ascertained following a complication in a single individual but only 25% of relatives, some of whom had reached their 70s or 80s without incidents, had a complication and only 30% had any minor clinical features of EDS type IV. In families with osteogenesis imperfecta that results from mutations in the *COL1A1* gene, more than 50% of affected individuals have haploinsufficiency mutations and have OI type I, the mildest OI phenotype. Because null mutations in *COL3A1* are expected to be as common as those in *COL1A1*, our data suggest that they are far less penetrant than missense and splicing mutations yet may be causes of late onset arterial aneurysms. Since ascertainment on the basis of clinical findings alone has a low yield, genetic testing for *COL3A1* mutations should be offered to all first degree relatives of an individual identified with a *COL3A1* null mutation, and should be considered in those with compatible vascular complications at a young age and, potentially, in individuals with late onset arterial events.

1671/W

Expanding the Phenotypic Overlap Between CHARGE and Kallmann Syndromes due to CHD7 Mutations. *H. Feret[1], D.M. McDonald-McGinn[1], A. Santani[2], E.H. Zackai[1].* 1) Division of Human Genetics, Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, PA; 2) Dept of Pathology & Lab Medicine, Children's Hospital of Philadelphia, PA.

Kallmann syndrome (KS), characterized by hypogonadotropic hypogonadism and anosmia, is a genetically heterogeneous condition, with multiple modes of inheritance described. Approximately 6% of KS is caused by mutations in CHD7. CHD7 also causes CHARGE syndrome, an autosomal dominant condition with multisystemic involvement in which the majority of cases are the result of de novo mutations. In previous studies, the majority of patients with KS as a result of CHD7 mutations have had some findings consistent with CHARGE syndrome. Additionally, until more recently, anosmia and arrhinencephaly were not recognized as important diagnostic criteria suggesting a CHARGE syndrome diagnosis. Here we report 2 families in which the fathers, with signs consistent with Kallmann syndrome, had children with CHD7 mutations and a CHARGE syndrome phenotype, as well as a newborn with multiple congenital anomalies including arrhinencephaly with a novel CHD7 mutation. The proband of Family 1 is a 19 month old male with bilateral chorioretinal colobomas, dysplasia of the semicircular canals, and slightly thickened left helix. His 2 =BD month old sister has bilateral cleft lip and palate, bilateral retinal and optic nerve colobomas, and right microphthalmia. The father has anosmia, with absence of the olfactory tacks and bulbs. Physical exam of the father revealed no other findings suggestive of CHARGE syndrome. All three individuals were found to be heterozygous for a R2319C missense alteration in the CHD7 gene. The proband of Family 2 is a 7 year old male with unilateral cleft lip and palate, right facial palsy, developmental delay, short stature, and dysmorphic ears. His father was diagnosed with Kallmann Syndrome, requiring the use of a GnRH agonist pulsatile pump to conceive. CHD7 sequencing in the proband revealed a heterozygous missense mutation, H2096R. Parental testing is pending. Patient 3 is an ex-34 week old male with growth retardation, bilateral cleft lip and palate, congenital heart disease, arrhinencephaly, intestinal malrotation, microphallus and cryptorchidism. CHD7 sequencing revealed a novel deletion of two bases (delAA) from nucleotide 3572_3573, resulting in a frameshift and premature stop codon. These cases suggest CHD7 mutation analysis be considered in cases of isolated KS or anosmia, regardless of the presence of additional features of CHARGE syndrome, in order to provide appropriate diagnosis and genetic counseling.

1672/W

Presymptomatic testing in 1554 at risk persons for late onset inherited neurological diseases. *M. Gargiulo[1], A. Herson[1], A. Mallet[1], C. Cazeneuve[1], C. Depienne[1,2], J. Feingold[1,2], A. Durr[1,2].* 1) AP-HP, Hôpital de la Salpêtrière, Department of Genetics, Paris, France; 2) CR-icm, INSERM/UPMC, UMR_S975, Paris ,France.

Since 1992, 1554 at risk persons for late onset inherited neurological diseases entered a presymptomatic testing (PT) procedure in our centre, including multistep and multidisciplinary care with genetic counseling, psychological and social interviews before bloos sampling, molecular analysis, test disclosure and follow up. They were at risk for Huntington diseases (HD, n= 1329/85%), but also for autosomal dominant cerebellar ataxias (SCA1, 2, 3, 6, 7 n=179/11.5%), autosomal dominant spastic paraplegias (SPG, n=33/2.1%), Creutzfeld-Jacob disease and fronto-temporal dementias (CJD/FTD n=13/0.8%). Mean age at first contact (34.7 ±11.9 years) was similar in all groups, close to the mean onset of the disease. After a variable delay, only part of the testeees decided to take the test and asked for their result: 85% for CJD/FTD, 68% for HD, 53% for SCAs, but only 45% for SPG ($p<0.001$). This indicated that proportion of those taking the test increases in with greater disease severity. The most frequent motive for PT is the need to know (34.4%). Less frequent were reproductive decision making (16.9%), anticipation and preparation (10.9%), and information of children about their risk (9.8%). Even if all carriers considered themselves as being unaffected, perceived first subtle symptoms motivated 10.3% of the testees to take the test, specially in the SCA group (20.1%, $p<0.002$). 3% had no clear motivation (3.2%). Interestingly, the more motivations are mentioned by the testees, the more likely they continue until the result compared to those who decided not to take the test in the end: the need to know 37.6% versus 28.4% ($p<0.001$), reproductive decision making 18.7% versus 13.6% ($p=0.012$), inform their children about their risk 11.4% versus 6.9% ($p=0.005$) and the need to anticipate and prepare the future 12.7% versus 7.5% ($p=0.002$). 981 testees (63%) asked for result disclosure and were non carriers in 56% and 40.5% carriers for HD, 58.9% and 37.9% for SCA, 80% and 20% for SPG. During follow up, prenatal testing was option for at risk persons only in 16.5% for HD, 8% for SCA, 0% for SPG and CJD/DFT . In conclusion, PT for late onset inherited neurological diseases remains an overall rare request. Increased disease severity and detailed motivations seemed to promote the uptake of PT and prenatal diagnosis is clearly not a direct consequence of PT in carriers.

1673/W

Combining genotype and phenotype to enhance risk estimation of a common complex disease: The REVEAL Study. *D.M. Lautenbach[1], C.A. Chen[3], L.A. Cupples[4,5], J.S. Roberts[6], R.C. Petersen[7], R.C. Green[1,2,5], for the REVEAL Study Group.* 1) Neurology, Boston University School of Medicine, Boston, MA; 2) Medicine (Genetics Program), Boston University School of Medicine, Boston, MA; 3) Data Coordinating Center, Boston University School of Public Health, Boston, MA; 4) Biostatistics, Boston University School of Public Health, Boston, MA; 5) Epidemiology, Boston University School of Public Health, Boston, MA; 6) Health Behavior and Health Education, University of Michigan School of Public Health, Ann Arbor, MI; 7) Neurology and Health Sciences Research, Mayo Clinic College of Medicine, Rochester, MN.

Background: The presence of specific clinical symptoms or signs may enhance the predictive utility of genetic tests, but very few examples of this have been developed using risk genes for common complex diseases. Mild Cognitive Impairment (MCI) is a clinical syndrome in which patients have mild memory problems but not dementia, and is considered a risk factor for Alzheimer's disease (AD). *APOE* is a polymorphic genotype where one or two copies of the ε4 allele increase the risk of AD. We analyzed *APOE* genotype data along with AD conversion data collected in a clinical treatment trial to create risk curves demonstrating 3-year "imminent" risk of AD for individuals with MCI. **Methods:** Data were obtained from a medication trial involving 769 MCI patients ("The Memory Impairment Study" Petersen et al. 2005), which provided three-year risk data stratified by *APOE* genotype. Cox proportional hazards regression revealed a significant difference in AD risk by age and *APOE* ε4 status. The sample was divided into approximate tertiles to create age groups, and three-year risk curves were created for each age group and *APOE* ε4 category (presence vs. absence of ε4 allele). Using an average 1.5% annual AD conversion rate among individuals without MCI, a three-year general population risk curve was generated. **Results:** The three-year risks for each age-group were: 8.4% for *APOE* ε4 negative and 42.0% for *APOE* ε4 positive individuals (age group: 55-70 years), 20.5% for *APOE* ε4 negative and 47.4% for *APOE* ε4 positive (age group: 71-77 years), and 30.7% for *APOE* ε4 negative and 57.1% for *APOE* ε4 positive (age group 78 years or older). A risk communication protocol has been developed, which involves presenting three curves: 1) three-year general population AD risk 2) three-year AD risk based on MCI diagnosis alone and 3) three-year AD risk based on MCI diagnosis and *APOE* ε4 status. Pictographs have been created to aid in numerical risk communication. **Conclusion:** The resulting risk estimates and curves will be employed as part of a new randomized trial in the NIH-funded REVEAL Study. Estimating and communicating risk for a late-onset, common complex disease based on both genotype and phenotype information is a novel concept in genetic risk counseling, which may become more common in the genomic era. Data from the REVEAL Study will inform refinement of disease risk estimation and disclosure based on both genotype and phenotype information.

1674/W

Confined Placental Mosaicism For Tetrasomy - Be Careful Not To Falsely Reassure. *K. Bajaj, M. Simard, S. Klugman.* Reproductive Genetics, OB-GYN, Montefiore Medical Center, New York, NY.

BACKGROUND: Confined placental mosaicism (CPM), or a discrepancy between fetal karyotype and placental karyotype was first described in 1993 by Kalousek and Dill. When reported at the time of chorionic villus sampling, true fetal mosaicism is found in approximately 10%.of the cases of placental mosaicism. CPM is usually described with trisomies and marker chromosomes and to our knowledge has only been reported twice with tetrasomy. Tetrasomy for the short arm of chromosome 18 has been associated with facial dysmorphism, skeletal abnormalities, ataxia, seizures, and moderate to severe mental retardation. CASE: 36 year-old healthy female of Eastern-European descent with one prior normal female child underwent chorionic villus sampling for advanced maternal age at 12 weeks gestation. The karyotype result revealed mosaicism for tetrasomy of the short arm of chromosome 18 (47, XX, i(18)(p10)[10]/46, XX[10]). The patient was counseled regarding the possibility of a severe phenotype associated with i(18p) and that though it was uncertain whether this result represented confined placental mosaicism or true fetal mosaicism, the risk of true fetal mosaicism was 10% percent. The possible mechanisms for tetrasomy 18p were reviewed. Karyotypes performed on both the patient and her partner, as well as an early anatomic survey, were normal. Given these findings, the patient felt reassured. Unfortunately, an amniocentesis was performed at 16 weeks gestation; the result confirmed true fetal mosaicism 47, XX,+i(18)(p10)dn[11]/46,XX[12]. The patient opted for termination. CONCLUSION: Our patient was falsely reassured that it was unlikely that the true fetal karyotype was mosaic for tetrasomy 18p. The data on confined placental mosaicism do not include tetrasomies and thus genetics providers must be careful when counseling patients with this unique but important clinical scenario.

1675/W

Large scale population screening for SMN1 gene copy number, clinical implications. *S. Ben-Shachar[1], A. Orr-Urtreger[1,2], E. Bardugo[1], R. Shomrat[1], Y. Yaron[1,2].* 1) Gnetic Institute, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel; 2) Sackler Faculty of Medicine, tel Aviv University, Tel Aviv, Israel.

Background: Spinal muscular atrophy (SMA) is a common autosomal recessive disorder characterized by degeneration of motor neurons in the spinal cord, resulting in a progressive muscular atrophy. The majority of SMA cases are caused by homozygous deletion of exon 7 of the *SMN1* gene. The aim of our study was to determine the frequency of *SMN*1 deletion carriers in the Israeli population and to determine feasibility of population screening for SMA.

Methods: From March 2007 to August 2009, 6394 individuals with no family history of SMA underwent genetic screening for SMA at the Genetic Institute, Tel Aviv Medical Center. Analysis was performed using multiplex ligation-dependent probe amplification (MLPA, MRC-Holland), designed to detect *SMN*1 exon 7 and exon 8 copy number.

Results: A total of 159 individuals were found to carry a *SMN1* heterozygous exon 7 deletion, a carrier frequency of 1:40. In addition, 690 individuals (10.8%) were found to carry 3 or more *SMN1* exon 7 copies, confirming the observation that some individuals carry more than one *SMN1* copy per chromosome (*cis* configuration). This result implies that about 1:740 individuals detected with 2 copies of SMN1 exon 7, are in fact carriers of exon 7 deletion on one chromosome and have 2 copies on the other chromosome. These individuals cannot be detected by the current MLPA or similar quantitative methods, leading to false negative diagnosis.

Conclusions: Our initial experience from this large-scale population based SMA screening program confirms that SMA screening is effective and feasible. Due to the inability of this screen to detect SMA carriers with *cis* configuration, individuals with SMN1 sequence mutations, and *de novo* fetal mutations, it is estimated that only about 90% of SMA carriers will be detected. Detection rates may be further increased by testing exon 7 copy number in both parents and performing prenatal diagnosis even when only one parent is found to be a carrier. However, as a result of invasive testing, an increased risk of miscarriages may be expected.

1676/W

Prenatal Molecular Diagnosis; Experience from a Large Center in Israel. *E. Pras[1, 2], L. Peleg[1, 2], H. Reznik-Wolf[1], H. Lahat[1], H. Yonath[1, 2], M. Karpati[1], L. Ries-Levavi[1], M. Berkenstadt[1], B. Feldman[1], M. Frydman[1, 2].* 1) Institute of Human Genetics, Sheba Medical Center, Ramat Gan, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Israel.

Parental tolerance for genetic diseases in Israel is extremely low. Prevention efforts begin with premarital or pre-gestational screening programs and continue with increasing attempts to perform molecular diagnosis when there is an affected child in the family. The overall result is an increasing demand for prenatal diagnosis of a growing number of genetic diseases. Over a two year period, between January 2008 to December 2009, we have performed 470 prenatal molecular diagnoses for 73 different Mendelian disorders. The prenatal procedure chosen, chorionic villus sampling (CVS) or amniocentesis was determined according to the risk of having an affected fetus. For a risk of 10% or more CVS was performed (dominant, recessive X-linked, fragile X with more then 70 repeats), otherwise amniocentesis was done. Each molecular diagnosis was performed by two different methods in order to minimize mistakes. Common disorders were diagnosed with commercial assays. For rare disorders we used direct sequencing combined with family haplotype analysis. In 4 cases (0.8%) the disease causing mutation was not known and therefore the diagnosis relied solely on family haplotype analysis. The most common problem encountered was maternal contamination (10 samples) which led to a repeated procedure. The most common disorders requiring prenatal diagnoses were fragile X (175 cases), followed by Tay-Sacks (75), cystic fibrosis (33), spinal muscular atrophy (20), Gaucher (16), skeletal dysplasias (15) and familial dysautonomia (9). Prenatal diagnosis was also offered for adult onset diseases such as Marfan syndrome (13), polycystic kidney disease (3), Huntington chorea (4), and also for potentially treatable disorders such as connexin 26/30 related hearing loss (15) and phenylketonutia (3). Sixty one affected fetuses were diagnosed, the vast majority of which were aborted. One case of misdiagnosis was encountered. This series represents one of the largest of its kind.

The importance of psychoanalysis for dealing with genetic mutations. *J. Forbes[1,2], T. Genesini[1,2], C. Riolfi[1,2], M. Barbosa[1,2], R. Chiavassa[1,2], L. Lise[1,2], E. Macedo[1,2], J. Palma[1,2], D. Rudiger[1,2], M. Zatz[1].* 1) Human Genome Res Ctr, Univesity Sao Paulo (USP), São Paulo, Brazil; 2) Institute of Lacanian Psychoanalysis (IPLA), São Paulo, São Paulo, Brazil.

One important aspect of genetic disorders is that they often affect not only individuals but the entire family. We have hypothesized that a social virus that we have denominated RC (resignation from patients and compassion from relatives) has a negative impact on families with patients affected by genetic disorders. In progressive neurodegenerative disorders it may also accelerate the progression of the symptoms leading affected patients to exclude themselves from social life prematurely. From September 2006 to October 2009 we have interviewed 52 subjects belonging to families with affected members of whom 43 were submitted to psychoanalysis, 11 of them were normal relatives (not affected) and 32 were affected with: 8 spinocerebelar ataxia, 8 myotonic dystrophy, 6 limb-girdle muscular dystrophy, 4 facioscapulohumeral , 2 spinal muscular atrophy, 2 Duchenne, 1 Becker and 1 Freidreich ataxia. The patients were seen in a weekly basis by a trained team of supervised psychoanalysts. The treatment approach is based on obtaining the maximum separation between the subject and the prêt-à-porter feelings that are, at least hypothetically, caused by his degenerative condition. In order to increase the treatment effectiveness, the psychoanalysts did not fulfill the patients' expectation to receive the same amount of compassion that they were used to receiving from their relatives. Interestingly, although all religions preach compassion towards handicapped individuals, all the interviewed patients declared that they did not want people to feel compassionate for them. Every three months the patients were reexamined by the geneticist and by the psychoanalyst who is responsible to supervise the whole team (namely, Zatz and Forbes, respectively) and the treatment impact reassessed. The results showed that patients began to show a responsible and inventive way of dealing with the disease. Moreover, the family resumed their lives by creating a new relationship with the affected relative. The advances in human genome sequencing will result in an enormous amount of information and a trained team of genetic counselors to help individuals to interpret them. We anticipate that psychoanalysis will play a growing role helping individuals dealing not only with genetic disorders but also with the knowledge of their own genome. Supported by FAPESP/CEPID, ABDIM, IPLA.

New and Improved Medical Genetics Resources at NCBI. *B.L. Kattman, D.R. Maglott.* National Center for Biotechnology Information - NCBI/NLM/NIH, Bethesda, MD.

The last decade has seen tremendous advances in our knowledge of the genetic and genomic factors involved in health and disease. NCBI has led the way in providing large quantities of data for a wide variety of users via databases, and the tools and viewers to access them. To improve service to the medical community, NCBI is enhancing current resources and creating new resources to facilitate exploration, interpretation, and evaluation of human variation.

With all the information being generated about human variation, processing these complex data is a service best supplied by a centralized database provider such as NCBI. dbSNP, dbVAR, and dbGaP provide essential roles in accessioning and processing reported variants. However, views aggregating information about the traits associated with each variant or set of variants, and the validity of any clinical interpretation of a variant or set of variants have not been readily available. Currently, users of NCBI resources can browse, search for and/or visualize data about variants maintained in dbSNP, dbVAR, dbGaP, OMIM, GeneReviews, GeneTests, LOVD at NCBI, PubMed, PubMedCentral, and the sequence databases, but not easily, nor in an integrated fashion. To bridge this gap and support expert review and curation, NCBI is developing two new resources:

• ClinVar, a public database to aggregate information relating variation to phenotype, (http://www.ncbi.nlm.nih.gov/clinvar) and

• The Genetic Testing Registry (GTR), a centralized, public resource that will provide information about the availability, scientific basis, and usefulness of genetic tests. http://www.ncbi.nlm.nih.gov/gtr

Here, we present a brief summary of our current tools and resources applicable to medical genetics, and then focus on the details of our exciting new projects, ClinVar and the GTR.

1679/W

Incorporating Genetic Risk Information for Type 2 Diabetes (T2D) Into Primary Care Clinics: Feasibility In Two Diverse Clinics - A Prototype Model? *M.L. Bembe, D.L. Baker, G.S. Ginsburg, A. Cho.* IGSP, Duke University, Durham, NC.

Genetic risk information for Type 2 Diabetes (T2D) is not typically utilized in primary care clinics. Is there synergism in a model that combines a standardized risk assessment (SRA) for T2D with genetic risk information? Duke University Institute for Genome Sciences & Policy (IGSP) partnered with 2 diverse clinics (an internal medicine primary care practice and a community and family medicine clinic) to test this. Outpatients were approached by research study coordinators, and if interested, enrolled that day. Four study visits over ~ 14 months included baseline, risk counsel visit (RCV), a remote post-RCV 3 months later, and final visit 12 months post-RCV. Baseline measures included blood work (fasting glucose and insulin), family history, metrics (BMI and waist circumference), medication use, lifestyle (self-report of diet and exercise) plus surveys. Genetic testing for 4 genes associated with increased diabetes risk, validated in other studies, was obtained by buccal swab. RCVs 1-2 months post baseline involved 30-40 minutes with a clinic provider; all subjects received education packets with individualized profiles for combined diabetes risk. Participants were randomized to receive genetic test results at RCV or at study completion. A remote 3 months post-RCV captured current weight and additional surveys. Final visit, 12 months post-RCV, included repeat fasting blood work, metrics and surveys. In 12 months, at two different clinics, over 1300 patients have been approached. A log of reasons for patient non-participation shows the most common reason for refusal to be no time that day. Over 350 of 400 enrolled subjects remain active. There have been 280 RCVs with 189 of 209 three-month surveys completed. Final twelve-month visits are scheduled to begin in two months. Study recruitment and follow-up participation indicate many primary care patients are receptive to genetic risk testing for T2D, especially when included as part of diabetes SRA and presented by a clinic provider. Subjects receive a personalized risk assessment of their combined diabetes risk, with genetic risk as only one component. This exemplifies a novel approach that demonstrates the feasibility of integrating T2D genetic risk research with diabetes standard risk assessment in diverse primary care clinics, perhaps a prototype for personalized, preventative medicine in the future.

1680/W

Lower numeracy is associated with lower recall of genetic risk information for Alzheimer's disease: The REVEAL Study. *A.G. Besser[1], C.A. Chen[2], J.S. Roberts[3], D.M. Lautenbach[4], L.A. Cupples[5,6], R.C. Green[4,6,7] for the REVEAL Study Group.* 1) Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Data Coordinating Center, Boston University School of Public Health, Boston, MA; 3) Health Behavior and Health Education, University of Michigan School of Public Health, Ann Arbor, MI; 4) Neurology, Boston University School of Medicine, Boston, MA; 5) Biostatistics, Boston University School of Public Health, Boston, MA; 6) Epidemiology, Boston University School of Public Health, Boston, MA; 7) Medicine (Genetics Program), Boston University School of Medicine, Boston, MA.

Background: Numeracy, the ability to comprehend, use, and attach meaning to numbers, is essential for understanding risk information. Previous research has demonstrated an association between low numeracy and impaired risk comprehension, but this relationship has not been explored in the context of genetic susceptibility testing for common diseases. As risk recall is commonly used to measure risk understanding, we hypothesized that individuals with low numeracy will show lower levels of risk recall than individuals with higher numeracy. **Methods:** Data were obtained through the Risk Evaluation and Education for Alzheimer's Disease (REVEAL) Study, a multi-site randomized clinical trial, in which lifetime risk of developing Alzheimer's disease (AD) and *APOE* genotype (an AD susceptibility polymorphism) were disclosed to individuals seeking a risk assessment for AD. Six weeks after disclosure, participants were asked to recall their lifetime risk, *APOE* genotype, and the number of risk-increasing alleles they were found to possess. Multivariate logistic regression was performed to determine whether recall was associated with mathematical aptitude (objective numeracy) and self-perceived mathematical abilities (subjective numeracy), as measured by two validated numeracy scales. The regression model was adjusted for age, education, gender, and race, as well as levels of cognition, distress, and anxiety, as measured by validated psychological scales. **Results:** Data from 236 participants were analyzed (mean age = 58.3 years; 54.2% female, 45.8% male; 86.9% Caucasian, 13.1% African-American; 94.5% with college education or higher). Of these, 136 (57.6%) were able to correctly recall all three measures of risk, whereas 100 (42.4%) were unable to recall at least one of these measures. Lower subjective numeracy was found to be a significant predictor of poorer recall (p = 0.04). **Conclusions:** Individuals with lower subjective numeracy have lower recall of genetic risk information. Lower risk recall may indicate decreased risk understanding and have negative consequences for medical decision-making. Genetic counselors should be aware that low numeracy is an obstacle to risk understanding and should tailor risk assessments to individuals' numerical abilities in order to provide optimal care.

1681/W

Molecular characteristics of Multiple epiphyseal dysplasia in sixty-nine Korean patients. *S. Park[1], H. Park[1,2], O.H. Kim[3], T.J. Cho[4], S.I. Cho[1], I.K. Yeo[1], H.R. Song[5], G. Nishimura[6], S. Unger[7], A. Superti-Furga[8], I.H. Choi[4], W.J. Yoo[4], J.S. Shim[9], H.W. Kim[10], C.Y. Chung[11], C.W. Oh[12], C. Jeong[13], K.S. Song[14], S.Y. Kim[1], M.W. Seong[15], S.S. Park[1].* 1) Department of Laboratory Medicine, Seoul National University Hospital, Seoul, Korea; 2) Yeon Cheon Health Center and County Hospital, Yeon Cheon, Korea; 3) Department of Radiology, Ajou University Hospital, Suwon, Korea; 4) Department of Orthopaedic Surgery, Seoul National University Children's Hospital, Seoul, Korea; 5) Department of Orthopedic Surgery, Korea University Guro Hospital, Seoul, Korea; 6) Department of Radiology, Tokyo Metropolitan Kiyose Children's Hospital, Kiyose, Japan; 7) Institute for Human Genetics, Freiburg University Hospital, Freiburg, Germany; 8) Center of Pediatrics and Adolescent Medicine, Freiburg University Hospital, Freiburg, Germany; 9) Department of Orthopaedic Surgery, Sungkyunkwan University Samsung Medical Center, Seoul, Korea; 10) Department of Orthopaedic Surgery, Yonsei University Severance Children's Hospital, Seoul, Korea; 11) Department of Orthopaedic Surgery, Seoul National University Bundang Hospital, Seongnam, Korea; 12) Department of Orthopedic Surgery, Kyungpook National University Hospital, Daegu, Korea; 13) Department of Orthopedic Surgery, Catholic University Holy Family Hospital, Bucheon, Korea; 14) Department of Orthopaedic Surgery, Keimyung University Dongsan Medical Center, Daegu, Korea; 15) Department of Laboratory Medicine, National Cancer Center, Goyang, Korea.

Background: Multiple epiphyseal dysplasia (MED) is a clinically and genetically heterogeneous group of diseases characterized by mild short stature, limb deformity, arthralgia and early-onset of osteoarthritis mainly in the hip and knee joints. At least six genes are reported to be causative : *COMP*, *MATN3*, *COL9A1*, *COL9A2*, *COL9A3* and *SLC26A2*. In this study, we present the molecular genetic characteristics of MED in 69 Korean patients who were preselected under the impression of MED. Methods: We sequentially analyzed exon 1, 2 of *MATN3*, exon 8-19 of *COMP*, exon 8, 9 of *COL9A1*, exon 3, 4 of *COL9A2*, exon 3 of *COL9A3*, entire three exons of *SLC26A2* and their flanking regions by direct sequencing, until any mutation was detected. Results: In fifty-nine out of 69 patients (85.5%), sequence variations which had already been reported to or were presumed to be causative for MED phenotype were identified. Thirty-three patients had mutations in *MATN3* gene (55.9%, 33/59), twenty-five in *COMP* (42.4%, 25/59), one in *COL9A2* (1.7%, 1/59), and one in *SLC26A2* (1.7%, 1/59). Mutations in *MATN3* and *COMP* genes were concurrently found in one patient. The most common genotype in this series was *MATN3*: c.361C>T (p.R121W), which accounted for 35.6% (21/59) of MED patients and 63.6% (21/33) of the *MATN3* gene mutations. Conclusions: We identified causative mutation of *COMP*, *MATN3*, *COL9A2* or *SLC26A2* in 85.5% of MED patients diagnosed clinically. Pattern of genotypes in MED patients in Korean population was different from those in other ethnic groups. Based upon this data, we believe that sequential analysis of *MATN3* gene followed by *COMP* and other genes would be an efficient way for the molecular diagnosis of Korean MED patients.

1682/T

VIVO: Enabling National Networking of Scientists. *M.R. Tennant[1,2], K.L. Holmes[3,4], S. Henning[1], M. Linnemeier[5], K. Börner[5], V. Davis[6], S. Russell Gonzalez[6], N. Ma[5], C. Tank[5], M. Conlon[7], VIVO Collaboration.* 1) Health Science Center Libraries, University of Florida, Gainesville, FL; 2) UF Genetics Institute, University of Florida, Gainesville, FL; 3) The Bernard Becker Medical Library, Washington University School of Medicine in St. Louis; 4) Department of Genetics, Washington University School of Medicine in St. Louis; 5) Cyberinfrastructure for Network Science Center, Indiana University; 6) Marston Science Library, University of Florida; 7) Clinical and Translational Science Institute, University of Florida.

VIVO is an open source semantic web application that enables discovery of research and scholarship across an institution. The VIVO application was developed by Cornell University in 2003 and today serves as the basis for $12.2M award by the National Center for Research Resources to facilitate national networking of scientists. There are seven partner institutions involved in the project: University of Florida (project lead), Cornell University, Indiana University, Ponce School of Medicine, The Scripps Research Institute, Washington University School of Medicine, and Weill Cornell Medical College. VIVO is populated with information about researchers and allows them to highlight areas of expertise, display academic credentials, visualize academic and social networks and display information such as publications, grants, teaching, service, and more. Profile information can be automatically imported from authoritative data sources such as institutional records, and bibliographic and grant databases. VIVO can offer a way to stay on top of the literature and keep current on the efforts of colleagues and competitors, alike. VIVO can help identify potential collaborators, events, seminars, programs, and facilities on the local campus and beyond. VIVO allows students to showcase their research - essential when applying for fellowships and post doctoral and faculty positions. VIVO is a resource to attract new students and faculty and offers them a way to visualize the academic environment virtually. It can be difficult to grasp cutting edge trends and identify collaboration networks, as science is often evolving faster than it can be documented. VIVO provides network analysis and visualization tools to maximize the benefits afforded by the data available in VIVO. VIVO enables high quality data to be revealed about researchers, their collaborators, their funding sources, and more. This data can serve as the foundation for further network analyses and elegant visualizations of the research enterprise on the individual, local, and global levels. There are a number of ways that you can get involved with the VIVO project: adoption, data provision, application development, and data consumption. The open source VIVO software and ontology are available for download at http://vivoweb.org. Over the next year, there will be many updates to the software and ontology and we look forward to participating in events that support collaboration and discovery.

Personalized Cancer Genetics Training for Personalized Medicine: Improving community-based health care through a genetically literate workforce. *K. Blazer[1], D. MacDonald[1], J. Culver[1], C. Huizenga[1], G. Uman[2], J. Weitzel[1].* 1) Clinical Cancer Genetics, City Hope Comprehensive Cancer Ctr, Duarte, CA; 2) Vital Research, Los Angeles, CA.

Context: Genetic cancer risk assessment (GCRA) is an established standard-of-care practice. Community healthcare providers are increasingly requested to provide cancer risk assessment and genetic testing, but many are inadequately prepared to provide these services. Objective: Develop and assess the efficacy of a multi-modal interdisciplinary course in GCRA for community-based practitioners that combines traditional and distance learning methods delivered in three phases to facilitate didactic learning, interdisciplinary training and continuing support for the integration of clinical GCRA skills and research participation into practice through CME Web-conference activities. Design and Participants: A prospective analysis of competitively-selected MDs, advanced-practice nurses (APNs)and genetic counselors (GCs), representing areas of need across the U.S.(selected based on geographic and/or underserved need) who participated in one of six sessions between 2006-2010. Outcome Measures: Assess the impact of the course on cancer genetics knowledge, cancer genetics risk assessment skills, professional self-efficacy, changes in practice and participation in research activities measured by multiple instruments at baseline, immediate- and 12-month-post course. Results: 131 participants(48 MDs,41 APNs,42 GCs) were included in the analysis. GCRA-related knowledge ($p<.001$; mean 28%;range 12.2%-38.5%) and skills ($p=.003$)increased significantly across all disciplines and cohorts. Subset analysis (n=49) showed significant increases in professional self-efficacy through 12-months post course. Significant increases reported in the number of alumni who provided GCRA services ($p=.018$), disseminated cancer prevention information ($p=.005$) and/or high-risk screening and prevention recommendations ($p=.004$), enrolled patients in a hereditary cancer registry ($p=.013$),and conducted educational outreach about GCRA ($p=.003$). Conclusions:Significant gains in GCRA-related knowledge,skills,self efficacy and practice change demonstrate the effectiveness of the multimodal, multiphase course. Sustained alumni participation in post-course professional development activities beyond the prescribed 12-month period has evolved into a dynamic distance-mediated Community of Practice in clinical cancer genetics. This innovative course models the goal of lifelong learning and improved patient care envisioned by the Institute of Medicine and other leading CME stakeholders.

1684/T

Baseline genetic knowledge among participants in the Coriell Personalized Medicine Collaborative. *M.A. Keller[1], E.S. Gordon[1], C.B. Stack[1], T.J. Schmidlen[1], M.F. Christman[1], M. Daly[2].* 1) Coriell Institute for Medical Research, Camden, NJ; 2) Fox Chase Cancer Center, Philadelphia, PA.

While historically physicians and genetic counselors were expected to interpret and understand genetic test results, the shift to direct-to-consumer testing in the area of genetics, increases the need for patients to have a baseline knowledge of genetics. The Coriell Personalized Medicine Collaborative (CPMC®) is a longitudinal observational study designed to investigate the utility of personalized genomic information in health management. Participants in the CPMC receive risk reports for a number of common complex diseases based on genetic and non-genetic risk factors and answer questions about what they did with the information. The CPMC enrolls adults into its “Community Cohort” directly through group informed consent sessions. These sessions are open to the public with additional sessions for employees of partner hospitals. In addition to required questionnaires related to medical and family history, participants were asked to complete a baseline genetic knowledge assessment consisting of 15 knowledge questions, and 5 genetic education background questions. As of December 2009, 2189 participants completed the genetic knowledge assessment. Sixty three percent of participants were female with an average age of 50 years. Respondents were predominantly Caucasian (93%) with a bachelor’s degree or higher (67%). Across all respondents, the mean score was 76% correct (11.4/15). Using an ANOVA model that adjusted for multiple participant characteristics, several demographic factors were found to be associated with the number of correct responses. Age was inversely associated with the number of correct responses, with younger individuals performing better than older individuals ($p<0.001$). Level of education (bachelors or graduate degree) was associated with an increased number of correct responses ($p<0.001$), as was employment in healthcare (as a physician, pharmacist or genetic counselor) or the life, physical, or social sciences ($p<0.001$). Males scored slightly higher than females (78% vs. 75% correct; $p<0.001$). There were no differences by income level ($p=0.74$). The fact that income did not contribute to differences in genetic knowledge suggests that there may be more equality in access to genetic education than previously thought. Further, the fact that on average, respondents with a high school diploma answered 67% correct suggests an overall basic understanding of genetics across the population.

1685/T

The concept of "Molecular Anatomy of the Cell" provides the link between molecular biology and human genetics. *J. Korabecny[1], M. Korabecna[2].* 1) FamilyCell, Pilsen, Czech Republic; 2) Faculty of Medicine in Pilsen, Charles University, Pilsen, Czech Republic.

We present "Molecular Anatomy of the Cell" as a new concept for teaching molecular biology and genetics during medical education. The users of the presented material (200 tables either in printed or electronic version) should be mainly undergraduate students not only at medical faculties -the material has been successfully applied also during education of biology teachers. The explanation of molecular biology is based on illustrations - icons - created by an experienced designer in cooperation with a teacher of biology and genetics. For creation of pictures of molecules, structures and their stereological relations, the programs allowing the 3D modeling used in designer practice were used (for example Rhinoceros). Molecular structures are depicted in agreement with the newest international textbooks of molecular biology with regard to the studies based on electron microscopy. The structures and events for presentations are selected to provide direct link to human genetics. The products of genes playing the known role in monogenic or complex diseases are especially mentioned together with the brief explanation of clinical problems connected the diagnosis with. For further reading, students can find OMIM numbers of the all in "Molecular Anatomy of the Cell" mentioned entries. This approach has been tested in practice at Faculty of Medicine in Pilsen (Charles University) and at the Faculty of Education (Westbohemian University) in Pilsen, it seems to stimulate the interest of students in further study and continuation in the field of human genetics having the logical link to basic principles of molecular biology. The work has been supported by grants of the Ministry of Education, Youth and Sport of the Czech Republic numbers C54-2008, C35-2009 and 14/89 - 2009.

1686/T

Social Networks as an strategy for Education in Genomic Medicine. *S. March, J. Bedolla, N. Alvarez, J. Avila, C. Davila, X. Soberon.* Education and Outreach, INMEGEN, Mexico, Mexico City, Mexico.

Conventional media such as tv, radio, printed ads or books, used to promote, diseminate or communicate ideas, products or information related to any topic are now in lower rate consumption. Actually, digital medias will increase the communications, and the way to keep in touch with people who wants to know about genomics. New generations are most of the time wired to various types of electronic devices such as internet. It is not rare social media to use as part of their daily lives. In developing countries such as Mexico, people between 12 and 25 years old are becoming more experience digital media users. Social media like Twitter, Facebook and YouTube are changing the way that many research centers contact their targets. The National Institute of Genomic Medicine (INMEGEN) started using social media as a tool for education in genomic medicine since 2008, using interactive or Multimedia CD (images, videos, sounds, animations) to give information to spanish speaker users. Real time web transmissions (RTWT) such as seminars, lectures, simposiums, among others, became one of the most important tools for the development of an educational platform in genomic medicine in Mexico. This strategy focus on scientific researchers, life sciences students, decision makers, politicians, the Mexican congress and general public. In 2009 we started to podcast information using Facebook (http://www.facebook. com/inmegen),Twitter (http://twitter.com/INMEGEN), Youtube (http://www.youtube.com/inmegen medios) purpose in order to attract talent into genomic medicine, as well as promote research and academic networks worlwide, and to get even closer to general public. In this first analysis from October 2009 until now, INMEGEN's podcasts have been downloaded for a total of 3541 times (http://www.inmegen.gob.mx/index.php?option=com_content&task=view&id=1071&Itemid=155&lang=en). The main users came from Mexico and China. RTWT have increased to 75 connected institutions for a 3750 audience in Mexico, USA and some Latin American countries. This educational effort contributed to support the national platform in the development of genomic medicine in Mexico, will allow Mexican society to promote the discussion of ethical and social challenges related to genomic medicine. In addition this communication strategy will lead to a better understanding of genomic medicine, its benefits for health care and the economic development of Mexico and Latin America.

1687/T

Building A Genomics Pathway. *M. Slifer.* HIHG, Univ Miami, Miami, FL.

Medical School Pathway Programs are designed to provide select medical students with additional education opportunities in areas of special interest relevant across medical specialties, as well as introduce these students to the potential of Physician Scientist research. Several medical schools have adopted the four year Pathway approach to enhance training in community-based and social medicine. In 2005, the University of Miami Miller School of Medicine, initiated a Pathway Program in Human Genetics and Genomics. The Pathway was built around a genetics and genomics lecture series and mentored Summer research projects. However, we experienced a 100% drop-out rate for what would have been the first graduating class. Student evaluations consistently expressed dissatisfaction with the emphasis on basic science research, and students struggled to appreciate its relevance to clinical medicine and Physician careers. Incorporating these concerns, the Pathway was revamped. For the lecture series, we developed a clinical case-based curriculum. Students were provided background materials to review prior to lectures. Then, expert lecturers presented cases and encouraged an open discussion of the relevant genetic bases, therapeutic options, and the family/social context impacting each case. Additionally, the summer research program was revised to provide more exposure to different facets within each student's research project. Among the changes, students are encouraged to attend clinics and clinical rounds in addition to their bench and/or informatics research. Satisfaction has improved (4.8 out of 5 on the Satisfaction scale) and Pathway retention is currently 24 of 26 medical students (8% drop-out). The two students who dropped, are pursuing other competing interests (student government, and a different research program) and neither student endorsed dissatisfaction with the present Genetics and Genomics Pathway. By aligning Pathway procedures with student preferences we are able to achieve Pathway educational goals and have increased participation, retention, and satisfaction with the Human Genetics and Genomics Pathway.

1688/T

Results from a survey investigating the background and training of pre- and post-doctoral fellows in statistical genetics and genetic epidemiology. *A. Wilson, M. Krishnan, The NIH Working Group on Statistical Geneticists Training Needs.* Genometrics Section, NIH/NHGRI, Baltimore, MD.

With increasing numbers of genome-wide association and sequencing studies being performed, the scientific community has been deluged with data that require scientists who can develop and perform statistical genetic analyses. There is concern that there are not enough scientists to perform these analyses. A survey was conducted in 2008-2009 to determine the number of pre- and post-doctoral trainees and their type of training and potential expertise. The survey also queried the background and expertise of their faculty level trainers, whether the number of training slots available was adequate and whether these positions were filled. Members of the International Genetic Epidemiology (IGES) were invited to participate through the IGES newsletters prior to the 2008 IGES annual meeting. A second notice went to the IGES membership at the end of January and to selected members of the American Society of Human Genetics. In February 2009, there were 391 responses, with 197 from faculty level trainers, and 96 and 100 responses from pre- and post-doctoral trainees, respectively. Sixty-one percent (105/172) of the Faculty level trainers had NIH funding, and 32% (55/171) had pre-doctoral students supported on NIH T32 training or F fellowship grants. The number of current pre-doctoral trainees per trainer was 2.4 (132 trainers) and the total number of pre-doctoral trainees "in the pipeline" was 318. Similarly, the average number of post-doctoral trainees per trainer was 1.2 (130 trainers) and the total number of post-doctoral trainees "in the pipeline" was 150. The most frequent response for the reason that training slots were unfilled was that there were not enough qualified domestic applicants. The distribution of pre-doctoral fellows (96) was roughly normally distributed with the largest number of pre-docs in their third year of training. At least 40% of the pre-doctoral trainees had not had a single formal course in the following disciplines: computational biology, computer science, genetics, mathematics, medical genetics, molecular biology, population genetics or quantitative genetics. The distribution of years of training for post-doctoral fellows was more uniform than that of pre-doctoral fellows, with 64% (51/80) having two or less years of training. Based on the distribution of length of post-doctoral fellowships, roughly 11 - 17 post-doctoral fellows complete training each year.

1689/T

Newborn Screening Clearinghouse: Access to Information for All. *N. Bonhomme[1], L. Simon[2], A. Harris[2], S.F. Terry[1].* 1) Genetic Alliance, Washington, DC; 2) Health Resources and Services Administration, Rockville, MD.

State newborn screening programs strive for quality and excellence in serving the newborns of our country, and they are constantly balancing these goals with limited resources and healthcare priorities. Individuals, families, and communities have an increased interest in health information, particularly in online and interactive forms. Despite the public's increased attention to health, parents are still generally unaware of the availability and need for newborn screening. Likewise, as increasing numbers of newborns are screened for more conditions, parents and healthcare providers have a growing need for centralized, easily accessible and accurate information. The Newborn Screening Clearinghouse (NBSC) is intended to connect parents and healthcare providers with information about the conditions screened, the programs screening and other available resources through a cooperative agreement between the Health Resources and Services Administration, Genetic Services Branch and Genetic Alliance. Genetic Alliance will partner with the National Newborn Screening and Genetics Resource Center, the Genetics and Newborn Screening Regional Collaborative Groups, March of Dimes, the Association of Public Health Laboratories and many other partners to build on resources already available. The NBSC will allow for extensive networking and resource sharing by improving activities already ongoing and creating new avenues for information exchange. It will create a central connection to informational resources and data on newborn screening quality indicators. The NBSC will be responsive to emerging technologies and the challenges that public health programs face. We will report on the status of the NBSC, its developing website, input from regional and national stakeholders, and future plans.

1690/T

Community genetics and health forums: a model community engagement program for leadership development. *L. Stark, H. Aiono.* Gen Sci Learning Ctr, Univ Utah, Salt Lake City, UT.

The Genetic Science Learning Center (GSLC) at the University of Utah used community-based education programs as a vehicle for collaboratively developing a Community Council. The programs engaged community leaders and members in learning about chronic diseases common in their community, the contributions of genetics and lifestyle choices to chronic disease risk, and the benefits of collecting a family health history. Leaders of diverse Salt Lake City, Utah communities were invited to apply for $5,000 mini-grants to support development and presentation of mini-forums on these topics in their communities. Based on their applications, grants were awarded to organizations representing the African American, African refugee, Chinese, Hispanic/Latino, Native American, and Tongan communities. The GSLC's Community Liaison worked with each community organization and its leaders to identify the chronic diseases of highest concern in their community, to design appropriate educational programs (mini-forums), and to identify suitable presenters. Family health history served as the "hook" to engage community members, since it personalized the information and made it relevant. Many programs used materials available on the GSLC's Learn.Genetics website (Connection Between Heredity and Health section at http://learn.genetics.utah.edu/content/begin/traits/activities/); culturally appropriate adaptations were developed for communities that requested them. The Community Leadership Team met monthly to collaboratively plan a multi-cultural forum involving all communities, which they titled Community Faces: A Genetics and Health Forum. These meetings supported the development of trusting relationships among community leaders and with participating University faculty/staff, enhanced members' leadership confidence and capacity, built their knowledge about genetics and health, and provided an opportunity to share and learn from each other's mini-forum experiences. The Forum provided a focus for the Team's work together and a common, successful sharing and learning experience. As a result of its experience with this project, the Community Leadership Team has decided to continue working together and is evolving into a Community Council. Funding for this project was provided by the Education and Community Involvement Branch of the NIH National Human Genome Research Institute with additional support from the University of Utah Center for Clinical and Translational Science.

A MICRORNA PROFILE FOR TWO CELL MODELS COMMONLY USED IN GENETIC EXPRESSION GENERATED BY MIRDEEP. *V. Williamson[1,3], A. Kim[1,2], B. Xie[4], O. McMichael[1], Y. Gao[4], V. Vladimirov[1].* 1) Psychiatry, Virginia Institute for Psychiatric and Behavioral Genetics, Richmond, VA; 2) Department of Human Genetics, Virginia Commonwealth University, Richmond, Va; 3) Integrative Life Sciences, Virginia Commonwealth University, Richmond, Va; 4) Center for the Study of Biological Complexity, Virginia Commonwealth University, Richmond, Va.

The discovery of microRNAs (miRNA) reshaped our appreciation of gene regulation. Deep sequencing is ideal for the absolute quantification of known and discovery of new miRNAs because of its decided depth and coverage. Next generation machines can produce 32 gigabytes of sequence in a single run with an average read length of 32 bases, which is more than adequate to study small non-coding RNAs such as miRNAs. We describe miRNA profiles for two, neuroblastoma derived (BE2-C) and lymphoblastoid (LC) cell lines, using the MiRDeep algorithm. MiRDeep employs a probabilistic algorithm of miRNA biogenesis to discover known and novel miRNAs species in a deep sequencing run(1). To indicate prediction strength, MiRDeep generates a score based on posterior Bayes statistics. This score indexes the number of times in which a read sequence conforms to traditional miRNA biogenesis as well as its overall frequency in the dataset. MiRNA precursors have a specific hairpin structure, which play an important role in the processing of the miRNA precursor. MiRNA hairpin structure formation is sequence dependent and highly specific to the miRNA species, allowing us to distinguish real miRNA hairpins from pseudo hairpins(2). MiRDeep allows the user to permute the sequence of predicted miRNA,thus to assess the reliability of such predictions. Also, some miRNAs show high evolutionary conservation across species, whereas others more recently evolved, are likely to be species specific. To answer this question we examined the overall level of species preservation of the novel predictions determining what degree these novel miRNAs can be considered uniquely human. In order to truly understand the role miRNAs play in gene regulation, we must first have adequate knowledge of cell models in which they are tested. Therefore we examine total (known and novel) miRNA expression profiles in both cell lines. We evaluate expression differences using chi-square statistics as previously shown(3). We observed significant differences in the level of expression in hsa-mir-17 and hsa-let-7g between the two cell lines ($\chi 2 = 69.94$, df=1, $p<0.0001$). The differences concerning hsa-mir-17 may be of note because this miRNA has been recently implicated in Schizophrenia(4). 1. M. Friedländer et al., Nat. Biotech 26:407(2008). 2. Jiang,P. et al., Nucleic Acids Research 35: 339(2007). 3. P.L. Auer et al. Genetics 110.114983 (2010). 4. N.J. Beveridge et al., Cellular Signaling 21:1837(2009).

A novel pathway analysis method to prioritize 'susceptibility pathways' in multigenic traits. *N. Akula[1], A. Baranova[2], D. Seto[3], J. Solka[3], M. Nalls[4], A. Singleton[4], L. Ferrucci[5], T. Tanaka[5], S. Bandinelli[6], Y.S. Cho[7], Y.J. Kim[7], J-Y. Lee[7], B-G. Han[7], BiGS. Consortium[8], F.J. McMahon[1].* 1) Mood & Anxiety Disorders, NIH, Bethesda, MD; 2) Molecular and Microbiology Department, George Mason University, Fairfax, VA; 3) Department of Bioinformatics and Computational Biology, George Mason University, Manassas, VA; 4) Molecular Genetics Section, Laboratory of Neurogenetics, National Institute on Aging, Bethesda, MD; 5) Longitudinal Studies Section, National Institute on Aging, National Institute of Health, Baltimore, MD; 6) Geriatric Unit, Azienda Sanitaria di Firenze, Florence, Italy; 7) Center for Genome Science, National Institute of Health, Seoul, Korea; 8) Scripps Genomic Medicine and Scripps Translational Science Institute and Dept of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA, USA; Dept of Psychiatry, Univ of Chicago, Chicago, IL, USA; Dept of Psychiatry, Portland VA.

Genome-wide association studies (GWAS) are a valuable approach to complex traits. However, single markers often fail to achieve levels of statistical significance required to withstand correction for multiple testing, and genetic association signals may fail to replicate. Alternative approaches that embrace the multi-genic basis of complex traits are needed. Here we introduce Network Interface Miner for Multigenic Interactions (NIMMI), a network-based method that combines GWAS signals with existing data from the human interactome. NIMMI builds biological networks using human protein-protein interactions (PPIs), weighted by connectivity estimated with a modification of the Google Page Rank algorithm. These weights are combined with genetic association p-values, thus producing what we call 'susceptibility networks'. There is no requirement for pre-selection of the most significant subset of SNPs, but users can specify SNP inclusion thresholds as desired. As a proof of principle, NIMMI was tested on 3 GWAS datasets previously analyzed for height, a classical polygenic trait. Despite the differences in sample size and ethnic background, NIMMI captured 100% of known height-associated genes within the top 20% of ranked networks and demonstrated its superiority to a single marker approach. A comparison of networks scored within the top 3% revealed significant enrichment in genes involved in the processes of development, signal transduction, transport, regulation of gene expression, nucleic acid, protein and zinc metabolism. All these networks were successfully replicated across all 3 GWAS datasets. NIMMI efficiently combines genetic association data with biological networks, thus prioritizing susceptibility pathways for further studies. NIMMI is a simple, user-friendly, open-source software tool which is available at http://mapgenetics.nimh.nih.gov/datashare.html.

CIDRSeqSuite: Software Utilities for Automation of Next-Generation Sequencing Tasks. *M.W. Barnhart, S.M.L. Griffith, K.N. Hetrick, J.L. Goldstein, D. Mohr, B.A. Marosy, D.R. Leary, B.D. Craig, L. Watkins, Jr., K.F. Doheny.* IGM/CIDR, Johns Hopkins Univ/CIDR, Baltimore, MD.

The Center for Inherited Disease Research provides high quality genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to common disease. In exploring next-generation sequencing technologies, CIDR found the need to automate a variety of bioinformatic workflows and analyses. Developed at CIDR to run on 64-bit Linux, CIDRSeqSuite is a highly configurable collection of Java 1.6 and Perl software tools that processes sequencing data generated by Illumina's GAII instrument. The suite also allows users to generate quality control reports, perform analyses, and annotate SNP data via SeattleSeq. By wrapping open source tools, CIDRSeqSuite automates workflows that would otherwise require several independent steps at the command line. For example, using a single command, a set of Illumina raw sequence output (qseq.txt files) is processed through to SNP list generation with QC metrics summary reports generated at various stages of the analysis. Available reports include capture efficiency (used for targeted resequencing projects), SNP transition/transversion ratio, allelic composition of all reads at a given genomic position, and summary coverage statistics for targeted regions. In addition, the software can compare SNP genotype calls between array data and sequencing data. Also available are graphical outputs such as quality-score box plots and nucleotide distributions. Command-line utilities allow conversion among various file formats, e.g., SAM to BAM and vice versa, and between the Sanger, Solexa, and Illumina FASTQ formats. Additionally, CIDRSeqSuite contains a workflow that estimates capture efficiency after the first read of a paired-end run has been completed, allowing CIDR to save instrument time and to reprioritize samples for resequencing in the event of a laboratory problem, such as an error during the target sequence enrichment process. Current work involves demultiplexing qseq.txt files for GAII indexed-sample runs in order to provide a workflow independent of vendor-supplied tools. Each user can customize CIDRSeqSuite to launch specific versions of the wrapped programs: Maq, BWA, Picard, SAMTools, Bowtie, and FASTX-Toolkit. CIDRSeqSuite can adapt dynamically to its runtime environment, making the best use of available computing resources. This software has enabled CIDR to assess next-generation sequencing data quality quickly while reducing human error.

Genetic ME - A visualization application for merging and editing pedigrees for genetic studies. *D.K. Bui[1], M.C. Ortube, MD[2], D.E. Weeks, PhD[3], A. Martinez, MS, MS[2], Y. Conley, PhD[4], M.B. Gorin, MD, PhD[2]*. 1) David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Department of Retinal Disorders and Ophthalmic Genetics, Jules Stein Eye Institute, Los Angeles, CA; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 4) Department of Health Promotion & Development, School of Nursing at University of Pittsburgh, Pittsburgh, PA.

Purpose: In order to study the genetics of diseases more accurately and effectively, software is needed to facilitate the reconciliation of genetic information collected independently from multiple members of the same family. We identified a need for an application that would allow for the visual comparison, editing, and merging of overlapping pedigree structures given by related individuals to create a unified pedigree for family-based studies with a clear mechanism for tracking that reconciliation process.

Methods: Genetic ME is a Java application designed to meet the need mentioned above. It leverages the existing technology of Cranefoot, a powerful and flexible open source pedigree drawing tool. It provides a graphical user interface (GUI) that allows users to view two pedigrees and their corresponding familial, demographic, clinical, and genotyping data side by side for easy comparison. Mock family data was created and used to assess the capabilities of this new application.

Results: Using the GUI, users can edit current individuals' information, add new individuals, or remove existing individuals from the displayed data. Users can reconcile differences between the two displayed pedigrees by applying one of three merging algorithms (replacement of an individual or branch from one pedigree by the other, combination of data from one pedigree into another, and appending individuals and sublineages from one pedigree to the other). Individuals and data can be merged from pedigree #1 to pedigree #2 or vice versa. The application then displays the merged pedigree with the new changes for approval before any modifications are saved into a new composite file. The original and resulting text files are stored in tab-delimited format and the graphic files in Portable Network Graphics (PNG) format for future use. Tracking is implemented so that all of the changes made to the data set for the individuals and to create the merged pedigree can be tracked to their original source material.

Conclusion: Genetic ME is an open source Java application developed for the ease of viewing, editing and merging pedigree structures and for comparing and reconciling disparate clinical or genetic information of individuals from two or more sources. An executable file and source code will be available for download in fall 2010.

Phylogenetic analysis of the human microflora. *E.R. Chan, J. Hester, D. Serre*. Genomic Medicine Institute, Cleveland Clinic Foundation, Cleveland, OH.

Advances in DNA sequencing technology have expanded our ability to study the impact of the microflora on human health and disease. This impact is not trivial considering the microbiome contains over 100 times the genes in the human genome. A common method of capturing the diversity of the microflora is by sequencing of the 16S ribosomal RNA gene. This gene is required in all prokaryotic cells and has highly variable regions flanked by conserved regions which allows for 1) amplification using universal primers and 2) phylogenetic analysis and taxonomic identification. Deep sequencing of this gene provides a comprehensive view of the species that are contained in a particular microbial environment but requires novel methods to analyze the massive amounts of data that can now be generated. Previous taxonomic approaches compared individual sequences to a database of annotated 16S rRNA sequences which relies on the sequences (or closely related sequences) to be in the database, accuracy of the database, as well as the algorithm developed to match the sequence to the annotated entries. Alternatively, a phylogenetic approach has been developed to infer global differences in bacterial composition between microenvironments by examining a phylogenetic tree comprised of all the sequences captured. This method can distinguish whether there is an overall difference in the microflora between samples but provides no taxonomic information of the bacteria involved. Here we describe a novel method of analyzing deep sequencing data of 16S rRNA genes using a phylogenetic approach which incorporates a dynamic hierarchical tree cutting method to define groups of similar bacteria irrespective of their annotation (or lack thereof). The advantage of this approach is that taxonomic information can still be applied to these defined groups using existing 16S rRNA databases. We apply this method to examine the microflora composition in cases and controls for several pilot studies including a study on colorectal cancer in humans and the effects of bariatric surgery using a rat model. We also apply our method to a previously published data set involving TLR5 knock-out mice. We believe that the method described here will significantly improve our understanding of the role of the microflora on human disease by providing a comprehensive analysis of the microbiome and identifying communities whose proportion differs with regards to disease state without the need for previous annotations.

Updated Tools for Genomic DNA Alignments. *D. Church, R. Agarwala, N. Bouk, C. Clausen, V. Schneider, A. Astashyn, D. Maglott, M. DiCuccio.* NCBI,NLM,NIH, Bldg 38A Rm 6S614K1, Bethesda, MD.

The decreased cost of sequencing has led to an increased cost of the analyses of these sequences. The increased burdens associated with sequence analysis can be seen in tasks ranging from read production to the analysis of assembled genomes. Many projects, including read analysis of sequences from second generation sequencing machines, alignment of assembled sequences to identify large-scale genomic variation and the alignment of individual de novo assemblies to each other require robust alignments to a reference assembly . NCBI has been working to provide a suite of tools to improve genomic analysis specifically in the area of genomic alignments. Additionally, tools to interrogate and visualize these alignments are being developed. We have focused our efforts in four areas: (1) producing alignment algorithms that take advantage of modern assemblies that represent allelic diversity(such as the human public reference assembly, GRCh37), (2) producing alignments that can better represent structural variation, (3) producing more robust assembly-assembly alignments and (4) providing better tools for interrogation and visualization of alignment data. We will demonstrate the use of these tools in numerous applications, including the alignment of second generation sequencing data to GRCh37 and the alignment of structurally variant BAC and fosmid clones to GRCh37. Additionally we will introduce a new tool called NCBI Remap (http://www.ncbi.nlm.nih.gov/genome/tools/remap), which allows users to project features from one genome assembly onto another. NCBI Remap produces mapping summaries, feature by feature reports, as well as remapped annotation data than can be loaded to most browsers. Additionally, the results, along with the underlying assembly-assembly alignments, are packaged in files that can be visualized using our client-side genome analysis tool, Genome Workbench (http://www.ncbi.nlm.nih.gov/projects/gbench). Finally, we will present a comparison of the NCBI Remap tool to the UCSC lift-over tool. Acknowledgments Work at NCBI is supported by the NIH Intramural Research Program and the National Library of Medicine.

MutaREPORTER software to define, characterize and archive mutations leading to human genetic disease. *M. Devisscher[1], F. Decouttere[1], K. De Boulle[2], P.J. Willems[2].* 1) Genohm, Zwijnaarde, Belgium; 2) GENDIA, Antwerp, Belgium.

Only a small fraction of the mutations causing genetic disease have been published in the literature or listed in public mutation databases, Consequently, the clinical significance of many novel mutations remains undetermined. To address these problems we developed MutaDATABASE, a standardized, centralized, and free open access database, and MutaREPORTER, specific software, which is designed to define, characterize and archive variations in human disease genes. MutaREPORTER has bidirectional communication with MutaDATABASE as it both retrieves all existing information out of MutaDATABASE, and also allows easy entry of new data, including novel mutations into MutaDATABASE. This makes submission of novel variations to an integral part of the diagnostic workflow. All new information sent by MutaREPORTER to MutaDATABASE is verified by an assigned MutaCURATOR before entry into MutaDATABASE. MutaREPORTER also contains an integrated organized communication tool, allowing groups of genetic labs that offer diagnostic testing for the same gene (MutaCIRCLES) to discuss novel gene variations, additions to the phenotypic spectrum and unusual findings related to that specific gene with all members of that MutaCIRCLE. MutaREPORTER is a Flex-based Web 2.0 application with a user friendly interface that specifically targets genetic labs. The performance of the visualization engine is assured by semantic zooming, view porting and a caching mechanism. The underlying architecture makes the framework easily extensible with future tools and functionalities. MutaREPORTER currently provides: • Access to all info in MutaDATABASE • A genome browser with comprehensive, user-customizable, track-based views of the genomic sequence, gene structure, protein sequence, and conservation. • A variation checker that checks whether the HGVS nomenclature has been issued to describe the variation • Facilitated access to prediction tools that are important in the assessment of the pathogenicity of variants (Splice site prediction, SIFT, POLYPHEN) • Possibility to automatically import variants from in-house databases (requires some software that interacts with the lab's LIMS) • Possibility to easily submit variants into MutaDATABASE, both graphically as by using HGVS nomenclature • Possibility to communicate with other genetic labs that offer diagnostic testing for the same gene (MutaCIRCLES).

1698/W

From candidate to modifier genes, non-coding RNA in genetic diseases with miRiFix database. *M. Girard[1], S. Bandiera[1], C. Mugnier[2], M. Le Merrer[1], A. Munnich[1], S. Lyonnet[1], A. Henrion Caude[1].* 1) Inserm U781, Department of Genetics, Hopital Necker-Enfants Malades, University Paris Descartes, Paris, France; 2) University Paris Descartes, Paris, France.

Identification and analysis of microRNAs (miRs) enhance our understanding of the important roles that non-coding RNAs play in complex regulatory networks. However, there are still few data supporting the involvement of miRs in Mendelian disease inheritance other than cancer. MiRs may be regarded either as candidate gene within a disease locus, or as putative modifier gene, which can regulate the expression of a given disease-causing gene. At this latter level, single nucleotide polymorphisms (SNPs) within the target gene add a supplemental layer of complexity. Herein, we present a comprehensive resource, aimed at linking small and long non-coding RNAs with hereditary diseases : mirifix.com. MiRiFix is an easy-to-use, web-accessible framework of tool and data integration. Our model crosses up-to-date information on human miRs and the Genatlas database, which provides integrated data on gene mapping and genetic diseases. MiRiFix enables to systematically explore the computational involvement of miRs in the pathogenesis of diseases, and retrieves : (i) miR as a candidate gene from a locus, using the updated compendium of human miRs and their mapping information, (ii) a set of miRs predicted to regulate a disease-causing gene, in both its 3'-UTR and coding sequence, using distinct algorithms, and finally (iii) a set of SNPs predicted to be functional in terms of miR regulation. We will present the efficiency of miRiFix in predicting previously established links, but also in retrieving novel data on mapped diseases orphan of identified genes. Our web resource provides a unique integrated way to assess computational roles of non-coding RNAs in hereditary disease.

1699/W

The Functionality of Missense Mutations is Dependent on both the Algorithm and Multiple Sequence Alignment. *S. Hicks[1], S.E. Plon[2,3], D.A. Wheeler[2], M. Kimmel[1].* 1) Department of Statistics, Rice University, Houston, Texas; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas; 3) Texas Children's Cancer Center, Department of Pediatrics, Baylor College of Medicine, Houston, Texas.

Large-scale sequencing projects yield missense mutations with unknown biological significance. Several computational algorithms have been developed to predict the impact of missense mutations on protein structure and function. Informative classification is highly dependent on the algorithm of choice and the parameters used in the algorithm. The goal of this study is to investigate the variability in predictions of missense mutations from three commonly used algorithms with four different multiple sequence alignments, each having their own bias towards a particular algorithm. The three methods, SIFT, Align-GVGD, PolyPhen-2 were evaluated using both a small number of common polymorphisms (n=4) and a large number (n=140) of cancer associated missense mutations from the TP53 mutation IARC database (http://www-p53.iarc.fr/). We also evaluated a more recent method Xvar (http://xvar.org) and will include it in the analysis as the ability to accept a users alignment becomes available. We compared the results from each algorithm providing the following alignments: (1) a small highly curated alignment with long evolutionary depth ideal for Align-GVGD, (2) an uncurated alignment automatically generated in Uniprot using the built in ClustalW feature with sequences included based on a criteria of 90% or 50% identity, (3) an automatically generated alignment from SIFT, and (4) an automatically generated alignment from PolyPhen-2 with a wide breadth of sequences. Using manually curated alignments the results show PolyPhen-2 had a slightly higher specificity than Align-GVGD and SIFT. In contrast, all of the programs dramatically change their predictions using uncurated alignments. As the number of sequences in the alignment increases, Align-GVGD dramatically overcalls variants as neutral for example it miscalls all 140 deleterious variants as neutral when using the PolyPhen-2 or 50% identity alignment. In contrast, Polyphen-2 cautiously predicts variants as neutral when there are a limited number of sequences in the uncurated alignment, but as the number of sequences increases the algorithm is able to make a more informed prediction. Similar results are seen using a larger set of missense mutations with sufficient evidence of clinical neutrality from the BRCA1 and BRCA2 mutation database (BIC). Thus, informative classification is dependent on the algorithm used, the number of sequences in the alignment, and whether or not the alignment has been manually curated.

Identifying differential expressed genes and detecting full length transcripts with mRNA-seq data. *W. Huang, L. Li.* NIEHS, NIH, Research Triangle Park, NC.

Next-Gen sequencing-based mRNA-seq has been increasingly used for identifying novel transcripts and differential expressed genes. The lack of computational methods and tools for analyzing mRNA-seq data, however, limits its broad adoption for biomedical research. The widely used mRNA-seq applications include identification of differentially expressed genes in comparative studies, and detection of full length transcripts. To facilitate mRNA-seq data analysis from these applications, here we describe a new statistical framework for identifying transcripts with different abundance levels among different samples. In addition, we present a computational strategy for locating full length transcripts using paired-end read data. We also introduce a new efficient tool, EpiCenter, for analyzing mRNA-seq data. Some key features of our methods are: 1) multiple traditional and novel data normalization procedures adapted for different scenarios, 2) accounting for large variability of read depth of coverage to reduce false discovery rate, and 3) computationally efficient. To test effectiveness of our methods, we applied our methods and tools to two real whole genome mRNA-seq data for mouse and *Schizosaccharomyces* pombe, respectively. We then compared the results with those from microarray data analysis from the same samples. While the results from mRNA-seq data and microarray data are largely consistent, the comparison suggests mRNA-seq is more powerful than microarray in detecting true differentially expressed genes.

CEP290*base*: A Unique Overview of *CEP290* Mutations and Their Associated Phenotypes. *S. Lefever, F. Coppieters, E. De Baere.* Center for Medical Genetics, Ghent University, Ghent, Belgium.

Mutations in *CEP290* may cause a wide spectrum of partially overlapping ciliopathies, ranging from isolated Leber Congenital Amaurosis to the lethal Meckel-Grüber syndrome. Although some mutations seem to be phenotype-specific, others segregate with distinct diseases. In addition, the phenotype is highly variable, probably due to the presence of modifier alleles in other members of the ciliary proteome. The goal of this study was to design a locus-specific database for mutations in the *CEP290* gene, containing both genotypic and phenotypic information. The database was created using MySQL. PHP and JavaScript were used to develop the web-based interface. Mutation nomenclature is according to the HGVS guidelines. CEP290*base*(http://medgen.ugent.be/CEP290base) contains all mutations in *CEP290* published so far, including detailed information on their pathogenic potential. The database links to dbSNP, UniProt and OMIM and automatically fills in queries for PolyPhen and SIFT. In addition, a comprehensive description of phenotypic features is provided for each patient in different systems (ocular, renal and neurological). The database lists all variants in both an overview and graphical representation, and offers easy access to patients and variants through several query possibilities. For patients with *CEP290* mutations, variants in other genes can also be included, thereby providing the opportunity to link modifiers to associated clinical manifestations. Last but not least, users can submit novel or known variants they have identified. In conclusion, CEP290*base* offers the first comprehensive locus-specific mutation database of all mutations identified in *CEP290* to date, and their associated phenotypes. The database contributes to the establishment of genotype-phenotype correlations, and may assist in providing prognostic information for a patient with *CEP290*-related pathology.

1702/W

On the identification of condition specific sub-networks from microarray gene expression profiles. *H. Ma[1], E. Schadt[2], L. Kaplan[3], H. Zhao[4].* 1) Program in Computational Biology and Bioinformatics,Yale University, New Haven, CT; 2) Pacific Biosciences, Menlo Park, CA; 3) Gastrointestinal Unit and MGH Weight Center, Massachusetts General Hospital and Department of Medicine, Harvard Medical School, Boston, MA; 4) Department of Epidemiology, Public Health and Genetics, Yale University, New Haven, Connecticut.

[Background] The identification of condition specific sub-networks has important biological applications such as selecting disease-associated biomarkers as well as discovering alterations in regulatory or signaling pathways across different phenotype groups. In this paper, we propose a new method of extracting condition specific sub-networks from microarray gene expression data, COSINE (COndition SpecIfic sub-NEtwork). COSINE uses a scoring function that jointly considers the differential expression of single genes and the differential co-expression patterns of gene pairs, and that employs the genetic algorithm to search for the sub-network that maximizes the scoring function among sets of different conditions. [Results] We compare COSINE with other methods on both simulated data with various patterns of expression alterations, and real data from cross population comparisons among HapMap samples. The results demonstrate that COSINE is more powerful in terms of identifying the truly significant sub-networks of appropriate size and meaningful biological interpretation. Additionally, the weight parameter λ in the scoring function allows for fine tuning the relative emphasis on single gene differential expression versus gene pair differential co-expression, thereby providing more flexibility in the structural feature of the selected sub-networks. Pathway enrichment analysis of the identified networks from the HapMap dataset shows that a number of immune related pathways play a leading role in differentiating the expression profiles across human populations, an observation that may not be identified using traditional analytical methods. [Conclusions] Our new method COSINE has a number of advantages over existing methods to identify meaningful responsive sub-networks from several gene expression profiles. The network perspective and global optimization approach can be very helpful in understanding the conditional changes of important biological processes.

Tertiary Analysis For Variant Detection In Next-Generation Datasets. *D. Mohr[1], B. Craig[2], B. Marosy[2], K. Hetrick[2], M. Barnhart[2], S. Griffith[2], J. Goldstein[2], A.F. Scott[1], K.F. Doheny[2].* 1) Genetic Resources Core Facility (GRCF) High Throughput Sequencing Center, Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Center for Inherited Disease Research (CIDR), Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

As next generation sequencing becomes more readily available, more and more investigators that lack access to dedicated bioinformaticians are finding themselves overwhelmed with analysis of large datasets. Many facilities will provide primary and secondary analysis (basecalls in fastq format and initial alignment to reference in SAM or vendor format), but few open access facilities have the capacity to offer tertiary analysis (variants, indels, etc), and if they do, the investigator is left to mine these lists for biologically meaningful information. Many commercial solutions are available, but are often cost prohibitive and/or lacking features essential for variant detection. At the GRCF High Throughput Sequencing Center, using CIDRSeqSuite, Illumina base calls are converted to fastq format, aligned to reference, converted to pileup format, duplicates are marked and filtered to produce variant lists, and subsequently submitted to and annotated by the SeattleSeq SNP annotation server. Here we present a tertiary workflow using readily available open source tools, including Sequence Variant Analyzer (SVA), Integrated Genomics Viewer (IGV), Polymorphism Phenotyping (PolyPhen), and SeattleSeq to mine potential variants generated by high throughput sequencing.

1704/W

Exome sequencing allows for rapid gene identification in a Charcot-Marie-Tooth disease family. *G. Montenegro[1], E. Powell[1], J. Huang[1], Y. Edwards[1], G. Beecham[1], W. Hulme[1], C. Siskind[2], M. Shy[2], J. Vance[1], S. Zuchner[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Neurology and Center for Molecular Medicine and Genetics, Wayne State University School of Medicine, Detroit, MI.

Charcot-Marie-Tooth (CMT) disease comprises a large number of genetically distinct forms of inherited peripheral neuropathies. The relative uniform phenotypes in many patients with CMT make it difficult to decide which of the over 35 known CMT genes are affected in a given patient. Genetic testing decision trees are therefore broadly based on a small number of major subtypes (e.g. CMT1, CMT2) and the observed mutation frequency for CMT genes. Since conventional genetic testing is expensive many rare genes are often not being tested at all. As a novel and alternative approach whole exome sequencing has recently been introduced. This method is capable of re-sequencing the near complete set of coding exons of an individual. We performed whole exome sequencing in an undiagnosed family with CMT. Across 40 neuropathy related genes screened by this approach we identified a non-synonymous GJB1 (Cx32) mutation, V95M. This variant had been reported previously as pathogenic in X-linked CMT families. Sanger sequencing confirmed complete co-segregation in seven affected individuals. Affected individuals had a marked early involvement of the upper distal extremities and displayed a mild reduction of nerve conduction velocities. We have shown for the first time in a genetically highly heterogeneous dominant disease that exome sequencing is a valuable method for comprehensive medical genetic diagnoses. Further improvements of exon capture design, next-generation sequencing accuracy, and a constant price decline will soon lead to the adoption of genomic approaches in gene testing of Mendelian disease.

1705/W

The Gentrepid candidate gene prediction web server. *M. Oti[1], J.Y. Liu[1], S. Ballouz[1,2], D. Fatkin[1,2], M. Wouters[1,2].* 1) Victor Chang Cardiac Research Institute, Sydney, NSW, Australia; 2) University of New South Wales, Sydney, NSW, Australia.

Gentrepid (https://www.gentrepid.org/) is a web resource which predicts and prioritizes candidate disease genes for both Mendelian and complex diseases. It uses two approaches to prioritize candidate disease genes, Common Pathway Scanning (CPS) and Common Module Profiling (CMP). CPS assumes specific phenotypes are associated with dysfunction in proteins that participate in the same complex or pathway and applies network data derived from protein-protein interaction and pathway databases to identify relationships between genes. CMP is based on the hypothesis that disruption of genes of similar function will lead to the same phenotype and identifies likely candidates using a domain-based sequence similarity approach. In a benchmark using Mendelian diseases, the two methods had a combined sensitivity of 0.52 and specificity of 0.97, reducing the candidate list by 13-fold. Another benchmark against highly significant Type II Diabetes GWAS SNP data resulted in a sensitivity of 0.18 and a specificity of 0.96 while reducing the candidate list by 19-fold, indicating its applicability to complex diseases as well. These approaches are also applicable to candidate gene prediction in other species. Here I describe the Gentrepid system and its web interface.

MutationTaster - Rapid evaluation of the disease-potential of sequence alterations. *J.M. Schwarz[1,2], C. Rödelsperger[3,4], M. Schuelke[1,2], D. Seelow[1,2].* 1) Neuropaediatrics, Charité - Universitätsmedizin Berlin, Berlin, Germany; 2) NeuroCure Clinical Research Center, Charité - Universitätsmedizin Berlin, Berlin, Germany; 3) Institute for Genetics, Charité - Universitätsmedizin Berlin, Berlin, Germany; 4) Max Planck Institute for Molecular Genetics, Berlin, Germany.

With the advent of Next Generation Sequencing, the search for disease mutations is currently shifting from a single gene approach to sequencing the whole exome, complete linkage regions or large numbers of candidate genes simultaneously. These approaches inevitably reveal numerous exonic or intronic alterations (recent studies suggest more than 1,000 alterations per Mbp in one individual). Testing all of them for their disease potential is obviously not feasible, so there is a growing need for an automated pre-evaluation. However, currently available prediction tools only analyse single amino acid substitutions and are usually not able to process hundreds or thousands of queries in a reasonable time.

We have therefore developed MutationTaster, a web-based application aimed at the prediction of the disease potential of DNA sequence alterations in humans. MutationTaster incorporates many different biological analyses such as amino acid exchanges, evolutionary conservation, the loss of protein features or of splice-sites and hence allows a better distinction between harmless and disease causing alterations. Moreover, it can also analyze intronic or silent alterations.

The prediction is generated by a naïve Bayes classifier which was trained with more than 500,000 SNPs validated by HapMap, 8,000 InDel polymorphisms, and 55,000 known disease mutations, leading to a ratio of correct predictions above 90%. The evaluation of a single alteration usually takes less than 0.3 seconds, making MutationTaster an ideal tool for the analysis of the high numbers of alterations found by Next Generation Sequencing. For this task, we additionally offer alignment software which handles raw data from all common deep sequencing platforms as well as scripts for batch analysis of the alterations found. Besides, we designed an intuitive web interface for the query of single alterations. The software is freely available at http://www.mutationtaster.org.

To our knowledge, MutationTaster is the first comprehensive application covering the whole process from raw Next Generation data to the prediction of the disease potential of the detected alterations.

1707/W

The GeneCascade - a website for the identification of disease genes and the evaluation of sequence alterations. *D. Seelow[1,2], J.M. Schwarz[1,2], M. Schuelke[1,2].* 1) Neuropaediatrics, Charité - Universitätsmedizin Berlin, Berlin, Germany; 2) NeuroCure Clinical Research Center, Charité - Universitätsmedizin Berlin, Berlin, Germany.

We have developed a comprehensive software suite for identification of disease genes and prediction of the disease potential of sequence alterations. Our suite consists of 3 intuitive tools, is completely web-based and freely accessible at http://neurocore.charite.de/. **HomozygosityMapper** (http://www.homozygositymapper.org) allows the rapid identification of disease-linked regions in individuals with an inbreeding background. It is based on a model-free algorithm, robust against genotyping errors and numbers of magnitudes faster than conventional linkage analysis. HomozygosityMapper detects candidate regions and displays the underlying genotypes graphically. For each candidate region, it provides a direct link to GeneDistiller. Researchers can at any point decide to share their results with co-workers or to make them publicly accessible on our website; HomozygosityMapper can hence be used as a public repository. **GeneDistiller** (http://www.genedistiller.org) is our candidate gene search engine which integrates data from various biomedical databases. It displays all genes within a genomic region or from a list of candidate genes with user-selected gene-specific data such as molecular function or known corresponding phenotypes. GeneDistiller can highlight interesting features and score similarities or interactions with known disease genes. Users can sort and filter genes by any of their properties. Besides, GeneDistiller offers a user-driven ranking of the genes placing the most likely candidates on top of the list. This process remains transparent and researchers can interactively adjust prioritisation settings on behalf of their own background knowledge and expectations. The last step in identifying disease-causing mutations is the sequence analysis of candidate genes or of whole linkage intervals and the evaluation of every single alteration detected. Our tool, **MutationTaster** (http://www.mutationtaster.org), scores the disease potential of exonic as well as of intronic sequence alterations by various tests for different protein and gene properties. It outperforms most similar applications in terms of accuracy (>90% correct predictions) and speed (<0.3s). It also provides an interface to automatically analyse the vast number of alterations found by *Next Generation Sequencing* and to manage the results.

1708/W

Methods for analyzing next-gen whole exome sequence variation in small pedigrees with unknown diseases. *M. Sincan[1,2], TC. Markello[1,2], DA. Adams[1,2], K. Fuentes-Fajardo[2], H. Carlson-Donohoe[1,2], C. Toro[2], C. Tifft[2], PF. Cherukuri[3], JK. Teer[3], P. Cruz[3], N. Hansen[3], JC. Mullikin[3,4], WA. Gahl[1,2].* 1) Medical Genetics Branch, NIH/NHGRI, Bethesda, MD; 2) NIH Undiagnosed Diseases Program, NIH, Bethesda, MD; 3) Genome Technology Branch, NHGRI, NIH Bethesda MD; 4) NIH Intramural Sequencing Center, NIH, Bethesda MD.

Next generation sequencing technologies are becoming more available as a tool to diagnose genetic causes of diseases. We have sequenced 28 individuals from 8 families with undiagnosed diseases. Our families include both affected and unaffected individuals. Each family has three or four individuals with one or two affected individuals. The power of next gen sequencing gives us a very long list of potentially disease causing variations that are shared among various members of the families. For our families, the number of variants is between 79,710 and 107,817. Using conserved domain based analysis to determine the potential deleteriousness of these variants can reduce the number of variants to between 6,051 and 7,613. This is still a very big number to analyze. To this end, we have applied Mendelian filters to check if genotypes of family members are concordant with affected and unaffected status and various Mendelian inheritance models that are not in conflict with the current pedigree. The nature of our problem, i.e. dealing with undiagnosed diseases, forces us to apply different possible inheritance models. After we remove the positions that are not compatible with our filter, we still end up with a list of variants numbering in the hundreds for a single family. We also applied filters based on other families and SNPs that have frequency information. We assume that our cases are most likely rare diseases, if we find the same variants in other families and/or in dbSNP with a reasonable frequency, we flag them as potentially less likely to cause the disease in question. We found that it is a complex task to search for disease causing changes in the human genome, but data available to meta tag the variome is becoming increasingly available and tools we develop let us cross match our patients' data to this growing body of information. We illustrate the tools we have developed to make these analyses.

1709/W

Prioritizing loci by gene category analysis implicates SNPs of moderate effect on serum lipid levels. *A.V. Smith[1,2], E. Losievskaja[1], G. Eiriksdottir[1], T. Aspelund[1,2], L. Launer[3], T. Harris[3], V. Gudnason[1,2].* 1) Icelandic Heart Association, Kopavogur, Iceland; 2) University of Iceland, Reykjavik, Iceland; 3) National Institute on Aging, National Institutes of Health, Bethesda, MD, USA.

A major issue in the understanding and interpretation of genome-wide association studies is missing heritability. One hypothesis is that additional variants not reaching stringent levels of significance contribute to additional heritability; notable recent work on schizophrenia has demonstrated more inclusive sets of SNP increase explained variation (International Schizophrenia Consortium Nature 2009). While this type of approach suggests many additional hits of moderate effect, it does not provide any mechanism for prioritizing particular regions or genes of biological interest to a disease. Since numerous published association scans have observed clear enrichment of specific gene categories, we hypothesized that SNPs at moderate p-value could be prioritized on a genome-wide basis using gene categories to more efficiently reveal SNPs of moderate effect than sets chosen solely via p-value threshold. We have tested this hypothesis using association scans on serum lipid levels in the AGES-Reykjavik study. Leveraging a novel in-house pipeline which identifies gene categories significantly enriched in a genome scan, we first identified Gene Ontology Biological Process categories which are significantly enriched in association scans of LDL cholesterol, HDL cholesterol and TG levels in two publicly available studies (Willer et al. Nature Genetics 2008; Kathiresan et al. Nature Genetics 2009). A number of lipid metabolic processes are clearly enriched in these scans (including, for example, "Triglyceride Metabolic Process" and "High-density Lipoprotein Particle Remodeling"). We subsequently examined whether SNPs from additional loci in the same categories not reaching genome-wide significance themselves are significantly associated beyond expectations in the independent AGES-Reykjavik cohort. We have observed that these prioritized, category-based SNP sets significantly increase explained variation in the AGES-Reykjavik cohort, and to a greater level than any observed from comparable sets of SNPs prioritized solely using p-value thresholds in the discovery sets. By comparing the seed gene sets from the two starting scans, this increased predictability extends beyond effects attributable to new hits from increased sample size. These results suggest that prioritizing loci by gene categories associated with top hits could speed the discovery of additional variants with disease at more moderate levels.

1710/W

One-way cryptographic hashes to detect overlapping individuals across samples. *M.C. Turchin[1,2], J.N. Hirschhorn[1,2,3].* 1) Program in Genomics and Divisions of Genetics and Endocrinology, Children's Hospital, Boston, Massachusetts, United States of America; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and Massachusetts Institute of Technology, Cambridge, Massachusetts, United States of America; 3) Department of Genetics, Harvard Medical School, Boston, Massachusetts, United States of America.

To achieve sufficient power for discovery, genome-wide association studies often involve consortia in which investigators share summary association statistics but not individual level data due to IRB and/or consent-related restrictions. Because studies sometimes recruit in overlapping areas, there may be undetected duplication of individuals across studies, which could lead to inflation of meta-analysis association statistics. We have developed a tool to search for identical individuals across different samples by comparing one-way-encrypted hashes derived from individual-level data that is only shared by investigators in this strongly encrypted format.

Cryptographic hash functions are algorithms that produce a unique output for every unique input, and make it extremely difficult to reconstruct inputs from the outputs . By splitting individual-level data into many small groups of SNP genotypes, and creating hashes for each group of genotypes, one can quickly compare lists of encrypted values to identify duplicated individuals. Ideally, at genotype accuracies of 100%, duplicate individuals should produce identical sets of cryptographic hashes. In practice, because of missing data and genotype errors, the majority of hashes will match, and given enough sets of genotypes, the level of matching will rise well above that expected by chance.

We developed a software package, gEncrypt, which implements this cryptographic hash procedure. We applied gEncrypt to the GoKinD data set available from dbGAP. This data set contains 5 individuals who, based on near perfect genetic identity, were either genotyped twice or have identical twins in the study. We split the dataset into two halves, with one of each of the duplicate pairs residing in each half. The two resulting datasets were encrypted using gEncrypt, and the resulting lists of cryptographic hashes were compared against one another. The resulting data identified all 5 pairs of duplicate individuals with >80% identity of the hash outputs. gEncrypt could enable investigators from different studies to compare genomic datasets across studies for the presence of identical (and perhaps closely related) individuals, with minimal risks to individual-level privacy.

Preterm Delivery: A Novel Bioinformatics and Genomics Approach. *A. Uzun[1,2,4], S. Sharma[1], G.D. Papandonatos[3], S. Istrail[3], J.F. Padbury[1,4].* 1) Pediatrics, Women and Infants Hospital, Providence, RI; 2) Center for Computational Molecular Biology, Brown University; 3) Center for Statistical Sciences, Brown University; 4) Brown Alpert Medical School.

Statement of purpose Preterm birth (PTB) in the United States is now 12.7 %. Premature infants have an increased risk of neonatal mortality as well as serious health problems. The governing paradigm is that term and preterm births involve parallel mechanisms. Labor occurs via similar final common pathway(s). Clinical care and investigations into the etiology of PTB have relied heavily on the assessment of these pathways. Nonetheless, the pathogenesis has remained elusive. New tools are needed to interrogate this enigmatic disease. **Methods** We have developed a web-based aggregation tool to create a database for the genes, genetic variations and pathways involved in preterm birth, the *Database for Preterm Birth* (dbPTB). dbPTB was implemented using a MySQL database running on a Linux server with PERL and PHP scripts used for all data retrieval and output. dbPTB uses *SciMiner* to extract the gene and protein information from published articles specific to PTB. All articles deposited to dbPTB were reviewed by a team of curators consisting of researchers and students trained in the molecular and cell biology of PTB. Genes identified from public databases, archives from expression arrays and genomic regions from linkage analyses are aggregated with genes curated from literature. Lastly, pathway analysis is used to impute genes from pathways identified in the curations. **Summary of results**Our aim is to have the complete set of putative genes involved in PTB from these in silico sources. Computational analysis will be used to identify minimally informative set of SNPs and/or haplotype blocks to compare the genetic architecture in a case controlled comparison preterm vs. term births. It is also important to recognize that the approach we have developed is generalizable to other diseases. To date, dbPTB identified 898 putative genes which are supported by 817 journal articles, drawn from a total of 18 million records in PubMed, 5053 unique MeSH terms, and 28,712 unique entries in HGNC. The pathways and articles which carry information about PTB and related links to bioinformatics sources in dbPTB include UCSC Genome bioinformatics, OMIM, NCBI Entrez Genes, and HGNC. Development of new tools and databases allow researchers to visualize problems in broad extensions. Building biological databases is an approach that will enable biomedical informatics to contribute new insights into disease pathogenesis and novel treatments.

1712/W

MARVEL: genome-scale variant annotation and prioritization for human genetic studies. *O. Valladares[1,2], M.R. Han[1,2], L.D. Hwang[3], E. Clevac[1,2], K. Cao[1,2], B.B. Gregory[4,5], G.B. Schellenberg[1,6], L.S. Wang[1,2,5,6].* 1) Department of Pathology and Laboratory Medicine, University of Pennslyvania, Philadelphia, PA; 2) Penn Center for Bioinformatics,University of Pennslyvania, Philadelphia, PA; 3) Bioengineering Graduate Program; 4) Master of Biotechnology Graduate Program; 5) Penn Genome Frontiers Institute; 6) Institute on Aging, University of Pennsylvania.

The latest wave of high-throughput genotyping and sequencing technologies has brought enormous success but also challenges of analyzing data with unprecedented size both in numbers of sample and loci. To address the finding that simple association tests such as GWAS only explain part of the observed heritability, new strategies using functional knowledge and rare variants and mutations with strong effects are necessary. These approaches require flexible and comprehensive bioinformatic solutions that incorporate functional genomic data in an automatic fashion. We report MARVEL (Multiple Annotation of Relevant Variants, Elements, and Loci), a LAMP application that annotates and prioritizes genetic variants using public functional genomic databases. MARVEL currently accepts SNPs from next generation DNA sequencing and genome-wide SNP arrays. MARVEL carries out two types of annotations: (1) location-wise annotation identifies affected genes, transcribed regions, and other functional elements such as eSNPs; (2) sequence-dependent annotation predicts the strength of impact on the function and structure of protein by amino-acid substitutions. MARVEL supports password-protected login and provides a web-based interface that allows users to filter and rank variants, link to external databases, and view on the UCSC genome browser directly. We tested MARVEL on a whole-exome targeted Solexa sequencing dataset on a Linux desktop with 2.4Ghz Intel Core2 CPU and 2GB RAM. MARVEL annotated 89,753 SNPs in 11 seconds and identified 6,029 synonymous and 10,161 non-synonymous exonic SNPs on 5,960 genes, and 430 published eSNPs. A beta version of MARVEL is currently available as a web service (wanglab.pcbi.upenn.edu/marvel) and as a standalone download in September 2010. We plan to add support for indels by sequencing and CNVs from SNP and aCGH arrays, and tissue/disease-specific annotation capabilities.

1713/W

KARMA: K-tuple Alignment with Rapid Matching Algorithm. *X. Zhan, P. Anderson, Y. Li, G. Abecasis.* Center for Statistical Genetics, Biostatics, University of Michigan, Ann Arbor, MI 48109.

Rapidly evolving sequencing platforms are transforming the analysis of DNA sequence data, with many studies generating whole genome sequence data for hundreds or thousands of individuals. Accurately handling these data poses many computational challenges. One of these concerns the accurate alignment of short DNA sequence reads. An accurate aligner should be able to adapt to reads of varying quality, gracefully handle repeated regions of the genome, use base quality information, effectively use computational resources, and allow for polymorphism in the reference. With these goals in mind, we are developing KARMA, a hash-table based aligner, that handles Illumina and ABI SOLiD short read sequence data and can handle ~1 Gigabase of sequence per CPU per hour. We will describe performance metrics for our aligner, including accuracy of alignments, and provide several illustrative use cases. We will also illustrate several of the features currently under active development.

1714/W

Pathway Analysis for Multiple Traits in Genome-Wide Association Studies. *J.G. Zhang[1], J. Li[1], H.W. Deng[1,2,3].* 1) Dept Basic Med Sci, Univ Missouri, Kansas, Kansas City, MO; 2) College of Life Sciences & Bioengineering, Beijing Jiaotong University, Beijing, P. R. China; 3) Systematic Biomedicine Research Center, University of Shanghai for Science and Technology, Shanghai, P.R. China.

Pleiotropy, a phenomenon that single genes contribute to multiple phenotypes, is commonly observed in studies of human complex diseases. The availability of genome-wide association study (GWAS) provides an opportunity for systematically analyzing pleiotropic genes and deciphering the genetic architecture of complex diseases. Although a set of correlated phenotype data related to complex diseases of interest are usually collected for GWAS, these phenotypes tend to be analyzed separately in a single-trait analysis framework. This strategy ignored potential genetic correlations among phenotypes and hence may miss pleiotropic genes that can play crucial roles in the pathogenesis of diseases. In this study, we develop a method to identify potential pleiotropic pathways and genes by incorporating multivariate analysis and gene set analysis. We also elaborate the reduction of irrelevant SNPs and the extraction of a core set of candidate pleiotropic SNPs, which contribute to the statistical variation of phenotypes of interest. The utility of our method is demonstrated through analyses on empirical GWA data. The results show that our method can detect pleiotropic pathways and genes responsible for affecting hip bone mineral density and body mass index. In summary, our method offers a powerful tool for researchers to examine the pleiotropic pathways and genes associated with complex human diseases, and can be a useful complement to classical GWAS analyses in a single-trait analysis framework.

1715/W

Managing multi-platform next generation sequencing data - a unified approach. *X. Zhang[1,2], Q. Chen[1,2], M. Yeager[1,2], K. Jacobs[1,2].* 1) Core Genotyping Facility, SAIC-Frederick Inc., NCI-Frederick, Gaithersburg, MD; 2) Division of Cancer Epidemiology and Genetics, NCI,NIH, Bethesda, MD 20892, USA.

The complexity and volume of the data produced by Next Generation platforms such as Roche's 454 FLX, ABI's SOLiD, Illumina's GA, HiScan, and HiSeq, and Pacific BioScience's SMRT sequencers pose many data management challenges. The NCI's Core Genotyping Facility has developed architecture and an automated data management pipeline to support multiple sequencing platforms to standardize the laboratory data management and make data processing automatic, transparent, efficient, and reproducible. The data architecture accommodates the need for capturing all of the important information required or generated during a workflow for a sequencing research project. The automated pipeline takes a project manifest and raw image data produced by sequencing platforms as input, and execute the tasks that will: perform image and signal analysis to produce base calls, sequencing reads, and pre-alignment QC metrics; align sequencing reads to a reference genome; generate standard SAM/BAM files with required genomic annotations; perform post-alignment QC, and filter out failed reads/alignments, samples and sequencing runs; generate QC and executive reports including summary statistics and granular coverage plots; call SNPs and structural variations; manage project storage space by implementing a data retention policy that serves as a guide for compression and automated data archiving. The data architecture and pipeline has been applied in several exome and targeted sequencing projects, and has significantly reduced turnaround time for sequencing data generation, QC, analysis, and delivery.

1716/W

GeneDistiller - the interactive search and prioritization of candidate disease genes. *M. Schuelke[1,2], J.M. Schwarz[1,2], D. Seelow[1,2].* 1) Neuropaediatrics, Charité - Universitätsmedizin Berlin, Berlin, Germany; 2) NeuroCure Clinical Research Center, Charité - Universitätsmedizin Berlin, Berlin, Germany.

Linkage studies often yield intervals containing several hundred positional candidate genes. Different manual or automatic approaches exist for the determination of the gene most likely to cause the disease. While the manual search is very flexible and takes advantage of the researchers' background knowledge and intuition, it may be very cumbersome to collect and study the relevant data from a plethora of public databases. Automatic solutions on the other hand usually focus on certain models and algorithms ranging from protein interactions to text mining approaches, but remain 'black boxes' and only offer a very limited degree of flexibility. The main disadvantage of these approaches is the neglect of the researchers' previous knowledge or their concept of the character of a certain disease.

We have therefore developed a freely available web-based application that combines the advantages of both approaches. Information from various data sources such as gene-phenotype associations, organ/tissue-specific gene expression patterns and protein-protein interactions was integrated into a central database. Researchers can define a list of genes of interest by specifying a candidate interval or by directly entering candidate genes. They can select which information shall be displayed and taken into account for the candidate gene search. Genes can thus interactively be filtered, sorted and prioritized according to criteria derived from the background knowledge and preconception of the researcher.

GeneDistiller provides knowledge-driven, fully interactive and intuitive access to multiple data sources. It displays maximum relevant information, while saving the user from drowning in the flood of data. A typical query takes less than two seconds, thus allowing an interactive and explorative approach to the hunt for the candidate gene. The results of the search can be printed or saved as HTML pages or as Excel-files. GeneDistiller can be freely accessed at http://www.genedistiller.org.

1717/W

Autosomal chromosomal abnormalities in genome wide association studies. A report from the Mayo electronic MEdical Records and GEnomics Network (eMERGE) Study. *H. Jouni[1], K. Shameer[1], Y.W. Asmann[2], M. de Andrade[2], C.G. Chute[2], I.J. Kullo[1].* 1) Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 2) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN.

Background: The phenotypic correlates of autosomal chromosomal abnormalities detected in genome wide association studies (GWAS) are unknown. **Methods:** As a part of the eMERGE consortium, 3,412 patients were recruited for a GWAS of peripheral arterial disease (PAD-1,687 cases and 1,725 controls). Genotyping was performed using the Illumina Human 660W-QuadV1 platform (561,490 SNPs/95,876 intensity-only probes). Three Illumina algorithms (cnvPartition1.2.1, LOH detector, and ChromoZone) were run using Log R ratio and B-allele frequency data to identify regions with copy number variation, loss of heterozygosity (LOH), and mitotic events. A chromosomal abnormality was defined as having an aberration exceeding 20% of a chromosome's total length. The electronic medical record (EMR) of these patients was reviewed to ascertain associated disease states. **Findings:** Intensity plots were abnormal in 25 patients: LOH (8), mitotic events (8), deletions (del=6), and amplifications (3). We focused on 5 patients who had interstitial deletions of 20q, of whom 4 had a myeloproliferative disorder (MPD) [polycythemia vera (2), essential thrombocythemia (1), myeloproliferative/myelodysplastic syndrome, unclassified (1)]. All 3 men in this group had PAD and prostate cancer (Ca) in addition to MPD. Bioinformatic analysis of del20q showed a common deleted region (38511024 bp® 48638502 bp) encompassing ~10 Mb. When compared to human reference genome (GRCh37/hg19), the common deleted region was found to include ~118 candidate genes that could be implicated in MPD/ PAD/ prostate Ca. We also implemented a novel data mining technique using hierarchical clustering of overlapping International Classification of Disease codes which successfully detected the 3 men with MPD, PAD, and prostate Ca.

Characteristics of the 5 Patients with 20q Deletions

Age	Gender	Atherosclerotic Disease	Hematologic Disorder	Other Significant Medical History
75	M	PAD	Polycythemia vera	Prostate cancer and squamous cell carcinoma
84	M	CAD/PAD	Myelodysplastic/Myeloproliferative disorder, unclassified	Prostate cancer and basal cell carcinoma
87	M	CAD/PAD	Essential thrombocythemia	Prostate cancer and squamous cell carcinoma
70	F	None	Polycythemia vera	Pulmonary arterial hypertension, multiple sclerosis, and pyoderma gangrenosum
72	F	PAD	persistently elevated ESR of unknown etiology	Premature atherosclerosis: PAD diagnosed at age 62

CAD: coronary artery disease - PAD: peripheral arterial disease.

Conclusion: In a GWAS of 3,412 adults, we detected autosomal chromosomal abnormalities in 25 patients. Mining of the EMR in these patients can yield novel insight into disease pathophysiology. We identified a subset of 5 patients with del20q, of whom MPD was present in 4, and all 3 men had prostate Ca and PAD. We plan further correlation studies of autosomal chromosomal abnormalities with disease states leveraging the eMERGE consortium of ~18,000 adults with high density genotyping data linked to the EMR.

1718/W

PedHunter 2.0 and the Anabaptist Genealogy Database (AGDB). *W.-J. Lee[1], T.I. Pollin[2], J.R. O'Connell[2,3], R. Agarwala[1], A.A. Schaffer[1].* 1) National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, DHHS, 8600 Rockville Pike, Bethesda, Maryland 20894, USA; 2) Department of Medicine, Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, 660 W. Redwood Street, Baltimore, Maryland 21201, USA; 3) Animal Improvement Programs Laboratory, Agricultural Research Service, United States Department of Agriculture, 10300 Baltimore Avenue, Beltsville, Maryland 20705, USA.

Version 1.0 of the software PedHunter was released in 1998 to solve optimal pedigree connection problems and other problems related to pedigree construction, verification, and analysis. PedHunter 2.0 released in 2010 supports 50 queries in four categories: 1) testing a relationship; 2) finding all individuals satisfying a certain relationship; 3) printing information; and 4) complex queries. Additionally, PedHunter 2.0 provides seven utility programs including pedigree trimming and pedigree renumbering. PedHunter was initially designed to search the Anabaptist Genealogy Database (AGDB), which is described below. PedHunter has also been used to construct genealogies for linkage and haplotype analyses on Hutterite families, an Icelandic population, a Southern Italy population, and a Northern Italy population. PedHunter is freely available and can be downloaded from http://www.ncbi.nlm.nih.gov/CBBresearch/Schaffer/pedhunter.html. There have been several versions of AGDB based on three genealogy sources and multiple updates. AGDB version 4.0 (AGDB4), containing 417,789 individuals and 102,341 marriages, was created in 2004. The numbers of individuals from the three sources in AGDB4 are 30,821, 66,014 and 376,152, among which only 1,122 individuals are commonly found in all three sources. Usage of the AGDB requires an Institutional Review Board (IRB)-approved protocol to study an Amish or Mennonite population. Several groups have used AGDB in their research on rare and common diseases. Although AGDB contains no explicit phenotype data, lifespan can be inferred when both birth and death dates are available. Several studies on lifespan using AGDB have established that lifespan is heritable, that lifespan may be associated with other implicit traits, and that lifespan can be associated with experimentally measured traits. Using newly available updates to two of the AGDB genealogy sources, we are preparing AGDB version 5 (AGDB5) and expect it to contain at least 100,000 more individuals than AGDB4. Using PedHunter 2.0 to query AGDB4, we quantified the extent to which the Old Order Amish (OOA) are a closed population ideal for elucidating the role of genetic variation. Specifically, we quantified the number of founders and their genetic contribution to ~34,000 presumed living Lancaster County, Pennsylvania OOA individuals born in 1930-2000. The completion of AGDB5 will enable us to update OOA studies to include individuals born in 2000-2009.

1719/W

The Genome-Wide Annotation Repository (GWAR). *B. Winfrey, J. Giles, W. Bush.* Ctr Human Genetics, Vanderbilt Univ Medical Ctr, Nashville, TN.

The explosion of high-throughput data collection approaches for biological sciences and the analysis of their results has dramatically expanded the amount of information available for annotation of existing result sets and the generation of new hypotheses. Often, the results of an individual analysis are published in a stand-alone database or are simply released as flat-files, which limits their utility in other analyses. To address these issues, we constructed the Genome-Wide Annotation Repository (GWAR) to centrally house and inter-relate analysis results and genomic annotations from multiple sources. These include SNP-based annotations, such as expression QTLs (eQTLs) and sites of selection, and gene-based annotations, such as KEGG or Reactome pathway membership or protein structure families. Currently, information within the repository can be used in a variety of ways to conduct analysis of genome-wide association data, including enrichment analysis using PARIS, and epistasis analysis using Biofilter and ATHENA. As new data sources are added to the repository, they become available for downstream analysis tools allowing novel re-analysis of existing GWAS data. Possible analyses include enrichment by protein family or transcription factor binding site rather than traditional pathways, or epistasis analysis among eQTLs for genes in a relevant biological process from the Gene Ontology (GO).

1720/W

TE-scape of the Human Regulome. *W. Makalowski[1], A. Pande[1], I. Makalowska[2].* 1) Institute of Bioinformatics, University of Muenster, Muenster, Germany; 2) Laboratory of Evolutionary Genomics, Adam Mickiewicz University, Poznan, Poland.

At least half of of the human genome originated in transposable elements (TEs). It is not surprising then that TE-originated genome fragments affect many cellular processes. Using publicly available data and computational tools we investigated their role in the human genome both as dynamic collaborators to robust controllers. This prompted us to look for the TEs as performers contributing to bi-directional promoters regions, cis regulatory modules (CRMs) and insulators. Bidirectional gene organization is defined as two genes arranged head to head on opposite strands with less than 1,000 bp between their transcription start sites. It was suggested that bidirectional organization may provide stronger resistance to invasion by transposable elements, which is possibly one of the reason why many important genes, e.g. 30% of housekeeping genes, are arranged in this way. Interestingly, 67% of the analyzed human biderctional genes contain TEs in their promoter regions. Cis regulatory modules are at the heart of differential gene regulation for generation of patterns and the diversity of cell types in a multicellular organisms. These are genomic regions that are bound by transcription factors (TFs) that control spatio-temporal gene expression in developmental networks. Our analysis of the human CRMs derived from the TiGER database revealed that TEs occupy 48% of these “rewireable” networks, regulating different facets of developmental dynamics. Moreover, 36% of the tissue specific enhancer regions in the human genome originated in TEs. Probing into the diversity of differential gene expression leading to diversity of cell types took us to the insulator regions within the human genome. These zinc-finger protein binding sites are involved in several transcriptional mechanisms, such as gene repression and enhancer blocking. Our analysis shows that a significant fraction of the CTCF binding sites derived out of TEs. This leads credence to the contribution of TEs to expression and robust control of the nucleosome and genome dynamics through regulation and control by virtue of “action-at-a-distance”. Undeniably, TEs act as catalysts in functional resilience for the transcriptional networks in the human genome. A resonating presence within promoters, insulators, enhancers, and the cis regulatory networks reflects their modulatory propensity through evolution.

Genomic Reconstruction of the Evolutionary History of DUF1220 Domains. *M. O'Bleness[1], L. Dumas[1], H. Kehrer-Sawatzki[2], J. Sikela[1].* 1) Human Medical Genetics and Neuroscience Programs, Department of Pharmacology, University of Colorado School of Medicine, Aurora, CO 80045 USA; 2) Institute of Human Genetics, University of Ulm Albert-Einstein-Allee 11 89081 Ulm, Germany.

One of the most evolutionarily striking copy number variations (CNVs) that has been identified to date is the dramatic human lineage-specific amplification of a 65 amino acid protein domain of unknown function, DUF1220. Sequences encoding DUF1220 domains are increasingly amplified generally as a function of a species evolutionary proximity to humans, where the greatest number of copies is found (218). DUF1220 domains are virtually all primate specific and are typically found within the NBPF (neuroblastoma break point factor) gene family. Recently 1q21.1 CNVs that either encompass or flank DUF1220 domains have been implicated in a number of human diseases, including microcephaly, macrocephaly, autism, schizophrenia, mental retardation and heart disease, suggesting a link between DUF1220 amplification and the etiology of these disorders. The recent availability of numerous mammalian genome sequences presents an opportunity to investigate the evolutionary history of DUF1220 domain amplifications in unprecedented detail. To accomplish this, available mammalian genome sequences were interrogated and all DUF1220 domains and the genes in which they are found were identified. Interestingly previously unidentified NBPF genes were found in several non-primate mammalian genomes (only recently made available and heretofore not known to contain NBPF genes), and a newly identified non-primate mammalian conserved promoter region, upstream of several NBPF genes, was also identified. These new findings represent the most complete picture of DUF1220 evolution so far reported and lend further support to the view that there have been strong selection pressures that favored the rapid copy number expansion (~16 copies added/Myr in human lineage since the homo/pan split) of these domains over recent evolutionary time.

SequenceVariantAnalyzer: Software for the annotation, visualization, and analysis of variants emerging from whole-genome and whole-exome sequencing. *D. Ge[1,2], E.K. Ruzzo[1], M. He[1], D.B. Goldstein[1].* 1) Center for Human Genome Variation, Duke Univ, Durham, NC; 2) Department of Biostatistics and Bioinformatics, Duke Univ, Durham, NC.

SequenceVariantAnalyzer (SVA) is a user-friendly software tool designed for the interrogation and interpretation of human genetic variants identified by next-generation sequencing studies. This software environment allows the simultaneous analysis of multiple genomes, each of which can be stratified by basic phenotypic information (case or control status). SVA takes as input a set of genetic variants (differences from a reference genome) from one or more genomes and allows users to visualize these variants in their genomic contexts using a built-in genome browser. The “annotation module” is the preliminary routine within SVA which functions to give each genetic variant a genomic context based on the SVA interface with publicly available databases, such as dbSNP and Ensembl. The annotation module also classifies each identified variant based on its predicted biological function into major “functional categories”, such as “premature stop” or “nonsynonymous coding”. This annotation also enables the user to filter the entire list of identified variants based on many important properties, including: genotype, presence in case or control genomes, functional category, or genomic location. In addition to this detailed characterization of each identified variant, SVA can also carry out a variety of association tests based on phenotypic designations for all variants or for select groups of variants. These tests comprise the “analysis module” and are used to prioritize the genetic variants by their observed association with, or contribution to, the human disease or biological trait of interest. Both the annotation and analysis modules within SVA allow for user-customization based on hypotheses about the biological trait of interest. The computational performance of SVA (maximum memory usage and time requirements) has been thoroughly evaluated using both whole-genome and whole-exome sequencing data. The performance of SVA exhibits its feasibility for use in large next-generation sequencing datasets, especially for large whole-exome studies where the computational demands are nominal. The biological utility of SVA has been demonstrated through its application to two datasets where the genetic causes of two human diseases were readily identified from whole-genome sequencing data. SVA is available at: http://www.svaproject.org/.

Differential analysis to identify genome-wide DNA methylation markers using enrichment-based sequencing data. *Y. Xu[1,2], A. Ting[1], H. Hu[1,2].* 1) Quantitative Hlth Sci, Cleveland Clinic, Cleveland, OH; 2) Statistics, Case Western Reserve University, Cleveland, OH.

DNA methylation is an epigenetic modification of human and mammalian genomes, involved in both normal developmental processes and disease states through the modulation of gene expression and the maintenance of genomic structure. Study of whole genome DNA methylation profiles may hold substantial promise for identifying mechanisms through which genetic and environmental factors jointly contribute to disease risk. Next-generation sequencing technologies have emerged as powerful tools for whole-genome profiling of epigenetic modifications, and there is great interest in strategies for analyzing genome-wide/whole-genome DNA methylation data using high-throughput next-generation sequencer. We propose an integrated statistical and computational approach that conducts the differential analyses of methylation profiles in a multiple comparative study design. Our method is particularly suitable to the clinical data from large patient populations that need to correlate with patient groups and clinical parameters. We applied our approach to a colon cancer study with whole-genome methylation profile data generated using MBD-isolated Genome Sequencing (MiGS) with the Illumina Genome Analyzer II. The results are validated using the conventional bisulfite sequencing.

1724/W

A high-throughput analytical pipeline for genome-wide association scans. *X. Deng[1,2], Z. Wang[1,2], Q. Chen[1,2], M. Yeager[1,2], G.S. Tobias[2], M.A. Tucker[2], S.J. Chanock[2], K.B. Jacobs[1,2].* 1) Core Genotyping Facility, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD 21702, USA; 2) Division of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD 20892, USA.

The NCI's Core Genotyping Facility (CGF) has built a robust and high-throughput analytical pipeline that has been used to perform over 12 Genome-wide Association Studies (GWAS) on multiple cancer sites including: prostate, breast, pancreas, lung, kidney, bladder, testes, gastric, and brain. These scans included subjects collected from many large cohorts and case/control studies. Our data infrastructure facilitates creation of datasets for quality control, population characterization, and association analysis, drawing genotypes from multiple projects that often combine genotypes across genotyping platforms, assays panel, laboratory processing methods, and genotyping centers. Genome-wide SNP assays from Illumina (317K, 240S, 370K, 550K, 610K, 660K and 1M, Omni1, and OmniExpress) and Affymetrix (500k and 6.0) are harmonized across various assay products and versions, as the different chip content is non-uniform and often uses conflicting identifiers and annotation, e.g. different dbSNP and human genome builds. The genotype calling process is designed to reduce differential misclassification that often occurs when combining data from samples collected, prepared, or genotyped heterogeneously. Phenotype information from various sources are harmonized and stored according to a common schema, which facilitates downstream analyses. The data infrastructure is highly automated and all analysis and data deliveries are versioned and tracked via a formal build process. Once a GWAS genotype/phenotype dataset has been built, the pipeline performs standard analyses, which include comprehensive genotype QC, duplicate detection/verification, population admixture analysis (model based and PCA), reference panel and missing SNP imputation, genotype-phenotype association analysis, CNV data export and segmentation. The pipeline proves highly efficient and robust particularly for conducting GWAS on data merged across multiple Illumina chip types. Funded by NCI Contract No. HHSN261200800001E.

1725/W

Identifying Sets of Susceptibility SNPs Using Generalized Ridge Logistic Regression. *Z. Liu[1], Y. Shen[1], J. Ott[1,2].* 1) Beijing Institute of Genomics, Chinese Academy of Sciences, No.7 Bei Tu Cheng West Road, Beijing 100029, China; 2) Rockefeller University, 1230 York Avenue, New York, NY 10065.

In genome-wide case-control association studies, association scan statistic is a powerful approach to detect susceptibility genomic regions and map disease-causing genes located on them. However, this method suffers from several drawbacks: (1) It is not always easy to determine the size of each sliding window, where different sizes may lead to different results; (2) linkage disequilibrium (LD) within local genomic regions is seldom taken into account; (3) consecutive genetic makers are simultaneously selected, which can lead to much "noise" and thus reduce power. In order to overcome these disadvantages of association scan statistics, we propose a novel method for identifying sets of susceptibility single-nucleotide polymorphisms (SNPs) based on a forward model selection procedure, using generalized ridge logistic regression (GRLR) for stepwise fitness. GRLR imposes a proper penalty on each SNP in the genomic region of interest based on its distance from the region center. Our method automatically combines information from local chromosomal regions and selects sets of genetic markers that are not necessarily adjacent to each other and whose associated significance levels are evaluated in randomization samples. In simulation studies, we compare the performance of our method with that of five other methods in current use, including standard logistic regression, Fisher product method, truncated product method, Lasso logistic regression and the elastic net method. Results show that in most scenarios our method outperforms the other methods. We also present a published whole-genome dataset on age-related macular degeneration with approximately 100 cases and 100 controls and 10,000 SNPs, where our method successfully detects a set of two SNPs whose associated empirical p-value is less than 0.05.

1726/W

Systematic Removal of Outliers Reduces Heterogeneity in Case-Control Association Studies. *Y. Shen[1], Z. Liu[1], J. Ott[1,2].* 1) Beijing Institute of Genomics, Chinese Academy of Sciences, No.7 Bei Tu Cheng West Road, Beijing, China 100029; 2) Rockefeller University, 1230 York Avenue, New York, NY 10065.

In human case-control association studies, population heterogeneity is often present and can lead to increased false positive results. Various methods have been proposed to remove its deleterious effects, including genomic control (GC), principal component analysis (PCA), and multidimensional scaling (MDS). We assume that heterogeneity is due to a relatively small number of individuals (outliers) whose allele or genotype frequencies differ from those of the remainder of the sample. For this situation, we propose a novel method of handling heterogeneity as follows: In a coordinate system of the largest four principal components in MDS, we systematically remove one after another of the most extreme outlying individuals and each time compute the largest association test statistic and its associated p-value. Generally this leads to a gradual decrease of the resulting p-values (increase of significance) even though individuals are removed from the dataset. We stop when the p-values begin to increase again and take the smallest p-value as our overall test statistic, whose associated significance level is assessed in randomization samples. In power simulations of our methods and three other approaches in current use, averaged over various scenarios, our method is often more powerful than genomic control and standard logistic regression although the overall best method turned out to be the logistic regression analysis with MDS components as covariates. We also apply our method and the other approaches discussed above to two published datasets: One is a genome-wide dataset with 541 case and control individuals and approximately 408,000 SNPs, where our method has better performance than other methods; the other is a genome-wide dataset with 96 cases and 50 controls and approximately 104,000 SNPs, where our method validates the discoveries in previous investigations. While our method is competitive with other method for handling heterogeneity (although not generally superior to them), the main advantage of our approach is that it represents an adaptive and statistically rigorous procedure to remove outliers.

The NCBI dbGaP database of genotypes and phenotypes provides resources for genome-wide association studies and medical resequencing. *S. Sherry, M. Feolo, Y. Jin, M. Kimura, K. Tryka, R. Bagoutdinov, J. Paschall, L. Hao, A. Sturcke, L. Phan, M. Quintos, N. Popova, S. Pretel, L. Ziyabari, M. Lee, Y. Shao, Z. Wang, M. Xu, M. Kholodov, G. Godynskiy, N. Sharopova, A. Pshenichnov, J. Ostell.* National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD.

The dbGaP database of Genotypes and Phenotypes (www.ncbi.nlm.nih.gov/dbgap) archives and redistributes comprehensive data sets from genome-scale studies, thus providing summary reports, documents, data browsers and connections to other information resources. For authorized investigators, dbGaP distributes de-identified, individual-level phenotype and genetic data, and aggregate-level association results. 78 dbGaP studies provide individual-level data for 188,466 study participants including 69,376 phenotype measures, 132 billion genotypes, and 10 terabases of sequence data.

Any Principal Investigator (PI) registered in the NIH Federated Commons (eRA) system may request access to individual level data through the dbGaP controlled access system. Completed applications are automatically routed to the PI's institutional signing official (SO) for approval, and then forwarded for review and an approval decision by an NIH Data Access Committee. Submission of the data access request constitutes agreement and acknowledgment to the terms of use for the requested data sets. These terms are detailed in the "Data Use Certification" documents and generally include agreements to adhere to indicated limitations of use; not redistribute the data; not attempt to identify or contact study participants; acknowledge intellectual property principles; and adhere to publication embargo policies.

Public data in dbGaP includes study descriptions, documents, variable summaries, descriptions of controlled-access components and limited aggregate data. NCBI provides a growing collection of tools to **browse** catalogs of published association results, and **examine** multiple GWAS association results simultaneously in genome coordinates. dbGaP content is connected when possible to other public information resources, including NHGRI's Genome Wide Association Catalog, PubMed, Gene, SRA and dbSNP.

The dbGaP FTP site provides all public content. There you will find study release notes, documents in XML markup and PDF formats, a report describing all of the components available through controlled access, and phenotype variable summary data.

Genotype Library and Utilities (GLU): a suite of tools for performing genome-wide association scans. *Z. Wang[1,2], C. Liu[1,2], Q. Chen[1,2], M. Yeager[1,2], S.J. Chanock[2], K.B. Jacobs[1,2].* 1) Core Genotyping Facility, SAIC-F/NCI, Bethesda, MD; 2) Division of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD.

GLU is a software package for managing and analyzing large scale genotype data that was initially developed to support the NCI Cancer Genetic Marker of Susceptibility (CGEMS) projects. It was designed around key novel conceptual approaches, including efficient binary genotype representations and storage, a data streaming model, and an extensible and interoperable modular framework. GLU is a data management tool: handling many different genotype format transformation including high-performance native text and binary formats, PLINK text (PED) and binary formats, and WTCCC formats; filtering genotype data based on inclusion or exclusion criteria; sample renaming and locus remapping; file utilities for table joining and in-memory queries on relational sample meta data files. GLU is also a genotype quality control tool: summary genotype statistics for locus and sample; genotype concordance and duplicate check; deviations from Hardy-Weinberg proportions; IBD estimation and relatedness check. In addition, GLU provides analytic tools such as: linear and logistic regression models for high-throughput association testing; LD estimation, filtering, coverage and tagging; an embedded SNP and gene annotation database. GLU also includes features to characterize population structure such as population admixture estimation and principal component analysis on genetic correlations. Overall, GLU has the essential features to perform GWAS analysis, from parsing the raw genotype data, conducting quality control filtering, population structure analysis, to association analyses. It is the primary tool used by the GWAS pipeline at the NCI's Core Genotyping Facility and has supported all major GWAS discoveries and publications since 2006. GLU is a free and open source project that is steadily improving and accessible to the scientific community from http://code.google.com/p/glu-genetics. Funded by NCI Contract No. HHSN261200800001E.

1729/W

Integrating genetic and gene expression evidence into genome-wide association analysis of gene sets. *Q. Xiong[1], N. Ancona[2], ER. Hauser[3], S. Mukherjee[1,4,5,6], TS. Furey[1,5,7].* 1) Institute for Genome Sciences and Policy, Duke University, Durham, NC 27708; 2) Institute of Intelligent Systems for Automation National Research Council, Bari IT 70126; 3) Department of Medicine, Center for Human Genetics, Duke University Medical Center, Durham, NC 27710; 4) Departments of Statistical Science, Duke University, Durham, NC 27708; 5) Department of Computer Science, Duke University, Durham, NC 27708; 6) Department of Mathematics, Duke University, Durham, NC 27708; 7) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC 27708.

Single variant or single gene analyses generally account for only a small proportion of phenotypic variation in complex traits and often result in high rates of false positive associations. As a result, a variety of statistical or computational methods have been developed to identify associations between gene expression or genetic variation and phenotypic variation in the context of gene sets/pathways. However, a computational platform for joint analysis of multiple types of genomic data in a single statistical framework is currently not available. We propose a novel methodology, Gene Set Association Analysis (GSAA), which integrates gene expression analysis with genome-wide association studies. GSAA employs a priori defined gene sets to infer sets of genes enriched for differential expression across two conditions and/or trait-associated genetic markers. The joint analysis in GSAA has important advantages compared with pathway analyses based on a single genomic data source or based on eQTLs. Compared with gene expression analysis alone or purely genotypic analysis, the data integration can reduce the effects of inherent noise in gene expression data and population stratification in SNP data that often lead to high rates of false positives. In addition, unlike eQTL-based analysis that only analyzes those SNPs responsible for gene expression variation, GSAA analyzes information from all genes and from all SNPs in the data sets simultaneously and integrates these two types of information as overall evidence of association. This procedure can make gene set association analysis more robust and comprehensive. Simulation studies illustrate that joint analyses of genomic data increase the power to detect real associations when compared to gene set methods that use only one genomic data source or a two-step regression method. We applied GSAA to glioblastoma data identifying p53 signaling as the most significant pathway along with others related to cell-cycle checkpoint response and transition between phases. Analysis of Crohn's disease data found that top-ranked pathways are most associated with NF-κB signaling and consequent molecular events caused by the deregulation of this pathway. These results are consistent with the theoretical framework elucidating the etiology established by experimental studies demonstrating that GSAA accurately identifies molecular pathways deregulated in disease. Software is freely available at http://gsaa.genome.duke.edu.

Ontology derived systems biology approach to infer polygenic models for GWA Studies. *W. Zheng[1], L. Tsoi[1], T. Qin[1], E. Kistner-Griffin[2,3], A. Lawson[2].* 1) Biochemistry and Molecular Biology, Med Univ South Carolina, Charleston, SC; 2) Division of Biostatistics & Epidemiology, Department of Medicine, Medical University of South Carolina, Charleston, SC; 3) Hollings Cancer Center, Medical University of South Carolina, Charleston, SC.

Many evidences show that human diseases are caused by cumulative effect of multiple genetic variants. This polygenic model poses a significant challenge to current Genome-wide Association (GWA) study, as variants in a polygenetic model do not show strong association with the disease phenotype individually. A systems biology approach can be used to identify polygenic model from genes that are marginally associated with disease phenotypes from GWA study. We have developed the concept of ontology fingerprints (OntoFing), a list of ontology terms overrepresented in the PubMed abstracts linked to a gene or a disease along with their corresponding enrichment p-value, to characterize genes and diseases. By using OntoFing, we are also able to quantify relationships between genes to construct OntoFing-derived network. In this network, genes are nodes and the similarity scores between genes are weighted edges. We further developed a Bayesian hierarchical model to use existing pathway information to infer biologically relevant threshold for the weighted edges in the network. By examining the biological coherency between genes in the network, we are able to identify gene modules that show strong biological relevance to LDL, HDL and TG using data from a GWA study on dyslipidemia. We ranked the identified modules based on the similarity with the phenotype, and showed that the high ranking modules have higher proportion of genes previously identified to have polygenic effects on dyslipidemia. One module contains LPL and ABCA1, consistent with their polygenic effect on lipid concentration supported by other study. Additional genes in the same module point to a potential multi-gene model that influences lipid concentration. Such network modules have significant implication for the genetic bases of the polygenic disease model. Our methodology provides a novel way to analyze GWA study to infer novel polygenic model that may contribute to human disease. We are also applying the OntoFing approach to result from a GWA study investigating genetic variants associated with nephropathy among Type I diabetes patients. While no statistically significant genetic variants were identified to be associated with the phenotype after multiple testing correction, the prior information provided by OntoFing could potentially provide additional knowledge to increase the power for identifying genes involved in polygenic effect of nephropathy.

1731/W

Identifying unique sequences directly from the human genome. *J.C. Patrick[1], B.C. Shirley[1], P.K. Rogan[1,2].* 1) Computer Science, University of Western Ontario, London, Ontario, Canada; 2) Biochemistry.

We implement an *ab initio* method for finding locations of unique sequence intervals in the genome that obviates the requirement for comparison with a database of consensus repetitive sequence family members. The method exploits a state space search stategy similar to a depth-first search algorithm. It determines copy number of seed subsequences of a larger input sequence (eg. a complete chromosome) which are then compared at low stringency with a sequenced genome in parallel on a cluster computer. To define the boundaries of single copy segments, the above steps are recursively run on branched subsequences of repeat-containing intervals that occur adjacent to single copy segments discovered in the previous step. In addition to finding known repeat sequence families, ab initio is capable of detecting repeat elements that have not been previously recognized. To measure sensitivity, specificity, and accuracy of our *ab initio* implementation, 10 two million nucleotide long regions were selected for analysis, representative of a range of repeat content densities. Between 6 and 15 recursions were required to define single copy sequences in these target regions, corresponding to seed lengths ranging from 300 to 1500 nt. The algorithm achieves high specificity and sensitivity for detection of single copy sequences and resolves the boundaries between single copy and cataloged repetitive elements to within 20 nt resolution.

1732/W

Nonlinear Geographical Mapping for Genetic Structures. *W. Yang[1], E. Eskin[2].* 1) Bioinformatics Program, University of California, Los Angeles; 2) Computer Science Dept, Human Genetics Dept, University of California, Los Angeles.

Understanding the genetic structure of human populations plays a key role in medical, genetic, and anthropological researches. Previously, Principle Component Analysis (PCA) has been widely used to analyze the genetic data to reveal the population structure. However, using PCA for geographical mapping in two dimensions might not be able to accurately reveal the intrinsic genetic structure of population. There are two main reasons: (1) PCA is a linear method designed to model linear variability, but population variance is very likely to be nonlinear manifold in high dimensional space; (2) PCA is not a customized method for geographical mapping, as it computes a ranking list of principle directions but no guarantee that using only two of them could attain the original structure. Therefore, it is more suitable to use nonlinear dimension reduction method for genetic data analysis, especially, for geographical mapping. These methods generally aim at preserving local neighbor information while projecting to lower dimensional space, which coincides with the basic biological intuition that genetic similarity leads to locational similarity. The nonlinear dimension reduction techniques generally work as follows: 1. Identify k nearest neighbor samples for each genetic sample, 2. Compute the reconstructing weights using these neighbors for each sample, 3. Project the samples to a geographical location while preserving the reconstructing weights. The above procedure usually can be solved efficiently by spectral decomposition, thus is scalable for large data set. We apply this method to a single nucleotide polymorphism (SNP) data from European populations and observe better geographical mapping than the PCA method.

1733/W

CAGI: The Critical Assessment of Genome Interpretation, a community experiment to evaluate phenotype prediction. *S.E. Brenner[1], R.K. Hart[2], J. Moult[3].* 1) 461A Koshland Hall #3102, University of California, Berkeley, CA 94720-3102; 2) 324G Stanley Hall, University of California, Berkeley, CA 94720; 3) IBBR, University of Maryland, Rockville, MD 20850.

The Critical Assessment of Genome Interpretation (CAGI, kā'-jē) is a community experiment to evaluate computational methods for predicting the phenotypic impacts of genomic variation. Participants will be given unpublished genetic variants and will make predictions of resulting phenotype. These predictions will be objectively assessed against experimental characterizations. The long-term goal for CAGI is to improve the accuracy of phenotype and disease predictions of rare variants in clinical settings.

CAGI, which is based on the framework of the long-running Critical Assessment of Structure Prediction (CASP), will entail four phases:

- Unpublished associations of genotypes with molecular, cellular, or organismal phenotypes will be collected by the organizers from experimental and clinical labs
- Participants will make computational predictions of phenotypes from provided genotypes
- Experimental and clinical scientists will assess predictions
- A community workshop will be held to disseminate results and evaluate our collective ability to make accurate and meaningful predictions.

From this experiment, we expect to understand the diversity of mechanisms of genome variation, identify bottlenecks in genome interpretation, inform critical areas of future research, and connect researchers from diverse disciplines whose expertise is essential to methods for genome interpretation. Preliminary data sets we have be offered include enzymatic activity of human metabolic enzymes, segregation of rare variants identified in from resequencing in cancer cases and controls, efficiency of transcription for variants of a checkpoint protein variants, pathogenicity of mitochondrial variants, clinical phenotypes associated with complete genomes, and molecular mechanisms underlying GWAS disease associations. For more information, see http://genomecommons.org/cagi/.

1734/W

GSD: a web-based data management system for large-scale genetic studies. *F. Kuo[1,2], C. Huang[1], S. Diehl[1,2].* 1) Center for Pharmacogenomics & Complex Disease Research, UMDNJ-New Jersey Dental School, Newark, NJ; 2) Biomedical Informatics, UMDNJ-School of Health Related Professions, Newark, NJ.

Mapping genes for complex diseases requires large numbers of samples and genetic markers. With current genotyping technologies, family linkage or genome-wide association studies can accumulate billions of genotypes. In addition, as the study data dynamically grow from beginning to end, flexibility of managing and manipulating the information (with an audit trail) is essential. Here we describe a secure web-based Genetic Studies Data (GSD) management system for high-throughput population and family based genetic studies. GSD is a platform independent web-based DBMS system supporting of HTTP protocols over an encrypted Secure Sockets Layer (SSL)/Transport Layer Security (TLS) transport mechanism. It can accommodate genotypes generated by various genotyping platforms from an in-house laboratory or from collaborators' laboratories. In addition to marker genotypes, it can also manage multiple clinical and demographic/risk factor variables. Pedigree drawing is another useful functionality, and the software allows users to visualize pedigree structures along with affection status, genotypes and phenotypes displayed. Together with comprehensive user account management and study data access control, GSD is designed to comply with the requirements of IRBs in large-scale and/or multi-site collaborations for genetic or pharmacogenomic studies. The underlying database of GSD is an Oracle relational database, offering exceptional flexibility, facilitating complex data table and query designs, and expediting data quality control. The front end user interface is built on an Apache web server with SSL/TLS encryption by Perl CGI programming. Therefore, any modern web browser with encryption capability can act as a client. GSD aims to ease the burden of managing multiple on-going studies and integrating and managing data from fieldwork and the laboratory for these studies. Data import can be readily done by text copy/paste or data file uploads through the interface. For genetic association studies, GSD provides a number of statistical tests including Chi-Square, Fisher-Exact, and Trend Tests as well as linear and logistic regression analyses with categorical or continuous covariates. GSD's data export functionality includes formats used by most publicly available statistical analysis programs including LINKAGE, GENEHUNTER, MERLIN and PLINK. This research was supported by grants NIDCR DE13102 and DE016057, DE017900, NIEHS ES015864 and the Foundation of UMDNJ.

1735/W

ExprTarget: an integrative approach to predicting human microRNA targets. *W. Zhang[1,2], E.R. Gamazon[3], H.K. Im[4], S. Duan[5], Y.A. Lussier[3], N.J. Cox[3,6], M.E. Dolan[3]*. 1) Institute for Human Genetics, University of Illinois at Chicago, Chicago, IL; 2) Dept. of Pediatrics, University of Illinois at Chicago, Chicago, IL; 3) Dept. of Medicine, University of Chicago, Chicago, IL; 4) Dept. of Health Studies, University of Chicago, Chicago, IL; 5) Singapore Institute for Clinical Sciences, A-STAR, Singapore; 6) Dept. of Human Genetics, University of Chicago, Chicago, IL.

Variation in gene expression has been observed in natural populations and associated with complex traits or phenotypes such as risks for common diseases and differences in chemotherapy outcomes. Gene expression itself is a complex phenotype controlled by various genetic and non-genetic factors. The binding of a class of small RNA molecules, microRNAs (miRNAs), to the mRNAs has recently been demonstrated as an important mechanism of gene regulation. The regulation of miRNAs in gene expression has also been found to be associated with complex diseases including certain cancers. Because individual miRNAs may regulate the expression of multiple gene targets by binding to their mRNA transcripts, a comprehensive and reliable catalogue of miRNA-regulated targets will be critical to understanding the complex network of gene regulation and human diseases. Though experimental approaches have been used to identify many miRNA targets, considering cost and efficiency, miRNA target identification still relies largely on computational algorithms that aim to take advantage of different biochemical/thermodynamic properties of the sequences of miRNAs and their gene targets. Though successful to some extent, the prediction results of these computational methods often lack support by each other and experimental evidence. A novel approach (based on weighted logistic regression), therefore, was proposed to integrate some of the most common miRNA target prediction methods (miRanda, PicTar, TargetScan) and using the miRNA expression (together with the mRNA baseline expression) data (~220 expressed miRNAs) generated by our laboratory on 58 unrelated HapMap CEU (Caucasians from Utah, USA) samples and the TarBase (an archive of the miRNA targets validated by experiments) to represent positive predictions. Though with some limitations, our approach improved the miRNA target prediction relative to individual algorithms in terms of sensitivity and specificity. A database of human miRNA targets (ExprTarget, http://www.scandb.org/newinterface/download/microrna/) predicted by this approach was built to house this data and to facilitate future studies pertaining to gene regulation by miRNAs. ExprTarget will be integrated into www.PharmGKB.org. This work was funded through the Pharmacogenetics of Anticancer Agents Research Group grant U01GM61393, CA136765, P50CA125183, and the UC Cancer Center Pilot Project Program. Data deposits are supported by the PharmGKB grant U01GM61374.

Phenome-wide association study on 40 loci replicates 22 known associations and proposes new disease-SNP associations. *J.C. Denny[1], L.A. Bastarache[1], M.A. Basford[1], M.D. Ritchie[1], J.M. Pulley[1], E. Bowton[1], C. McCarty[2], P. Peissig[2], L. Rasmussen[2], D.R. Masys[1], D.C. Crawford[1], D.M. Roden[1]*. 1) Dept of Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Biomedical Informatics Research Center, Marshfield Clinic, Marshfield, WI.

Genome-wide association studies (GWAS) have elucidated genetic associations for many diseases and phenotypes. Genetic data coupled to longitudinal electronic medical records (EMR) offers the possibility of the inverse experiment, phenome-wide association scans (PheWAS), to search for conditions associated with specific genetic variants. We performed a PheWAS in 40 single nucleotide polymorphisms (SNPs) with 52 previously known associations for 25 diseases. We used extant genotype data for 8,865 European Americans derived from BioVU, the Vanderbilt DNA Databank, which currently contains >86,000 DNA samples linked to de-identified EMR data. The genetic data consisted of targeted genotyping and GWAS data (Illumina's 660-Quad), the latter derived as part of the eMERGE network. Diseases were identified using International Classification of Disease, 9th edition, codes accrued from normal clinical billing processes, and then mapped to 776 custom-defined code groupings that combined similar diseases together (e.g., codes 401.X-404.X are all mapped to "hypertension"). Control populations were defined for each disease by excluding patients with the target disease and related conditions. New associations were subject to replication in a population of 4,164 individuals from the Marshfield Clinic Personalized Medicine Research Project. The Vanderbilt PheWAS replicated 22 of 52 previously known associations with p values from $9.7x10^{-11}$ to 0.047, median p-value $7.4x10^{-3}$. Diseases with significant known associations included multiple sclerosis, rheumatoid arthritis, type 2 diabetes, gout, atrial fibrillation, macular degeneration, hemochromatosis, schizophrenia, bipolar disease, coronary disease, obesity, Crohn's disease, and breast and ovarian cancer. In addition, PheWAS methods revealed ten new gene-disease associations with $p<0.01$ that replicated in the Marshfield data set ($p<0.05$). Examples of possible new associations included histoplasmosis with rs3135388 ($p=3x10^{-4}$, OR 4.2), lymphoid leukemia with rs2476601 ($p=7.9x10^{-3}$, OR 1.97), rs17696736 and acquired hypothyroidism ($p=5.0x10^{-3}$, OR 1.16). This study further validates EMR-based PheWAS as a method to discover SNP-disease associations by reusing existing genetic data, and posits several new associations in heretofore-unassociated genes. The PheWAS code and code translations software are freely available at http://knowledgemap.mc.vanderbilt.edu/research.

Defining Optimal Experimental Design and Analytical Strategies for RNA Seq experiments. *J. Hester, J. Schweitzer, E. Sehayek, D. Serre.* Cleveland Clinic, Cleveland, OH.

RNA-Seq, sequencing a sample's transcriptome using next-generation sequencing, is a rapidly expanding technique that may replace gene expression microarrays in the next few years. However the bioinformatic analysis of these datasets is still in the early stages and strategies to design and analyze the wealth of data generated by these experiments remain to be optimized. To define key parameters in RNA-Seq design and specifically assess the cost-effectiveness of various read length and paired-end sequencing, we simulated ~30 million 36 bp and 51 bp reads, both single and paired-end, from human RefSeq transcripts. We also introduced random mutations in the sequences to assess the effect of sequencing errors on the results. We then used the TopHat algorithm to map the reads to the Human reference genome and identify splice junctions. Our simulations i) clearly indicate that different sequencing designs should be used to quantify transcript levels and to identify alternative splicing, and ii) provide analytical strategies to reduce the number of false positives. Applying of these strategies to a CACO-2 cell line found that by using proper filtering criteria even a single lane of 51bp paired reads of the Illumina GAIIx sequencer can provide a tremendous amount of information on transcript level, isoform structure, novel transcripts, coding polymorphisms or large chromosomal rearrangements.

A Bayesian measurement error model approach to two-channel cell-based RNAi data with replicates. *I. Chang[1], C. Chen[2], W. Su[3], C. Chen[2], J. Huang[3], F. Tsai[2], W. Wang[2], C. Hsiung[2], J. Jeng[3].* 1) National Institute of Cancer Reasearch, National Health Research Institutes, Miaoli, Taiwan; 2) Division of Biostatistics and Bioinformatics, National Health Research Institutes, Miaoli, Taiwan; 3) Institute of Molecular Biology, Academia Sinica, Taipei, Taiwan.

RNA interference (RNAi) is an endogenous cellular process in which small double-stranded RNAs lead to the destruction of mRNAs with complementary nucleoside sequence. With the production of RNAi libraries, large-scale RNAi screening in human cells can be conducted to identify unknown genes involved in a biological pathway. One challenge in these studies is to deal with the multiple testing issue and the related false positive rate (FDR) and false negative rate (FNR). This paper proposes a Bayesian measurement error model for the analysis of data from a two-channel RNAi high-throughput experiment with replicates, in which both the activity of a particular biological pathway and cell viability are monitored and the goal is to identify shRNAs that affect the pathway activity without affecting cell activity. Simulation studies indicate the excellent numerical performance of this method and provide insight into the effects of prior distributions and the number of replicates on FDR and FNR. This method is illustrated in analyzing the data from a RNAi high-throughput screening that searches for cellular factors affecting HCV replication without affecting cell viability; comparisons of the results from this HCV study and some of those reported in the literature are included.

Integrated Visualization Tools for SNP Genotyping Quality Control. *C. Huang[1], F. Kuo[1,2], S. Diehl[1,2].* 1) Center for Pharmacogenomics and Complex Disease Research, UMDNJ-New Jersey Dental School, Newark, NJ; 2) Health Informatics, UMDNJ-School of Health Related Professions, Newark, NJ.

The accuracy of Single Nucleotide Polymorphism (SNP) genotype calls has a potentially great impact on statistical results of gene association studies. Most available software systems provide only a basic two dimension cluster calling algorithm to make genotype calls, and don't integrate the overall laboratory design to maximize quality control. Ideally, both positive and negative controls need to be included and tracked in DNA plate layouts, and used downstream to assess the quality of genotype calls. A false genotype call may be caused by many reasons including DNA and oligonucleotide quality, lab processing errors, contamination, failed instrument readings, etc. When there are many failed calls on a plate, it can be very helpful for troubleshooting to view where the failures on a plate layout most consistently occur to identify the possible causes. It is very helpful to have a tool that allows laboratory scientists to visualize signal intensities and genotype calls and performance of DNA samples across multiple assay plates. These features can help reduce genotyping costs and errors dramatically. It is also very valuable that the software can automatically perform quality checking and evaluate potential problems such as edge effects and consistency of positive controls and quickly generate a quality report based on wells, samples, SNPs, plates, studies, etc., so when laboratory problems occur they are rapidly detected and corrected so that damage to a genetic research project is minimized. Here, we present our SNPtyper software program that has been developed to provide these essential visualization and quality control capabilities. The program can automatically make genotype calls, perform quality controls, check for consistency among duplicated DNA samples and positive controls across multiple assay plates, and rapidly generate reports for both lab staff and bioinformatics personnel. Our software can also rapidly provide genotype call quality score based on fit to Hardy Weinberg expected frequencies in different races or ethnic groups intermingled on the same assay plate. It has the ability to display multiple genotype plate plots and layouts to compare the results of same DNA source plate. Examples of how the tool has helped identify the genotyping errors, plate miss-arrangements will be presented. This research was supported by grants NIDCR DE13102, DE016057 and DE017900, NIEHS ES015864 and the Foundation of UMDNJ.

NCBI database for genetic associations with high-throughput molecular phenotypes. *J. Paschall[1], D. Hoffman[1], N. Sharopova[1], W. Gan[2], M. Feolo[1], S. Sherry[1], J. Ostell[1], JP. Struewing[2].* 1) National Center for Biotechnology Information, Bethesda, MD; 2) Natiional Human Genome Research Institute,Bethesda MD.

The success of genome wide association studies (GWAS) has identified hundreds of robust genetic associations across a range of disease phenotypes. In most instances, however, the causative variants and thus the molecular pathways linking a genomic variant to disease susceptibility remain unknown when the associated SNPs do not map to exons. It is critical for post-GWAS studies to identify which of these may influence gene regulation. An important approach to bridging this gap is testing for association between genomic variants and molecular level phenotypes such as gene expression (eQTL), epigenomic, and proteomic data. The NCBI has developed a searchable database focused on archiving and visualizing genetic associations with high throughput molecular phenotype data: (http://www.ncbi.nlm.nih.gov/gtex). This effort originated with the eQTL data from the NIH Common Fund Genotype-Tissue Expression (GTEx) project http://nihroadmap.nih.gov/GTEx/ which will assess the genetic component of gene expression variation across many different human tissues. The scope of this database extends to all existing and future high-throughput molecular association datasets. Current datasets include those derived from both microarray and RNA-seq technology. Association results are searchable by expressed gene, genomic variant, and tissue-type, and are visualized graphically as histograms and as tracks within a genome browser. Links will be computed and automatically updated between SNPs found to be associated with molecular phenotypes, and SNPs found to have disease phenotype associations as recorded in dbGaP and the NHGRI GWAS catalog (www.genome.gov/gwastudies). The goal is to allow the results of a new disease phenotype study to be quickly queried against all available molecular phenotype association data. This will provide additional biological support in interpreting those results, and allow for background processes to re-scan both disease and molecular phenotype associations over time in a continuous data-mining effort.

Tbx20 gene targets and regulatory networks in the adult mouse heart. *N. Sakabe[1], I. Aneas[1], T. Shen[2], S. Evans[2], M. Nobrega[1].* 1) Human Gen Dept, Univ Chicago, Chicago, IL; 2) Skaggs School of Pharmacy and Pharmaceutical Sciences, UCSD, San Diego, CA.

Tbx20 is a transcription factor (TF) important for heart development. To assess its role in the adult heart, we created a heart Tbx20 knockdown mouse on which we observed a lethal phenotype involving severe cardiac abnormalities. To better understand the role of Tbx20 in the adult heart, we sought to identify regulatory regions, gene targets and pathways that could explain the knockdown phenotype. To this end, we used chromatin immunoprecipitation (ChIP) of Tbx20 to locate Tbx20 binding sites in the genome of 6 weeks whole heart mouse tissue. At 9% FDR, we identified 4,012 peaks. To our surprise, the canonical Tbx20 motif was not strikingly overrepresented, but instead, we discovered a highly overrepresented motif that resembles a T-box in ~65% of the peaks (2-fold enrichment). Peaks with and without the newly found Tbx20 motif presented conservation around the peak centers above expectation, which supports functionality. We called putative Tbx20 gene targets by assigning peaks to genes where they lie or to the flanking genes (~22% of the peaks were located within +- 6kb of the transcription start site). To assess pathways that were directly regulated by Tbx20, we analysed Gene Ontology (GO) enrichment of the putative gene targets. GO terms related to heart contraction, calcium transport and energy metabolism were among the highly enriched which hints for biological pathways that are regulated by Tbx20. We then searched Tbx20 peaks for other overrepresented motifs to identify potential partners for this TF and to try to identify TF combinations that would be important in adult heart function. Among many heart related motifs were MEF2A, CREB1, TEAD1 and ESRRb which are independently known to play a role in ion transport in the heart. We mutagenized individual high-scoring instances of these motifs and using a zebrafish reporter system, we observed ablation of enhancer function of selected Tbx20 ChIP peaks near ion channel genes. When we selected only genes near peaks containing the 4 motifs, we found that they are particularly assigned to ion transport genes. The GO and motif data, together with physiological observations in the knockdown mouse indicate that Tbx20 plays a major role in ion transport regulation in the heart. We will pursue more analysis similar to this one to discover other pathways that might be regulated by Tbx20 and that could explain the phenotype of the knockdown mouse at the molecular level.

Intron gain in mammalian retrogenes. *I. Makalowska, M. SzczeÅ niak, J. Ciomborowska.* Faculty of Biology, Adam Mickiewicz University, Poznan, Poland.

For a long time intron gain phenomenon in mammals has been elusive and, despite intensive genome wide analyses, only few instances of 'intronisation' in mammals are known. Reported previously intron gains in mammalian genomes arised in retrogenes and are associated with either fusion with host genes or recruitment of new exons. We performed comparative analysis of human, chimpanzee and mouse genomes in order to identify 'intronisation' cases in retrogenes. We were mostly, although not only, interested in cases where the exon was split in result of new sequence insertion or as a consequence of mutations and emergence of splicing signals. Using BLAST searches and homology annotations we identified a number of novel retrogenes that underwent 'intronisation'. Many of them, beside the intron gain, show additional interesting features, including exaptation of repetitive elements, overlapping with other genes and alternative splicing. The latter is especially interesting, as it was not seen previously in retrogenes. Splicing forms, which we proved experimentally for RNF113B gene in human, show tissue-specific expression profiles. It also appears that they arose relatively recently and often are species specific. Results of our studies demonstrate new functions of retrogenes in the transcriptome diversification and show that retrogenes may be responsible for a wealth of species-specific features including species-specfic introns and splice variants.

NSIT: Novel Sequence Identification Tool. *B. Pupacdi[1], A. Javed[2], M.J. Zaki[3].* 1) Chulabhorn Research Institute, Bangkok, Thailand; 2) IBM Thomas J. Watson Research Center, Yorktown Heights, NY; 3) Computer Science Department, Rensselaer Polytechnic Institute, NY.

Identification of novel sequences in a *de novo* human genome assembly is an important task. Recently Li *et al.* report that such assembly may contain as high as 5Mbps not present in the extant reference genome. Here we introduce **NSIT (Novel Sequence Identification Tool)** which quickly aligns a *de novo* assembly against a reference genome and accurately identifies all novel sequences. The challenge lies in the fact that a *de novo* assembly typically consists of a few hundred thousand scaffolds and contigs whose sizes vary greatly and respective chromosomal positions are unknown post-assembled. Querying each one against the reference sequence index is computationally daunting, even with fast alignment programs like BLAT and LASTZ. Unlike those algorithms, NSIT takes advantage of the fact that two human genomes are highly similar and only focuses on the main diagonal alignment as opposed to all chains of high-scoring segment pairs. As a result, its search space for identifying novel sequences greatly reduces. It indexes all possible k-mers per chromosome of the reference sequence, then coarsely maps each scaffold and contig onto a unique chromosome. Fine-scale alignment onto the assigned chromosomes follows. The coarse alignment only uses k-mers from every n-th position (n<50), and the detailed alignment uses all. Consecutive non-overlapping k-mers of the query are streamed against its respective index to find maximal unique matches, which become alignment anchors. No scoring matrices are used. Experiments show that NSIT aligned all but only 45Mbps of the *de novo* YH genome to the Build 36 genome within 1.5hrs using <2GB of RAM on a commodity desktop. All of the YH novel sequences were contained in these 45Mbps. Li *et al.* used BLAT and LASTZ as the first two steps and subsequently BLAST to align the remaining unmapped regions. NSIT offers a faster alternative step prior to using BLAST. Although the paper did not report their timings of BLAT and LASTZ, we suspect them to take much longer due to the larger search space. (Running BLAT on the YH assembly against just Chr 1 Build 36 lasted >12hrs and did not finish on our computer.) NSIT took 1.5hrs and BLAST took <15hrs on the remaining 45Mbps region. Our results contained exactly the ~5Mbps novel sequences reported in their paper. In conclusion, NSIT is a fast and accurate tool to identify novel sequences in a *de novo* genome assembly and will be a very useful tool as human genome sequencing becomes more routine.

1744/W

CYP1B1 Sequence Variations in a Cohort of Patients with Sturge-Weber syndrome from the U.S. *T.L. Yanovitch[1], S.F. Freedman[1], K.N. Tran-Viet[2], R. Metlapally[2], W. Call[2], E. Burner[1], T.L. Young[1,2].* 1) Ophthalmology, Duke Eye Center, Durham, NC; 2) Human Genetics, Duke University, Durham, NC.

Purpose: Sturge-Weber syndrome (SWS) is a rare, sporadic, neurocutaneous disorder characterized by ipsilateral facial port-wine staining in the ophthalmic distribution of the trigeminal nerve, glaucoma with associated vascular eye abnormalities, and occipital leptomeningeal hemangioma. The genetic and environmental factors resulting in this disorder are unknown. A recent report from India describes CYP1B1 mutations in patients with SWS that have buphthalmos and gyral calcifications. The purpose of this study was to screen patients with SWS from the U.S. for possible causative CYP1B1 sequence variants. Methods: After approval from the Duke University Institutional Review Board, informed consent was obtained from SWS patients and/or their parents. Direct genomic sequencing of the CYP1B1 gene was performed on patient DNA that had been extracted from blood or saliva. Base pair comparisons were made with known reference sequences to identify possible sequence variants. Array comparative genomic hybridization (CGH) was also performed to determine copy number variations. Results: A total of 11 patients were ascertained. About one-half (45%) of the patients were male. The median age was 12 years (range 3-51). In terms of ethnicity, 8 (73%) were Caucasian, 1 (9%) was African American, 1 (9%) was African, and 1 (9%) was of mixed race. The location of the facial port-wine stain was on the right side in 5 patients, the left side in 1 patient, and bilateral in 5 patients. All of the patients had glaucoma, with 4 (36%) having bilateral disease. Glaucoma was diagnosed before 1 year of age in 9 patients (81%). The remaining 2 patients presented with glaucoma as children. 10 (91%) patients had choroidal hemangiomas, and 3 (27%) had exudative retinal detachments. 4 (37%) patients had homonymous hemianopia visual field defects. Seizure disorder was present in 7 (64%) patients. Neuroimaging results were not available on all of these patients, but 1 patient had gyral calcifications. There were no disease-causing sequence variants (11 subjects) or copy number variant changes (3 subjects) found in CYP1B1. Conclusion: In our cohort of patients with SWS and associated infantile or juvenile-onset glaucoma, none were found to have CYP1B1 mutations. Array CGH also failed to identify variants in the region of CYP1B1. The absence of sequence variant findings suggests that other genes and factors are responsible for SWS associated glaucoma in the U.S. population.

1745/W

Construction of 330K Japanese BAC Library, YAMATO, and BAC DNA sequencing by SOliD3 in comparison to 3730 capillary sequencer. *T. Hirano[1,2], M. Tsukahara[2], I. Kikuzato[2], K. Morita[1], Y. Terabayashi[1], K. Fujimori[1,2], M. Machida[1,2], M. Nezuo[2], O. Asato[2], H. Irifukuhama[2], Y. Sato[2], N. Matsumoto[3].* 1) AIST, Tsukuba, Japan; 2) OCGP, Okinawa Cutting-Genome Project, Okinawa, Japan; 3) Graduate School of Medicine, Yokohama City University, Yokohama, Japan.

An original 330K BAC (bacterial artificial chromosome) library, named YAMATO, was constructed from cord blood cells of a single male, established as Japanese based on genetic analysis in HLA region. The average size of BAC was about 130K, which indicates 14.2 times coverage of human genome by just one YAMATO library About the half of the whole library was amplified, corresponding BAC DNA was purified, and the both terminal sequence was analyzed by capillary sequencer, resulting in more than 90% coverage for whole human genome based on NCBI human genome data. One BAC DNA located in HLA region, was shot gun sequenced by 3730, and total 171,735 bases were established by using sequencher. Simultaneously the same BAC DNA was analyzed by SOliD3, and mapped on either own capillary sequenced data or the corresponding NCBI data as reference sequence. Through the comparison of the sequence data obtained by 3730 and SOLiD3, the accuracy of SOLiD3 was estimated to be more than 99.99%. The Japanese BAC DNA sequence established was compared with the corresponding sequence of NCBI human genome data. The comparison revealed 4 large scale deletions, 4 major insertions and 2 translocations, as well as new 14,072 SNP candidates (8.2% of entire BAC sequence), most of them (96%) were not listed in DBSNP. Even just one BAC DNA analysis, these results clearly indicate the difference between Japanese and NCBI Caucasian genome. Such precise analysis based on BAC DNA is indispensable to establish the ultimate difference and diversity in human genome.

1746/W

Collecting gene sequence variants in all Mendelian disease genes from resequenced personal genomes in LSDBs. *P.E.M Taschner, I.F.A.C. Fokkema, J. Celli, J.T. den Dunnen, the Gen2Phen Consortium (http://www.gen2phen.org).* Dept Human Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands.

Since the late eighties, starting with monogenic disorders, we have successfully linked sequence variants in specific genes to specific diseases. Now we approach the time that we can explore not a single gene but the entire genome for sequence variants and start to link these to complete individual phenotypes, disease-related, healthy or even prognostic. For the interpretation of all these variants, powerful tools are needed to efficiently sift through all variants found, link them to existing knowledge and prioritizing those that need further attention, especially those related to an individuals health. To support DNA diagnostics of monogenic diseases, gene-specific collections have been generated listing all variants identified world-wide, so called gene variant databases (Locus-Specific DataBases, LSDBs). Although generally accepted as essential in supporting an accurate and fast clinical diagnosis based on the latest findings, effective collection of these variants has been shown to be difficult. Many reasons for this exist, one of them being the lack of a central web-based gene-based repository in a format familiar to clinical geneticists. In the setting of the EU-funded Gen2-Phen project we have now established a gene variant database (LSDB) for all genes accepting all gene variant data available, including those obtained from complete exome or genome resequencing (see www.LOVD.nl). However, to make this resource most useful, we need the help of guardians for these database, who will curate incoming information and thereby ensure data quality. Therefore, we invite clinicians and researchers working on genetic disorders world-wide to become the guardian of their gene(s) of interest. As an incentive for the submission of new variants, tools linked to LOVD enable automatic conversion of chromosomal positions to gene-related positions used by LSDBs as well as links to available variant information. This approach would use the database as a reference to allow identification of variants occurring with low frequency, which are likely to be involved in genetic disorders and should be prioritized for further investigation. Funded by the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement n=BA 200754 - the GEN2PHEN project.

Comparative Analysis of Mitochondria Genome: Clinical Approaches. *L. Chou[1], K. Mallempati[1], R. Mao[1,2].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, Utah; 2) Department of Pathology, University of Utah Health Sciences Center, Salt Lake City, Utah.

Background: Human mitochondria genome is a double stranded circular DNA and mostly maternally inherited. It has no introns and 80%-93% of the sequences are coding regions. Common mutations in the mitochondria DNA cause diseases including Leber hereditary optic neuropathy (LHON), Myoclonic epilepsy with ragged red fibers (MERRF), and Neuropathy, ataxia, retinitis pigmentosa (NARP). Due to lack of histone and DNA mismatch repair mechanism, mitochondria has high mutation rate. During cell division, the proportion of mutant mitochondria DNA in daughter cells can shift. This level of heteroplasmy may differ between cells and tissues thus making accurate diagnosis of mitochondria related diseases more difficult. Methods: Fifteen previously genotyped samples (by DHPLC plus targeted Sanger sequencing), four normal samples, and nine Coriell samples were used to initially validate the chip-based re-sequencing microarray (Affymetrix). The original re-sequencing microarray protocol was modified and stream-lined to fit in a clinical workflow. The assay accuracy and reproducibility were accessed and any additional sequence variants detected were confirmed by a second method, Sanger sequencing. The next generation sequencing (NGS) approach was also evaluated. In this high-throughput approach, up to three different samples were barcoded and ran through the same lane in the GAII system (Illumina) to be more cost-efficient in comparison to the gold standard Sanger sequencing. The GAII data was extracted and analyzed by customized NextGENe software (SoftGenetics) for codon usage of mitochondria. Results and Discussions: Our modified re-sequencing microarray method showed 100% concordance when compared to the genotyped results, with an overall call rate (entire chip) between 97%-99%. Additional sequence variants (non-pathogenic) detected by the re-sequencing microarray but not reported by the DHPLC-Sanger method were re-amplified by in-house designed primers and Sanger sequenced for final confirmation. Although this modified microarray protocol fits in a clinical workflow very well, however, different levels of heteroplasmy can not be determined. The NGS with a barcode system is a potential approach for analyzing the mitochondria genome. In our study, cost per sample sequenced was decreased, the low level heteroplasmy (below 5%) was determined, and the potential of visualizing large deletions was accessed by high sequencing coverage.

1748/W

A matter of life and death: How microsatellites emerge and disappear from the human genome. *Y.D. Kelkar[2,1], F. Chiaromonte[3,1], K.D. Makova[2,1].* 1) Center for Medical Genomics, The Pennsylvania State University, State College, PA; 2) Department of Biology, The Pennsylvania State University, State College, PA; 3) Department of Statistics, The Pennsylvania State University, State College, PA.

Microsatellites - tandem repeats of short motifs - are abundant in human genome, and have high mutation rates. Their instability is implicated in 40 known genetic diseases; however, a systematic study of the molecular processes involved in microsatellite emergence and disappearance in the genome has been lacking. Microsatellite loci are hypothesized to follow a *life cycle*, wherein microsatellite are born (the *birth phase*), expand leading to the *adulthood phase*, until interruptions or large deletions cause their degradation (the *death phase*). Here we carried out a large-scale comparative genomic study to identify microsatellite births/deaths in three primate species, determined the causal mutational processes, and found the local genomic features that may drive the births/deaths. Using publicly available genome alignments, we identified a genome-wide set of *de novo* microsatellite birth/death events in human, chimpanzee, and orangutan, using macaque and marmoset as outgroups. Using maximum parsimony, we determined the causal mutational steps (substitutions, insertions and deletions) for the majority of the identified birth/death events. We mapped the events to transposable elements and genes in the human genome, and discerned the effect of these environments on microsatellite birth/death propensities. To identify the drivers of birth/death events among many regional genomic features, we implemented a multiple regression approach. We came to the following conclusions. First, although substitutions were the predominant cause for births/deaths of small microsatellites (under 12 bp), insertions and deletions were increasingly important for births/deaths of larger ones. Second, LINE and younger SINE elements showed higher and lower propensity for birth/death events, respectively. There was a dearth of births/deaths in the proximity of genic regions, even in introns, indicating that such events have long-term functional consequences. Supporting these observations, multiple regressions indicated that regions surrounding birth/death loci are marked by high substitution rates, skewed nucleotide composition, and high and low density of LINE and SINE elements, respectively. Using this, we could estimate the probability of functionally important regions to bear microsatellite genesis and loss. This has important applications, given that, while many extant microsatellites play important regulatory roles, some microsatellites' instability has major health consequences.

eQTLs and sQTLs in Human Cerebellum and Parietal Cortex. *C. Liu, L. Cheng, F. Pibiri, J. Badner, C. Chen, C. Zhang, K. Grennan, E. Gershon.* Dept Psychiatry, Knapp Res Ctr, Univ Chicago, Chicago, IL.

About 150 Human cerebellum and parietal cortex samples from the Stanley Medical Research Institute were profiled for gene expression using the Affymetrix Human Gene 1.0 ST array. With SNP genotype data obtained from the Affymetrix 5.0 array, we performed expression quantitative trait locus (eQTL) and splicing quantitative trait locus (sQTL) mapping. After controlling batch effects and covariates, cis- and trans- associations have been detected in both brain regions. eQTLs and sQTLs shared by the two brain regions, and brain-region specific transcripts and splicing isoforms were identified with their corresponding SNPs.

1750/W

High Coverage Gene Expression Profiling on the Applied Biosystems 3500xL Genetic Analyzer. *A. Pradhan[1], C. Davidson[1], M. Kondo[2], A. Felton[1], R. Araki[3], S. Ando[3], M. Abe[3].* 1) Applied Biosystems, Foster City, CA; 2) Applied Biosystems Japan, Tokyo, Japan; 3) 3Transcriptome Profiling Group, National Institute of Radiological Sciences, Chiba, Japan.

Whole transcriptome expression profiling is typically performed using hybridization-based microarray methodologies. However, there are a number of limitations to microarray-based approaches such as low sensitivity and specificity, poor dynamic range, and, importantly, microarray expression profiling results are restricted to specific sequence annotations and content. The AFLP-based HiCEP (High Coverage gene Expression Profiling) method was developed to address the above shortcomings in gene expression profiling and provide a sensitive method for detecting a large proportion of transcripts in both known and unknown genes, with low false positive rate. Here we demonstrate the use of the new Applied Biosystems 3500xL Genetic Analyzer for the detection of known transcripts unregulated by ionizing radiation (IR). mRNA samples were prepared from mouse embryonic fibroblasts (MEFs) at 0, 3, 6 and 24 hours after IR exposure. The expression of *p21*, *CyclinG1*, *Gadd45a* was assessed to demonstrate the in-lane normalization functionality of the 3500xL system. Further, the expression changes detected by capillary electrophoresis (CE) were compared to TaqMan® Gene Expression Assays for the above transcripts. When the same sample is analyzed by CE, a certain amount of variation in signal strength may be observed within a single instrument among different capillaries; or among different injections from the same capillary. For applications such as HiCEP, minimal signal variation is desired and data analysis can be aided by reducing signal variation. Here we demonstrate that the normalization functionality incorporated into the 3500 Series of Genetic Analyzers is useful for the analysis of HiCEP gene expression data. Normalization increased the precision and accuracy of peak height determinations, which are particularly important for the detection of slight expression changes. An improved understanding of the differences in HiCEP sample replicates was possible following the application of 3500 calculated normalization. Normalization of HiCEP data also assists in statistically differentiating between peak height group means for *p21*, *CyclinG1*, and *Gadd45a* at various time points. Taken together, these analyses indicate that normalization improves consistency of HiCEP data and facilitates the comparison of replicate samples (both mRNA preparation and HiCEP reaction replicates) between injections and between capillaries within the same injection.

Systems Genetics Analysis of Gene-Environment Interactions in Macrophage Inflammatory Responses. *L.D. Orozco[1], B.J. Bennett[1], C.R. Farber[2], A.J. Lusis[1].* 1) Human Genetics, University of California, Los Angeles, Los Angeles, CA; 2) School of Medicine, University of Virginia, Charlottesville, VA.

Genetic variation in naturally occurring populations can have a tremendous effect on how individuals respond to environmental stimuli. Recent genome-wide association studies in humans and mice have demonstrated the contribution of genetic variation to complex phenotypes such as atherosclerosis, as well as gene expression traits in various tissues. However, the contribution of gene-by-environment interactions (GxE) in gene expression traits or clinical phenotypes remains largely unexplored. Macrophages play critical roles in innate immunity, inflammatory responses, and complex traits such as atherosclerosis. We sought to understand the contribution of natural genetic variation, environmental stimuli and GxE interactions to genome-wide expression levels of primary macrophages. In order to examine the effect of genetic and environmental responses, we have developed a resource, called the Hybrid Mouse Diversity Panel (HMDP) consisting of 100 classical inbred as well as recombinant inbred strains. We obtained primary peritoneal macrophages and exposed them to control media, media containing bacterial lipopolysaccharide (LPS), or to oxidized phospholipids (oxPAPC) as inflammatory and oxidative stimuli. We then examined genome-wide gene expression levels using microarray analysis and integrated the data as a function of genetics. We identified loci mediating macrophage inflammatory responses and evidence of GxE interactions in thousands of genes. Interestingly, we identified several gene expression "hotspots" in LPS-treated macrophages, but not in oxPAPC-treated cells, suggesting 1) the presence of master regulators controlling the expression of hundreds of genes, and 2) that global effects of genetics and GxE interactions are decidedly context specific. In addition, because the HMDP consists of permanent inbred strains, we propose that the data generated through the use of the HDMP constitute a cumulative resource that can be used for the integration of genetic, phenotype and gene expression data, ideal for systems genetics.

Strand-specific RNA sequencing of HepG2 cells identifies genes that are differentially expressed and alternatively spliced in response to TGF-beta. *C. Wadelius[1], S. Enroth[2], O. Wallerman[1], B. Touch[3], C. Barbacioru[3], M. Bysani[1], R. Andersson[2], S. Termén[4], A. Moustakas[4], C.-H. Heldin[4], S. Stanley[3], J. Gu[5], S. Kuersten[5], M. Barker[3], J. Komorowski[2, 6], K. McKernan[7], F. de la Vega[3].* 1) Dept Gen & Pathology, Uppsala Univ, Uppsala, Sweden; 2) The Linnaeus Centre for Bioinformatics, Uppsala University, Sweden; 3) Life Technologies, Foster City, CA, USA; 4) Ludwig Institute for Cancer Research, Uppsala, Sweden; 5) Life Technologies, Austin, TX, USA; 6) Interdisciplinary Centre for Mathematical and Computer Modeling, Warsaw University, Poland; 7) Life Technologies, Beverly, MA, USA.

Transforming growth factor-beta (TGF-beta) controls many complex behaviors of normal and transformed cells. In early stage adenomas TGF-beta acts as a tumor suppressor, whereas in advanced carcinomas it promotes tumor cell invasiveness and metastasis. HepG2 cells provide a good model for advanced tumor cells. RNA sequencing (RNA-Seq) can provide a detailed view of the dynamic transcriptional landscape of cells experiencing environmental perturbation and was therefore applied here to study TGF-beta response. We serum starved HepG2 cells for 24 hours and then treated for 1 hour with 2 ng/ml TGF-beta1 or with vehicle control. Total RNA was isolated, depleted of rRNA, fragmented and then used to create strand-specific cDNA libraries with the SOLiD™ Small RNA Expression Kit. Approximately one billion 50 bp reads were sequenced with the SOLiD™ System, over half of which could be uniquely aligned to the human genome. The aligned transcriptomes cover roughly 4% of each strand of the genome and more than half of the reads align within known transcribed regions. The expression level of each gene was defined and hundreds of genes were determined to be differentially expressed between the two conditions. The 50 bp length of the sequenced fragments permitted us to accurately align reads to splice junctions. In all, ~5 million reads aligned to ~90,000 known and putative splice junctions in both the control and stimulated conditions, which allowed us to determine the effects of TGF-beta on alternative splicing. The data suggests that many genes change splice pattern after stimulation. Furthermore, we have determined positions of nucleosome and critical histone modifications to see how they are related to the transcriptional output.

Linkage mapping of eQTL acting in brain and blood. *A.J. Jasinska[1], S. Service[1], M.K. Lin[1], O-C. Choi[1], J. DeYoung[1], O. GrujiC[1], S-Y. Kong[1], M. Jorgensen[2], J. Bailey[1], S. Breidenthal[1], L.A. Fairbanks[1], R.P. Woods[3], J.D. Jentsch[4], N.B. Freimer[1].* 1) Center for Neurobehavioral Genetics, University of California, Los Angeles, CA; 2) Department of Pathology, Section on Comparative Medicine, Wake Forest University Health Sciences, Winston-Salem, NC; 3) Departments of Neurology and Psychiatry and Biobehavioral Sciences, David Geffen School of Medicine, University of California, Los Angeles, CA;; 4) Department of Psychology, University of California, Los Angeles, CA.

The expression of a substantial fraction of the brain transcriptome is reflected in the expression of peripheral blood which allows for efficient mapping of brain-acting eQTL using blood as a surrogate for brain tissue. To test this hypothesis, we used as a model organism the vervet monkey (*Chlorocebus aethiops sabaeus*). Using vervets housed in uniform rearing conditions, we were able to obtain high quality RNA from brain tissues collected according to a stringent protocol, reducing possible environmental confounders. We used an Illumina HumanRef-8 v2 chip to measure transcript levels in blood from 347 individuals from an extended inbred vervet pedigree from the Vervet Research Colony (VRC). Linkage eQTL mapping was performed with SOLAR using genome-wide genotypes from 261 STR markers typed in the VRC pedigree. We focused on transcripts for which duplicate measurements in blood demonstrated relatively stable levels over time allowing for efficient eQTL mapping in this tissue. Here we present results of eQTL mapping for 29 heritable transcripts for which expression levels between brain and blood are well correlated, and which displayed greater inter-individual variation than intra-individual variation between these tissues. Among 29 candidate transcripts for mapping brain eQTL in peripheral blood, 10 showed significant *cis* eQTL and 2 transcripts showed significant *trans* eQTL (LOD>3). Vervet sequence analysis showed that a SNP polymorphism in the probe interacting region occurred in 37.5 % of probes. To interpret eQTL mapping results and exclude possible false positive findings, we performed Q-RT PCR validation for 9 identified eQTL. Microarray results were validated for 6/9 eQTL transcripts (TMEM14C, B3GALTL, STOM, SMOX, TMED3 and CDNKA1A) and not validated for 3/9 (TUBA1B, TSPAN14, TMEM111) transcripts. All tested monomorphic probes and 2/3 of polymorphic probes were validated. This result indicates that the presence of microarray probe sequence polymorphism does not necessarily invalidate eQTL linkage mapping results. Our findings demonstrate that it is possible to successfully map eQTL from inaccessible tissue (such as brain) using readily available tissue (such as blood). This approach is possible only for the methodically-defined fraction of the transcriptome which is comparable between the two tissues.

Global transcriptome analysis in an online multimodal atlas of the human brain. *S. Sunkin, D. Bertagnolli, M. Chakravarty, C. Dang, C. Lau, A. Guillozet-Bongaarts, C. Lee, E. Lein, M. Hawrylycz, J. Hohmann, L. Ng, C. Overly, Z. Riley, K. Smith, P. Wohnoutka, E. Shen, A. Jones.* Allen Institute for Brain Science, Seattle, WA.

The Allen Human Brain Atlas is an online multimodal atlas of human brain that integrates anatomic and genomic information coupled with a suite of visualization and mining tools. A key component of the resource is an 'all genes, all structures' dataset of microarray-based gene expression profiles from normal non-diseased postmortem brain. To create the Atlas, a process for collection of multiple data types from each brain and sampling of specific anatomic structures for microarray analysis was created such that the various data modalities could be mapped back into three-dimensional space. The process involved collection of T1- and T2-weighted magnetic resonance (MR) and diffusion tensor (DT) data, followed by multiple brain and tissue subdivision steps with increased resolution of histological data at each step, ultimately resulting in delineation and dissection of small tissue samples for microarray analysis. Quality control steps were inserted throughout the process to ensure data integrity and quality. Microarray data were generated using custom-designed Agilent 8x60K arrays. All data were normalized across the dataset to ensure brain-wide comparability of expression levels. Basic data analyses revealed variation in gene expression levels throughout the brain with differential expression detected across major anatomic divisions as well as between anatomic subdivisions within a structure. To enable unified navigation and visualization for users, spatial correspondences between histology data and MR images from the sampled brain were obtained via a series of assisted registration processes. MR images provide navigation through the anatomic sampling and gene expression data, with anatomy and histology data annotated using an ontology developed for this resource. Normalized gene expression data can be viewed in heatmap format across multiple structures and multiple gene probes. Gene expression profiles and MR and DT images are also downloadable from this site. Launched in May 2010 with expression profiles for over 700 anatomically distinct cortical and subcortical samples from one brain, more data and more sophisticated application features will be added throughout the remainder of this 5-year project. The Atlas can be accessed via the Allen Brain Atlas data portal at www.brain-map.org.

A nanoliter scale method for high throughput, real-time PCR gene expression profiling in oncology and miRNA gene sets using the SmartChipTM System from WaferGen Biosystems. *T. Dodge, R. Bohenzky, S. Anandakrishnan, T. Boone, D. Dickens, D. Gelfand, P. Lin, S. Husain, H. Hubschle, S. Prasad, J. Sandhu, S. Taffler, M. Tan, H. Veereshlingam, S. Wei.* WaferGen Biosystems, Fremont, CA.

The SmartChipTM Real-Time System from WaferGen Biosystems is a platform for performing massively parallel real-time PCR assays for multiple applications, including gene expression studies. This system combines the benefits of real-time PCR, including sensitivity, precision and dynamic range, with the low cost per sample and high throughput profiling power of hybridization arrays. The system consists of three components; a SmartChipTM, comprising 5184 nanowells preprogrammed with gene-specific reaction content, a SmartChipTM Nanodispenser for applying sample and reaction mix to the SmartChipsTM, and a SmartChipTM Cycler for performing and collecting data from the real-time PCR assays. Using cDNA as an input for this system, one can generate thousands of data points which can comprise a thorough portrait of relative gene expression in a sample.

The SmartChipTM system has been extensively tested with two expression profiling panels: Human Oncology Expression Panel and the Human miRNA Expression Panel. These panels of 969 oncology related genes and over 800 miRNA's respectively show strong intra-gene precision and inter-panel reproducibility. Various controls build into the SmartChipTM allow for better interpretation of the results. The SmartChipTM Panels were also used to test cDNA from a variety of samples, including commercially available RNA tissue extracts, RNA from cells and RNA from clinical samples for research.

The data generated on the SmartChipTM system demonstrates that you can achieve the simplicity and robustness of real-time PCR with the high throughput and cost effectiveness of microarrays.

Differential gene expression profiles in steroid treatment early response from children with acute lymphoblastic leukemia. *O. Perez-Gonzalez Sr, R. Cardenas-Cardos Mrs, R. Rivera-Luna, R. Coronel-Moran, N. Carranza-Rodriguez.* Experimental Oncology Laboratory, Experimental Medicine Dept, National Institute of Pediatrics, Mexico City, Mexico.

Purpose: The steroid initial treatment response of Acute Lymphoblastic Leukemia (ALL) patients is an important component of the classification criteria, designating high risk for those cases that do not present a suitable response. Nevertheless, these classification criteria do not have enough precision to assign the treatment according to the neoplastic behavior in all the cases. With the aim of identifying the associated patterns of genomic expression related to steroid initial treatment response, we propose a prospective, comparative and cross-sectional study using Affymetrix microarray platform with the HG-U133 2.0 Plus array. **Method**: We included 50 pediatric patients with confirmed diagnosis of Acute Lymphoblastic Leukemia treated at the National Institute of Pediatrics, Mexico. Once we obtained the consent, we performed bone marrow aspirate by usual methodologies for diagnosis confirmation and lymphoblast sampling for microarray hybridization. The diagnosis, treatment and response evaluation were realized according to the conventional procedures of the National Institute of Pediatrics. The statistic analysis was performed with Affymetrix Expression Console v1.1 and Partek's Genomics Suite for quality assessment (with RMA, Robust Multi-Chip Analysis) and gene expression profiles detection. **Results**: RMA algorithm showed a correlation between all the included microarrays from 0.83 to 1.0, considering all the microarray data adequate for the statistical analysis. We found a list of genes differentially expressed according to the steroid treatment response, and to the B or T immunophenotype, and then we integrated the metabolic pathways apparently related to differentially expressed genes with the Database for Annotation, Visualization and Integrated Discovery (DAVID Bioinformatics Resources 6.7) free-online software. Details of thes results will be presented at the meeting. **Conclusion**: These results show that gene expression profiles may clearly differentiate ALL patients according to their steroid treatment response including differences in the immunophenotype B or T. Differential gene expression profiles in ALL are being analyzed as a diagnostic tool to provide a more accurate allocation criteria for antineoplastic treatments in patients with this disease and allow us to understand the neoplastic behavior on different treatment response scenarios.

Combinatory Pearson correlation coefficient and Kolmogorov-Smirnov distance metrics for identification of disease-specific biomarker genes. *Z. Zhao[1,2,3], H.C. Huang[1,2], S. Zheng[1,2].* 1) Biomedical Informatics, Vanderbilt Univ, Nashville, TN; 2) Bioinformatics Resource Center, Vanderbilt Univ, Nashville, TN; 3) Vanderbilt-Ingram Cancer Center (VICC), Vanderbilt Univ, Nashville, TN.

Gene expression microarrays have been widely used in disease studies. Disease-specific biomarker genes likely share gene expression profiles (GEPs) that are distinct in disease samples as compared with normal samples. The similarity of the GEPs may be evaluated by Pearson Correlation Coefficient (PCC) and the distinctness of GEPs may be assessed by Kolmogorov-Smirnov distance (KSD). In this study, we applied PCC and KSD metrics for GEPs to identify disease-specific biomarkers. We first analyzed and compared GEPs using microarray datasets for smoking and lung cancer. We found that the number of genes with highly different GEPs between comparing groups in smoking dataset was much larger than that in lung cancer dataset; this observation was further verified when we compared GEPs in smoking dataset with prostate cancer datasets. Moreover, our Gene Ontology analysis revealed that the top ranked biomarker candidate genes for prostate cancer were highly enriched in molecular function categories such as 'cytoskeletal protein binding' and biological process categories such as 'muscle contraction'. Furthermore, we picked top 20 significantly up-regulated and top 20 down-regulated genes based on PCC and KSD sorting. We found gene pairs comprising one up-regulated and another down-regulated had always best prediction performance. Finally, we used the top two ranked genes, *ACTA1* (encoding an actin subunit) and *HPN* (encoding hepsin), to explore the feasibility of diagnosing and monitoring prostate cancer using the expression intensity histograms of marker genes. In summary, our results suggested that this approach might prove promising and powerful for diagnosing and monitoring the patients who come to the clinic for screening or evaluation of a disease state including cancer.

Analysis of genes that are co-expressed in mouse mesenchymal cell types reveals candidate genes for connective tissue diseases. *K. Summers.* Roslin Inst, Univ Edinburgh, Roslin, United Kingdom.

Connective tissue is composed of cells of mesenchymal origin, such as adipocytes, osteoblasts, chondrocytes, smooth muscle cells and fibroblasts. To identify genes which are specific to connective tissue, the tool Biolayout *Express*^{3D} was employed to cluster sets of genes with shared expression patterns across mouse cell types using microarray data. Fifteen clusters containing at least 15 transcripts showed expression restricted to cell types of mesenchymal origin. The largest of these clusters consisted of 220 transcripts which had high expression in osteoblasts and some expression in chondrocytes. These included *Adam12*, where knock out mice have abnormal muscle and adipose development and *Zic1*, associated with Dandy Walker malformation in mice. A smaller cluster (27 transcripts) shared high expression in chondrocytes and lower expression in osteoblasts. This group included *Fbn2*, the gene responsible congenital contractural arachnodactyly, which affects bones and ligaments. A cluster of 86 transcripts had expression restricted to chondrocytes. These genes included cartilage specific collagens (*Col9a1* and *Col10a1*) and *Halpn1* (cartilage link protein) as well as *Agc1*, encoding a protein associated with skeletal dysplasias in humans and *Bmp5*, encoding bone morphogenic protein 5 (associated with skeletal abnormalities in mutant mice). Another cluster of 29 transcripts expressed only in osteoblasts included many genes traditionally associated with muscle phenotypes, such as *Myog* and genes for myosin light and heavy chains. A cluster of 75 transcripts expressed at high level in all mesenchyme cell types contained *Fbn1* (Marfan syndrome) and other genes affecting a broad range of connective tissue phenotypes. The clusters contained structural protein genes, genes for the proteins which process the structural proteins in the endoplasmic reticulum, transmembrane receptors, transporter proteins and transcription factors which are likely to coordinate expression of other genes in the cluster. More than 15% of the genes had limited annotation. In different clusters these genes included putative transcription factors of unknown target and other genes with no homology to any known protein domain. Knowledge of the cluster in which they appeared provides a functional annotation. In addition, co-expressed genes are likely to be involved in the same function and therefore this novel clustering approach identifies candidates for diseases of similar phenotype.

1759/W

The Cartagene Genomics Project: Systems Biology of Human Functional Variation. *Y. Idaghdour[1,2], J. Hussin[1,2], C. Boileau[2], E. Gbeha[1], P. Awadalla[1,2].* 1) Sainte-Justine Research Center, University of Montreal, Montreal, Quebec, Canada; 2) CARTaGENE, Montreal, H3V 1A2, Canada.

An area of fundamental biomedical research that merges population and quantitative genomics is the identification of transcriptional and other intermediate biomarkers for disease susceptibility and disease status. These biomarkers are quantitative traits whose architecture is modulated through mechanisms that can incorporate genetic and environmental cues. But what are the relative magnitudes of these effects, and how gene expression profiles correlate with biomedical endophenotypes? To address these questions, we generated gene expression profiles from peripheral blood samples from a random aging cohort in Québec, Canada, coming from a number of different geographic locations and lifestyles and for which clinical material and medical information spanning a wide range of medically relevant phenotypes from a well characterized and extended pedigree have been collected. We documented latent structure in gene expression profiles and identified genes and networks of genes that best correlate with haematological and cardiovascular phenotypes. The analysis is being extended to incorporate genotypic data in order to identify the genetic control points of the transcriptional and clinical traits studied.

1760/W

Transcriptome characterization of a human embryonic stem cell line and an induced germ stem cell line. *H. Jiao[1,2], L. Vesterlund[1], V. Töhönen[1], P. Unneberg[1], J. Inzunza[1], A. Feki[4,5], O. Hovatta[3], J. Kere[1,2].* 1) Department of Biosciences and Nutrition, Karolinska Institutet, SE-141 57 Stockholm, Sweden; 2) Clinical Research Centre, Karolinska University Hospital, SE-141 57 Stockholm, Sweden; 3) Department of Clinical Science, Intervention and Technology, Karolinska Institute, Karolinska University Hospital Huddinge, Stockholm, Sweden; 4) Laboratory of Stem Cell Research, and Department of Obstetrics and Gynecology, Geneva University Hospitals, Geneva, Switzerland; 5) Department of Obstetrics and Gynecology, Geneva University Hospitals, Geneva, Switzerland.

Pluripotent embryonic stem cells (ES) isolated from in vitro culture of preimplantation embryos may be used in variety of studies to understand molecular basis in early development in human. Recently the development of induced pluripotent stem cells (iPS) artificially derived from non-pluripotent somatic cells by introducing the expression of certain reprogramming genes attracts even more attention because of their potentially therapeutic uses. However, the full potential of iPS cells and their relation to natural pluripotent stem cells is still being under investigation. The transduced cell lines are not always fully pluripotent, and such partially re-programmed lines offer us particularly interesting information about regulation of gene function. Transcriptome analysis has been a key area of biological research to understand the variety of gene functions in a cell. Next-generation sequencing technologies have revolutionized transcriptomics by providing opportunities for multidimensional examinations of cellular transcriptomes with manifold increased sensitivity. In order to characterize gene expression profiles of ES and a partially re-programmed iPS cell line, which only gives origin to germ cell lineage, we have performed a comparison between two different types of human cells, a human embryonic stem cell line (HS401) and the induced partially pluripotent germ cell line (ChiPSA) at whole transcriptome levels by RNA-Seq using SOLiD 3 System. The sequencing yielded millions of reads from the two cell lines and about 64% of the reads were mapped to the human genome in both lines. Out of these, 40% - 50% of the reads were uniquely mapped. Among 29409 evaluated genes/transcripts from 22 autosomal chromosomes and the X and Y chromosomes, we found that 20108 genes were expressed in both cell lines, while 6095 genes were not expressed in any of the two. Furthermore, 1825 genes were found uniquely expressed in ChiPSA, compared to 1381 genes solely expressed in HS401. Eighty-nine genes were highly differentially expressed. Our transcriptome data provide high-resolution information on the characteristics of the studied ES and iPS cell lines, adding important knowledge to research application of these cell lines.

1761/W

Role of the *ACACB* Gene in Human Metabolic Syndrome. *L. Ma, B.I. Freedman, M. Murea, A.K. Mondal, S.C. Elbein.* Internal Medicine, Wake Forest University Health Sciences, Winston Salem, NC.

The widely expressed acetyl CoA carboxylase β gene (*ACACB*) is a key negative regulator of fatty acid oxidation through carnitine palmitoyltransferase-1 (CPT-1). We hypothesized that *ACACB* expression would differ with insulin sensitivity (SI) in humans, and that expression levels would be controlled by DNA variation. We first evaluated *ACACB* expression in adipose and muscle taken from 22 African American (AA) and 40 Caucasian (CA) individuals who were divided equally between the extremes of SI. *ACACB* expression was increased by 1.7-fold in insulin sensitive CA subjects, but was not associated with SI in AA. These results were confirmed in a larger set of 107 CA, where *ACACB* levels remained correlated with SI (r=0.31; p=0.002, adjusted for age and gender), but not in 47 AA. Two local SNPs (rs2075259 & rs2075263) were associated with adipose *ACACB* expression in 62 non-diabetic subjects (40 CA; 22 AA; $p=3x10^{-8}$ and $5x10^{-7}$ respectively) in our prior microarray screening. These two SNPs, together with rs2075260 (V2141I), showed nominal associations with adipose *ACACB* expression by real time qPCR in 107 CA and 47 AA subjects (Stouffer p<0.001, recessive model). *ACACB* SNP rs2300455 was nominally associated with T2D (p= 0.00088) in publicly available data from the DIAGRAM consortium. We tested for association with body mass index (BMI), SI, acute insulin response to glucose (AIRG), and adipose *ACACB* expression for 8 *ACACB* coding SNPs. After adjusting for age and gender, subjects with allele T of synonymous SNP rs7135947 (C/T, Gly728Gly) had trend to lower adipose *ACACB* expression level (p = 0.03 in 47 AAs; p = 0.09 in 106 CAs; Stouffer p=0.01; additive model), and a lower BMI (p=0.0045, dominant model: TT+CT vs. CC; n=158) in AA, but not in CA. AA subjects with the T allele had higher AIRG (p=0.04) after adjusting for age, gender, protocol, BMI, and SI, and this association remained significant in all 497 subjects (AA and CA, combined p= 0.007, dominant model). Adipose *ACACB* expression was negatively correlated with BMI after adjusting for age and gender in CA (p=0.0002, r=-0.35, n=107), but not in AA (p=0.32, n=47). Allelic expression imbalance studies of 6 SNPs supported the existence of cis acting variants, as did total *ACACB* expression in transformed lymphocyte cell lines. Our data supports cis acting variants controlling *ACACB* expression in adipose and transformed lymphocytes, and may suggest ethnic-specific roles for *ACACB* in human glucose homeostasis.

1762/W

Pervasive Epigenomic Regulation in a Mouse Model of Maternal Obesity. *D. Serre[1], H. Miller[1], J. Hester[1], D. Buchner[2], J. Nadeau[2].* 1) Genomic Medicine, Cleveland Clinic, Cleveland, OH; 2) Dept of Genetics, Case Western Reserve University, Cleveland, OH.

Epidemiological studies and animal models have shown that maternal obesity during pregnancy increases the risk for the offspring to develop metabolic diseases in adulthood. However, the molecular bases underlying these life-long consequences remain poorly understood. We have developed a mouse model for studying the influence of maternal obesity and test how early developmental stresses are translated into lasting metabolic dysregulations. Briefly, we assigned C57BL/6J females to low-fat (LF, 10%kcal from coconut oil) diet or a high-fat (HF, 58%kcal from coconut oil) diet for 5 weeks before mating and maintained the pregnant dams on these diets throughout pregnancy and lactation. At weaning, we randomly assigned half of the offspring from LF and HF fed mice to a HF or LF postnatal diet to test if the nutritional conditions during early development could influence the response to an obesogenic environment. At nine weeks of age, we sacrificed the offspring and characterized in 80 animals the genome-wide gene expression profiles of six tissues (brain, liver, pancreas, muscle, adipose tissue and heart). Overall, we observed that postnatal diet influenced the expression of 30-45% of the genes in all tissues but liver where the effect is more pronounced (~60% of the genes were differentially expressed between offspring fed on HF and LF diet after weaning). In contrast, the maternal diet shows very heterogeneous effects across tissues: muscle and adipose tissues show no main effects of the maternal diet while in brain and liver roughly 35% of the genes are differentially expressed according to the maternal diet. In addition, the effect of the maternal diet varies dramatically depending on the postnatal nutritional conditions. To better understand the origin and consequences of these effects of maternal obesity on gene expression regulation, we have complemented the gene expression profiles with a comprehensive characterization of the genome-wide DNA methylation patterns in liver and an extensive quantitative assessment of plasma molecules.

1763/W

Profiling the transcriptome of human brain regions using high-throughput Capped Analysis of Gene Expression (CAGE) sequence analysis. *L. Pardo Cortes[1], P. Rizzu[1], M. Francescatto[1], M. Vitezic[2], H. Takahashi[2], N. Bertin[2], C. Daub[2], P. Carninci[2], P. Heutnik[1].* 1) Clinical Genetics, Section of Medical Genomics.VU medical Center, The Netherlands; 2) RIKEN OMICS SCIENCE CENTER, RIKEN YOKOHAMA INSTITUTE, Yokohama, Japan.

We are analyzing the transcriptome of post-mortem tissue from different aged human brain regions using CAGE to identify Transcription Start Sites (TSS) and their promoter regions. We prepared 25 CAGE libraries from total RNA isolated from 5 brain regions (caudate nucleus, frontal lobe, hippocampus, putamen and temporal lobe) from 5 subjects who died from non-neurological conditions. Mapping, expression normalization and clustering of the tags were carried out using automated pipelines (OSC, RIKEN). More than 14 million CAGE tags were mapped to unique positions in the human genome. We estimated differences in expression between regions using both global and pairwise tests based on uniquely mapped CAGE tags (TSS) present in at least 3 libraries. Over 76% and 47% of TSS originated from known RefSeq transcripts and from the promoter regions (-300 to +100bp)around RefSeq TSS, respectively. Many of the 'intergenic' TSS were represented by high tag counts, which suggests that these are not the result of background transcription. We divided the TSS into 3 groups according to their level of expression: highly expressed (HE; top 25%), moderately expressed (ME, middle 50%) and lowly expressed (LE; bottom 25%). Most (93%) of HE TSS were derived from known genes. Functional annotation analysis showed that HE genes were significantly overrepresented in categories such as metabolic processes, were located more often in mitochondria and were more often transcription factors. Unlike HE TSS, only 70% and 24% of ME and LE TSS, respectively were derived from known genes. We found that 21% of all TSS were differentially expressed (DE) across brain regions (1%FDR). The hippocampus accounted for most differentially expressed TSS and had the largest group of region specific TSS. Examples of these were TSS mapping to the RGL1, SOX5, and ITM2B genes. The most dissimilar regions were the hippocampus and caudate nucleus. DE genes between caudate and hippocampus included calcium channel genes (e.g. CACNA2D1, calmodulins) and transcription factors (e.g. TCF4 and CAMTA1). 19% of DE hippocampal TSS, mapped to intergenic regions. Our results shows that genes involved in metabolic processes are highly expressed throughout all brain regions. 19% of hippocampal TSS may represent novel promoters. ITM2B a gene involved in dementia was one of the most DE genes in hippocampus. This suggests that ITM2B is also an interesting target for expression studies of aging and cognitive decline.

BACKGROUND: Autism Spectrum Disorder (ASD) is a pervasive developmental disorder characterized by a triad of defects: impairments in social interaction and communication, and restricted and repetitive behaviour. The genetics underlying ASD is highly complex, with heritability estimates of greater than 90%. The genetic cause for a majority of cases has yet to be identified, but is likely to involve multiple genes. One approach to understanding the molecular changes that occur in ASD is through gene expression profiling. RESULTS: Here we report the results of a profiling study with peripheral blood gene expression data from 258 patients with ASDs and 158 controls enrolled in Boston area hospitals. We developed a 245-gene prediction model that achieves 80% cross-validation accuracy on a sample cohort of 90 male patients with ASDs and 55 male controls (AUC 0.83). More significantly, this model achieves 74% accuracy in an independent population of 168 patients with ASDs and 103 controls (AUC 0.78). Several immune and neuronal signalling pathways are significantly enriched in both populations. This signature also distinguishes post-mortem brain gene expression profiles of 11 patients with ASDs from 11 controls. RT-qPCR measures further validate these findings. CONCLUSIONS: Our findings suggest that changes in peripheral blood gene expression reflect those found in the ASD brain, as well as implicate the processes of neurodevelopment and immune signalling in disease.

Significant *cis* regulatory effects are detectable for a large proportion of genes expressed in human lymphocytes. *E. Drigalenko[1], J.E. Curran[1], M.P. Johnson[1], M.A. Carless[1], J.W. Kent Jr[1], J. Peralta[2], T.D. Dyer[1], S.A. Cole[1], L. Almasy[1], A.G. Comuzzie[1], M.C. Mahaney[1], E.K. Moses[1], J. Blangero[1], H.H.H. Göring[1].* 1) Dept. of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Universidad de Costa Rica, San Pedro, Costa Rica.

Much of the genetic variation underlying common human diseases are thought to be regulatory rather than structural in nature. Fine-scale statistical genetic analyses of genome-wide transcriptional profile data can be used to identify the genetic factors that are significantly associated with quantitative gene expression levels. This information in turn can be used to shed light on which genes and variants likely are the etiologically functional elements within complex disease candidate regions identified by genome-wide linkage and association analysis. By now it has been established that the proximal locus, *i.e.* the genomic region including and surrounding a particular gene, often contains functional genetic variants that determine the quantitative expression level. These variants are thought to act in *cis* and can have strong effects. The power to detect these *cis*-acting variants is much higher than for *trans*-acting variants located elsewhere in the genome because the former only requires examination of the proximal locus, and hence involves a much reduced multiple testing burden compared to genome-wide analysis. We have undertaken an examination of the frequency and strength of putative *cis* regulation in human lymphocytes in the San Antonio Family Heart Study. Using genome-wide transcriptional profiles data (Illumina; 16,681 significantly expressed and highly heritable transcripts) and SNP genotype data (Illumina; 542,944 SNPs after QC) from 1,189 Mexican Americans, and joint linkage and association analysis, we detect statistically significant evidence of *cis* regulation (at the false discovery rate of 0.05) for 43% of transcripts. In many cases the evidence is beyond all reasonable doubt (with p-values << $1.3x10^{-7}$, which corresponds to an empirically determined 0.05 genome-wide significance level). Detection of putative *cis* effects is maximized at a 20 kbp symmetrical window around genes, as compared to smaller or larger window sizes (we evaluated 0-1 Mb intervals), though some putative *cis* variants can be detected at a substantial distance. Overall, *cis* variants appear to be roughly equally likely to be positioned upstream or downstream of genes. ~4% of all SNPs genotyped in the genome show significant *cis* association results with at least one nearby transcript. We conclude that *cis* regulation is likely universal, impacting every gene, and that a database of *cis* variants should help in pinpointing which variants have the potential to be functional.

Genome-wide search strategies for detecting *trans*-regulatory variants influencing human gene expression levels. *H.H.H. Goring[1], E. Drigalenko[1], J.E. Curran[1], M.P. Johnson[1], M.A. Carless[1], J.W. Kent Jr[1], J. Peralta[2], T.D. Dyer[1], S.A. Cole[1], L. Almasy[1], A.G. Comuzzie[1], M.C. Mahaney[1], E.K. Moses[1], J. Blangero[1].* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Universidad de Costa Rica, San Pedro, Costa Rica.

While it is now well established that *cis*-regulation plays an important role in influencing quantitative gene transcription levels, much less is known about *trans*-acting factors. The search for such factors is complicated by the fact that it requires genome-wide searching, as there is no *a priori* candidate region for where these factors likely are located. Power is thus reduced due to the enormous multiple testing burden. We have performed a large-scale empirical comparison of three different genome-wide search strategies for detecting trans regulators, based on quantitative gene expression data and SNP genotype data for lymphocyte samples from 1,189 Mexican American participants in the San Antonio Family Heart Study. The three examined strategies are: (1) The customary genome-wide search, based on 542,944 SNPs. As we seek to identify *trans*-acting factors, we excluded the proximal locus (here taken to be 10 Mb around a gene). We used an empirically derived genome-wide 0.05 significance level (pointwise p-value of 1.3x10-7). (2) A genome-wide search using a subset of genotyped SNPs, namely putative *cis*-acting variants. We have identified ~20K SNPs that show significant association with the expression level of at least one gene located nearby. This strategy is based on the idea that such variants tag genomic regions harboring regulatory variants. The reason is that *cis*-acting factors may often have trans-acting effects, namely when the *cis*-regulated gene (such as a transcription factor) regulates the transcription of genes located elsewhere in the genome. (3) A search focused on specific candidate regions. We have generated a gene network based on the genetic correlations of transcript levels. Pairs of significantly genetically correlated genes that are located far from each other presumably include pairs where one gene acts as a trans regulator of the other gene. Hence, for such pairs of transcripts, we have an *a priori* candidate region, which we search using only the putative *cis*-acting SNPs located in the region. This approach also allows us to gain directional information about the relationship of these gene pairs. So far, we have identified significant putative trans associations for ~10% of transcripts, with about one half of those transcripts pointing to more than one trans locus. Our results suggest that smart search strategies can be useful in identifying subtle *trans*-regulatory variation influencing gene expression levels in humans.

Cis-rSNPs can be directly interrogated and mapped in human cells using genome-wide allelic expression (AE) measurements on Illumina 1M BeadChips (NG 2009;41:1216). Expression is assessed for unspliced primary transcript, therefore providing a unique view of transcriptional variation at a population level. Previously, we have shown that in HapMap CEU lymphoblastoid cells (LCLs) up to 35% of transcripts harbor significant *cis*-variation that maps to common SNPs. A subset of these can be assigned at high confidence to full length primary transcripts, which are likely to represent effects on variable transcription rates. Fine-mapping of these variants in LCLs derived from CEU and YRI population using 1000 Genomes data reveals strong overlaps with functional regulatory sites independently described by the ENCODE project. Traditional approaches for validation of cis-rSNP function yields positive results. Extension of population-based AE-mapping to human cells of distinct lineages (purified monocytes and primary fibroblasts) indicates a pervasive influence of *cis*-rSNPs on transcription. Up to 60% of human genes that are expressed in all three cell types show strong evidence of *cis*-rSNPs that alter the expression of full-length primary transcripts in at least one cell type. Cell-type independent cis-rSNPs that alter transcription demonstrate strong predilection to immediate vicinity of transcription start sites (TSSs), whereas *cis*-rSNPs restricted to cell types map more distally from TSS. Furthermore, the effect size of *cis*-rSNPs is correlated with distance from TSS, suggesting that genetic variation in distal elements exert more subtle modulation of transcription. Large collection of *cis*-rSNPs in multiple cell types will enhance our ability to interpret genetic association studies: one fifth (365/1896) of GWAS hits published to date not only overlap significant (FDR 5%) cis-rSNP, but are also in strong LD (r2 above 0.5) with the top cis-rSNP that alter transcription. E.g. *cis*-rSNPs for LDLR and HMGCR that correlate with LDL GWAS hits as well as IL6R *cis*-rSNP for circulating CRP concentration are among these hundreds of functional SNPs. Overall, the mapped *cis*-rSNPs provide a large number of pathophysiological clues for common traits. We will discuss the implications of fine-mapping causal variants and the advantages of comprehensive catalogues of functional SNPs in the human genome across multiple cellular lineages.

The impact of genetic polymorphism on inter-individual and inter-population differences in the response to glucocorticoids. *F. Luca, J. Maranville, A. Richards, X. Wen, D. Witonsky, M. Stephens, A. Di Rienzo.* Department of Human Genetics, University of Chicago, Chicago, IL.

Glucocorticoids (GCs) are steroid hormones produced by the human body in response to environmental stress. GCs modulate a large number of biological processes including cell survival and inflammation and are widely used as pharmacological agents in the treatment of common diseases such as cancer and asthma. GC action is largely mediated by the interaction with the GC receptor (GR), which activates a transcriptional cascade by regulating gene expression of direct targets. Because GCs modulate the response to environmental stressors, and human populations inhabit a wide variety of environments, we have hypothesized that the transcriptional response to GCs varies across human populations and that this variation is due to genetic variants that diverged in allele frequency possibly because of natural selection. To test this hypothesis, we analyzed the response to GC treatment (8 hours) in EBV-transformed lymphoblast cell lines (LCLs) from two HapMap populations, i.e. Yoruba from Nigeria and Tuscans from Italy (58 samples each). We performed eQTL mapping by applying a novel Bayesian approach. Specifically, we compared five different models under which genetic variation may affect gene expression in the presence/absence of GC treatment. This approach allows us to discriminate between genetic variants that affect gene expression equally (stable eQTLs) or differently (response eQTLs) in the presence and absence of GCs. We were able to identify 445 responsive genes (FDR<0.005) with stable eQTLs and 224 genes with response eQTLs (Bayes factor>100 for eQTLs in both cases). We also identified 307 genes (FDR<0.05) with significant differences in transcriptional response between populations. These differences are substantially reduced when we remove the effect of eQTLs (corresponding to genotype effect and allele frequency), suggesting a genetic basis for between population differences. Our study shows that genetic variation affects the transcriptional response to GCs and may account for some of the differences observed between populations in GC-related phenotypes. Additionally, our Bayesian approach to QTL mapping provides testable hypotheses of the molecular mechanisms underlying the identified QTLs. We are currently in the process of testing these hypotheses by performing genome-wide chromatin immunoprecipitation experiments for the GR and cooperating transcription factors.

Transcriptional response signature of immune cells to IFN-β reveals distinct patterns in monocytes. *N. Avidan[1], N. Henig[1], T. Paperna[1], R.Y. Pinter[3], A. Miller[1,2].* 1) Pharmacogenetics and Translational Genetics Center Rappaport Faculty of Medicine & Research Institute, Technion-Israel Institute of Technology, Haifa, Israel; 2) Division of Neuroimmunology & Multiple Sclerosis Center, Carmel Medical Center. Haifa, Israel; 3) Department of Computer Science, Technion-Israel Institute of Technology, Haifa, Israel.

Monocytes, which have been acknowledged as important players in MS pathogenesis, are outnumbered by neutrophils and lymphocytes in peripheral blood mononuclear cells (PBMC). Interferon-b (IFN-β) is a widely used immuno-modulatory drug in MS and much effort has been invested to identify a gene expression signature associated with either good or poor response to the drug. We hypothesized that the monocytes unique expression profile might be obscured by T-cells, which are much more abundant in PBMC. Moreover, we suggest that this distinct response might underlie novel IFN-β functions and pathways. Using cell specific surface markers, CD14+ monocytes and CD3+ T lymphocytes were isolated from 3 healthy blood donors and exposed to IFN-β overnight. The expression profiles of the two cell types in response to IFN-β treatment were evaluated using Illumina HumanWG-6 microarray. Analysis was carried out using JMP Genomics and pathway enrichment was evaluated using GOrilla. Two-way analysis of variance revealed 280 and 47 genes with more than 2 fold change after FDR correction in monocytes and in T cells respectively, from which 38 were common to both cell types. Functional enrichment analysis revealed in T-cells the expected pathways of "immune system process"," response to virus", and "inflammatory response". However, although five times as many genes were differentially expressed in monocytes, less functional pathways were found to be enriched, suggesting that in monocytes IFN-β activates a signaling pathway that is in one way or another different from the established ones. The cell-specific IFN-β response was validated by RT-PCR for eight genes, and further validation on the protein level is in progress. We propose that in MS patients' monocytes expression profile may be better predictors for drug response than PBMC expression profile, and that these cell-specific immuno-modulatory pathways might have been overlooked. Future studies should evaluate the role of monocyte-specific genes, and possibly additional immune cell subsets, in the response profile of MS patients treated with IFN-β.

Transcriptional profiling, brain ratio and the search of human genes involved in mental retardation. *P. Chiurazzi[1], F. Pirozzi[1], U. Moscato[2], P.J. van der Spek[3], G. Neri[1].* 1) Institute of Medical Genetics, Catholic University, Rome, Italy; 2) Institute of Hygiene, Catholic University, Rome, Italy; 3) Department of Bioinformatics, Erasmus University Medical Center, Rotterdam, The Netherlands.

Mental retardation (MR) is defined by a defect in intellectual functioning and adaptive behaviour. MR can be caused by genetic defects, environmental factors or a combination thereof. Among the monogenic causes of MR, the best characterized group is that of X-linked Mental Retardation (XLMR). Using available data downloaded from Gene Expression Omnibus (www.ncbi.nlm.nih.gov/geo), we reconstructed the expression profile of 20588 transcripts in 79 human tissues, including 30 samples derived from the central nervous tissue. We also calculated a "brain ratio" for all transcripts, estimating the relative level of expression in the nervous system compared to non-nervous tissues, and ranked them according to such ratio. Then we compared the brain ratio of all transcripts with that of the 90 known XLMR genes and of the approximately 1000 genes encoding for synaptic proteins listed in the Genes to Cognition or G2C catalogue (www.genes2cognition.org). Finally we compared the individual human chromosomes in order to identify which of them are richer in genes with high brain ratio. The analysis of the XLMR genes showed that a strong correlation exists between the brain ratio and the clinical presentation, namely a low brain ratio (indicating an ubiquitous expression in many tissues) predicts a syndromic presentation while a high brain ratio usually associates with a neurologic or "pure MR" clinical picture. G2C genes tend to have very high brain ratios as expected, given that they encode synaptic proteins and many of them have already been found mutated in human neurologic disorders that includes MR. Finally, when individual chromosomes are considered, only 3 chromosomes have more than 10% of genes expressed more than two-fold in brain compared to other tissues, namely chromosome 18 (12.9%), 13 (11.5%) and chromosome X (10.8%). In conclusion, although genes involved in the pathogenesis of MR may have a low brain ratio, it is likely that mutations in genes with a high brain ratio cause MR. Therefore, we suggest that knowledge of the brain ratio of individual genes contained in a given chromosomal region or linkage interval may be useful to prioritize candidates which should be analyzed first if the clinical condition is mainly characterized by MR.

Batch effects in microarray experiments: performance evaluation of six algorithms. *C. Chen, D. Zhang, J. Badner, E. Gershon, C. Liu.* Psychiatry, University of Chicago, CHICAGO, IL.

The microarray expression study is currently a popular approach to explore a variety of biological questions. However, the technology per se remains unresolved "batch effects" in the thousands of microarray papers published every year: the systematic error introduced when samples are processed in multiple batches. Although thoughtful experimental design can reduce batch effect but not eliminate it except completing a study in one batch. Therefore, an additional step is helpful to adjust microarray data for batch effect before analysis. A number of programs using a variety of algorithms are now available. Here, we systematically compare six of these programs and demonstrate ComBat outperforms the others in multiple measures of precision and accuracy. We also show that it is essential to standardize replicate data at the probe level, due to the sizeable probe effect in microarray data which can inflate the correlation among replicates.

1772/W

Gene Expression Meta-Analysis in Schizophrenia and Bipolar Disorder. *D. Greco[1], K. Qian[2], A. Di Lieto[2], J. Corander[2], P. Auvinen[2].* 1) University of Helsinki Central Hospital, Helsinki, Finland; 2) University of Helsinki, Finland.

Background: The differential diagnosis of schizophrenia (SZ) and bipolar disorder (BD) is based solely on clinical features and upon a subset of overlapping symptoms. Within the last years, an increasing amount of clinical, epidemiological and genetic data do not support the model that bipolar disorder and schizophrenia would be independent syndromes, challenging the Kraepelinian dichotomy. Methods: We performed meta-analysis of 140 individuals' gene expression microarray data obtained from post mortem prefrontal cortex of bipolar disorder and schizophrenia patients and matched controls from independent experiments. Results: We found 535 and 213 genes specifically altered in bipolar disorder and schizophrenia respectively. Of these, 30 genes were shared between the syndromes. In addition, we identified genes of the transcriptional and post-transcriptional machineries altered in bipolar disorder and genes of the development changed in schizophrenia. Conclusions: Our results confirm that, on the gene expression level, bipolar disorder and schizophrenia can still be considered independent diagnoses according to the clinical model of the Kraepelinian dichotomy.

1773/W

Genome-wide transcriptome analysis of human placenta. *J. Kim[1], L. Lin[2], S. Shen[3], J.C. Murray[1,4], Y. Xing[2,3,5].* 1) Department of Anatomy and Cell Biology, Univ Iowa, Iowa City, IA; 2) Department of Internal Medicine, Univ Iowa, Iowa City, IA; 3) Department of Biostatistics, Univ Iowa, Iowa City, IA; 4) Department of Pediatrics, Univ Iowa, Iowa City, IA; 5) Department of Biomedical Engineering, Univ Iowa, Iowa City, IA.

The placenta is a multifunctional organ with transport, metabolic, endocrine, and immunologic activities that are vital to fetal development and pregnancy maintenance. Malfunction of the placenta can cause fetal growth impairment, prematurity, and other pregnancy complications, and identification of genes important for normal placental function may contribute to a better understanding of mechanisms underlying these adverse pregnancy outcomes. In this study, we characterized the placental transcriptome by conducting gene- and exon-level expression profiling in human placental amnion (N=23), using Affymetrix GeneChip Human Exon Junction Array. We first sought to identify genes distinctively expressed in the placenta by comparing with the gene expression patterns in other normal human tissues (cerebellum, epithelium, and blood). Our analysis revealed 236 differentially expressed genes (> 2-fold, FDR < 1%) that are enriched for nucleic acid and ion binding, transporter activity, and transcription regulation activity. Expression levels of selected genes including *TRIM29*, *CCL4*, and *SFRS14* were validated by quantitative real-time polymerase chain reaction (qRT-PCR). We next sought to identify genes that are involved in the process of normal labor, thus, when altered, could potentially contribute to undesirable obstetric complications. To this end, we subgrouped the placental amnionic samples into those obtained before and after the onset of labor. We found that a total of 42 genes were differentially expressed between the labor (N= 12) and non-labor (N=11) groups with 25 genes upregulated and 17 genes downregulated in the former group (≥ 1.5-fold, FDR < 1%). The differential expression of selected genes including *BMP2*, *GABRP*, and *PLIN2* was confirmed by qRT-PCR by analyzing identical samples used in the microarray experiment. Our study revealed gene-expression patterns unique to normal placenta and transcriptional changes associated with normal labor, which may lead to an improved understanding of placental biology as well as pathobiology. Examination of detailed isoform-level changes and expression patterns in other anatomical parts of the placenta may provide valuable clues to further understanding the pathophysiology of placenta-associated complications.

1774/W

Defects in protein metabolism pathways in a conditional muscle-specific transgenic mouse model over-expressing Pitx1. *S.N. Pandey[1], J. Cabotage[1], R. Shi[1], Y.W. Chen[1,2].* 1) Research Cenetr for Genetic Medicine, Children National Medical Center, Washington , DC 20010; 2) Department of Integrative Systems Biology and Pediatrics, George Washington University, Washington, DC 48109.

We previously showed that paired-like homeodomain transcription factor 1 (PITX1) was specifically up-regulated in patients with facioscapulohumeral muscular dystrophy (FSHD) comparing to 11 other neuromuscular disorders by expression profiling. We hypothesized that the up-regulation of PITX1 in skeletal muscles caused muscle atrophy in FSHD. To test the hypothesis we generated tet-repressible muscle-specific Pitx1 transgenic mice in which over-expression of Pitx1 is induced in skeletal muscles by doxycycline withdrawal. The Pitx1 transgenic mice showed muscle atrophy phenotype after over-expressing Pitx1 for 5 weeks. To study the molecular mechanisms of the muscle wasting, mRNA profiling of muscles collected from mice over-expressing Pitx1 for 3 weeks (n=5) was performed using mouse430_2 Affymatrix microarrays. Expression level of mRNA was calculated using two algorithms (MAS5.0 and PLIER). Using Welch T test in Genespring 7.3.1 with cut-off value of p< 0.01, 3280 genes were significantly differentially expressed between the Pitx1 transgenic mice and the control littermates. Ingenuity pathway analysis (IPA) was used to further categorize genes into functional groups and networks. The IAP results showed that genes involved in amino acid metabolisms and protein synthesis were significantly down-regulated. Interestingly, some ubiquitin-conjugating enzymes that are known up-regulated in muscle atrophy such as NEDD4l and atrogin-1/MAFbx showed changes in the opposite direction. The results suggest that muscle atrophy induced by Pitx1 may not share common mechanisms with other conditions commonly causing muscle atrophy.

Enhanced ROC (EROC) for discovery of differentially expressed transcripts in microarray data. *D. Wroblewski, E. Wroblewska*. BioFormatix, Inc., San Diego, CA.

Purpose. To test a new methodology for identification of genomic biomarkers in microarray experiments with small number of replicates.

Methods. We use a robust, non-parametric estimate of noise distribution that is derived through resampling of analyzed data set. At least two replicates are required per condition. The differentially expressed genes (transcripts) are identified with non-parametric ROC (Receiver Operating Characteristic) uni-variate analysis. The approach viability is shown through comparison with three widely used 'benchmark' methods (RankProd, SAM, MAANOVA) and through knowledge-based analysis of results.

We used Mouse Gene Atlas (GNF, San Diego), which contains expression data for 78 normal mouse tissues obtained with Affymetrix mouse array (MOE430), with two experimental repeats per tissue. To produce comparisons for experiments with a larger number of repeats, we generated simulated data. Lists of differentially expressed probes were produced by each of the methods for pair-wise comparisons of tissues. Tissues with diverse levels of similarity were compared.

Summary of Results. EROC is effective in discovering differentially expressed probes in experiments with small number of experimental replicates. Overall, it performs better than the benchmark methods. Several metrics of performance were considered. (1) When the same detection criteria are used, EROC finds similar number of up/down regulated probes, independent of the number of experimental repeats. For other methods, the number of detected probes increases significantly with the number of repeats. (2) EROC probe lists show high consistency for experiments with different number of replicates. RankProd shows somewhat higher consistency that may be related to its ranking being highly correlated with fold change. (3) EROC shows reasonable and consistent correlation between fold change and ranking. For SAM and MAANOVA, the correlation coefficient increases with the number of experimental repeats. (4) EROC shows superior (but comparable to RankProd) ability to detect genes that are known to be expressed in certain tissues.

MicroRNA expression profiling in the human cartilage growth plate. *Y. Xue[1], V. Funari[1,2].* 1) Genomics Core, GCRC Department, Cedars-Sinai Medical Center, Los Angeles, CA, 90048; 2) Medical Genetics Research Institute, Cedars-Sinai Medical Center, Los Angeles, CA, 90048.

INTRODUCTION The endochondral growth plate is a well-organized developmental structure with a spatial distribution of chondrocytes in different proliferation and differentiation stages. MicroRNAs (miRNAs), noncoding RNAs of 18-25 nucleotides, are generally believed to regulate gene expression at the post-transcriptional level by inducing degradation of target mRNAs that involve cell proliferation, differentiation and apoptosis. Identifying miRNAs expressed in growth plates and their prospective targets will enable further characterization of miRNAs role in endochondral ossification and skeletal dysplasias. METHODS AND RESULTS Total RNA isolated from four human cartilage samples were subdivided, then pooled into two subgroups. Commercially available total RNA from 16 tissues were subdivided into two pools of eight assorted tissues. RNAs from the two pooled cartilage samples and the two pooled non-cartilage samples were labeled and hybridized to Affymetrix GeneChip miRNA array. Cartilage miRNA data were compared to non-cartilage miRNA data to identify differentially expressed miRNAs. Forty-three miRNAs were found significantly altered in cartilage with 17 up-regulated and 25 down-regulated. MiRNA 140, specifically expressed in cartilage, was found up-regulated nine fold in cartilage tissue. A cartilage gene enriched list of 2500 genes derived from a previous microarray analysis was used to predict the mRNA targets. Target genes of three miRNAs (miRNAs 433, 140, 424) with the most significant changes and number of targets were chosen for Gene Ontology (GO) analysis and found significantly correlated with changes in intracellular organelle, transcription regulation and developmental processes, respectively. CONCLUSION The first miRNA profile for human cartilage tissue was identified. The finding of differentially expressed cartilage miRNAs and their targets will help enable the study of gene regulation in the development of growth plate.

Using transcription modules to identify pathways perturbed in Williams-Beuren syndrome. *C.N. Hor[1], G. Csardi[2,3], M.-T. Zabot[4], C. Fusco[5], S. Bergmann[2,3], G. Merla[5], A. Reymond[1].* 1) Centre for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 2) Department of Medical Genetics, University of Lausanne, Lausanne, Switzerland; 3) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 4) Centre de Biotechnologie Cellulaire, Hospices Civils de Lyon, groupement hospitalier Est, BRON, France; 5) Laboratory of Medical Genetics, IRCCS "Casa Sollievo della Sofferenza", San Giovanni Rotondo, Italy.

The global dysregulations caused by the Williams-Beuren Syndrome (WBS) deletion have been only partially characterised. We profiled the transcriptomes of skin fibroblast cell lines from WBS patients and compared them to matched controls. We identified 366 differentially expressed genes that were significantly enriched in extracellular matrix genes, major histocompatibility complex (MHC) genes, as well as genes the products of which localise to the actin cytoskeleton, microsome and vesicular fractions. We then used public expression datasets from human fibroblasts and the Iterative Signature Algorithm (ISA) to establish "transcription modules", i.e. subsets of genes that exhibit a coherent expression profile over a subset of microarray experiments. The majority of these modules are highly enriched in genes with common functional annotation, but they have the added advantage of including genes that have no or fragmented annotation. Hence, this modular approach increases the power to identify pathways dysregulated in WBS patients, thus providing additional candidates for genes and their interactions modulating the WBS phenotypes. Dysregulated modules are often interconnected and share multiple common genes, suggesting that intricate regulatory networks connected by a handful of central factors are disturbed in WBS. Our results emphasize the role of the extracellular space in the pathophysiology of WBS and provide novel clues about other affected processes. We identified, for example, variations in the expression of GABA receptor components that could have consequences at the cellular and synaptic level and common features with other syndromes, such as dysregulation of the Di George Syndrome critical region 2 gene (DGCR2).

1778/W

Conditional expression of TGFβ1 in skeletal muscles causes endomysial fibrosis and myofiber atrophy. *J.H. Narola[1], S.N. Pandey[1], R.L. Marathi[1], A. Glick[3], Y.W. Chen[1,2].* 1) Department of Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Department of Integrative Systems Biology and Department of Pediatrics, George Washington University, Washington DC; 3) Department of Veterinary and Biomedical Sciences, Pennsylvania State University, PA.

To study the effects of TGF-β1 over-expression by skeletal muscles, we generated a tet-repressible conditional muscle-specific TGF-β1 transgenic mouse model (mCK-tTA/TRE-TGF-β1). The TGF-β1 transgene was induced when the mice were 4 weeks old. Among the 24 TGF-β1 mice examined, 50% of them showed muscle weakness and reduced body weight within 2 weeks after TGF-β1 gene induction, 30% showed the phenotype after 5-10 weeks and 20% showed no phenotype during our observation period (19 weeks). We defined the mice that showed phenotype within two weeks of TGF-β1 overexpression as early phenotype (EP) and the rest as the late phenotype (LP). H&E staining of skeletal muscle sections showed that the myofibers of TGF-β1 transgenic mice were significantly smaller in both the EP ($p<0.001$) and LP ($p<0.01$) groups comparing to the controls. In addition, the myofibers of the mice in the EP group were significantly smaller than those in the LP group ($p<0.001$). Pico sirius red staining showed that the endomysial collagen accumulation was significantly higher in the TGF-β1 mice in both EP (9.3±1.6%, $p<0.005$) and LP groups (3.2±0.15%, $p<0.001$) comparing to controls (1±0.3%). The TGF-β1 level in blood sera and in muscle was examined using enzyme-linked immunosorbant assay (ELISA). In the sera, active TGF-β1 and total TGF-β1 (active and latent) level was significantly higher in the EP group comparing to control, while there was no significant difference between the LP group and the controls. In the muscle, active TGF-β1 ($p<0.01$) and total TGF-β1 level ($p<0.005$) in the EP was higher than the control group but no significant difference between the LP group and the control. The studies showed that over-expression of TGF-β1 causes muscle wasting and endomysial fibrosis with individual variability, which suggests involvement of additional regulatory mechanisms that affect the responses to the TGF-β1 expression in the transgenic mice.

DUX4, an FSHD candidate gene, induces pathways involved in DNA damage and hypoxia. *V. Sharma[1,2], R. Shi[1], J. Narola[1], N. Harafuji[1], Y. Chen[1,3].* 1) Center for Genetic Medicine, Children's National Medical Center, Washington, DC 20010; 2) Institute for Biomedical Sciences, George Washington University, Washington, DC 20037; 3) Department of Integrative Systems Biology and Department of Pediatrics, George Washington University, Washington, DC 48109.

Facioscapulohumeral muscular dystrophy (FSHD) is linked to the deletion of the D4Z4 arrays at chromosome 4q35 subtelomeric region. Each D4Z4 array contains a double homeobox 4 (DUX4) open reading frame. We previously showed that the DUX4 functioned as a transcription factor and regulated expression of paired-like homeodomain transcription factor 1 (PITX1) which was identified specifically upregulated in FSHD by expression profiling. In this study, we identified additional downstream targets and regulatory pathways of DUX4 by expression profiling C2C12 myoblasts transfected with expression vectors containing DUX4. Expression vectors containing homologues of DUX4, namely DUX4c and DUX1, and insertless vectors were used as controls. The expression profiling study was conducted using the Affymetrix 430_2 microarrays. The data was analyzed using Affymetrix MAS 5.0 followed by Weltch t test using Genespring GX 7.3.1. We identified 869 genes to be differentially expressed in the cells expressing the DUX4 gene compared to the insertless control ($p < 0.05$). Among them, 756 genes were specific to DUX4. The 5 top ranked canonical pathways identified using the Ingenuity Pathway Analysis were activation of IRF by cytosolic pattern recognition receptors, pyrimidine metabolism, ATM signaling, mitotic roles of polo-like kinase, and alanine, and aspartate metabolism. The 5 top ranked biological functions were cell cycle, RNA post-transcriptional modification, DNA replication, recombination and repair, cardiovascular system development and function, and infection mechanism. The data suggest that DUX4 is likely responsible for induction of DNA damage which in turn triggers a DNA repair response through multiple canonical pathways such as the IRF signaling pathway, ATM signaling pathway as well as the mitotic signaling pathway of polo-like kinase. The ATM signaling and polo-like kinase pathways are involved in cell-cycle checkpoints. Additionally, the DUX4 gene could also be involved in ischemic conditions as evidenced by upregulation of the alanine/aspartate metabolism signaling and IRF signaling pathway, which are frequently found to be misregulated in hypoxic conditions.

Simultaneous gene expression profiling of protein-coding and long non-coding RNA. *A. Bergstrom Lucas[1], M. Guttman[2], P. Tsang[3], G. Lin[1], J. Donaghey[2], J. Rinn[2], L. Bruhn[3].* 1) Genomics R&D, Agilent Technologies, Santa Clara, CA; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Agilent Labs, Agilent Technologies, Santa Clara, CA.

Recently thousands of large intergenic non-coding RNA (lincRNA) transcripts were identified in human and mouse cells from genome-wide chromatin-state maps. Through the comparison of lincRNA expression profiles to known protein-coding gene pathways, lincRNAs have been implicated in diverse biological processes such as stem cell pluripotency, innate immunity, and cell cycle regulation and many lincRNAs have been shown to play a role in these pathways through regulation of gene expression. To enable systematic profiling of all lincRNAs and protein-coding genes, we have developed both human and mouse microarrays comprised of all known protein-coding mRNAs and lincRNAs thus allowing for simultaneous detection from a single sample. In validating these new array designs, RNA samples from a variety of mouse tissues were labeled and applied to the new mouse arrays to detect differences in coding and non-coding gene expression profiles. Using this approach, we are able to identify novel differentially expressed lincRNAs. Here we show examples of how profiling mRNA and lincRNA from the same sample can allow researchers to further define the role of lincRNAs in gene regulation. Together, these results highlight the power of simultaneously profiling lincRNAs and protein-coding genes on the same array.

1781/W

Gene regulatory network modeling using L1 regularized graphical models. *X. Zhang[1,2], J. Listgarten[1], C. Kadie[1], W. Wang[2], D. Heckerman[1].* 1) Microsoft Research; 2) Univeristy of North Carolina at Chapel Hill.

Understanding the mechanisms of gene transcriptional regulation through analysis of high-throughput gene expression data is a central problem in computational systems biology. Although extensive research has been done to estimate gene regulatory networks, two challenges need to be better addressed. The first challenge is the high-dimension, low-sample-size problem, wherein the number of dimensions (genes) is much larger than the number of samples. The second challenge is how to model our (partial) knowledge about transcription factors and other confounding factors. We present a sparse graphical model to address these two challenges. Our model incorporates known transcription factors and introduces hidden variables to represent unknown transcription and confounding factors. The expression level of a gene is thus modeled as a linear combination of the expression levels of known transcription factors and hidden factors. To address the high-dimension, low-sample-size problem, we add an L1 regularization penalty to the log likelihood function to impose sparseness on the learned model. Using large gene expression data measured with 39,296 oligonucleotide probes from 1109 human liver samples, we demonstrate that our model better predicts out of-sample-data than a model with no hidden variables. We also show that some of the gene sets associated with hidden variables are strongly correlated with Gene Ontology categories and could therefore correspond to newly identified regulators.

The use of a water-soluble, inert chemical matrix to stabilize RNA in the liquid state at room temperature. *H. Martinez, D. Wong, C. Shi, B. Dalby, R. Nunez, M. Saghbini.* GenVault Corporation, Carlsbad, CA.

The purpose of this study was to examine the ability of an inert, water-soluble chemical matrix composed of antioxidents and RNase inhibitors to preserve the integrity of purified RNA stored in the liquid state at room temperature for up to one month. High quality RNA purified from rat liver, human white blood cells or HeLa cells was examined. RNA samples were applied to 1.5ml tubes containing a chemical matrix, known as GenTegra RNA, mixed to solubilize the chemicals with the RNA, and air-dried. Following dry state storage for up to two weeks, samples were rehydrated in molecular-grade water and stored at room temperature (25°C) or refrigerated (4°C) for two to four weeks. Controls stored frozen at -80°C, or in liquid state at 25°C and 4°C in the absence of the chemical matrix were also examined. RNA integrity was assessed using the RNA 6000 Nano Chip on the Agilent 2100 Bioanalyzer and by gel electrophoresis. Rat liver, human white blood cell or HeLa RNA stored in the dry state for up to two weeks in the presence of a chemical matrix, rehydrated, and stored at 25°C or 4°C for up to four weeks was indistinguishable from RNA stored frozen at -80°C. Conversely, RNA stored in the absence of the chemical matrix at 25°C or 4°C exhibited significant degradation during the same time period. RNA stored in the chemical matrix has been used successfully for gene expression analysis on the Affymetrix GeneChip Human Genome U133 Plus 2.0 Array and the Illumina Human HT-12 Expression BeadChips. In these studies, a greater than 96% correlation was observed between samples stored in the presence of the chemical matrix and controls stored at -80°C. Here, we have shown that a water-soluble, inert chemical matrix has the ability to stabilize purified RNA from various sources for up to one month when stored in the liquid state at room temperature or refrigerated. Storing RNA in the liquid state saves time and eliminates the potentially damaging effects of freeze-thaw cycles for RNA samples that will be used in multiple experiments. RNA stored in this manner can be successfully analyzed on the leading gene expression platforms.

1783/W

A Comparison of Next Generation Sequencing Technologies for Quantifying Transcriptional Response and Host-Agent Interaction. *A. Sivakumar[1, 2], J. Proescher[1], D. Drewry III[1], S. Kinahan[1], F. Ahmed[1], L. McNew[3], A. Chakravarti[2], E. Van Gieson[1].* 1) Johns Hopkins University Applied Physics Laboratory, Laurel, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 3) Edgewood Chemical and Biological Center, Aberdeen Proving Ground, MD.

Greater understanding of the host-agent interaction at the molecular level in the spatial and temporal context of exposure is needed to help identify better and earlier markers of infection, guide regulations for exposure limits, and identify targets for therapeutics. Next generation sequencing (NGS) technologies are poised to revolutionize transcriptional profiling, yet experimental workflow and data analysis processes are still evolving. In this study, a lymphoblastoid cell line from the fully sequenced HapMap sample, NA18507, were exposed to two different doses of bleomycin (10 μg/mL and 20 μg/mL) in order to quantify differential transcriptional response compared to the control treatment. The bleomycin/lymphoblastoid challenge represents a well-characterized system that offers an opportunity to compare sequencing-based expression analysis to other modalities of expression analysis previously performed with this challenge system. Our efforts compared the Roche/454 and Illumina/GAII NGS platforms for transcriptional profiling. Currently available computational tools and statistical packages were evaluated to identify capabilities and limitations of these processes to characterize mechanisms of agent interaction. The Roche/454 protocol resulted on the order of 1 x 10^5 reads per treatment with an average length of 200 bp. In contrast, the Illumina/GAII protocol resulted on the order of 1 x 10^7 reads per treatment with a length of 100 bp. The unique length and depth characteristics of each NGS platform were analyzed to investigate unmapped reads and provide insight into novel splice junction discovery. Both platforms agreed with validation performed using RT-PCR and Q-PCR for known bleomycin-associated genes (SIAH2, CDKN1A, DDB2, and FDXR). In addition, both platforms were shown to be in concordance with each other for known housekeeping genes. The primary metric to quantify gene expression was Reads per Kilobase of Exon Length per Million Mapped Reads (RPKM; Mortazavi et. al, 2008) and its advantages and disadvantages, as compared to alternative statistics are examined. Finally, the potential of NGS technologies to uncover novel transcripts expressed through such treatments is also discussed.

Identification of DNA-associated Proteins by Sequence-Specific Capture and Mass Spectrometry. *H. Guillen Ahlers[1], S. Mirza[1], S. Zhang[1], M. Zickus[1], R. Cole[1], M. Zelembaba[1], M. Chesnik[1], C-H. Wu[2], S. Chen[2], Y. Yuan[2], G. Kreitinger[2], M. Scalf[2], M.R. Shortreed[2], L.A. Cirillo[1], L.M. Smith[2], M. Olivier[1].* 1) Wisconsin Center of Excellence in Genomics Science, Medical College of Wisconsin, Milwaukee, WI; 2) Wisconsin Center of Excellence in Genomics Science, University of Wisconsin, Madison, WI.

Recent advances in genomics and proteomics have brought us closer to reaching a detailed and comprehensive understanding of our genome and how it is regulated. Numerous proteins mediate DNA stability, control its activity, and regulate transcription of the genetic information. However, currently no technologies exist that allow the dissection of these protein-DNA interactions in a comprehensive global manner, and examine alterations in disease. To overcome this challenge, we report on the development of an entirely novel technology. Unlike ChIP-chip methodology, where DNA sequences that interact with individual known proteins are characterized, the Wisconsin Center for Excellence in Genomics Science (CEGS) utilizes an oligonucleotide capture technology to isolate targets of interest in a sequence-specific manner in order to analyze protein complexes attached to these regions. In an initial study, the mouse insulin-like growth factor-binding protein 1 (IGFBP1) promoter region was used as an in vitro model system. Specific capture oligonucleotides were designed and attached to gold surfaces using linker chemistry and amino-terminated oligonucleotides. Hybridization was optimized to sequester PCR-products containing an exposed single-stranded overhang. After on-chip protease digestion, FoxO1 binding to the DNA sequence was detected by tandem mass spectrometry using an LTQ XL mass spectrometer. Due to its high binding affinity, the reaction was carried out without a cross-linking step between FoxO1 and the DNA. Our analysis demonstrates efficient capture of FoxO1-DNA complexes in a sequence-specific manner. Capture technology and mass spectrometry allowed the detection of 1 pMol of captured FoxO1 protein using a PCR product with a FoxO1 binding site while an alternative PCR product with a mutated binding site did not lead to the detection of FoxO1. The on-chip digestion and sample preparation can be performed on small array surfaces (<5 mm2). Additional efforts are under way to allow the selective capture of restriction fragments directly from genomic DNA, rather than specific PCR products. This work was funded by the Wisconsin Center for Excellence in Genomics Science through NIH/NHGRI grant 1P50HG004952.

Regulatory network construction from co-regulatory QTLs. *K.S. Kompass, J.S. Witte.* Epidemiology & Biostatistics, UCSF, San Francisco, CA.

The gene regulatory networks that control human cellular health and disease remain poorly understood. With inexpensive, high-throughput methods for profiling gene expression and genotype, transcriptional regulation in humans can be dissected by examining naturally occurring genetic variation. We previously developed a multistep method to identify trans loci governing gene co-regulation (Kompass and Witte, submitted) where significant associations between regulatory loci and gene clusters are called co-regulatory QTLs (crQTLs). We extend this work to model crQTLs in gene regulatory networks, building on recently developed Bayesian methods for eQTLs that incorporate genetic and other existing information to improve prediction (Zhu et al., Cytogenet Genome Res 2004). We apply this approach to an endometrial cancer dataset, where tumors were expression-profiled and samples genotyped with commercial arrays (Salvesen et al., PNAS 2009) using the R package 'deal' (Boettcher and Dethlefsen, JSS 2003). Regulatory priors were estimated from the data for each locus by comparing the distributions of crQTL association p-values to the overall background distribution. From this analysis, the gene PTPRD was predicted to be a key regulatory node interacting with GRIP1, HS3ST3A1, INPP4B, SLITRK3, PPARGC1A, PTBP2, and CCNG1. PTPRD is a tyrosine phosphatase with key roles as a tumor suppressor in multiple cancers (Veeriah et al., PNAS 2009), and these results suggest that PTPRD acts coordinately through various downstream genes to exert its effects in multiple pathways. Because several of these predicted interactors also have putative roles in cancer, future studies should examine the interactions between these genes as they shape the development of neoplasia. In summary, by extending crQTL results with a Bayesian network, we were able to distinguish putative regulatory networks for disease.

Comparison of copy number variations using array-based SNP genotyping and massive parallel sequencing data. *A. Koike, K. Kiumura.* Cent Res Lab, Hitachi, Ltd, Kokubunji, Japan.

Array-based technologies and massive parallel sequencing technologies enabled us to detect copy number variations (CNVs) on a genome-wide scale. Especially, with the increased use of high density SNP arrays for genome wide association studies, CNV analysis based on these SNP arrays is becoming widely applied to explore disease-associated CNVs. However, due to the noise of SNP array data, the accurate CNV detections are quite thorny issues and several CNV detection methods have been developed. In this study, we calculated CNVs of one Yoruba individual and one trio family using publicly available affymetrix 6.0 SNP array data and massive parallel sequencing data and compared them to clarify their characteristics. In sequencing analysis, reads were first mapped on the reference genome with allowing edit distance 2 and considering multiple mapping sites. The depth of read coverage in each 200bp window was then calculated. Finally, continuous low coverage regions and high coverage regions longer than 1kbp were detected with correcting GC content bias and multiple mapping read bias. The influence of multiple mapping reads was considered by simulation data and their mapped data. For the array analysis, Circular Binary Segmentation, Gaussian process with adaptive criteria, and Hidden markov model were used. When compared with these results, about 80% of duplications and 93% of deletions of commonly detected CNVs by three array analysis methods were also detected by sequencing data. The Hidden Markov model showed the highest overlapping ratio of CNVs with sequencing results in all analysis methods and the ratio was about 50% in duplications and about 90% in deletions. The overlapping ratio was expected to be related to the re-producible CNV ratio in each array analysis (consistencies of CNV detection of different arrays using the same sample) and the consistency ratio of trio data (the ratio of CNVs in children which are observed in their mothers or fathers). Acknowledgement: This work was partly supported by the contract research fund "Integrated Database Project" from the Ministry of Education, Culture, Sports, Science, and Technology of Japan.

Genotyping of Copy Number Variations Using Model-based Clustering. *N. Kumasaka[1], H. Fujisawa[2], N. Hosono[1], A. Takahashi[1], M. Kubo[1], N. Kamatani[1].* 1) Ctr Genomic Med, RIKEN, Tokyo, Japan; 2) The Institute of Statistical Mathematics, Tokyo, Japan.

Copy number variations (CNVs) have been investigated as biological markers to identify the genes relevant to common diseases and adverse effects. A typical statistical method to identify CNVs is the hidden Markov model, but it often fails via commercial genome-wide SNP genotyping platforms because of the lack of SNP marker density. We propose a model-based clustering method using a bivariate Gaussian mixture model with the Kullback-Leibler divergence penalty, which provides fast and reliable genotyping of CNVs. Using the fluorescence intensity data from the Illumina 610k platform, 3,378 CNVs with deletions were genotyped for a sample of 25,857 subjects. Around 300 subjects were randomly selected within the sample to validate CNV calls of 13 probes using Taqman Real-Time PCR Assay. The concordance of calls between the two independent assays, Illumina and Taqman, undertaken on these subjects was 99.71% (95% CI: 99.46 - 99.84%).

1788/T

Array CGH analysis of copy number variation in 200 Asian individuals. *D. Lee, Y. Ju, S. Lee, J. Kim, J. Seo.* GMI, Seoul national university, Seoul, Seoul, Korea.

Copy number variants (CNVs) accounts for the majority of human genomic diversity in terms of base coverage. But we still can't understand most part of it. In previous studies, we found over 3000 putative Asian specific CNVs. Further more, we developed CGH Array Reference-free Algorithm (CARA), to infer reference-free personal CNVs across aCGH platforms, and designed customized array CGH chip especially for calling Asian specific CNVs. Using these methods, we analyzed 200 individuals, 45 Chinese, 45 Japanese, 45 Mongolian, 45 Korean, 20 yoruban, and 20 European, to validate the previous results and find novel CNVs. We could see the difference of allele frequency among the populations. We expect the result of this study will help the following studies and especially for studying Asian, the database we made can be the foundation stone to start. More over, this study will help understand a lot of veiled aspect of CNVs.

1789/T

Mobile element insertion polymorphisms from the 1000 Genomes Project. *C. Stewart[1], D. Kural[1], M.P. Stromberg[1], W.P. Lee[1], J.A. Walker[2], M. Konkel[2], A.M. Stutz[3], J.O. Korbel[3], M. Batzer[2], G. Marth[1], 1000 Genomes Project.* 1) Dept Biol, Boston College, Chestnut Hill, MA; 2) Dept Biol, Sciences, Louisiana State University, Baton Rouge, LA; 3) Genome Biology Unit, EMBL, Heidelberg, Germany.

Previous studies suggest that thousands of mobile element insertion (MEI) polymorphisms exist between any two unrelated individuals. These can have significant phenotypic consequences via interrupting exons, altering promoters, or altering splicing. Only by cataloging the specific insertion sites and measuring allele frequencies within populations will we be able to understand the functional consequences of these polymorphisms and their importance for personal genomics. MEI's can be observed from next-generation sequencing data (NGS) either directly as insertions in a given sample, or indirectly as deletions in the sample (corresponding to insertions in the reference genome). The direct detection of insertions presents the greater computational challenge. To address this challenge, we developed two different computational approaches, one Read-Pair (RP) and the other a Split-Read (SR) sequence based detection method. We applied these methods to the 1000 Genomes Project pilot data in both the high coverage family trio samples and the 150 low coverage unrelated samples. In the entire dataset, we identified a total of 5364 insertions, of which 4496 contain Alu elements, 789 L1s, and 79 SVA elements. The false discovery rate in this set was lower than 5% for either detection method, with a combined detection sensitivity exceedinög 80% in the high coverage family trio samples, and for events with 10% allele frequency or higher in the low coverage dataset. The number of direct insertions is comparable to the 4251 MEI deletions detected in the same samples. This study represents the largest set of MEI loci found to-date. We estimated the total number of MEI polymorphisms between two unrelated high coverage individuals (one CEU and one YRI sample both from HapMap) to be 3300+/-300 based on both direct and indirect detection. We measured the Allele Frequency Spectra (AFS) on the full pilot data, and find a higher fraction of low frequency alleles in YRI samples than the CEU or CHB/JPT samples. We also carried out Principle Component Analysis (PCA) which revealed population specific patterns of insertion loci equivalent to PCA analyses in the same populations using SNP data. This approach is generally applicable to any whole genome NGS dataset, including those collected for association studies to assess the contribution of MEI events to explain disease phenotypes.

1790/T

Whole-Genome Sequencing Analysis of Structural Variation and Genomic Stability in Human Induced Pluripotent Stem Cells (iPSC). *A. Urban[1], Y. Zhang[2], A. Kocabas[3], B. Bi[3], A. Abyzov[4], J. Mu[4], A. Szekely[2], D. Palejev[3], M. Gerstein[4], S. Weissman[2], F. Vaccarino[3].* 1) Psychiatry, Stanford University, Stanford, CA; 2) Genetics, Yale University, New Haven, CT; 3) Child Study, Yale University, New Haven, CT; 4) MBB, Yale University, New Haven, CT.

There are frequent reports about genomic instability in embryonic stem cells (ESC) in culture. Even at low to medium resolution of analysis, ESC are found to be prone to accumulation of Copy-Number and other Structural Variation (CNV/SV) events in their genomic sequence. Here we investigate the genomic stability of another promising tool in the arsenal of stem cell research, that of iPSC. Fibroblast cells are obtained by biopsy from human donors and then de-programmed into a stem cell-like pluripotent state. At each stage of the process we extract genomic DNA and generate medium-coverage (i.e. at least 4x-8x genomic sequence coverage) paired-end whole-genome sequencing data. We are using the Illumina HiSeq 2000 instrument to sequence paired-end constructs with an insert-length of 700 bp, generating 2x100 nt of sequence per construct and a minimum of 60 million, but up to 120 million, mapped paired-end reads per stage. We use this data to carry out paired-end mapping [following approaches described in Korbel, Urban, Affourtit et al., Science 2007; Korbel et al., Genome Biol. 2009], split-read analysis and read-depth analysis and can thus determine in a comprehensive fashion the catalog of sequence variants from point mutations and small InDels to large and very large (i.e. thousands to hundreds of thousands or millions of bp) CNV and SV, including deletions, duplications and insertions as well as copy-number neutral events such as inversions and balanced translocations. We discuss our findings regarding the occurrence of such sequence variation events in the genomes of iPS cells relative to the genomes of the corresponding primary tissue from the human donor.

1791/T

Genomic differences in discordant couples of sisters with MECP2 mutation: classic Rett versus Zappella variant. *F. Ariani[1], R. Artuso[1], FT. Papa[1], MA. Mencarelli[1], A. Rosseto[1], M. Mucciolo[1], V. Disciglio[1], E. Grillo[1], I. Meloni[1], M. Pollazzon[1], F. Mari[1], M. Zappella[2], J. Hayek[2], DH. Yasui[3], JM. LaSalle[3], A. Renieri[1].* 1) Dept Molecular Biol, Univ Siena, Siena, Italy; 2) Child Neuropsychiatry, Univ Siena, Italy; 3) Medical Microbiology and Immunology, Rowe Program in Human Genetics, School of Medicine, Univ of California, Davis, CA.

Previous studies suggest that MECP2 mutation type and XCI are not sufficient to explain the wide phenotypic variability observed in Rett syndrome ranging from severely affected girls (classic RTT) to girls recovering motor and language function (Zappella variant RTT). We previously suggested a digenic model in which the phenotype is strongly dependent on the status of a second gene while the MECP2 mutation alone leads to X-linked recessive mental retardation (Renieri et al J Mol Med 2003). We present here array-CGH analysis (Agilent 105K) with 15kb resolution in two couples of Rett sisters with discordant phenotype (one classic RTT and one Zappella variant RTT), balanced XCI, and the same MECP2 mutation (http://www.biobank.unisi.it). We identified 7 CNVs and 9 CNVs in the two couples, respectively. One of them located on 8p11.23, extending 158 kb and containing two genes is shared by both couples and the variation is in the same direction: the classic RTT girls have a double copy. Expression and functional analysis of these genes is ongoing. It is also possible that the key player gene(s) is(are) located in a region not shared by the two couples and that the couple with normal copy number has functional modulation by SNP variation. For this reason we analyzed the gene content of the remaining regions for containing MeCP2 target genes (Yasui et al Proc Natl Acad Sci U S A. 2007) or for being previously reported to be involved in phenotype modulation. Interesting MeCP2 target genes were found to be located in 16p11.2, NFATC2IP and SPIN1 genes, in 1p36.3, CROCC, in 5p15.33, ZDHHC11, and in 15q11.2, HERC2P3. The variation of this last region was previously reported associated in patients with MECP2 mutation (Longo et al Eur J Hum Genet 2004) and the variation is in the same direction: the classic RTT girls have half a copy. Expression analysis on the above reported genes indicated that for only half of them the CNV at genomic level corresponds to mRNA variation, narrowing the groups of the key players.

1792/T

A Comparison of Genotyping Technologies to Clinically Assess SULT1A1 Copy Number Variation. *A.B. Freeman[1], M. Arefayene[1], J.A. Baker[1], Y. Guo-Avrutin[1], B. Staton[1], S. Hebbring[2], R. Weinshilboum[2], K. Hillgren[1].* 1) Eli Lilly and Company, Indianapolis, IN; 2) Mayo Clinic, Rochester, MN.

Human cytosolic sulfotransferase 1A1 (SULT1A1, Ch16) catalyzes the conjugation of several endogenous substrates and xenobiotics (Hildebrandt et al., 2004). Large variations in the levels and activity of human SULT1A1 have been attributed to inherited genetic variability, including copy number variations or CNVs (Price et al., 1989). SULT1A1 variability has potential clinical implications in individuals who conjugate therapeutic drugs and hormones via this enzyme.

Previous internally-generated data indicated that quantitative PCR (qPCR) was the most reliable technology to clinically assess CNVs. More recently, Hebbring et al. reported using fragment analysis to assess CNVs (2007). Therefore, we assessed the SULT1A1 CNVs in 145 liver DNAs using three genotyping methods; qPCR, fragment analysis, and quantitative SNP genotyping (qSNP) for three variants (rs9282861, rs750155, and rs3760091).

Overall, SULT1A1 CNV genotype calls from the three methodologies produced an 89.0% concordance rate with average frequencies of 5.2%, 61.8%, 27.6%, 6.2%, and 0.7% for 1, 2, 3, 4, and >4 SULT1A1 copies, respectively. Since >80% of the liver samples were obtained from Caucasians, the SULT1A1 CNV distribution observed in the cohort was consistent with previous reports in the Caucasian population (Hebbring et al., 2007). Liver samples containing 1, 2, 3, and 4 SULT1A1 copies contributed 2.1%, 54.1%, 34.2%, and 9.6% of the 333 total SNP alleles, respectively. In addition, the "C" alleles of rs9282861, rs750155, and rs3760091 had frequencies of 70.9%, 53.0%, and 39.9%, respectively.

Comparing the three technologies, 96.5% concordance of SULT1A1 genotype calls was observed between fragment analysis and qSNP genotyping in the liver samples. Quantitative PCR was the most discordant technology with only 89.0% and 92.4% concordance with fragment analysis and qSNP, respectively. Contrarily, the qSNP methodology was highly accurate, but was unable to genotype heterozygotes independently. Although additional studies are required, these results suggest that fragment analysis is the most accurate and independent methodology of the three we tested to assess SULT1A1 copy number.

1793/T

Evaluation of a novel, single molecule, amplification-free method for the detection of Copy Number Variation (CNV). *T. Guettouche[1], Y. Cardentey[1], M.A. Pericak-Vance[2], J.R. Gilbert[2], D.J. Hedges[2].* 1) Oncogenomics Core Facility, Sylvester Comprehensive Cancer Center, University of Miami Miller School of Medicine, Miami, FL; 2) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL.

Copy number Variation (CNV) is a major component of the genomic diversity present within the human population. Several methods for genome-wide discovery of structural variants now exist , including array-based genomic hybridization and High throughput SNP genotyping arrays (i.e. GWAS arrays). More recently, structural variation has also been inferred from Next Generation Sequencing data . As CNV calls made from each of these approaches can be subject to appreciable false positive rates, detected variants of interest are generally corroborated by an independent laboratory method. The method of choice for CNV confirmation has primarily been real-time quantitative PCR. Here we report the evalution of a novel copy number assay based on the Nanostring nCounter system. The nCounter system uses a hybridization-based single molecule capture approach that does not require amplification of input DNA. Individual tripartite complexes of the target molecule, a biotin labeled probe and a fluorescently labeled ("barcoded") probe are directly counted. We compared the performance of the nCounter system at 30 putative CNV loci in a set of 96 human samples, all of which have data at these same loci from ABI Taqman CNV assays. A subset of these samples also have data available from Agilent aCGH 244k custom arrays and Illumina 1M Infinium arrays. Preliminary results show that the Nanostring method exibits 86% agreement with the ABI Taqman CNV assays across all studied loci and individuals. When three problematic repetitive loci are excluded, concordance rises to 96%. We are presently continuing our evaluation process to include a total set of 300 individuals. Our initial results suggest that the nCounter system will provide a promising alternative for the validation of copy number variants.

Genome-wide association study of CNVs in Korean right isomerism patients. *E. Seo[1,2], J. Lee[1], K. Kim[1], I. Park[1,3].* 1) Genome Research Center for Birth defects and Genetic disorders, Asan Med Center, Seoul, Korea; 2) Dept. of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 3) Dept. of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

Right isomerism is characterizaed by asplenia, mirror-image symmetrical right lungs and complex cardiac anomalies with bilateral, morphologically identical right atrial appendages. Total incidence of heterotaxy syndrome including right isomerism is very low, but some reports suggested that right isomerism is more prevalent in oriental children. Although mutations have been identified in genes, NODAL, CFC1, ACVR2B, LEFTYA within the nodal signal transduction pathway of the left-right asymmetry, mutation prevalence of each genes is approximately 2 to 10%. Previous study has proposed a gene-dosage-sensitive genetic interactions between nodal signals in asymmetrical patterning. We performed copy number variations (CNVs)-association studies to identify dosage-sensitive genes susceptible to right isomerism. In order to explore the presence of CNVs, we designed a custom CGH 60K microarrays (Agilent) to cover 1562 genes involved in heart development or heart defects as well as other 5000 genes located in important chromosomal loci. Array CGH was performed on 39 Korean right isomerism patients and 100 Korean healthy individuals using NA 10851 DNA as a reference, and Agilent Genomic Workbench 6.0 was used to analyze microarray data and CNV-association. The CNVs detected in this study were validated through real-time quantitative PCR using TaqMan probes for specific regions. We found four statistically significant CNV loci in three genes, IGKC, COX6A2, and FOXC2. The 40-kb loss of proximal region of IGKC was detected in 26 patients, but not in 100 controls. Inversely, the 60-kb gain of distal region of IGKC was much frequently found in controls. The third was 357-bp gain on 16p12 detected in 16 patients and 18 controls. This region contains only one gene, COX6A2 involved in the heart/muscle isoform of cytochrome c oxidase subunit. The 1-Kb gain on 16q24 in 8 patients and 9 controls, FOXC2 (forkhead box C2, mesenchvme forkhead 1), as a key regulator of adipocyte metabolism.

Genomewide high-resolution aCGH analysis of a patient with mild dysmorphism and behavioral problems. *R.R. Haraksingh[1, 2], A.E. Urban[3], A. Szekely[4], S. Weissman[4], M.P. Snyder[2].* 1) MCDB, Yale Univ, New Haven, CT; 2) Genetics, Stanford School of Medicine, Stanford, CA; 3) Psychiatry, Stanford School of Medicine, Stanford, CA; 4) Genetics, Yale School of Medicine, New Haven, CT.

Copy Number Variantion (CNV) represents a major source of human genetic diversity that may be inherited or occur de novo in individuals. These events occur by both recombination and replication based mechanisms and act as substrates for further genomic rearrangements and genome evolution. The CNVs reported in the human genome are catalogued in the Database of Genomic Variants (DGV, http://projects.tcag.ca/variation/) and comprise both benign and pathogenic variants. Several well-documented, pathogenic deletion/duplication events are routinely tested for in cytogenetic laboratories. However, novel, clinically relevant CNV haplotypes are not revealed in an unbiased way by these methods. Here we report the high resolution CNV profile of a family trio with unaffected parents and affected son. The patient is a middle aged adult male with mild but distinct dysmorphic features and a distinct constellation of behavioral problems including prominent anxiety and phobias along with more subtle autistic features. The trio was initially analyzed by Chromosome Microarray Comparative Genome Hybridization (CM-CGH) on an Agilent 180K array that tests for more than 140 microdeletion/duplication syndromes. The proband was found to possess a maternally inherited 93kb duplication on chromosome 15q21.2. This duplication has not been documented in the DGV and affects two genes; the entire TMOD3 gene and the last exon of the TMOD2 gene. Tropomodulins have been implicated in learning and memory function and in animal models of autism. Further high-resolution array CGH using a NimbleGen 2.1million whole genome tiling array (Roche-NimbleGen) revealed several other CNVs of unknown significance that have not been reported in the DGV. These include a 39kb deletion in the proband on 5q22.1 in a highly conserved intron of the TMEM232 gene. It is possible that a subset of the CNV complement of the proband including novel and private events working in concert may account for part of the phenotype by a multiple-hit mechanism.

1796/T

Identification and characterization of copy number changes: case study of familiar hemoglobinopathy. *L. Noskova[1], H. Hartmannova[1], V. Stranecky[1], L. Veprekova[2,3], S. Kmoch[1,4].* 1) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague and General Teaching Hospital, Ke Karlovu 2, Prague 2, Czech Republic; 2) Pediatric Clinic of the General Teaching Hospital, Ke Karlovu 2, Prague 2, Czech Republic; 3) Trombotic centre CHL VFN, Karlovo náměstí 32, Prague 2, Czech Republic; 4) Center for Applied Genomics, Prague, Czech Republic.

Copy number variations (CNVs) are together with single nucleotide polymorphisms (SNPs) the main source of genetic variability in men. With regard to the extent of CNVs, they may posses significant phenotypic impact and are linked to group of pathological conditions and clinical syndromes. Using methods of DNA arrays, quantitative PCR, standard PCR and sequencing, we have identified and characterized large deletion in family with autosomal dominant familiar hemoglobinopathy. Hemoglobinopathies are very heterogenic group of disorders caused by the presence of abnormal structural variants of globin proteins or by underproduction of normal globin genes due to defects in α- or β- globin chain syntheses (thalassemias). We have studied family diagnosed by hemoglobinopathy with following clinical symptoms: preterm birth of severe anemic child with marked microcytosis and hepatopathy of various intensity, mild to severe anemia and marked microcytosis after several months of blood transfusions. We have performed mapping analysis using Affymetrix GeneChip Human Mapping 250K array and found heterozygous deletion 765 kb in length at chromosome 11: 5, 088, 500 - 5, 853, 400. This region contains β - globin cluster involving genes of β - globin chain (globin β, γ1, γ2, ε). To refine break in deleted region, we have designed real-time PCR probes using Roche Universal Probe Library. Narowing of the interval allowed sequencing of delimited region. Finally, fast and simple assay for detection of deletion in other family members is set up. This study was supported by the grant funded by the Ministry of Education of the Czech Republic (MSM0021620806).

Unprecedented resolution for the detection of inherited and de novo structural variation by mate-pair sequencing of a family trio. *W. Kloosterman[1], V. Guryev[2], M. van Roosmalen[1], R. Hochstenbach[1], K. Duran[1], M. Poot[1], E. Cuppen[1, 2].* 1) Department of Medical Genetics, University Medical Center Utrecht, Universiteitsweg 100, 3584 CG, The Netherlands; 2) Hubrecht Institute and University Medical Center Utrecht, Uppsalalaan 8, 3584 CT Utrecht, The Netherlands.

Structural genomic variation may contribute to phenotypic diversity and disease. While copy number changes have well been studied, the nature and prevalence of for instance copy-neutral genomic rearrangements and indels is poorly understood. Here we performed genome-wide sequencing of a long mate-pair library with 2.5 kb insert size of a child with severe psychomotor retardation and complete absence of expressive speech. The same methodology was used for sequencing of both parents to discriminate between inherited and acquired structural genomic variants. We obtained more than 10x average clone coverage throughout the genome. We detected hundreds of balanced and unbalanced structural rearrangements of which several occurred de novo in the child. Sanger sequencing identified breakpoints of all de novo structural variations at base-pair resolution. We fine-mapped the breakpoints of the de novo t(1;10;4)(p23.4;q21;q23) translocation in the child that was previously identified by karyotyping. The other de novo events were insertions, deletions and inversions in the vicinity of the breakpoints on chromosome 10 and 4. One of these de novo events disrupts the PCDH15 gene and may be involved in part of the phenotype(s) of the child. Most of the de novo events were accompanied by microdeletions, micro-homology or micro-insertions at the breakpoints. Our results provide an insight into the generation rate of de novo structural events in the human genome and emphasize the need for high-resolution methods to determine genetic aberrations in individuals with congenital anomalies.

Increased Sensitivity of Copy Number Variation Detection Using a High-Density Array CGH Platform. *R. Selzer, C. Shaw, K. O'Moore, T. Richmond, J. Geoghegan, N. Jiang, R. James, J. Luckey.* R&D, Roche NimbleGen, Inc, Madison, WI.

Array CGH methods are widely used to investigate DNA copy number variation (CNV) associated with complex disorders. Disease-association studies have become increasingly focused on CNVs, and recent reports show links between CNVs and schizophrenia (Stefansson 2008; Stone 2008), autism (Sebat 2007; Marshall 2008; Glessner 2009), and cancer. More recently, the focus of CNV research has migrated to detection of rare variants, with an allelic frequency of less than 5% (Conrad 2009, Manolio 2009). In an effort to increase detection of rare variants as well as more common CNVs, we sought to develop the highest density oligo array available for CNV detection, as well as a more sensitive algorithm for CNV detection on NimbleGen arrays. The NimbleGen 2.1M and 3x720K CNV arrays contain empirically optimized probes, with the most comprehensive collection of targeted regions available, including Asian population-specific CNV regions. Utilization of the CNV arrays enabled detection of several hundred CNVs per individual. When compared to whole-genome tiling arrays, 2- to 3- fold more CNVs were detected with the CNV arrays. The NimbleGen CNV arrays detected 300% and 245% more CNVs, respectively, and the higher probe density allowed 2-fold higher detection of CNVs shorter than 1 kb when compared to competitor arrays. The increased sensitivity of CNV detection was aided by an improved segmentation algorithm (segMNT), included in NimbleScan v2.6 software. A comparison between the segMNT v1.1 and segMNT v1.2 algorithms shows increased sensitivity in detection of CNVs resulting in about 2-fold more CNVs detected per sample with segMNT v1.2.

Intrachromosomal mitotic non-allelic homologous recombination is the major molecular mechanism underlying type-2 *NF1* deletions. *H. Kehrer-Sawatzki[1], A.C. Roehl[1], T. Mussotter[1], J. Vogt[1], A. Zickler[1], J. Högel[1], N.A. Chuzhanova[2], K. Wimmer[3], L. Kluwe[4], V.F. Mautner[4], D.N. Cooper[5].* 1) Insititue of Human Genetics, University of Ulm, Ulm, Germany; 2) School of Science and Technology, Nottingham Trent University, UK; 3) Division of Human Genetics, Medical University, Innsbruck, Austria; 4) Department of Maxillofacial Surgery, University Medical Centre, Hamburg-Eppendorf, Germany; 5) Institute of Medical Genetics, School of Medicine, Cardiff University, UK.

Non-allelic homologous recombination (NAHR) is responsible for the recurrent rearrangements that give rise to genomic disorders. Although meiotic NAHR has been investigated in multiple contexts, much less is known about mitotic NAHR despite its importance for tumorigenesis. Since type-2 *NF1* microdeletions frequently result from mitotic NAHR, they represent a good model in which to investigate the features of mitotic NAHR. We have used microsatellite analysis and SNP arrays to distinguish between the various alternative recombinational possibilities, thereby ascertaining that 17 of 18 type-2 *NF1* deletions, with breakpoints in the SUZ12 gene and its highly homologous pseudogene, originated via intrachromosomal recombination. This high rate of intrachromosomal NAHR causing somatic type-2 *NF1* deletions contrasts with the interchromosomal origin of germline type-1 *NF1* microdeletions, whose breakpoints are located within the NF1-REPs (low-copy repeats located adjacent to the SUZ12 sequences). Further, meiotic NAHR causing type-1 *NF1* deletions occurs within recombination hotspots characterized by high GC-content and DNA duplex stability, whereas the type-2 breakpoints associated with the mitotic NAHR events investigated here do not cluster within hotspots and are located within regions of significantly lower GC-content and DNA stability. Our findings therefore point to fundamental mechanistic differences between the determinants of mitotic and meiotic NAHR.

Copy number variations unmask recessive mutations and identify novel candidates for Bardet-Biedl syndrome. *K.J. Meyer[1,2], D.Y. Nishimura[3,4], J.S. Beck[3,4], L.K. Davis[5], E.M. Stone[2,4,6], T.H. Wassink[1,2], V.C. Sheffield[2,3,4].* 1) Department of Psychiatry, University of Iowa, Iowa City, IA; 2) Interdisciplinary Genetics Program, University of Iowa, Iowa City, IA; 3) Department of Pediatrics, University of Iowa, Iowa City, IA; 4) Howard Hughes Medical Institute, University of Iowa, Iowa City, IA; 5) Department of Psychiatry, University of Illinois, Chicago, IL; 6) Ophthalmology and Visual Sciences, University of Iowa, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a heterogeneous autosomal recessive disorder characterized by obesity, retinopathy, renal malformations, hypogonadism, and mental retardation. Although a rare disorder, BBS serves as a model to study these and other phenotypes that are individually common in the general population. Mutations in 12 different genes, *BBS1-12*, account for approximately 70% of BBS; causative mutations have yet to be discovered in the remainder of cases. In recent years genome-wide studies of copy number variants (CNVs) have been successful in indentifying rare chromosomal anomalies that confer risk to develop genetically complex disease. In this study, we apply copy number detection technology to a simple Mendelian disorder in an effort to identify novel disease genes and to define a role for CNVs in BBS. Thirty-two BBS patients from non-consanguineous families with unknown mutation were hybridized to the Affymetrix Genome-Wide Human SNP Array 5.0 and analyzed for copy number variants. From the data set, 11 CNVs that were novel to the Database of Genomic Variants and absent from our control set of 500 individuals were classified as high interest candidate regions for BBS. We identified one patient hemizygous for *BBS10* and detected a frame shift mutation in the remaining copy of BBS10 by direct sequencing. In addition, we identified a deletion of one exon of *MARK3*, a promising candidate gene, which is predicted to cause a frame shift and premature stop of the protein. Thus our analysis of this dataset supports the interrogation of CNVs in individuals with Mendelian disorders who harbor an unknown mutation.

1801/T

Genic and Nongenic Human DNA is biased against Nullizygosity. *F. Alkuraya[1,2,3], H. Khalak[1], F. Imtiaz[1], S. Wakil[1], L. Abu Safieh[1], M. Aldahmesh[1], M. Al-Dosari[1], D. Monies[1], N. Kaya[1], M. Al-Hamed[1], F. Alzahrani[1], L. Al-Jbali[1], K. Ramzan[1], N. Al-Tassan[1], H. Shamseldin[1], R. Shaheen[1], M. Al-Rashed[1], B. Baz[1], S. Hagos[1], N. Abu Dhaim[1], M. Hashem[1], B. Meyer[1], A. Alazami[1].* 1) Dept Gen, KFSH & RC, Riyadh, Saudi Arabia; 2) Dept Ped, KKUH & KSU, Riyadh, Saudi Arabia; 3) Dept Anat & Cell Bio, Alfaisal University, Riyadh, Saudi Arabia.

Copy number variants (CNVs) represent an important source of human genome diversity. Whether “benign” hemizygous CNVs are also tolerated in the nullizygous state is largely unknown. This question is difficult to address systematically because the relatively low frequency of individual CNVs means that a prohibitive number of normal individuals have to be screened for detection of the CNV in question in a nullizygous state. We have reasoned that an alternative approach is to study “normal” individuals whose parents are first cousins since their genomes are likely to be enriched for nullizygous CNVs and thus lend themselves to a rapid cataloging of nullizygous CNVs i.e. dispensable DNA in humans. We have studied 451 such individuals and found a highly significant bias against the occurrence of nullizygous changes. This has led us to hypothesize that the low frequency of nullizygous CNVs in public databases cannot be solely explained on the basis of low population frequency of individual CNVs and that a biological factor is likely to exist. To confirm this, we analyzed an independent cohort of 18 multiplex consanguineous families for which the parental genotypes are also available. By directly examining the shared hemizygous CNVs among the first cousin parents in each family we again found a highly significant deviation from the expected 25:50:25 Mendelian distribution of the resulting genotypes with the nullizygous genotype being grossly underrepresented. Importantly, this bias is not restricted to genic CNVs and is not accounted for by a high rate of miscarriages. Therefore, our data suggests a greater importance for “junk” DNA than previously thought in very early human development.

1802/T

Familial idiopathic clubfoot is associated with recurrent microduplications of chromosome 17q23.1q23.2 containing TBX2/TBX4. *D. Alvarado[1], H. Aferol[1], K. McCall[1], J. Huang[3], M. Techy[3], J. Buchan[4], P. Gonzales[4], M. Dobbs[1,5], C. Gurnett[1,2,3].* 1) Orthopaedic Surgery, Washington Univ, St. Louis, MO; 2) Pediatrics, Washington Univ, St. Louis, MO; 3) Neurology, Washington Univ, St. Louis, MO; 4) Division of Biology and Biomedical Sciences, St. Louis, MO; 5) St. Louis Shriners Hospital for Children, St. Louis, MO.

Idiopathic clubfoot is a common musculoskeletal birth defect for which few causative genes have been identified. To identify the genes responsible for idiopathic clubfoot, we screened for genomic copy number variants (CNVs) with the Affymetrix Genome-wide Human SNP Array 6.0. A recurrent chromosome 17q23.1q23.2 microduplication was identified in 3 of 66 probands with familial isolated idiopathic clubfoot. The chromosome 17q23.1q23.2 microduplication segregated with autosomal dominant clubfoot with reduced penetrance in all three families. Short stature was common and one female had isolated developmental hip dysplasia. Skeletal abnormalities consisted of broad and shortened metatarsals and calcanei, small distal tibial epiphyses, and thickened ischia. Several skeletal features were opposite to those recently described in the reciprocal chromosome 17q23.1q23.2 microdeletion syndrome associated with developmental delay, cardiac and limb abnormalities. The 17q23.1q23.2 region contains the T-box transcription factor TBX4, a likely target of the bicoid-homeodomain transcription factor PITX1 previously implicated in clubfoot etiology. This chromosome 17q23.1q23.2 microduplication is the most common cause of idiopathic clubfoot identified to date, and provides strong evidence linking clubfoot etiology to abnormal early limb development.

1803/T

Germline and somatic CNVs in 4 Mexican American monozygotic twin pairs. *A. Blackburn[1], H.H.H. Göring[2], S. Kumar[2], M. Carless[2], J. Curran[2], R. Duggirala[2], J. Blangero[2], D. Lehman[3].* 1) Cellular and Structural Biology, University of Texas Health Science Center, San Antonio, TX; 2) Southwest Foundation for Biomedical Research, Department of Genetics, San Antonio, TX; 3) Department of Medicine, Division of Clinical Epidemiology, University of Texas Health Science Center, San Antonio, TX.

Copy number variants (CNVs) occur commonly in the human genome, and account for more variation on a per nucleotide basis than single nucleotide polymorphisms (SNPs). There are conflicting reports regarding the contribution of CNVs to high levels of somatic mosaicism. SNP arrays are now commonly used to identify CNVs, however the results may vary by array and by statistical methodology. In this study we address three issues related to copy number variation by comparing 4 MZ twin pairs of Mexican American descent from the San Antonio Family Heart Study (SAFHS) and Family Diabetes/Gallbladder Study (SAFDGS). All four twin-pairs and four available parents were genotyped on the Illumina 1M Duo Beadchip. Individual twins were also genotyped on the 1M, 550, and 510 Beadchip platforms from Illumina. First we assessed the ability of the PennCNV package, and its supplementary tools, to identify germline CNVs by observing concordance between MZ twins on the same platform. Second, we assessed the concordance of germline CNV calls from PennCNV between platforms. Third, we assessed the extent of somatic mosaicism by calculating the absolute value of the difference between b-allele ratios for heterozygous SNPs on chromosome 6 between MZ twins and between duplicate samples. Chromosome 6 was chosen for its intermediate size to ease computation for initial investigation. We identified an average of 53 CNVs across the genome for samples genotyped on the 1M Duo using PennCNV. Genomic wave adjustment improved the concordance between MZ twins. ~50% of CNV calls had concordant breakpoints, suggesting that a minimum of 50% of CNV calls made by PennCNV on the 1MDuo platform have correct breakpoint identification. Overall, ~69% of CNVs inferred using PennCNV from the 1M Duo were observed in both MZ twins. We observed that the same CNVs can be detected across platforms, and that discordant breakpoints can be due to platform coverage differences. In our preliminary exploration of somatic mosaicism on chromosome 6, similar percentages of markers fell 1, 2, 3, and 4 standard deviations from the mean absolute difference between b-allele ratios for both MZ twins and duplicates. This suggests that the high level of somatic mosaicism previously implied may be within the normal variation for the assay. Further, out of 39 CNV calls on chromosome 6, all 7 discordant calls between MZ twins contained 0 heterozygous SNPs. We are extending the investigation to the entire genome.

1804/T

Detection of clinically relevant exonic copy-number changes by array CGH. *P.M. Boone[1], C.A. Bacino[1,2,3,4], C. Shaw[1,2], P.A. Eng[2], P.M. Hixson[2], A.N. Pursley[2], S-H.L. Kang[1,2], Y. Array comparative genomic hybridization (aCGH) is a powerful tool for the molecular elucidation and diagnosis of disorders resulting from genomic copy-number variation (CNV). However, intragenic deletions or duplications - those including genomic intervals of a size smaller than a gene - have remained beyond the detection limit of most clinical aCGH analyses. Increasing array probe number improves genomic resolution, although higher cost may limit implementation and enhanced detection of benign CNV can confound clinical interpretation. We designed an array with exonic coverage of selected disease and candidate genes and applied it clinically to identify losses or gains throughout the genome involving at least one exon and as small as several hundred base pairs in size. In some patients, the detected copy-number change occurs within a gene known to be causative of the observed clinical phenotype, demonstrating the ability of this array to detect clinically relevant CNVs with sub-kilobase resolution. Examples include: *MECP2* and Rett syndrome; *PTEN* and Bannayan-Riley-Ruvalcaba syndrome; *CREBBP* and *EP300* and Rubinstein-Taybi syndrome; *CDKL5* and X-linked infantile spasms; *ZDHHC9* and X-linked mental retardation; *FAM58A* and STAR syndrome; *HPRT1* and Lesch-Nyhan syndrome; *SCN2A*/*SCN3A* and infantile seizures; *STXBP1* and infantile seizures; *NRXN1* and developmental delay; *TCF4* and Pitt-Hopkins syndrome; *IL1RAPL1* and X-linked mental retardation; *EYA1* and branchiootic syndrome; and *JAG1* and Alagille syndrome. These conditions represent a variety of disease processes, including neurodevelopmental disorders, an enzyme deficiency syndrome, and other recognizable patterns of human malformation. Furthermore, many of these exonic CNVs have not been previously reported for these known disease genes. Perhaps of even greater interest, this approach may also enable elucidation of gene function for some of the large number of annotated genes in the human genome whose functions remain unknown. Thus, our approach allows new mutations to be described for known genetic conditions and also could potentially elucidate gene function. In summary, we demonstrate the utility of a custom-designed, exon-targeted oligonucleotide array to detect intragenic copy-number changes in patients with unexplained syndromic and non-syndromic mental retardation, congenital anomalies, and other clinically relevant phenotypes.

1805/T

Characterizing neutral drift in copy number variations of duplicating regions: model and test for non-neutral drift. *A. Caspi.* University of Pennsylvania. Philadelphia, PA.

With the recent survey of common copy number variants (CNVs) in several human populations [WTCC, 2010]*, it is now possible to characterize neutral drift in copy number variation across the human genome. We propose a model of neutral copy variation on duplicating genomic regions which assumes an underlying Markov process guides random drift in copy numbers. We learn the model parameters using a set of 1000 duplicating CNV regions selected from CNV's previously shown to be reliably genotyped by both Agilent CGH microarrays and Illumina Infinium genotyping platform. We removed any CNV's that could arise via deletions, to avoid confounding the model of selective pressure on deletions with those on duplications. This set was reported as impoverished in CNVs associated with diseases or complex traits, and the majority of genes overlapping these regions were annotated as functioning in the periphery of cellular networks. We use this set as a surrogate for randomly drifting CNVs. Using the learned model, we develop a method based on inter- and intra-population comparisons to test for duplicating CNV regions deviating from drift characteristics. Our test takes as input the allelic distribution of a CNV region for each of several subpopulations studied. In the present study, we observe frequencies for three HapMap populations: individuals of European Ancestry (CEU), in Yoruba (YRI), and in Tokyo and Beijing (CHP+JHT). We performed the test on the full set of over 5000 reliably genotyped CNV's assayed in 450 HapMap samples from the above populations. The test aims to identify regions for which observed copy number frequencies depart from those expected by the assumed background model of drift. We provide a ranking of CNV regions ordered in ascending likelihood that they exhibit non-neutral pressure. The analysis reveals strong candidate CNV regions, of which the top 16 contain the full set of three CNV's previously identified by [WTCC, 2010] as potentially disease associated regions. Given the reported paucity for disease-associated variants in this set, both the low number of candidate regions and the inclusion within this set of all regions identified in the original study are a testament to a successful application of the test. We propose this test as a solution for detecting CNV duplications under selective pressure in reliable genotyping data for forthcoming non-common copy number variant assays. *['common' is defined as minor allele frequency >5%].

1806/T

Evaluation of copy number variation in an African American type 2 diabetes and diabetic nephropathy Genome-Wide Association Study. *J.N. Cooke, N.D. Palmer, L. Lu, J.W. Chou, C.W. McDonough, B.I. Freedman, C.D. Langefeld, D.W. Bowden.* Wake Forest University, Winston-Salem, NC.

Type 2 diabetes (T2D) and T2D-associated end-stage renal disease (T2D-ESRD) disproportionately affect African Americans. We have assessed the contribution of copy number variation (CNV) to T2D or T2D-ESRD in African Americans. Using the Affymetrix 6.0 array, we performed a genome-wide association study (GWAS) on 965 African Americans with T2D-ESRD and 1,029 healthy African Americans recruited in the southeastern United States, interrogating 946K copy number probes across the genome. CNV data was analyzed using Genotyping Console 4.0 with version 30 library and annotation files. CNVs were categorized by deletion (CNV<2) and insertion (CNV>2) status and then used as predictors in a logistic regression model with age, gender, and Principal Component 1 adjustment for admixture to evaluate the odd ratios (OR) between cases and controls. A regional analysis of 1130 known CNVs identified association with an insertion on chromosome 1 in the pancreatic amylase precursor gene (AMY2B/2A) captured by CNP76 (p=6.20x10-5, OR=1.63 (CI 1.28-2.08)). This CNV has a deletion frequency of 43.2% in cases and 39.4% in controls. This is a previously identified common insertion; however, there have been no prior reports of association with disease. We also performed a secondary analysis by probe to detect de novo CNVs and novel, common CNVs in African Americans. This analysis identified a deletion on chromosome 14 in the gene encoding the alpha subunit of the T-cell antigen receptor (TCRA). The p-value for the nine probes spanning chr14:21959617-21967020 was 4.03x10-5, OR=0.07 (CI 0.02-0.24). The frequency of the deletion was approximately 0.3% in cases and 2.6% in controls, thus representing an uncommon variant not captured by common/known copy number polymorphism analysis. Adjacent probes located 186kb upstream and 32kb downstream of this region also support evidence of association (p=4.03x10-5-9.43x10-3). Other top hits from the by-probe analysis included a deletion on chromosome 1 in the gene encoding glutathione S-transferase μ2 (GSTM2; p=1.80x10-4-2.10x10-4, OR=2.04, CI=1.40-2.97 for three probes spanning chr1:110027431-110028023). The frequency of this deletion was 12.3% in cases and 7.8% in controls. We have observed both common and novel CNVs that appear to contribute to T2D and/or T2D-ESRD. These results suggest that CNVs contribute to susceptibility for T2D and/or T2D-ESRD in the African American population.

Identification of gene copy number variations using quantitative real-time PCR for whole genome amplified DNA. *C.L. Dagnall[1,2], A. McCary[1,2], A.A. Hutchinson[1,2].* 1) Core Genotyping Facility, SAIC-Frederick, Inc., NCI-Frederick, Frederick, Maryland, USA; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, DHHS, Bethesda, Maryland, USA.

Copy number variations (CNVs) are structural variations defined as a DNA segment of at least 1 kb in size, for which copy number differences have been observed in the comparison of two or more genomes. CNVs have been shown to be present in many cancers and have also been used to predict metastatic capabilities of some cancers. They have also been associated with other immune diseases, neurological disorders, and drug metabolism. Our laboratory currently uses the Applied BiosystemsTM TaqMan® Copy Number assays to accurately detect CNVs using gDNA as template material. This is a duplex real-time qPCR assay which compares the amplification of the target CNV to the amplification of a reference gene, known to have two copies in all human subjects, to determine the copy number of the target CNV relative to that of the reference gene. The target CNVs of interest to be assessed in this project are the GSTT1 (glutathione S-trasnferase theta 1) gene and GSTM1 (glutathione S-transferase M1) gene, and the reference gene used is RNase P. Since gDNA samples can be quickly exhausted using various analytical platforms, there is a need for pre-analysis processing to increase the quantity of the samples. Whole genome amplification (WGA) is a method that synthesizes duplicate copies of the template human genome and is capable of generating many micrograms of high molecular weight DNA from just nanograms of input material. Previous PCR-based methods of WGA have been generally abandoned due to problems created during amplification, including limited fragment length, allelic dropout, and amplification bias due to preferential binding of primers to certain DNA regions. The current WGA protocol of GE Healthcare's illustraTM GenomiPhi V2 and GenomiPhi HY kits are based on multiple displacement amplification (MDA), a non-PCR-based process using the Phi29 DNA polymerase which boasts excellent processivity and high fidelity. Here we assess the performance of WGA products on validated copy number assays to determine if wgaDNA can provide accurate quantitation suitable for determination of relevant copy number changes in the GSTM1 and GSTT1 genes. Included is a comparison of results and raw data values of gDNA, wgaDNA, and pooled wgaDNA samples from the same individuals for the two genes of interest. The results of samples from variable biologic sources (blood, buccal, and fibroblast) are also examined. Funded by NCI Contract No. HHSN261200800001E.

Nervous System Genes Are Enriched In Regions Affected By Dosage Changes in Hirschsprung Disease (HSCR). *B. Doan, S. Arnold, Intl. HSCR Genetics Consortium, A. Chakravarti.* Institute Genetic Medicine, Johns Hopkins Medicine, Baltimore, MD.

Patients with chromosomal mutations led to the identification of the HSCR susceptibility genes *RET*, *EDNRB*, and *ZFHX1B*. *RET* mutations are likely necessary to cause HSCR with mutations found in ~87% of patients. We conducted a GWAS on 220 trios using 500K SNPs (Affymetrix) to search for additional genes, and identified a second common risk locus, *SEMA3*. We also used these data, together with published gene expression and structural variation (SV) databases, to characterize the burden of dosage changes on HSCR risk using an integrative genome wide approach. Normalization and segmentation of log2 ratios (L2R) on raw allelic intensities were performed using ITALICS to generate gene dosage events (GDE); genotypes were called using CRLMM. GDE were filtered based on >2 probes and >0.25 absolute value L2R, and genotypes were cleaned using >0.95 confidence scores. Samples with >50 events were excluded since these arose from nosier than average array intensities. Inheritance (segregating/de novo) status, and Mendel errors (ME) were calculated for each event. In 218 offspring, 1333 events were identified: 102 >1Mb, 973 1kb-1Mb, and 259 <1kb: deletions were twice as frequent, 927 vs 406. For regions with >10 ME, 24 events >100kb were identified, mostly as segregating deletions (22 del/2 dup; 18 seg/6 de novo). A barcode analysis on human gene expression data identified all genes expressed in brain and gut to represent CNS and ENS specific genes. Additionally, 79 genes were identified from prior studies as HSCR susceptibility genes. For the 1333 GDE, 724 overlapped a RefSeq gene, and of these, 584 overlapped a SV/indel from databases. Of the 140 events that did not overlap any known SV (67 unique genes) none matched known HSCR genes: however, 24 (36%) were identified as CNS or ENS genes. Of the events overlapping a SV, 1085 unique genes were affected: 18 were known HSCR genes (23% of 79 HSCR genes), and 231 (21%) were of CNS/ENS origin. Additionally, a deletion involving the *SEMA3* locus was found. Thus, through an integrative approach, we have identified a series of dosage changes in affected offspring that both overlap HSCR susceptibility genes and have an enrichment of CNS/ENS expressing genes. These genes usually overlapped SV regions, suggesting that common dosage variation can be clinically relevant to disease. The most promising genes include: *TFF1*, *TFF3*, *SOD1*, *S100B*, *ERBB4*, *NAV2*, *PLEKHA1*. These results provide new pathways for studying HSCR genetic etiology.

DGV and DGVa - Curating and archiving structural variation data. *L. Feuk[1], M. Manker[2], J. Hinton[3], M. Maguire[3], J. Foong[2], J.R. MacDonald[2], B. Thiruvahindrapduram[2], I. Lappalainen[3], P. Flicek[3], S.W. Scherer[2].* 1) Rudbeck Laboratory, Dept Genetics & Pathology, Uppsala University, Uppsala, Sweden; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Canada; 3) The European Bioinformatics Institute, Wellcome Trust Genome Campus, Hinxton, UK.

The Database of Genomic Variants (http://projects.tcag.ca/variation/) was developed in 2004 to provide information about structural variation (SV) in the human genome for biomedical research. The main user group of the database and its associated genome browser are clinical geneticists utilizing the data to facilitate the interpretation of structural variation data from patients. Currently, the database holds nearly 90,000 published variants representing approximately 15,000 independent chromosomal loci. The recent explosion of data from diverse SV studies now necessitates that a more formal public data archive be developed. Two such efforts have recently been launched, entitled DGVa (started by European Bioinformatics Institute) and dbVAR (started by the National Center for Biotechnology Information), respectively. These databases provide accessioning and archiving of structural variation data. The main focus of DGV going forward will be to curate, interpret and visualize SV data to facilitate biomedical research and genetic diagnostics. DGV will work with DGVa, and accessioned data from select studies will be transferred from the archive to DGV, where the data will be further curated and made available to the user community. A new DGV database structure will ensure compatibility with SV data in the archival databases, accommodate better search functions and facilitate clinical interpretation of patient data. We will describe the DGV-DGVa collaboration, the development of the databases and how these changes will benefit the user community.

Recurrent and Non-recurrent Genomic Rearrangements in IKBKG locus, causing IP, are generated by different mechanisms and may involve the contiguous G6PD gene. *F. Fusco[1], M. Paciolla[1,2], F. Napolitano[1], A. Pescatore[1], E. Esposito[1], MB. Lioi[2], MG. Miano[1], MV. Ursini[1].* 1) Dept Human Molecular Genetics, IGB-ABT-CNR, Naples, Italy; 2) University of Basilicata, Potenza, Italy.

Incontinentia Pigmenti (IP) is an X-linked dominant disease caused by mutation in the IKBKG/NEMO located in a structurally complex region of Xq28. IKBKG gene maps in LCR1 while a second non-functional pseudogene copy, IKBKGP/deltaNEMO maps in LCR2, in opposite direction to IKBKG. Moreover, IKBKG is organized head-to-head with G6PD gene with which it shares a common bidirectional CpG promoter. The presence of clusters of repetitive sequences in the homologous LCRs (>99%) has a destabilizing effect, and might predispose the IP locus to generate benign or pathological rearrangements by different mechanisms. A recurrent genomic deletion of exon 4-10 of IKBKG (IKBKGdel) caused by nonallelic homologous recombination (NAHR) between two adjacent MER67B repeats is the most frequent cause of IP. Whereas, two recurrent benign copy number variations (CNVs), IKBKGPdeletion and MER67Bduplication, produced by (NAHR) due to misalignment between MER67B repeats located in the two LCRs may occur in the IKBKG locus. We identified also nonrecurrent rearrangements, which generate unique pathological CNVs in IKBKG locus. We investigated nine IP subjects by real time PCR and haplotype mapping and we identified six unique pathological CNVs, including four genomic deletions and two duplications. Each rearrangement includes IKBKG, or its conserved 5'-regulatory sequences. Breakpoint sequence analysis reveals that, differently from the predominant NAHR mechanism in recurrent rearrangement, various molecular mechanisms, including nonhomologous end joining, Alu-Alu-mediated recombination, and replication-based mechanisms (e.g., FoSTeS and/or MMBIR) can generate non-recurrent IKBKG pathologic rearrangements. In three IP subjects, the generation of pathological CNVs involve the pseudogene: in two cases the IKBKG mutation arose by gene conversion, in one case it occurred through intra chromosomal inversion between gene and pseudogene. Of note, one of the genomic deletions extends outside the coding sequence. In this case an Alu-Alu-mediated recombination removes the bidirectional IKBKG/G6PD promoter, spanning the exon 1B and 1C of IKBKG, in telomeric direction and the exon 1 and 2 (containing the ATG) of G6PD, in centromeric direction. This deletion abolishes G6PD transcription, while IKBKG is transcribed from a secondary distal promoter. The genetic and functional consequences of this nonrecurrent rearrangement on the expression of the two contiguous genes will be discussed.

A Comprehensive Functional Study of CNVs as Trait-Associated Polymorphisms and as Expression Quantitative Trait Loci. *E. Gamazon[1], D. Nicolae[1,2], N. Cox[1].* 1) Section of Genetic Medicine Department of Medicine University of Chicago Chicago, IL; 2) Department of Statistics University of Chicago Chicago, IL.

A recent study (WTCCC, Nature 2010) of CNVs and 8 complex disorders involving 16,000 cases and 3,000 controls concluded that common CNVs that can be typed on existing platforms are likely to have been interrogated by SNP-based genome wide association studies (GWAS) and unlikely to have a major role in the genetic basis of complex diseases. The same study also reported a paucity of enrichment of association signals among CNVs involving exonic deletions. We conducted a comprehensive functional study of CNVs well-tagged by SNPs (r2 > 0.8) by analyzing their effect on gene expression and their association with disease susceptibility and other traits. We tested whether these CNVs were disproportionately more likely to be functional than frequency-matched SNPs as trait-associated loci or as expression quantitative trait loci (eQTLs) influencing phenotype by altering gene regulation. Our study found that well-tagged CNVs are significantly enriched for eQTLs as well as for cis eQTLs; furthermore, these CNVs show an overrepresentation of reproducible trait associations relative to frequency-matched SNPs. Strikingly, we observed that these CNVs are more likely to simultaneously affect multiple expression traits than frequency-matched SNPs. The enrichment in reproducible trait associations holds robustly when we restrict the analysis to autoimmune diseases and to metabolic traits. Gene Ontology analysis shows that previously reported enrichment in immune response and response to external biotic stimuli for genes in CNV regions generalizes to the target genes of CNVs as eQTLs. Given these strong findings on the functional relevance of CNVs, we created an online resource of expression associated CNVs using the most comprehensive population-based map of CNVs (Conrad et al, Nature 2010) to supplement our earlier studies on eQTL SNPs and to inform future studies of complex traits (Nicolae et al, PLoS Genetics 2010). Our genome-wide gene expression analysis of HapMap CNVs shows that an even greater proportion predicts transcript levels than observed among the well-tagged CNVs in the WTCCC study. Collectively, our various findings show that caution must be exercised in assessments of the contribution of CNVs to complex human traits and in dismissing the possibility that taggable CNVs may indeed underlie certain complex phenotypes.

1812/T

Multiplexed, single-assay validation of whole genome microarray copy number data. *G. Geiss, N. Elliott, B. Birditt, P. Hengen, W. Buckingham.* Research and Development, NanoString Technologies, Seattle, WA.

We have developed a method for multiplexed measurements of copy number variants in genomic regions that can be performed in a single assay without the need for technical replicates. The assay utilizes color-coded barcodes to directly measure copy number variants with as little as100ng of genomic DNA. Since no amplification or technical replicates are required, the assay is extremely easy to use requiring less than 1 hour of hands-on time for 12 samples. Using a strategy of designing 3 probes per region of interest, we simultaneously measured 20 variant regions across 100 DNA samples from the International HapMap Consortium and compared the data to publically available microarray-based copy number results. Here, we show that this method accurately confirmed the published copy number over 94% of the time. Results from technical performance experiments indicate the assay is 99% reproducible across multiple users, days, and cartridges. Currently, using 3 probes per region, the assay can be customized for detection of up to 183 regions of genomic DNA and has been shown to be compatible with DNA isolated from saliva, blood and FFPE tissues. In summary, the nCounter copy number variation assay is an ideal choice for validating copy number variants obtained via whole genome sequencing or microarray analyses or screening large numbers of samples for defined sets of CNVs.

Efficient Algorithm for Tandem Copy Number Variation Reconstruction in Repeat-rich Regions. *D. He, N. Furlotte, E. Eskin.* University of California Los Angeles, Los Angeles, CA 90095, USA.

Copy Number Variations (CNV) are one type of structural variations that have attracted much recent attention due to their effect on gene expression, disease status and other observable phenotypes. The recent development of high-throughput sequencing techniques has enabled the generation of reads with high genome coverage, which has lead to the development of new methods for identifying and even reconstructing CNVs. Such methods map reads to a reference genome and interrogate mapping inconsistencies, which might indicate the presence of a CNV. These methods work well when CNVs lie within unique genomic regions. However, the problem of CNV identification and reconstruction becomes much more challenging when CNVs are in repeat-rich regions, due to the multiple mapping positions of the reads. In this study, we propose an efficient algorithm to handle these multi-mapping reads such that the CNVs can be reconstructed with high accuracy even for repeat-rich regions. To our knowledge, this is the first attempt to both identify and reconstruct CNVs in repeat-rich regions. Our experiments show that our method is not only computationally efficient but also accurate.

Exploring copy number variation in somatic mosaicism within human brain regions in neurodegeneration. *S. Iraola-Guzman[1], R. Rabionet[1], H. Mattlin[2], A. Ferrer[2], I. Ferrer[4], E. Martí[1], X. Estivill[1,3].* 1) Genes and Disease Program CRG-UPF and CIBERESP, Barcelona, Spain; 2) Microarray Core Facility, CRG, Barcelona, Spain; 3) Experimental and Helath Sciences Department, Pompeu Fabra University, Barcelona, Spain; 4) Anatomo-pathological service, IDIBELL-Hospital of Bellvitge, Barcelona, Spain.

The existence of genetic mosaicism in humans is well documented. For instance, about 1-2% of Down Syndrome cases are caused by mosaicism between normal and trisomic cells. Although traditionally mosaicism has been mostly used for cytogenetic variants, it refers to the presence of two populations of cells with a different genotype; however, it is assumed that somatic cells are genetically identical within a single individual. Nevertheless, a previous study has shown differences in copy number among various tissues in three individuals, suggesting that humans are commonly affected by somatic mosaicism for “de novo” copy number variants (CNVs). In order to analyze the presence of somatic mosaicism of CNVs within different brain regions, we have performed high-density array-CGH of six areas (amygdala, frontal cortex, hippocampus, hypothalamus, substantia nigra and pons) against the corresponding cerebellar vermis (CV) in six different individuals (2 Parkinson’s disease, 2 Alzheimer disease and 2 Controls), including a self to self-hybridization. We have detected several regions showing differential hybridization between areas, including ten regions common to at least two individuals, and 22 regions shared between at least two different areas in a single individual. Regions shared among more than two areas have been selected for further validation either by MLPA, real time qPCR or by allele-specific PCR, depending on the type of CNV. Confirmation of somatic mosaicism for structural variants could have an important impact in neurodegenerative disease. Most genetic studies are performed on blood DNA, with the assumption that any variant related to disease, even if it is tissue specific, it can be detected in blood. If there is an important level of mosaicism within the brain, it could account for part of the missing genetic component in complex neurological disorders.

1815/T

De Novo Rates and Selection of Large Copy-Number Variation. *A. Itsara[1], H. Wu[2], J.D. Smith[1], D.A. Nickerson[1], I. Romieu[3], S.J. London[2], E.E. Eichler[1,4].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) National Institute of Environmental Health Sciences, National Institutes of Health, Department of Health and Human Services, Research Triangle Park, NC; 3) National Institute of Public Health, Cuernavaca, Mexico (current affiliation: International Agency for Research on Cancer, Lyon, France); 4) Howard Hughes Medical Institute, Seattle, WA.

While copy-number variation is an active area of research, *de novo* mutation rates within human populations are not well characterized. Here, focusing on large (>100 kbp) events, we estimate the rate of *de novo* formation of copy-number variants (CNVs) in humans by analyzing 4394 transmissions from human pedigrees with and without neurocognitive disease. Analyzing Phase I Hapmap trios, we attempted to validate four candidate *de novo* CNVs in CEU samples using a combination of array-CGH and marker analysis in the extended CEPH pedigrees and found that all events were likely somatic or cell line artifacts. This demonstrates that a significant limitation in directly measuring genomewide CNV mutation is accessing DNA derived from primary tissues as opposed to cell lines. We conservatively estimated the genomewide CNV mutation rate using SNP microarrays to analyze whole blood derived DNA from asthmatic trios, a collection in which we observed no elevation in the prevalence of large CNVs. At a resolution of ~30 kb, nine *de novo* CNVs were observed from 772 transmissions, corresponding to a genomewide CNV mutation rate of $\mu = 1.2 \times 10^{-2}$ CNVs per genome per transmission ($\mu = 6.5 \times 10^{-3}$ for CNVs >500 kb). Combined with previous estimates of the CNV population prevalence and assuming a model of mutation-selection balance, we estimate significant purifying selection for large (>500 kb) events at the genomewide level to be $s = 0.16$. Supporting this, we identify de novo CNVs in an analysis of 717 multiplex autism pedigrees from the AGRE collection and observe a significant ($p = 1.4 \times 10^{-3}$) four-fold enrichment for *de novo* CNVs segregating to cases of multiplex autism versus unaffected siblings suggesting that many *de novo* CNV mutations may be contributing a subtle, but significant risk for autism.

1816/T

Evaluation of the performance of gDNA from saliva collected with Oragene®•DNA for the purpose of CNV analysis on the Agilent Human Genome CGH Array 244A. *R.M. Iwasiow[1], M.A. Tayeb[1], P. Hu[2], R.F. Wintle[2], S. Scherer[2].* 1) DNA Genotek, Ottawa, ON, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada.

CGH microarrays are efficient, high-resolution tools for genome-wide profiling of copy number variation (CNV). The Agilent Human Genome CGH Array 244A, which contains over 236,000 distinct probes representing both coding and non-coding sequences, is useful for CNV analysis. The current study evaluates the performance of gDNA from saliva on the Agilent Human Genome CGH Array 244A. Oragene•DNA simplifies sample collection by providing an alternative to blood, eliminating phlebotomy cost and complexity while facilitating collection from subjects dispersed throughout the general population. Oragene•DNA is a non-invasive, self-collection device intended for collection of large quantities of high-molecular weight genomic DNA (gDNA) from saliva. DNA is stabilized at room temperature for extended periods enabling sample collection and transport via regular mail and flexibility to process in batches. Two saliva samples were collected from each of four donors using the Oragene•DNA kit and the gDNA extracted from each of these collections was analyzed. Performance of the gDNA from saliva was assessed by evaluating CNV calls from each sample and the reproducibility of the data was determined by comparing the results from two separate collections from the same donor. The Aberration Detection Method 2 (ADM-2) algorithm (with fuzzy zero correction) provided in the Agilent Genomic Workbench 5.0 software was used to analyze the data. Less than 29 CNVs per genome were detected in individual saliva samples and there was a high degree of concordance between replicate samples from the same donor. Additionally, >80% of the CNVs found in saliva were present in corresponding blood samples. The derivative log ratio spread (DLRS) for all saliva and blood samples was <0.2. All other metric parameters were within acceptable limits and no significant difference between blood and saliva samples was observed. The results indicate that gDNA isolated from saliva collected with Oragene•DNA is a suitable substitute for gDNA from blood for use on Agilent Human Genome CGH Arrays.

Genome-wide detection of CNVs in Lithuanian patients with mental retardation. *V. Kucinskas[1,2], V. Dirse[1], A. Utkus[1,2], E. Preiksaitiene[1], J. Kasnauskiene[1,2], K. Männik[3], A. Kurg[3].* 1) Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Vilnius, Lithuania; 2) Centre for Medical Genetics of Vilnius University Hospital Santariskiu Klinikos, Vilnius, Lithuania; 3) Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia.

Background: Mental retardation (MR) which occurs in about 1-3 % of population is etiologically very heterogeneous and remains unexplained in almost half of all cases. Whole-genome scanning technologies such as array CGH and SNP-CGH have enabled the detection of clinically relevant copy number variations in individuals with MR of unknown etiology. **Methods:** Twenty-three Lithuanian patients with MR/developmental delay (DD) and congenital malformations were enrolled in this study. We have used Infinium HD whole-genome genotyping HumanCytoSNP-12 (300K SNPs) and HumanOmniExpress (700K SNPs) BeadChips to detect significant copy number variations. Obtained data was analyzed with Illumina GenomeStudio, KaryoStudio and QuantiSNP software. **Results:** Two copy number variations with potential clinical relevance were detected. The first patient was a 12-year-old boy with moderate MR and speech delay. He was the second born child of healthy parents. Birth weight was 2550g, length 51 cm. At age 12 his height was 141 cm (3 centile), weight 27 kg (<3 centile), OFC 49 cm (<3 centile). He had microcephaly, sloping forehead, relatively large ears. Detected 1.8 Mb microdeletion at 17q21.33 contains among other genes *CACNA1G* and *CA10* which are important in neurological processes. The *CACNA1G* gene encodes voltage-dependent calcium channel which are thought to be involved in neuronal oscillations and resonance, pacemaking activity in central neurons, neurotransmission. The *CA10* gene encodes the protein which is acatalytic member of the alfa-carbonic anhydrase subgroup and it is thought to play significant role in the central nervous system, especially in brain development. *CACNA1G* and *CA10* might be good candidate genes for further studies to investigate whether these are involved in the development of phenotypical features of this patient. The second patient was referred because of MR/DD, particularly speech and language delay. Clinical phenotype was remarkable for several small areas of skin hypopigmentation and cafe-au-lait spots, mild joint hypermobility and medial deviation of the feet. 1.7 Mb subtelomeric microduplication at 4q35.2 was found which partially overlaps with similar 2.5 Mb microduplication reported in DECIPHER database. The research leading to these results is funded by the European Community's Seventh Framework Program [FP7/2007-2013] under grant agreement n° 223692, CHERISH project.

1818/T

Exploring De Novo Copy Number Variants in Three-Generation Families of Mongolia. *S. Lee[1,4], H. Park[1,5], YS. Ju[1,6], HJ. Kim[1,4], JI. Kim[1,2,3], JS. Seo[1,2,4,6].* 1) ILCHUN Genomic Medicine Institute, Medical Research Center, Seoul National University, Seoul, Korea; 2) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul, Korea; 3) Psoma Therapeutics Inc., Seoul, Korea; 4) Department of Biomedical Sciences, Seoul National University Graduate School, Seoul, Korea; 5) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA; 6) Macrogen Inc., Seoul, Korea.

After the discovery of copy number variation (CNV) a few years ago, we are starting to figure out that CNV is actually the huge portion of human genomic variation, and could affect a lot to many kinds of phenotypes we can imagine. Moreover, dislike SNPs, CNVs are known to be newly generated rather easily during cell division, so De Novo CNVs, which refers CNVs newly generated, could be discovered in the way of comparing CNVs of family members in different generations. In this study, we focused on this type of De Novo CNVs in three-generation families, and tried to approximate the true number of De Novo CNVs generated between parents and children. We used the DNA samples of three Mongolian families, each of which consists of 6 family members: grandparents, parents, and two children. We chose array comparative genomic hybridization (arrayCGH) as a CNV detection method, and used 1M custom design array. (Agilent Technology) This array has been designed to detect most of previously reported CNVs and simultaneously discover new kinds of CNVs by tiling the rest of probes throughout human genome. We used HapMap sample NA10851 as a reference DNA, and result files coming out of the arrayCGH experiments are transformed by a program, called 'CARA : CGH Array Reference-free Algorithm', which provides the correction of the effect of reference DNA. To remove false positive CNVs, we focused on one parent among family members, whose parents are the grandparents of our samples. Firstly, we collected De Novo CNV candidates which are detected in the target parent but not in grandparents, and then we selected CNVs which are transmitted to his or her children. As a result, we found 106, 35, and 102 De Novo CNVs in each family, and these CNV regions are now on validation using real-time PCR. Furthermore, we are also trying to propose candidate CNV regions which may result from somatic changes, and we could suggest more kinds of De Novo CNV candidates with children samples' CNV calls. With all these results together and further analysis on the sequence level, we are expecting to provide some clues about the mechanism of CNV generation.

1819/T

Copy Number Variants Associated with Refractive Error. *Y.J. Li[1, 2], D. Abbott[2], S. MacGregor[3], P.G. Hysi[4], A.W. Hewitt[5], D. Mackey[5], C.J. Hammond[4], T.L. Young[2].* 1) Department of Biostatistics & Bioinformatics, Duke Univ Med Ctr, Durham, NC; 2) Center for Human Genetics, Duke Univ Med Ctr, Durham, NC; 3) Genetics and Population Health, Queensland Institute of Medical Research, Brisbane, Australia; 4) Department of Twin Research and Genetic Epidemiology, King's College London School of Medicine, St. Thomas' Hospital, London, United Kingdom; 5) Centre for Eye Research Australia, University of Melbourne, Royal Victorian Eye and Ear Hospital, Melbourne, Australia.

Purpose: Copy-number variations (CNVs) are deletions, insertions, or duplications of chromosomal segments that may influence disease susceptibility. We conducted a genome-wide association of CNVs with refractive errors using twin samples. **Methods:** 3024 genomic DNA samples from a twin cohort were genotyped with the Illumina human610-quad beadchip. Both PennCNV and QuantiSNP programs, Hidden Markov modeling based methods, were used to detect CNV regions for each sample. The primary phenotype is spherical equivalent (SE=sphere+1/2(cylinder)). We tested whether a CNV event is associated with the average SE of both eyes (AvgSE). A linear regression was performed in the R package with AvgSE as an outcome variables and the CNV event (presence or absence) at a CNV SNP as a predictor variable. To fit model assumptions of normality, AvgSE was transformed using the ENQT method. Due to the insufficient sample size for CNV SNPs with low frequencies, CNV SNPs with a frequency less than 0.4% (12 samples) were excluded. CNV regions were prioritized based on a combination of significance thresholds of 0.0005 and 0.01 in either detection method. **Results:** Of 600,470 SNPs in the analysis, PennCNV detected 295,507 (49.2%) CNV SNPs while QuantiSNP detected 443,385 (73.8%) CNV SNPs. We excluded 85,337 (14.2%) CNV SNPs due to low sample counts. Five CNV regions met our criteria: 1) chr9: 106390295-106413750 ($p=0.01$, $4.58x10^{-5}$ for PennCNV and QuantiSNP, respectively); 2) chr10: 122759266-122777752 ($p=9.73x10^{-5}$, $9.73x10^{-5}$); 3) chr12: 20908303-20930416 ($p=3.39x10^{-4}$, $p=1.09x10^{-5}$); 4) chr17: 41730794-41780482 ($p=0.01$, $4x10^{-4}$); and 5) chr20: 51709859-51737515 ($p=0.007$, $1.4x10^{-4}$). Among these regions, chr10 region showed the best results with high consistency between PennCNV and QuantiSNP, but no genes mapped to this region. The most interesting regions were chr12, chr17, and chr20 - all with potential interval candidate genes. Notably, although PennCNV did not show an impressive p-value for the chr17, this region was detected by both methods when high myopia (SE < -5.00 diopter (D) for at least one eye) was compared to controls (-0.50 D < SE < +1.00D)($p=0.005$, 0.004). **Conclusions:** The present study identified potential loci with CNVs that may modify refractive error. Further investigation of these CNV intervals may lead to the identification of susceptibility genes for myopia.

A region-based CNV calling algorithm. *T. Liu, A. Thalamuthu.* Genome Inst Singapore, Singapore, Singapore.

A crucial step in studies of CNVs in human disease is to correctly identify those CNV events at the first place. Once CNVs are successfully identified, all types of downstream association tests can be performed to test the relatedness of a disease and the copy-number-variation of a particular region. Below we describe a region-based CNV calling algorithm, which can be applied to the intensity data generated by various platforms. Our algorithm works with predefined regions of known copy-number variation, especially suited for regions of common variations. Our algorithm is very useful in two circumstances, 1) we can use it to verify the CNV calls in those potentially interesting regions defined by using standard HMM-algorithms 2) given supplemental information from other published data with reported copy-number variations, we can incorporate these prior information and improve the CNV calls in known reported regions. Based on LRR values of the samples, the general idea of our algorithm is to combine the multi-dimensional Gaussian Mixture Model (GMM) and model-based hierarchical clustering to cluster samples into discrete copy number classes (0,1,2,3 and 4). The three advantage of our algorithm are 1) we are able to incorporate relevant reported knowledge with the data under study, which may potentially boost the accuracy of the estimation of copy number; 2) our algorithm takes the entire sample into account during the calling process, hence our algorithm is expected to be more sensitive than the HMM algorithm; 3) our algorithm is region based, which enable us to make adjustments for the batch-effects more effective and straightforward. We have tested our algorithm with the 90 Hapmap samples from Chinese Han population. The intensities were obtained using the Affimetrix 500k chip, and converted to the LRR values. We compared our results with those given by the Birdsuite algorithm (Broad Institute, 2008). The average consistency of our algorithm and the Birdsuite algorithm over these regions is 92.4%. Yet, in 173 regions, the consistency of the two algorithms is lower than 90%. We show that in these regions, the copy-number calling by our algorithm is more reliable, comparing to the current the Birdsuite algorithm (which by the way relies heavily on the prior information), when the prior information was possibly misleading.

Investigate the roles of DNA copy number variants in primary open-angle glaucoma. *Y. Liu[1], J. Gibson[1], C. Haynes[1], K. Hutchins[1], S. Schmidt[1], R.R. Allingham[2], M.A. Hauser[1,2].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Duke Eye Center, Duke University, Durham, NC.

Copy number variants (CNVs) have been shown to be involved in many human diseases, including autism, schizophrenia, and systemic lupus erythematosus. However, the role of CNVs in primary open-angle glaucoma (POAG) still remains unknown. POAG, as the most common form of glaucoma, affects more than 3 million people in the US. We used genome-wide Illumina microarrays containing over 610,000 genetic markers to genotype 100 primary open-angle glaucoma cases. At the same time, the genotype and raw intensity files were requested for over 900 Parkinson's disease controls from dbGAP in NCBI. PennCNV software was used to identify and analyze the CNV changes in POAG cases and controls. The CNV frequencies were compared between cases and controls using Fisher's exact test. We identified a heterozygous DNA copy number loss on the GALC gene (galactosylceramidase) in two POAG cases comparing to none in dbGAP controls (p=0.012). The association of this specific CNV loss was confirmed in our Caucasian case-control (470 cases and 468 controls) POAG dataset (p=0.03) using TaqMan-based realtime PCR CNV assays. The identified CNVs were further confirmed using chromosome 14 specific NimbleGen aCGH. The end points for CNV loss were defined so that CNV-specific PCRs were designed to further confirm the CNV loss. We have identified different end points for the CNV loss on GALC, suggesting the complexity of CNV changes at this locus. Very interestingly, the homozygous CNV loss of GALC accounts for 40-45% of Krabbe disease patients in the Caucasian population. Majority of the Krabbe disease patients show optic neuropathy or vision loss, which suggests a potential biological role of GALC in the pathogenesis of POAG. Our study will be the first to incorporate DNA copy number variants into the genetic association of glaucomatous optic neuropathy seen in POAG. To our knowledge, this is the first report describing the CNVs in the pathogenesis of POAG. This study provides important and novel information that, if corroborated, can be used to develop strategies for future genetic testing, diagnosis, and potential new therapies to treat POAG, a common blinding disease.

Autoantibody profile associates with *C4* gene copy number in Systemic Lupus Erythematosus. *E. Lundstrom[1], I. Gunnarsson[1], J. Gustavsson[1], YL. Wu[2], K. Elvin[3], CY. Yu[2], LO. Hansson[4], A. Larsson[4], L. Klareskog[1], L. Padyukov[1], E. Svenungsson[1].* 1) Dept Medicine, Karolinska Inst & Hosp, Stockholm, Sweden; 2) Dept of Molecular Virology, Immunology and Medical Genetics, the Ohio State University, Columbus, Ohio, USA; 3) Dept of Clinical Immunology and Transfusion Medicine, Unit of Clinical Immunology, Karolinska Institutet, Sweden; 4) Dept of Clinical Chemistry and Pharmacology, Akademiska Hospital, Uppsala, Sweden.

Objectives: Systemic lupus erythematosus (SLE) is a heterogeneous and complex systemic autoimmune disease characterized by autoantibody profile. Copy number variation (CNV) has been shown to be one of many possible sources of phenotypic heterogeneity. The region with strongest linkage to SLE (6p21.3) harbors the genes *C4A* and *C4B* which are known to exhibit CNV. In this study, we aimed to analyze the associations between *C4* CNV and SLE. In addition, we analyzed the association of *C4* CNV with plasma levels of complement and autoantibodies among SLE patients. **Methods**: 283 SLE patients and 180 controls matched for age, sex and region of living participated. *C4* CNV was determined with RT-PCR. Plasma levels of C4, C3, and C3d were measured in patients by rate nephelometry and autoantibodies with enzyme linked immuosorbent assay. The Lupus anticoagulant (LAC) test was performed with a Dilute Russel Viper Venom method. Associations were determined with Chi-square and Mann-Whitney tests. **Results**: SLE patients displayed more often low gene copy number of *C4A* (<2) (OR: 2.3, 95% CI: 1.4-3.7) or <4 copies of 'C4 total' (C4A+C4B) (OR: 2.3, 95% CI: 1.4-3.6) compared to controls. No association between *C4B* CNV and SLE was observed. Presence of SSA/SSB was significantly associated with SLE patients carrying <2 copies of *C4A* or <4 copies of C4tot (C4A+C4B) (OR C4A: 1.8, 95% CI: 1.1-3.1) (OR C4tot: 4.1, 95% CI: 2.4-7.00). SLE patients carrying <2 copies of *C4A* or <4 copies of C4tot, were less likely to have β2GP1 IgG (OR C4tot: 0.4 95% CI: 0.2-0.7), anticardiolipin (aCL) IgM (OR *C4A*: 0.5, 95% CI 0.2-0.9) or a positive LAC test (OR C4tot: 0.3, 95% CI: 0.1-0.5). In addition, our data reveal association between low copy numbers (<4 copies) and low serum levels of C4 (p = 0.02) among SLE patients. No association between *C4* CNV and plasma levels of C3 and C3d was observed. **Conclusion**: Our study demonstrates a significant association between *C4* CNV and autoantibody profile in SLE. Low gene copy numbers of *C4* were strongly associated with the presence of SSA and SSB antibodies while SLE patients with high numbers of C4 gene copies were more likely to have aPL antibodies. Our data support previous findings that low gene copy number of *C4* is associated with SLE and with low levels of C4 protein in plasma. Further studies related to the complement system are warranted to understand how genetics is related to subgroups of SLE patients with different autoantibody profile.

1823/T

An oligonucleotide array for detecting length polymorphisms of long tandem repeats in the human genome. *R. Margolis[1], L. Yu[1], G. Benson[2], P. Warburton[3], L. Delisi[4].* 1) Dept Psychiatry, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) Departments of Biology and Computer Science, Program in Bioinformatics, Boston University, Boston MA; 3) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York NY; 4) Department of Psychiatry, Harvard Medical School, Boston VA Brockton Health Services System, Brockton, Massachusetts.

There are more than 1 million tandem repeats in the human genome. Repeats with units of 2-12 bp in length have emerged both as powerful markers for linkage studies and as mutations causing a number of human diseases. We hypothesize that polymorphisms of longer tandem repeats (unit length of 50 bp to >150,000 bp), relatively unexplored features of the human genome, may also contribute to normal human variation and to disease, including schizophrenia. To systematically address this issue, we developed an oligonucleotide array specifically designed to detect length variations of those repeats. we selected repeats that were at least 250 bp in length with units a minimum of 50 bp in length and of at least 95% identity. A total of 6,763 non-redundant repeats were selected from the human genome reference sequence for potential inclusion. Using the Roche Nimblegen singleplex Comparative Genomic Hybridization (CGH) 12X135K oligonucleotide platform, a 136,363-probe set was generated for detecting 4,064 tandem repeats (~60% of the potential repeats) with a coverage of approximately 4 million base pairs. Twelve patients with schizophrenia (labelled with Cy3) and one healthy control (labelled with Cy5) were used as test and reference samples, respectively. The log2 ratio of test to reference signal intensities were determined for each probe, and then a log2 ratio for each repeat was determined by calculating the mean log2 ratios of all probes hybridizing to a given repeat. In total, we detected 495 repeats with substantial length polymorphism (log2 ratio >0.5 or <-0.5). For each individual tested, we detected 100-200 repeats with lengths substantially different from the reference sample. The presence or absence of polymorphism was confirmed for selected repeats using PCR. We conclude that this oligonucleotide array will be a novel tool for detecting repeat length variations associated with diseases.

Hakonarson[21], JN. Hirschhorn[1,4,8], JG. Wilson[14], B. Keating[22], SA. McCarroll[4,8].* 1) Metabolic Disease Initiative, Broad Inst, Cambridge, MA; 2) Genetic Analysis Platform, Broad Inst, Cambridge, MA; 3) Computational Biology and Bioinformatics Program, Broad Inst, Cambridge, MA; 4) Medical and Population Genetics Program, Broad Inst, Cambridge, MA; 5) School of Medicine, Boston University, Boston, MA; 6) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 7) Wake Forest University School of Medicine, Winston-Salem, NC; 8) Department of Genetics, Harvard Medical School, Boston, MA; 9) Institute of Molecular Medicine, University of Texas, Houston, TX; 10) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 11) Department of Medicine, Medical College of Georgia, Augusta, GA; 12) Department of Medicine, Université de Montréal, Montreal Heart Institute, Quebec, Canada; 13) Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA; 14) University of Mississippi Medical Center, Jackson MS; 15) Division of Prevention and Population Sciences, National Heart, Lung, and Blood Institute, Bethesda, MD; 16) Department of Medicine and Center for Clinical Investigation, Case Western Reserve University, Cleveland, OH; 17) Department of Epidemiology, University of Washington Seattle, WA; 18) Department of Public Health Sciences, University of Virginia, Charlottesville, VA; 19) Division of Cardiology, Department of Medicine, University of Washington, Seattle, WA; 20) Department of Biostatistics and Epidemiology, Case Western Reserve University, Cleveland, OH; 21) Department of Pediatrics, University of Pennsylvania, Philadelphia, PA; 22) Department of Cardiology, University of Pennsylvania, Philadelphia, PA.

We analyzed data from > 8,000 African Americans who were genotyped on the Affymetrix 6.0 Array to optimize detection of copy number variants (CNVs). Samples were from five cohorts in the NHLBI Candidate Gene Association Resource (CARe) project, including the Atherosclerosis Risk in Communities (ARIC) study, Cleveland Family Study, Coronary Artery Risk Development in Young Adults (CARDIA) study, Jackson Heart Study, and the Multi-Ethnic Study of Atherosclerosis (MESA). We used algorithms described in Korn et al. (Nat Genet 2008;40:1253-60) to call common (Canary) and rare (Birdseye) CNVs. Reference panels included data from both HapMap2 and HapMap3, and incorporated the more accurate and complete catalogs of copy number variation from the Genome Structural Variation Consortium (Nat Genet 2010;42:385-91). To construct prior probabilities for use in Canary, we applied a weighting of 4:1 YRI:CEU, reflecting typical ancestry of African Americans. We tested the impact on call rate of altering a variety of parameters and filters, as well as certain QC measures, such as apparent Mendelian inheritance errors in the Cleveland Family Study. Using CANARY, we analyzed over 1,000 diallelic CNVs that passed our QC filters, of which ~500 had minor allele frequency >1%. Parameters critical to CNV calling in African Americans included use of appropriate prior probabilities, careful attention to plate-specific artifacts, and judicious use of Hardy-Weinberg filtering in this admixed population. In ongoing work, we will assess the accuracy of these CNV calls by direct genotyping and will produce a set of CNVs for association testing with phenotypes that have been measured in the CARe cohorts.

Population Analysis of Copy Number Variation Regions with SNP Genotyping Array. *S. Moon, Y. Kim, C. Hong, Y. Shin, D. Kim, M. Park, J. Lee, H. Kim, B. Han, B. Kim.* Division of Structural and Functional Genomics, Center for Genome Science, Korea National Intsitute of Health,KCDC, Seoul 122-701, Korea.

To date, thousands of genomic variants associating with susceptibility to human complex disease have been reported through GWA studies. In spite of successful findings of GWAS, it is still not sufficient to find the missing heritability of complex diseases. To make up for finding the missing heritability, copy number variation analysis has been considered as an alternative and a complement way. Copy number analysis is defined as a loss or gain of long segments of DNA and it is relatively common in the human genome. Although tens of thousands of CNVs and CNV regions have been discovered from various CNV studies, only minorities of these studies were focused on the Asian. Thus, for considering more precise CNV analysis, it is essential to add Asian-specific CNV on the CNV map. In this study, we undertook a genome-wide analysis of copy number variation in community-based Korean population. We used the Affymetrix genome-wide Human SNP array 6.0 platform (including more than 906,600 SNP and more than 946,000 CN probes) to carry out genotyping 3,703 healthy controls from the KoGES (Korean Genome Epidemiology Study). After quality control test check, two kinds of CNV detection tools such as GADA and DNAcopy were used to analyze CNV locus. In conclusion, we identified a number of both common CNV loci and rare CNV loci through the quality control process and we also merged clusters of overlapping CNVs at the same level into CNV event (CNVE) according to the WTCCC protocol. These findings will be confirmed by follow-up study and validation study using qPCR.

1826/T

Genome-wide high-resolution array-CGH analysis of copy number variation in human somatic tissues. *M. O'Huallachain[1, 2], A.E. Urban[3], M.P. Snyder[2].* 1) MCDB, Yale Univerisy, New Haven, CT; 2) Genetics, Stanford University School of Medicine, Stanford, CA; 3) Psychiatry, Stanford University, Stanford, CA.

Human genomic variation is a key factor in understanding human diversity. Genomic changes range from single nucleotide polymorphisms to large chromosomal aberrations. Structural variation including copy number variation (CNV) affects chromosomal regions on the kilobase to megabase scale. Many studies in the past several years have demonstrated the significance of copy number variation to human genomic variation. CNVs have been implicated in multiple human genetic disorders. These studies generally used easily accessible DNA from blood or blood-derived cell lines. It was widely assumed that all healthy cells, with very few specific exceptions in the immune system and germ line, which arise from the same zygote, possess the same genomic content. However, recent evidence indicates that copy number variation exists between differentiated tissues within individuals. Our study aims to uncover the scope of somatic copy number variation using technology not previously available. Here we report findings from array-CGH experiments using Nimblegen 2.1M probe arrays. This array has the potential to detect copy-number changes as small as a few kilobases using unbiased tiling across the whole genome. At this time, we have tested a total of 13 tissues collected post mortem from two individuals. Our analysis of these experiments suggests that there are approximately 30 locations of potential copy number differences between tissues within an individual ranging in size from ~2kb to ~1.5Mb. Several of the CNVs encompass genes while others occur in intergenic regions. A number of them have been previously indentified based on the Database of Genomic Variants while some appear to be novel. Our findings suggest that somatic copy number variation is more frequent than has previously been reported.

1827/T

Towards a comprehensive structural variation map of an individual human genome. *A.W. Pang[1,2], J.R. MacDonald[2], D. Pinto[2], J. Wei[2], M.A. Rafiq[2], D.F. Conrad[3], H. Park[4], M.E. Hurles[3], C. Lee[4], J.C. Venter[5], E.F. Kirkness[5], S. Levy[5], L. Feuk[6], S.W. Scherer[1,2].* 1) Department of Molecular Genetics, University of Toronto,Toronto, Ontario, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Wellcome Trust Sanger Institute, The Wellcome Trust Genome Campus, Hinxton, Cambridge, United Kingdom; 4) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts, USA; 5) J. Craig Venter Institute, Rockville, Maryland, USA; 6) Department of Genetics and Pathology, Rudbeck Laboratory, Uppsala University, Uppsala, Sweden.

Several genomes have now been sequenced, with millions of genetic variants annotated. While significant progress has been made in mapping single nucleotide polymorphisms (SNPs) and small (<10bp) insertion/deletions (indels), the annotation of larger structural variants (SVs) has been less comprehensive. It is still unclear to what extent a typical genome differs from the reference assembly, and the analysis of the genomes sequenced to date have shown varying results for copy number variation (CNVs) and inversions. We have combined computational re-analysis of existing whole genome sequence data with novel microarray-based analysis, and detect 12,178 structural variants covering 40.6Mb that were not reported in the initial sequencing of the first published personal genome. We estimate a total non-SNP variation content of 48.8Mb in a single genome. Our results indicate that this genome differs from the consensus reference sequence by ~1.2% when considering indels/CNVs, 0.1% by SNPs and ~0.3% by inversions. The structural variants impact 4,867 genes, and >24% of structural variants would not be imputed by SNP-association. Our results indicate that a large number of structural variants have been unreported in the individual genomes published to date. This significant extent and complexity of structural variation, as well as the growing recognition of its medical relevance, necessitate it be actively studied in health-related analyses of personal genomes. The new catalogue of structural variation generated for this genome provides a crucial resource for future comparison studies. Finally, to continue the annotation of this human structural variation map, we are currently utilizing a number of next generation sequencing (NGS) technologies to discover novel variants, to refine variation breakpoints, and to elucidate the putative molecular mechanism in the formation of these variants.

1828/T

CONDR - COpy Number Detection with RNA-seq: A novel algorithm to infer copy number changes from RNA-seq data. *A. Ramachandran[1], M. Micsinai[2], I. Pe'er[1].* 1) Computer Science, Columbia University, New York City, NY; 2) NYU Cancer Institute, New York University School of Medicine, New York, NY.

Background: The recently emerged next generation sequencing technology applied to RNA (RNA-seq) is a powerful, high-resolution approach to quantitatively survey the transcriptome, revealing information about expression level as well as single nucleotide variants (SNVs). Current state-of-the-art algorithms easily detect SNVs from RNA-seq data, but copy number changes are more complicated to distinguish from transcription levels. To address this shortcoming, we developed a new computational method, CONDR, to identify abnormal copy number from RNA-seq data with application to germline copy number variants (CNVs), as well as somatic aberrations.

Methods: The CONDR algorithm uses an HMM to incorporate two sources of information: relative transcript abundance measured in Fragments Per Kilobase of transcript per Million mapped fragments (FPKM), and sequence information of mapped short reads that provides SNVs. These quantities are obtained from standard tools for RNA-seq mapping. In our HMM implementation we define six states that are biologically relevant and computationally feasible. The algorithm calls a copy number state, normal or any of the aberrant states for each exon along the genome. Aberrant states include homozygous deletion, heterozygous deletion, copy neutral loss-of-heterozygosity, chromatin change and copy number increase.

Computationally, the inference is based on each of the copy number states being characterized by particular fold changes in FPKM and rates of single nucleotide variants per kilobase. The modeled transitions are between the normal state and an aberrant state and their respective probabilities quantify the chances of initiation or termination of a copy number change in a particular gap between exons.

The emission probabilities are estimated from the expectations of FPKM and SNV rates for the normal state. Given the data, we use the forward-backward algorithm to compute the most likely state for each exon along the genome.

Results: We demonstrate CONDR performance on simulated and experimental data, where copy number change loci have been independently validated by qPCR.

1829/T

The impact of common copy number variation on gene expression phenotypes in asthmatics. *A.J. Rogers[1], J.H. Chu[1], K. Darvishi[2], J. Howrylak[1], B. Klanderman[1], R. Mills[2], I. Ionita-Laza[3], V. Carey[1], C. Lee[2], B.A. Raby[1].* 1) Channing Laboratory, Brigham & Women's Hospital, Boston, MA; 2) Department of Pathology, Brigham and Women's Hospital, Boston MA; 3) Columbia University, New York, New York.

Rationale: Common copy number variants (CNVs) constitute a substantial proportion of total genetic variation. However, the extent of their contribution to human phenotypic variation, as compared to single nucleotide variation, remains undetermined. Previously, an analysis using low-resolution CNV genotyping methods in HapMap lymphoblastoid cell lines estimated that ~17% of gene expression may be explained by CNVs (Stranger et al., Science 2007). The motivation of the current study is to evaluate the impact of CNVs on gene expression in a larger dataset using a higher resolution array, designed specifically for the purpose of CNV genotyping. **Methods**: Gene expression profiles from peripheral blood CD4+ lymphocytes from 153 Caucasian asthmatics were generated using Illumina HumanRef8 v2 BeadChip arrays. CNV genotyping was performed using a custom 180k Agilent CGH CNV genotyping array that interrogates ~20,000 known CNV regions identified in several recent high-resolution CNV discovery and sequencing projects, including the Structural Genomic Consortium, 1000 Genomes Project, and CNV genotyping in Asians (Park et al, Nat. Gen. 2010). Each CNV region was tagged with 6 to 9 probes and each sample was tested against a standard reference (HapMap NA10851). After filtering of minimally expressed genes, we measured the correlation of (log-transformed) transcription abundance with copy number (aCGH log2 ratio) for all CNV regions. **Results**: We observed strong correlation between CNV log2ratio and expression phenotype. Using p-value thresholds of $1x\ 10^{-4}$, $5x\ 10^{-5}$, and $1x\ 10^{-5}$, we found respectively 2487 (13%), 1619 (9%), and 589 (3%) of CNV associated with expression of at least one syntenic gene. The variance in gene expression explained by these CNVs was high (median 34%, range from 32% to 88%), and was considerably greater than that observed by SNP (median <22% for all eQTL studies reported to date). While most CNVs were associated with expression of only a single gene, more than 100 were associated with expression of at least 5 genes. **Conclusions**: The impact of CNV on gene expression is large. Though only a fraction of CNVs influence transcription, their phenotypic consequences on their target genes is greater than that observed for all but a limited number of SNP. Moreover, an important subset of expression-associated CNVs manifests "master regulator"-like effects. **Funding**: R01 HL093076, R01 HL086601, P01 HL083069, P41 HG004221, and K12 HL089990.

1830/T

***NRXN1* exonic deletions in psychiatric disorders - a mega-analysis of published data.** *D. Sato, D. Pinto, A.C. Lionel, A. Prasad, C.R. Marshall, S.W. Scherer.* The Centre for Applied Genomics and Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, M5G 1L7, Canada.

Autism spectrum disorders (ASDs) are a genetically complex group of neurodevelopmental disorders with incidence of ~1% in the general population. Despite a strong genetic basis underlying ASDs and some genes now identified, the majority of the genetic causes still remain largely unknown. Over the past years, the International Consortium Autism Genome Project (AGP) has shown that multiple rare de novo and inherited copy number variations (CNVs) contribute to >10% of ASDs. In 2007, the AGP reported two de novo deletions disrupting the *NRXN1* gene in two female siblings with ASD (Szatmari et al. 2007). The *NRXN1* gene encodes a synaptic neuronal adhesion molecule and represents one of the best candidate genes for ASDs based on its well-known role in synaptogenesis and its interaction with neuroligins. After that first report of *NRXN1* deletions associated with ASD, subsequent studies have identified *NRXN1* deletions in other ASD cohorts as well as in schizophrenia (SCZ) patients. Such CNVs may result in the expression of different neurodevelopmental phenotypes. Thus, we compiled all available published and our own unpublished data on CNVs affecting the *NRXN1* gene from various neuropsychiatric disorders. We found that *NRXN1* CNVs could be observed in ASDs, SCZ, intellectual disability, attention deficit hyperactivity disorder and bipolar disorder. We observed a significant excess of exonic CNVs overlapping *NRXN1* in neuropsychiatric disorder cases compared to controls. In our latest AGP study (Pinto et al. 2010), we identified three exonic deletions and one duplication in *NRXN1* in four out of 996 ASD cases versus none in 4,964 screened controls ($P=4.7x10^{-3}$). All four CNVs were de novo, further supporting a role in ASD pathogenesis. Moreover, in a mega-analysis of all cases, we found exonic deletions in 15 of 3,632 ASD cases and none in 7,719 controls ($P= 3.7\times10^{-8}$), and a total of 42 exonic deletions in 16,618 psychiatric disorder cases and 9 in 52,690 controls corresponding to an odds ratio of 14.8 (95%CI 7.2-30.5, $P=2.4\times10^{-18}$). Although we cannot exclude an overestimation of these frequencies due to some individuals being reported in multiple papers, these findings warrant further follow-up in larger patient cohorts, and existing cross-disorder sets where raw genotyping data is available. In addition, we are generating iPS (induced pluripotent stem) lines from ASD cases with *NRXN1* exonic deletions for functional studies.

1831/T

Recurrent rearrangements of 16p13.11: further evidence for a pathogenic role of deletions in Autism Spectrum Disorders (ASD). *A.F. Sequeira[1,2,3], C. Correia[1,2,3], J. Almeida[4], S. Mouga[4,5], C. Cafe[4], F. Duque[4], D. Pinto[6], P. Szatmari[7], S.W. Scherer[6], G. Oliveira[4,5], A.M. Vicente[1,2,3], The Autism Genome Project Consortium.* 1) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 2) Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisboa, Portugal; 3) Center of Biodiversity, Functional & Integrative Genomics (BioFig), Lisboa, Portugal; 4) Instituto Biomédico de Investigação de Luz e Imagem, Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal; 5) Centro de Desenvolvimento da Criança, Hospital Pediátrico de Coimbra, Coimbra, Portugal; 6) The Center for Applied Genomics and Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario M5G 1L7, Canada; 7) Department of Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton, Ontario L8N 3Z5, Canada.

Recent studies have established copy number variants (CNV) as an important class of rare variation that may cause or increase risk for autism. Deletions and reciprocal duplications of the chromosome 16p13.1 region have been reported in cases of intellectual disability (ID), autism and schizophrenia. Previous findings suggested that deletions are likely to be causal for the patient's phenotype, whereas the role of duplications remains uncertain. To clarify the relevance of 16p13.11 deletions and duplications in autism, we correlated CNVs in this region, identified through a whole genome CNV analysis carried out by the Autism Genome Project Consortium on 1275 patients, with detailed phenotypic data. We have identified 3 patients with rearrangements of the reported 16p13.11 microdeletion/microduplication region (~800kb). One patient carried a deletion, which was observed once in a total of 4964 control subjects of European ancestry. The deletion carrier is a male diagnosed with autism using the ADIR-R and ADOS, has mild ID (IQ=52), and presented severe behavioral problems (aggressiveness and coprolalia) from 2 years of age, but no language delay. Epilepsy and microcephaly, common features reported in some cases, were not present. The family history of this patient was positive for neuropsychiatric problems, with a sister with learning problems, an uncle with schizophrenia and a mother who had two depression episodes. The deletion was validated by qPCR and is larger than the typical deletion described for 16p13.11 (~1.5Mb), including ~15 Refseq genes. Candidate genes in the region include *NDE1*, *NTAN1*, and *RRN3*; mouse orthologues of these genes, when disrupted, result in abnormal neuronal phenotype and/or abnormal behavior. The other two patients with 16p13.11 rearrangements carried a duplication (~800Kb), inherited from their unaffected fathers. Both had normal IQ, language delay, no epilepsy and no dysmorphisms. The unaffected paternal half sister of one of the patients did not carry the rearrangement. Four duplications in this region were identified in the same control population. Together with previous observations, these findings suggest that 16p13.11 duplications may be rare benign or modulatory variants, while deletions are more likely to have a pathogenic role with a variable clinical presentation. Additional large cohorts including multiple psychiatric conditions are needed to fully understand the role of these variants in neuropsychiatric disease.

Detection of chromosomal imbalances in children with neurologic disorder by array CGH. *E. Shin[1], K. Lee[1], J. Byun[2], B. Eun[2].* 1) Genome Res Ctr, NeoDin Med Inst, Seoul, Korea; 2) Dept of Pediatrics, Korea Univ Guro Hopital, Seoul, Korea.

Microarray-based CGH has enabled the identification of previously unrecognized submicroscopic chromosome alterations and elucidated the etiologies of known syndromes. We performed a genome-wide assay for pediatrics neurologic disorder using Roche NimbleGen 135K (Roche NimbleGen Inc., USA) arrays on 3 children with epilepsy and seizure. Case 1 was a 12 year old boy with epilepsy, severe seizure, eyesight and hearing impairment, and has lived as a vegetable state since 5 year old. A deletion spanning 2 OMIM genes with an estimated size of 110 Kb was identified, located on chromosome band 1p36.33. In addition, a duplication spanning 2 OMIM genes with an estimated size of 115Kb was identified, located on chromosome band 21q22.13. The deletion is probably the cause of the boy's phenotype, since his clinical features overlap greatly with 1p36 deletion syndrome mentioned in previous reports despite his MELAS mutation. Another genomic imbalance on chromosome 21, involving 2 genes such as TTC3, DSCR2, should be interpreted depending on clinical phenotype as this region is related to Down syndrome. Therefore, the array result of this case was arr 1p36.33(825,513-935,943)x1, 21q22.13(37,432,798-37,548,446)x3 Abnormal Male. Case 2 was a 6 year old girl with rett syndrome, epilepsy, seizure and a behavioral disturbance with rubbing her hands. In case 2, no genomic deletion or duplication was not detected using 135,000 probes, but the patient's phenotype with rett syndrome should be determined with PCR-direct sequencing method for MECP2 on chromosome Xq28. Case 3 was a 4 year old girl with lissencephaly type 1 on brain MRI, seizure and normal karyotype. A deletion spanning 6 OMIM genes those are not related to her phenotype, with an estimated size of 1.81 Mb was identified, located on chromosome band 16p13.11. The deletion of chromosome 16p13.11 is probably the cause of this case, since her clinical features overlap greatly with 16p13.1 deletion syndrome and the array result was arr 16p13.11p12.3(14,957,300-16,768,273)x1 Abnormal Female. Oligonucleotide array CGH offers increased resolution compared to BAC array CGH, FISH, and karyotype analysis. It has enabled the discovery of novel microdeletion and microduplication syndromes and the detection of genomic imbalances of clinical significance will increase knowledge of the human genome by performing genotype-phenotype correlation.

1833/T

A definitive haplotype map derived from homozygous genomes as a basis for disease gene study. *T. Tahira[1], Y. Kukita[2], K. Yahara[3], M. Sonoda[1], K. Yamamoto[1], N. Wake[4], K. Hayashi[5].* 1) Div Genome Analysis, Kyushu Univ/Med Inst Bioreg, Fukuoka, Japan; 2) Research Institute, Osaka Medical Center for Cancer and Cardiovascular Diseases; 3) Division of Life Science System, Fujitsu Kyushu Systems Inc; 4) Department of Gynecology and Obstetrics, Graduate School of Medical Sciences, Kyushu University; 5) Faculty of Agriculture, Kyushu University.

Unexpected complexity in the haplotypes of human genomes, including SNPs and copy number variations (CNVs), has been realized as a cause of variation in disease susceptibility. CNVs are abundant, possibly variable among populations, and can confer various phenotypic variations such as risks to complex diseases. Even with the aid of recently developed genome-wide microarrays, it is still difficult to define CNV status in the target region. Taggability of CNVs with adjacent SNPs is confirmed to some extent, but not fully investigated, because delineating haplotype structure including SNPs and CNVs is difficult in the analysis of diploid cells. We have been proposing determining definitive haplotype, by analyzing a collection of complete hydatidiform moles (CHMs) of Japanese, using high-density DNA arrays. CHMs are tissues carrying duplicated haploid genomes that originated from single sperms. All of the genetic variants in a CHM genome are homozygous. This makes CHMs more advantageous as materials over conventional diploid cells in detecting CNVs, because greater signal to noise ratios in hybridization signals are expected, and data interpretation is not bothered by possible heterozygosities of overlapping CNV segments. We previously analyzed CHM genomes using Affymetrix SNP 6.0 array and detected many new CNVs in addition to reported ones. We also showed that boundary of CNV is variable even in the same haplotype background, indicating that haplotype-preferential occurrence of CNV event (Kukita et al, Am. J. Hum. Genet., 2010). Here we extended SNP and CNV analyses by genotyping the same CHM samples with Illumina beadarrays. By merging genotyping results of Affymetrix SNP 6.0 and Illumina 1M-duo, we obtained a definitive haplotype map that included 1.7 million SNPs. For the markers common to these two platforms, genotyping results were more than 99.9% concordant. The merging of CNV genotype data of the two systems is underway. Our previous finding of haplotype-preferential recurrences of CNV events were confirmed.

1834/T

High-resolution breakpoint mapping of 38 regulatory and *FOXL2* encompassing deletions in BPES using targeted microarrays. *H. Verdin[1], B. D'haene[1], P. Lapunzina[2], J. Nevado[2], B. Menten[1], E. De Baere[1].* 1) Center for Medical Genetics, Ghent University, Ghent, Belgium; 2) Instituto de Genética Médica Y Molecular (INGEMM), Hospital Universitario La Paz, Universidad Autónoma de Madrid, Madrid, CIBERER, U783-ISCIII, Spain.

Blepharophimosis syndrome (BPES) is an autosomal dominant developmental disorder characterized by a complex eyelid malformation associated or not with ovarian dysfunction. Deletions encompassing *FOXL2* and located outside its transcription unit represent 12% and 5% of molecular defects respectively. In total we identified 28 *FOXL2* encompassing and 10 regulatory deletions, of which the exact breakpoints remained unknown for 36 of them. In order to gain more insight into the mechanisms underlying these rearrangements we aimed to determine the precise location of breakpoints. A second purpose was to further refine genotype-phenotype correlations for extra-ocular features. We used high-resolution tiling arrays with 52,800 probes spaced at a density of ~200 bp to map the breakpoints to an interval that allows validation by junction PCR and sequencing. For 25 deletions, both breakpoint regions could be delineated to less than 7500 bp. The breakpoint regions of seven deletions ranged from 500 bp to 35.5 kb. Four remaining deletions could not be delineated so far. The fine-mapping results were used to design breakpoint PCRs. With regard to genotype-phenotype correlations, an *ATR* encompassing deletion was found in five of eight BPES patients with reported microcephaly. In the three patients with a normal *ATR* copy number, a *cis*-ruption mechanism deregulating *ATR* transcription cannot be excluded however. Interestingly, in two patients with joint abnormalities the *SOX14* gene was located within the deletion, potentially implicating this gene in the pathogenesis of this extra-ocular feature. In conclusion, in the largest series of *FOXL2* encompassing and regulatory deletions reported in BPES, high-resolution breakpoint mapping provided insights in the mechanisms underlying the deletions, and refined genotype-phenotype correlations for extra-ocular features.

1835/T

Common and rare copy number variants in Southeast Asian populations. *H. Xu[1], X. Sim[1], R.TH. Ong[1,2], C. Suo[1], W.T. Tay[3], E.S. Tai[2,4], T.Y. Wong[3,4,5], K.S. Chia[1,2], Y.Y. Teo[2,6,7].* 1) Centre for Molecular Epidemiology, National University of Singapore, Singapore, Singapore; 2) Department of Epidemiology, National University of Singapore, Singapore; 3) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore; 4) Department of Medicine, National University of Singapore, Singapore; 5) Centre for Eye Research Australia, University of Melbourne, Australia; 6) Department of Statistics and Applied Probability, National Unversity of Singapore, Singapore; 7) Genome Institute of Singapore, Agency for Science, Technology and Research, Sinagpore.

Copy number variants (CNVs) extend our understanding of the genetic diversity in humans. It has been reported that Caucasians and Asians share only a small fraction of their CNVs, and the frequencies of common CNVs vary significantly across populations. Since most CNV studies to date were conducted in Caucasians or small Asian samples, the distribution and characteristics of CNVs in Asian populations remain largely unexplored, especially for rare CNVs which have emerged as important genetic factors for complex traits. In the present study, we perform an in-depth investigation of common and rare CNVs in Southeast Asian populations. Illumina Human 1MDuo and 610KQuad arrays were used to genotype 3 population-based cohorts of Southeast Asian origin: Chinese (CHS, n=1945), Malays (MAS, n=2399) and Indians (INS, n=2217) in Singapore. CNVs were identified with pennCNV using stringent quality control criteria (e.g., SD of LRR <0.3, # SNPs/CNV >=10), and will be validated using quantiSNP. After QC we found ~16 CNVs/individual and the ratio of loss to gain events is ~2:1 in each population. The median size of deletions is shorter than that of duplications (CHS: 34.5kb vs. 63.5kb, MAS: 64.2kb vs. 83.4kb, INS: 60.8kb vs. 93.7kb). In each population, ~10% of the CNVs are considered novel as they do not overlap with any CNV in the DGV (Database of Genomic Variants). The frequencies of 90% of novel CNVs are lower than 0.5%, but >1/2 of them are shared by at least two populations and thus considered reliable calls. 60% of CNVs in each population overlap with refGene gene regions. CNVRs were constructed by merging overlapping CNVs from different individuals into discrete loci. In each population, about 4,000 unique CNVRs were defined, covering ~20% of the genome. The Malay and Indian populations share 75% of their CNVRs, while the Chinese population only shares 60% with either group. The population differentiation of these CNVRs will be further explored. To study rare CNVs, we have extracted CNVs with 0.5-5% frequency in each population, which constitute 15-20% of total CNVs. The median sizes are slightly smaller than the overall groups but the loss/gain proportions remain similar. 60% of rare CNVs overlap with refGene gene regions, and >60% are shared by at least two populations. Our samples have been quantified for various clinical traits, such as lipid levels and blood pressure, and we are investigating the effect of rare/novel CNVs on these phenotypes.

1836/T

The effect of diet in the evolution of human metabolic gene copy number variation among Korean and Mongolian population. *M. Yavartanoo[1, 2], J. Kim[1, 2, 4], Y. Ju[2], S. Lee[2, 3], J. Shin[2], H. Kim[2, 3], D. Lee[2, 3], J.S. Seo[1, 2, 3, 4].* 1) Department of Biochemistry and Molecular Biology, Seoul National University, college of Medicine, Seoul Korea; 2) Genomic Medicine Insitute, Medical Research Center, Seoul National University, Seoul 110-799 Korea; 3) Department of Biomedical Science, Seoul National University, Graduate School, Seoul, 110-799; 4) Psoma Therapeutic Inc., Seoul, 110-799.

The difference in the diet between agricultural societies and hunter gatherers may result to change in the copy number of genes that are related to digestion. According to previous studies, copy number of salivary amylase gene (AMY1) correlated positively with salivary amylase protein level such that individuals with high starch diet have, on the average, more copies of the AMY1 gene compared to those with low starch diet. The objective of this study is to determine the copy number variation of these different genes involved in milk, protein and fat digestion, namely, LCT, MCM6, AMY1, PNL1P, LIF, TRYX3 and BACE among Mongolians and Koreans who were known to have differences in diet. Method. Real time PCR was used to analyze the DNA samples. Results. Mongolian subjects were observed to have higher lactase gene copy number compared to Korean subjects. Conclusion. We have demonstrated that the pattern of variation in copy number of the human lactase gene is affected by the amount of intake of dairy products in their diet.

1837/T

Systematic detection of chromosomal abnormalities from multiple genome-wide association scans. *M. Yeager[1,2], K.B. Jacobs[1,2], L. Burdett[1,2], Z. Wang[1,2], L. Perez-Jurado[3,4], M.G. Cullen[1,2], S.J. Chanock[2].* 1) Core Genotyping Facility, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD 21702; 2) Division of Cancer Epidemiology and Genetics, NCI, NCI, NIH, Bethesda, MD 20892; 3) Department de Ciències Experimentals i de la Salut, Universitat Pompeu Fabra, E-08003 Barcelona, Spain; 4) CIBER de Enfermedades Raras, CIBERER, E-08003 Barcelona, Spain.

Over sixty thousand human DNA samples have been genotyped at the CGF using Illumina BeadArray assays, the vast majority derived from leukocytes found in blood samples and oral buccal cells (stratified squamous epithelium) and a small proportion from lymphoblastoid cell lines. While these samples were scanned to perform genome-wide association studies (GWAS) to detect heritable genetic risk factors of numerous cancer sites, the probe intensity data have been analyzed to detect large chromosomal abnormalities, including aneuploidy, tissue mosaicism, and large copy-number variants. Analyses were performed in two stages: 1) rapid detection of outlier missing genotype rates and heterozygosity using a sliding window algorithm along each chromosome to nominate samples for more in-depth study; 2) application of a more computationally intensive copy number segmentation algorithm on chromosomes nominated in stage 1 to estimate chromosomal breakpoints using normalized SNP probe intensity values adjusted for local GC and CpG sequence context. Probe intensity and allelic distribution plots were generated and annotated with the estimate CNV breakpoints for manual classification. This method is able to detect large chromosomal deletions and duplications, but not specific rearrangements or translocations. Although this effort is ongoing, preliminary results show significantly higher rates of chromosomal abnormalities than expected from published population rates for DNA extracted from both blood and buccal samples. Funded by NCI Contract No. HHSN261200800001E.

1838/T

Copy Number Variations in Three Singapore Populations. *R.Y.Y. Yong, L.S.H. Gan, S.H. Ng, E.P.H. Yap.* Defence Medical & Environmental Research Institute, DSO National Laboratories, Sinagpore.

Copy Number Variations (CNV) is now known to be an important class of global genetic variation in the human genome, and contributes to human genetic and phenotypic diversity. Therefore, cataloguing the pattern and frequency of CNV in the general populations is fundamental in understanding its role in human phenotypic diversity, and differentiating between benign verses pathogenic CNVs in future disease studies. We report here a preliminary database of autosomal CNVs larger than 10 Kb, detected in 304 healthy unrelated individuals (103 Chinese, 100 Malay and 101 Indian) representing 3 ethnic groups of Singapore. The samples were typed on high-density oligonucleotide microarray, Affymetrix SNP Array 6.0, and CNV called by GTC v3.0.2. In order to reduce false positive, we focused on CNV greater than 10Kb covered by at least 5 probes. Assessing only the autosomes, a total of 10,770 CNV events were recorded, which mapped to 1,884 non-redundant genomic regions (CNVR). About 38% of these CNVR are not reported in DGV (Database of Genomic Variants). Approximately 21.7% of these CNVR has a polymorphism frequency of >1%, while 6.3% has frequency of >5%. About 11.3% of the CNVR can be found at >1% in all 3 populations. The ratio of deletion verses duplication is about 2:1. The median size of deletion is 31 Kb while duplication is 67 Kb. The average CNV size and ratio of deletion verses duplication are similar across the 3 populations. There are higher number of population-specific CNV in the Indian, and more sharing of CNV between the Chinese and Malay. This work will provide a useful resource to assist future assessment of CNV in the context of human variation and disease susceptibility for Singapore populations. The work is on-going. We plan to do further validation through CNV-calling with other software and via wet-lab approach using real-time PCR for copy number quantification.

1839/T

Germline copy number variations in *BRCA1* mutation carrier. *K. Yoshihara[1], S. Adachi[1], A. Tajima[2], M. Sekine[3], T. Yahata[1], I. Inoue[2], K. Tanaka[1].* 1) Obstetrics and Gynecology, Niigata University, Niigata , Japan; 2) Molecular Life Science, Tokai University, Isehara, Japan; 3) Obstetrics and Gynecology, Nagaoka Red Cross Hospital, Nagaoka, Japan.

The lifetime risks of ovarian cancer for *BRCA1* mutation carriers show a wide range, from 24 to 44% by age 70 years. Therefore, the prediction of individual's lifetime risk for developing ovarian cancer in women with *BRCA1* mutation is very important in clinical management of *BRCA1* carriers. In this study, we aimed to investigate characteristics of germline copy number variations (CNVs) in *BRCA1* mutation carriers and to clarify the relationship between germline CNVs and susceptibility to ovarian cancer. Germline CNVs in 68 *BRCA1* carriers, 33 sporadic ovarian cancer patients and 47 healthy Japanese women were analyzed by both signal intensity and genotyping data using the Affymetrix Genome-Wide Human SNP Array 6.0. Total number of CNVs per genome was more frequent in sporadic group (mean, 24.0±5.3) than in *BRCA1* group (mean, 20.9±5.8; posthoc $p < 0.05$) or in normal group (mean, 20.5±5.8; posthoc $p < 0.05$). Amplifications per genome in sporadic group were more than in other two groups. On the other hand, deletions per genome in *BRCA1* group were more than in the others. Especially, microdeletions defined as segment size less than 50kb were significantly increased in *BRCA1* group (mean, 9.4±3.5) compared to sporadic group (mean, 6.5±3.3; posthoc $p<0.001$) or normal group (mean, 7.9±3.8; posthoc $p<0.05$). Moreover, several CNVs specific to *BRCA1* mutation carriers were detected in chromosome X. Although there was no difference in number of genomic regions between *BRCA1* mutation carriers unaffected with ovarian cancer and *BRCA1* mutation carriers affected with ovarian cancer, we identified some CNVs detected only in B*RCA1*-mutated daughter affected with ovarian cancer compared to *BRCA1*-mutated mother unaffected with ovarian cancer. We reported on the genome-wide profile of germline CNVs in *BRCA1* mutation carriers. Further study will be necessary to uncover the role of gernline CNVs in *BRCA1* mutation carriers.

1840/T

High resolution analysis of CNV breakpoints reveals potentially predisposing sequence motifs and variable mechanisms of genomic rearrangement. *H. Yu[1], E. Geiger[1], H. Xie[3], J. Perin[3], X. Gai[3], C. Haldeman-Englert[4], T. Shaikh[1,2].* 1) Department of Pediatrics, University of Colorado Denver, Aurora, CO; 2) IDDRC, University of Colorado Denver, Aurora, CO; 3) Bioinformatics Core, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Department of Pediatrics, Wake Forest University, School of Medicine, Winston-Salem, NC.

Copy number variations (CNVs) are an increasingly recognized cause of human disease and variation. Unstable genome architecture promotes the rearrangements which lead to CNVs associated with recurrent microdeletions and microduplications. A majority of these pathogenic CNVs appear to be mediated by non-allelic homologous recombination (NAHR) between segmental duplications (SDs). In this study, we have identified and analyzed 100 pathogenic CNVs, 70 deletions and 30 duplications. The sizes of CNVs ranged from 10Kb to more than 56Mb. The rearrangement breakpoints of 17/100 CNVs localized to highly homologous SDs, a significant enrichment, considering that SDs only make up 5% of the genome. Almost all of these 17 CNVs were found to be recurrent in multiple individuals and the frequency was directly proportional to the size and sequence identity shared between the paralogous SDs. The remaining 83 CNVs were mostly non-recurrent, singletons with a few instances of overlapping CNVs but with different breakpoints. We used custom-designed, tiling microarrays to refine the rearrangement breakpoints in a subset of these allowing the rapid cloning and sequencing of 42 breakpoints. Twenty-five breakpoints localized to repetitive DNA elements like Alus and LINEs, but none of these CNVs appeared to result from NAHR between repeats. The observation of microhomology and small nucleotide insertions at the majority of breakpoint junctions suggested alternative mechanisms for rearrangement for non-recurrent CNVs. These include, non-homologous end joining mechanisms (NHEJ) and/or replication-based mechanisms such as fork stalling and template switching (FoSTeS) or microhomology-mediated break-induced replication (MMBIR). We further analyzed each of the breakpoint regions for sequence motifs and palindromic sequences that have previously been identified at or near rearrangement breakpoints. Although many such "hotspot" motifs were identified, none were significantly enriched when compared to control sequences. Analysis using GLAM2 motif search program identified a Poly(-dA:dT) tract in the vicinity (average distance from BP is 85 bp) of 41/42 breakpoints. Poly(dA:dT) tracts have been shown to be important in nucleosome organization suggesting a correlation between breakpoints and chromatin structure. It will be important to determine if these variable rearrangement mechanisms are observed as more CNV breakpoints, both pathogenic and normal variants, are analyzed.

1841/T

Investigation of the break-point integrity of copy number variants suggests dynamic transmission. *F.R. Zahir[1], C.F. Boerkoel[1], J. Michaud[2], J.M. Friedman[1].* 1) Department of Medical Genetics and Child & Family Research Institute, Univ British Columbia, Vancouver, BC, Canada; 2) CHU Sainte-Justine Research Centre, Montreal, Quebec, Canada.

Copy number variants (CNVs) account for the most genomic variation between individuals. Recently described mechanisms for CNV formation highlight a replication based model (e.g., FoSTeS, MMBIR). We hypothesized that CNVs which have occurred via replication based models are less likely to preserve their structural integrity through cell divisions. We investigated the status of inherited CNVs in trios comprised of a child with idiopathic intellectual disability and both normal parents. We assessed CNV data obtained from 15 trios who were tested on Affymetrix 6.0 SNP chips®. 12 CNVs >100kb and involving >30 markers were identified that showed a 'shift' in one or more break-points in the child compared to that of the transmitting parent. Using quantitative PCR we confirmed and mapped break-point shifts in 3 of 5 CNVs tested in the child and both parents.

Two cases had inherited gains of chromosome 3q26.1. One child exhibited a shift of ~73 kb on one end of a paternally inherited CNV (i.e., the child's CNV was 73 kb longer than the corresponding CNV found in the father). The other child had a complex pattern of gained material interspersed with normal material on a maternally inherited CNV, whereas the parent had a single gain. No SNP probes were present in the affected region precluding parent-of-origin analysis for these cases. The third child had a paternally inherited duplication of chromosome 10q11.22. The child's CNV was 823 kb, while the father's was 802 kb. The region duplicated in the child but not the father involves the SYT15 gene. We found 8 informative SNP probes within the common CNV segment excluding sequence involved in segmental duplication. The mean ratio of the paternal allele:maternal allele for these SNPs was 1.8 (95% confidence intervals ±0.91), compared to a mean ratio of 0.98 (95% confidence intervals ±0.0055) for allele A: allele B for the entire chromosome 3 in the child, indicating that the duplication is indeed on the paternally transmitted chromosome.

In summary we have demonstrated that CNVs can be prone to breakpoint shifting during transmission. This work has important implications for our understanding of genomic stability. It re-addresses judging pathogenicity of inherited CNVs when there is a possibility for changes in CNV architecture during inheritance.

1842/T

Using family data as a verification standard to evaluate CNV calling strategies. *X. Zheng[1], J.R. Shaffer[1], C. McHugh[2], C. Laurie[2], M. Melbye[3], J.C. Murray[4], M.L. Marazita[1], E. Feingold[1].* 1) Biostatistics/Grad Sch PubHlth, Univ Pittsburgh, Pittsburgh, PA; 2) University of Washington, Seattle, WA; 3) Statens Serum Institut, Copenhagen, Denmark; 4) University of Iowa, Iowa City, IA.

A major statistical concern for all CNV detection algorithms is their reliability and repeatability. However, it is difficult to evaluate the validity of CNV calling strategies due to the lack of gold standard data that would tell us which CNVs are real. We propose that if called CNVs are reproducibly called in duplicate samples, or inherited from parent to child, then these can be considered validated CNVs. We used two large family-based Genome-Wide Association Study (GWAS) datasets from the GENEVA consortium (dental caries and premature birth) to look at concordance rates of CNV calls between duplicate samples, parent-child pairs, and unrelated pairs. Our goal was to make recommendations for appropriate ways to filter and use CNV calls in genome-wide association studies. We used PennCNV as our primary CNV-calling algorithm, and tested CNV calls using different datasets and different marker sets, with and without GC model adjustment, and with various filters on CNVs and samples. We found that using the Illumina core HumanHap550 SNP set, which was available for both studies, we saw duplicate concordance rates of approximately 55% and parent-child inheritance rates of approximately 28% in both datasets. This suggests an overall "reliability" rate of approximately 55% for these CNV calls. GC model adjustment, sample quality filtering, stratification on DNA sample type, and stratifying on the number of CNVs called for an individual all had very little effect on these reliability measures. Stratification on CNV size did have some effect, with duplicate concordance rates ranging from 31% for the smallest CNVs to 64% for the largest. Adding common CNV markers from the Illumina Human660W-Quad increased the number of CNVs called by a factor of six, but these common CNV calls had only slightly higher concordance and inheritance rates than the rare CNV calls. Overall, our results show that it is probably not possible to find a CNV calling strategy (including filtering and algorithm) that will give us a set of "reliable" CNV calls, at least using currently available chips. CNV calls will always need to be understood as having high error rates. But if we understand the features of that error process, we can still use them appropriately in genetic association studies. NIH grants DE018903, HG004423, T32 MH015169 and NIH contract HHSN268200782096C.

Genomic methylation deserts are hotspots of structural mutability in the human genome. *J. Li[1,2], R.A. Harris[1], P. Stankiewicz[1], S. Cheung[1], A. Patel[1], S. Kang[1], C. Shaw[1], A.C. Chinault[1], L.D. White[1], T. Gambin[3], A. Gambin[4], J.R. Lupski[1,5,6], A. Milosavljevic[1,2].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, 77030; 2) Program in Structural and Computational Biology and Molecular Biophysics, Baylor College of Medicine, Houston, TX, 77030; 3) Institute of Computer Science, Warsaw University of Technology, Warsaw, Poland; 4) Institute of Informatics, Warsaw University, Banacha 2, 02-097, Poland; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX, 77030; 6) Texas Children's Hospital, Houston, TX, 77030.

Approximately 10% of the human genome may be structurally polymorphic at submicroscopic scale, a much larger fraction than covered by SNPs. Early analyses of disease-associated hypermutable loci revealed the role of Non-Allelic Homologous Recombination (NAHR) in mediating deletions, duplications and inversions between homologous Low Copy Repeats (LCRs) and led to the concept of genomic disorders. Despite these early advances, the mechanistic basis for the highly nonuniform distribution of structural instability and structural polymorphisms observed across the human genome remains to be discovered. Prompted by the recently discovered association of hypomethylation and structural instability in white-cheeked gibbons, we examined the relative magnitudes of genome-wide submicroscopic structural mutability in humans attributable to both LCR-mediated NAHR and hypomethylation. We combined evidence from human genome evolution, structural polymorphisms in the human population, and disease studies. Our results show that Loci comprising 1.5% of the human genome that are extremely hypomethylated in the germline, which we refer to as methylation deserts, harbor 15% of 522 structural rearrangements that occurred in the human genome since the branching of human and chimpanzee. Permutation testing indicates that 22% of human-specific structural rearrangements are attributable to hypomethylation, a significantly larger fraction than attributable to NAHR mediated by LCRs. We validate the result by designing a custom whole-genome oligo-aCGH chip probing more densely within NAHR-promoting LCR regions and by applying it to 400 human samples, identifying more than 2,000 CNVs. Analysis of these data combined with the publicly available structural variation data collected on 270 HapMap samples, 450 HapMap samples, 19,000 samples from eight disease studies, and 6,672 samples from a recent study by the International Schizophrenia Consortium confirms stronger association of structural mutability with germline hypomethylation than with LCR-mediated NAHR. The individuals carrying larger numbers of CNVs and schizophrenia patients tend to have a larger fraction of CNVs within hypomethylated regions, pointing to a new connection between the epigenome, mutability, evolution and human disease.

The single-nucleotide structure of copy number variants (CNVs) and functional impact on gene expression. *Y. Ju[1,3], J. Kim[1,4], D. Hong[1], S. Lee[2], S. Kim[3], H. Park[5], C. Lee[5], J. Seo[1,3,4].* 1) Genomic Medicine Institute, Seoul National University, Seoul, Korea; 2) Department of Biomedical Science, Seoul National University College of Medicine, Seoul, Korea; 3) MacroGen, Seoul, Korea; 4) Psoma Therapeutics, Seoul, Korea; 5) Department of Pathology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

The fine-scale structure of genomic variants and its functional influence on gene expression Since 2004, CNVs have been discovered to determine what segments of human genome are frequently affected by deletion or amplification. However, its single-nucleotide level structure and the influence on gene expression are still under-ascertained. To characterize the structural and functional nature of human CNVs as a whole, we analyzed whole genome and transcriptome of 10 Asian individuals using massively parallel DNA and RNA sequencing (Illumina genome analyzer) as well as ultra-high resolution whole-genome tiling CGH arrays (Custom-designed Agilent platform), comprising 24 million probes. We identified ~ 700 accurate personal by combining read-depth data of sequencing coverage (average read-depth is 25x each individual) and the array CGH data. We characterized the precise breakpoint sequences of ~ 60% of the CNVs by analyzing the short-reads aligned on near the CNV breakpoint locations expected from the CGH microarrays. In addition we attempted to identify the location of copy number gain segments using short-read data. From the characteristics of breakpoint sequences, the mechanisms for CNV genesis are suggested. Then we figured out the influence of CNV on gene expression. Generally, CNV affected genes showed weak but positive relationship between copy number and expression level. However, expression of several specific genes was strongly controlled by CNVs, which suggests the potential influence CNVs on phenotypic variations and human complex diseases.

Chromosome-wide mapping of long-range interactions involved in Smith-Magenis and Potocki-Lupski syndromes. *N. Gheldof[1], B. Lajoie[2], J. Molina[3], G. Ricard[1], J. Chrast[1], J.R. Lupski[4], J. Dekker[2], K. Walz[3], A. Reymond[1].* 1) Center of Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 2) University of Massachusetts Medical School, Worcester, MA, USA; 3) University of Miami, Miami, FL, USA; 4) Baylor College of Medicine, Houston, TX, USA.

Copy number variations (CNVs) affect expression levels of the genes that map within the affected region, but also of genes located in the flanking regions. To understand the mechanisms at play, we studied gene expression and chromatin conformation in mice models of Smith-Magenis (SMS) and Potocki-Lupski (PTLS) syndromes, containing a microdeletion and its reciprocal microduplication, respectively, on mouse chromosome 11 (MMU11). We profiled the transcriptome of embryonic fibroblasts of mice with one, two, three and uniallelic two copies of the SMS/PTLS region in an otherwise identical genetic background. As expected, the most differentially expressed transcripts are mapping to the SMS/PTLS interval, but a significant proportion of most differentially expressed genes also map to the rest of MMU11. We hypothesized that these chromosome-wide effects might be caused by changes in long-range interactions along the entire chromosome. We therefore analyzed the chromatin structure of MMU11 of these four mouse strains by using the chromosome conformation capture carbon copy (5C) technology. We designed 1,748 5C primers that combined detect 708,651 long- and short-range interactions. Deep sequencing of the interacting fragments of the wild-type 5C library yielded 15 million reads. Further analysis of the data will allow comparing the chromatin structure and the presence of physical contacts between functionally interacting genomic elements in genotypes differing only by the number of copies of a CNV, and correlating these interaction maps with the observed differential gene expression. Detailed investigations of the different mechanisms by which CNVs alter the architecture of chromosomes are warranted to shed light on how CNVs influence gene expression. In addition, this study will provide a first comprehensive chromatin interaction map of an entire mouse chromosome.

Mobile interspersed repeats are major structural variants in the human genome. *C. Huang[1,2], A. Schneider[3], Y. Lu[1,2], T. Niranjan[2], P. Shen[3], M. Robinson[1], J. Steranka[1,2], D. Valle[1], C. Civin[4,6], T. Wang[1], S. Wheelan[4,5], H. Ji[5], J. Boeke[2,4], K. Burns[3,4].* 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore MD; 2) High Throughput Biology Center, Johns Hopkins University School of Medicine, Baltimore MD; 3) Department of Pathology, Johns Hopkins University School of Medicine, Baltimore MD; 4) Department of Oncology, Johns Hopkins University School of Medicine, Baltimore MD; 5) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, 615 North Wolfe Street, Baltimore MD; 6) Center for Stem Cell Biology & Regenerative Medicine; Department of Pediatrics, University of Maryland School of Medicine, Baltimore MD.

Despite the importance of characterizing structural variants in the human genome, no high-throughput genome-wide approach exists for detecting interspersed repeats. Thus, degrees to which mobile DNAs contribute to genetic diversity, heritable disease, and oncogenesis are sources of speculation. We exploited transposon insertion profiling by microarray (TIP-chip) to map human L1(Ta) retrotransposons (LINE-1s) genome-wide. This identified numerous novel human L1(Ta) insertional polymorphisms with highly variant allelic frequencies. We also explored TIP-chip's usefulness in candidate phenotype-associated allele discovery in clinical cohorts. Our data suggest occurrence of new insertions is more than double previous estimates, and that these repeats are under-recognized as sources of human genomic and phenotypic diversity. We have just begun to probe the complexity of human L1(Ta) polymorphisms, and as TIP-chip is applied to Alu SINEs, it will expand the catalog of genomic variants further still.

1847/T

A statistical model for loss of heterozygosity among tightly-linked SNP genotypes. *P. Scheet[1,2,3], S. Vattathil[1,2], R. Xia[1,3], Y. Guan[4].* 1) Dept. of Epidemiology, U. of Texas M. D. Anderson Cancer Ctr, Houston, TX; 2) U. of Texas Graduate School of Biomedical Sciences, Houston, TX; 3) Div. of Biostatistics, U. of Texas School of Public Health, Houston, TX; 4) Dept. of Statistics, Dept. of Human Genetics, Univ. of Chicago, Chicago, IL.

In SNP microarray data from unpaired tumor samples or constitutional DNA only, inferring loss of heterozygosity (LOH) is typically conducted based on patterns of SNP genotypes, namely the existence of unusually long runs of homozygosity. However, run length alone does not take into account all available information, since local variation in allele and haplotype frequencies also affects the size of homozygous regions. Here we present a model that accounts for these population-specific features of the data to enable more precise inference of LOH due to somatic events such as mitotic recombination, chromosome deletion, or gene conversion.

The statistical model is based on a multiple-layer hidden Markov model (HMM). In traditional "single layer" HMMs for genotype data, the hidden states represent template or consensus haplotypes. In this model, the hidden state space is expanded to include an LOH process that, when active, renders alleles from a single haplotype to be presented as homozygous genotypes. We assume the separate processes that capture linkage disequilibrium and somatic events leading to LOH to be independent a priori, but dependent conditional on the data. Our model can be used to estimate boundaries and obtain posterior probabilities of LOH events. We also develop a likelihood ratio test to quantify the evidence of somatic LOH in specific regions.

We apply our method to simulated data and compare results to those from more restrictive implementations to test the utility gained from relaxing individual assumptions, such as allowing for varying allele frequencies, accounting for the dependence among alleles at nearby markers (linkage disequilibrium), and modeling uncertainty in observed genotypes. Our method accommodates genotyping error and phase uncertainty, and is tractable for thousands of samples from whole-genome data sources, such as SNP arrays and next generation DNA sequencing data.

1848/T

Molecular diagnosis of unknown alpha-thalassemia deletions. *M. Fallah[1], Z. Sharifi[1], P. Fouladi[1], F. Rahimi-nezhad[1], R. Vahidi[1], M. Feizpour[1], S. Kianfar[1], M. Sadeghi[1], H. Bagherian[1], S. Zinali[1, 2].* 1) Kawsar Human Genetics Research Center, Tehran, Tehran, Iran; 2) Dep't of Mol. Med., Biotech Research Center, Pasteur Institute of Iran, Tehran, Iran.

Iran is located in world thalassemia belt and alpha-thalassemia is very prevalent in the country. Most of alpha thalassemia mutations include large deletion of one or both alpha globin genes. It play an important role to make a correct decision for performing prenatal diagnosis (PND) and differentiating unknown alpha-thalassemia from normal HbA2 beta thalassemia. Multiplex ligation-dependent probe amplification (MLPA), a simple technique appropriate for investigation of large deletions with unknown border, was used to determine new deletion in cases suspected of having alpha-thalassemia without any known mutation in alpha-globin gene cluster. Couples referred to Kawsar Genomics Center for PND, investigated for common deletional alpha-globin mutations and point mutation using multiplex Gap-PCR and direct sequencing respectively. Those remained unknown, further investigated for other deletions by MLPA methods. After denaturation, hybridization and ligation, PCR-amplification was performed with the specific SALSA primers. Electrophoresis of PCR products performed using ABI-3130 genetic-analyzer. Data analysis performed using GeneMarker V1.6 software. Conventional molecular study of alpha globin gene mutation for common deletions and point mutations, revealed a mutation in more than 75% of cases. From those remained unknown, 50 suspected cases were investigated further using gene dosage study. MLPA study of globin gene cluster determined a variety of diverse deletion patterns in probe set in 36 (72%) cases. Deletion patterns expanding from 3.5 to 9.3 kb upstream HBZ up to exon 3 HBQ1 (3.7 kb downstream HBA1). Span of deletion lengths varied from at least 9.1 kb up to 67.2 kb. Our study, showed using MLPA can increase accuracy of prenatal diagnosis for alpha thalassemia especially when we face with cases suspected to have large deletion.

1849/T

RNA-seq uncovers the influence of copy number variants on transcriptome diversity. *E. Ait Yahya Graison, A. Reymond.* CIG, Univ Lausanne, Lausanne, Switzerland.

Copy number variation (CNV) of DNA segments has been identified as a major source of genetic diversity, but a comprehensive understanding of the phenotypic effect of these structural variations is only beginning to emerge. Our group and others established extensive maps of CNVs in wild mice and inbred strains. These variable regions cover ~11% of their autosomal genome. CNVs are suggested to shape tissue transcriptomes on a global scale and thus represent a substantial source for within-species phenotypic variation. The recently emerged RNA-seq method has brought transcriptome analysis to a new level, because it addresses both gene expression and alternative splicing events simultaneously. We took advantages of this new technology to unravel the effects of CNVs on expression at the nucleotide rather than locus resolution level. We generated by ultra high-throughput sequencing >230 millions 75-bp RNA-seq reads from brain of three mouse inbred strains (129S2, DBA/2J (D2) and C57BL/6J (BL6)) to monitor expression changes of transcripts that map within and outside genomic regions that vary in copy numbers. We used TopHat v1.0.13 and Cufflinks v0.8.2 to map, assemble and estimate the abundance of assembled isoforms, respectively. When compared to the BL6 reference sample, 13,656 isoforms (representing 9,445 genes) and 11,754 splicing variants (9,034 genes) are differentially expressed in 129S2 and D2 brain, respectively. Among these, we observed a significant enrichment for CNV genes (p-value=2.55e-06 for 129S2, p-value=9.405e-09 for D2) meaning that alternative transcripts that derive from genes varying in copy numbers show significantly more differential expression between strains. This confirms previous observations made on expression arrays but at exon-level, a resolution never achieved before. We also tested difference in splicing events between strains and showed that 371 and 320 genes exhibit significant differential splicing between isoforms in 129S2 and D2 brain samples, respectively, compared to the BL6 reference. We are currently analyzing liver transcriptome sequencing and are, thus, producing the first transcriptome comparison at the nucleotide level of normal individuals of a population. This study provides a unique opportunity to extensively gauge the influence of CNVs on the transcriptome complexity and regulation.

1850/T

Exploration of European Type 2 Diabetes loci in an African American sample. *S.S. An, N.D. Palmer, J.N. Cooke, L. Lu, J. Divers, B.I. Freedman, M.C.Y. Ng, C.D. Langefeld, D.W. Bowden.* Wake Forest University School of Medicine, Winston-Salem, NC.

Type 2 diabetes (T2D) has a high prevalence in the African American (AA) population. Studies to date have focused on identification of T2D susceptibility genes in European-derived populations. We have performed a genome-wide association study of 965 AA T2D with end stage renal disease (T2D-ESRD) cases and 1029 controls using the Affymetrix 6.0 array to directly genotype 832,357 and impute 2.9 million SNPs. From this analysis, we evaluated previously identified European-derived T2D loci in our AA population. Given our sample size, we have >80% power to detect an OR of 1.23 given a MAF of 20% at 5% significance level, which is consistent with published effect sizes. Our analysis of genotyped and imputed SNPs included 19 known index variants defined in studies of European-derived samples. Of these variants, only the imputed SNP rs7903146 in TCF7L2 was convincingly associated with T2D in AA (p=3.2x10-6). Additionally, genotyped SNP rs486745 in JAZF1 showed a trend (p=0.09). These variants were have risk and protective effects against T2D with OR=1.41 and 0.88, respectively. Locus-wide analysis was performed by expanding to a ±10kb region around the gene or neighboring genes for intergenic variants. In the locus-wide analysis, 197 genotyped and 611 imputed SNPs were nominally associated with T2D with p£0.05. These variants are candidates for replication genotyping in independent sample sets. With the exception of rs7903146 in TCF7L2, no other imputed SNPs were found to have a stronger association with T2D compared to the genotyped SNPs among the 19 loci. Based on this analysis, the SNP with the strongest association with T2D in the directly genotyped variants, rs10906180, is in CAMK1D (p=8.5x10-5 OR=1.32). The European T2D index SNP, rs12779790, is located in an intergenic region between genes CDC123 and CAMK1D. However, this analysis points to CAMK1D as the T2D-susceptibility locus and warrants further evaluation. Within these genes, European LD blocks range between 2-164kb, with an average block size of 43kb, whereas Yoruba LD blocks range between 0-46kb, with an average block size of 13kb or 30% of the average Caucasian LD block. The 30kb difference in LD block size between European and Yoruba populations may facilitate the search for causal variants in the AA population. These results suggest that the genetic architecture of T2D in the AA population is unique and invaluable in the efforts to identify causal T2D variants.

1851/T

Changing with the times: the human reference genome. *V.A. Schneider[1], P. Flicek[2], T. Graves[3], T. Hubbard[4], D. Church[1].* 1) NCBI, Bethesda, MD 28092; 2) EBI, Hinxton, Cambridge, CB10 1SD, U.K; 3) The Genome Center at Washington University, St. Louis, MO 63108; 4) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, CB10 1SA, U.K.

Major efforts to sequence and assemble the human genome culminated in 2004, resulting in a reference assembly of very high coverage and quality. Since that time, the human reference genome has played critical and diverse roles in many different aspects of biological research. Among the many important findings facilitated by the reference genome was the discovery of an unanticipated degree of genetic variation between individuals, coupled with the realization that the extant assembly is insufficient in its representation of these often divergent and complex genomic regions. Providing alternative assemblies of such regions is a major focus of the Genome Reference Consortium (GRC), the group responsible for the reference genomes of human and mouse (http://genomereference.org). In 2009, the GRC released the current version of the human reference genome, GRCh37, which for the first time places alternate locus representations into a chromosome context. We will review these alternative assemblies and demonstrate their importance to personal genomics projects (especially those utilizing short read technologies) and improving phenotype to genotype correlations. The GRC also strives to correct sequencing errors and close the remaining gaps in the reference genome. While such assembly updates are necessary to provide the most accurate reference sequence and are crucial to researchers working in poorly-represented regions, frequent assembly releases disrupt the coordinate system relied upon by other researchers working at the whole-genome level. To balance the need for timely updates with the need for a relatively stable coordinate system, the GRC has now developed a system of assembly patches. The patches consist of new or updated sequence contigs defined outside the coordinate system of the current assembly that can be released between full assembly updates. Patches will be incorporated into the reference assembly at the time of the next full update. We will present the first set of assembly patches for GRCh37 and review their relationship to the current and future reference genomes, as well as their biological importance. The work presented is a collaborative effort of the GRC member institutions: NCBI, EBI, The Genome Center at Washington University and The Wellcome Trust Sanger Institute.

Jumping Genomes and Hanging Breakpoints: Novel sequencing methods for characterizing balanced rearrangements in developmental disorders. *M. Talkowski[1,2,5], C. Ernst[1], S. Liu[1,4], C. Hanscom[1], B. Mudduk-rishna[4], A. Heilbut[1], A. Kirby[1,5], T. Ohsumi[4], M. Borowsky[4], M.J. Daly[1,2,5], C.C. Morton[3,5], J.F. Gusella[1,2,5].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Departments of Genetics and Neurology, Harvard Medical School, Boston, MA; 3) Departments of Obstetrics and Gynecology, Reproductive Biology, Pathology, Harvard Medical School, Boston, MA; 4) Department of Molecular Biology, Massachusetts General Hospital, Boston, MA; 5) Program in Medical and Population Genetics, Broad Institute of M.I.T. and Harvard.

The recent technical revolution in genomics has greatly enhanced our ability to survey common variation and copy number changes associated with complex disorders, yet the contribution of balanced rearrangements remains unclear. Current array based methods are blind to their presence and traditional molecular approaches are inadequate to define precise breakpoints rapidly. In an effort to address this void in autism and related developmental disorders, we designed a series of sequencing experiments to precisely characterize balanced genomic rearrangements to base pair resolution. As a baseline analysis of the simplest approach to this problem we performed whole genome sequencing to map rearrangement breakpoints from small and large insert paired end libraries using published Illumina methods. Next, we developed two large-insert “jumping” library methods that use custom bar coded internal adapters to improve genomic coverage and diversity. Occasionally, patient samples are mapped to megabase resolution or less by cytogenetic methods and thus do not require whole-genome sequencing. To enable rapid survey of these rearrangements in a high throughput manner, we designed a novel capture sequencing strategy. We used individual-specific array-based probes of known genomic sequence to capture regions of interest in eight subjects with different chromosomal translocations. The pool of captured DNA fragments were sequenced on a single lane of a flow cell without indexing, thus delivering substantial improvements in time and cost over traditional approaches. We further created an algorithm to exhaustively identify split reads spanning structural variation breakpoints that would otherwise fail to align. Our experiments successfully detected translocation and inversion breakpoints in children with autism and other developmental disorders. The results suggest several causal loci in previously defined microdeletion syndromes, including 2q23.1 and 2q33.1, and novel targets for autism spectrum disorders. We also find significant complexity at the sequence level in many chromosomal rearrangements, and analyses of genomic signatures mediating such events are ongoing. Our methods have implications ranging from de novo assembly to clinical genetic mapping. The results suggest that highly optimized next-generation sequencing can be leveraged to characterize the contribution of these under-investigated sources of genomic variation to complex disease.

1853/T

NIH Roadmap Epigenomics project data at NCBI. *I. Fingerman, T. Barrett, R. Cohen, T. Hassan, Z. Jiang, P. Ledoux, R. Muertter, L. McDaniel, W. Ratzat, A. Soboleva, X. Zhang, G. Schuler.* National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, 45 Center Drive, Bethesda, MD 20892, USA.

Epigenetics refers to a gene activity state that may be stable over long periods of time, persist through many cell divisions, or inherited through several generations, all without any change to the primary DNA sequence. Epigenetic mechanisms include DNA methylation, post-translational modification of histone proteins and non-coding RNAs. These mechanisms of epigenetic regulation contribute to the epigenome. The distribution of methylated DNA, histone modifications, and non-coding RNA expression can be specific to a particular organism, a particular tissue, or a particular cell. The epigenome is dynamic, influenced by environmental factors and extracellular stimuli, and can change in response to these factors. Misregulation of epigenetic events has been observed in various cancers and human diseases. To better understand this, the NIH Roadmap Epigenomics Mapping Consortium was launched with the goal of producing a public resource of human epigenomic data to catalyze basic biology and disease-oriented research. The Consortium leverages experimental pipelines built around next-generation sequencing technologies to map DNA methylation, histone modifications, chromatin accessibility and small RNA transcripts in stem cells and primary *ex vivo* tissues selected to represent the normal counterparts of tissues and organ systems frequently involved in human disease. Data from the NIH Roadmap Epigenomics project are hosted at NCBI’s Gene Expression Omnibus (GEO) database (http://www.ncbi.nlm.nih.gov/geo/roadmap/epigenomics/). This data listings page allows users to browse and query project metadata, as well as download original sequence, alignment and track data files. Furthermore, Roadmap Epigenomics project data have been uploaded to NCBI’s new dedicated Epigenomics database at http://www.ncbi.nlm.nih.gov/epigenomics/. This resource enables users to explore and visualize Roadmap Epigenomics data alongside hundreds of other richly-annotated epigenomics datasets. It provides a unique interface to search and navigate epigenomic data in the context of biological sample information, as well as tools to select and view multiple sets of epigenomic data as tracks on genome browsers.

1854/T

Genome-wide search for a candidate gene in Idiopathic CD4+ T-cell lymphocytopenia by combination of SNP-based homozygosity mapping and next-generation sequencing. *A. KITAMURA, K. YASUTOMO.* Univ Tokushima Graduate Sch, Tokushima, Japan.

Idiopathic CD4+ T-cell lymphocytopenia (ICL) is defined by persistent CD4+ T-cell lymphopenia (< 300 cels/ul or < 20% of total T cells) in the absence of any infections including HIV-1 or drug therapies associated with reduction of CD4+ T lymphocyte. The clinical phenotype of ICL ranges from no symptom to life-threatening opportunistic infections and ICL patients are also susceptible to autoimmune disorders and malignancies. The causative gene of ICL has not been identified because of a very rare disease. We identified one consanguineous Japanese family with 2 affected and 1 unaffected sibling whose parents were first cousins. As the affected siblings presented frequent opportunistic infections and malignancy from an early childhood, bone marrow transplantations were performed on affected siblings, which restored CD4+ T lymphocyte counts. To identify an underlying gene, we performed a genome-wide homozygosity mapping using the high density SNP microarray (Human610-Quad, Illumina) in three siblings and revealed 6 homozygous regions that spanned from 4 Mb to 20 Mb. These loci spanned total 73.6 Mb and harbored 1233 genes. Next, we resequenced whole exons in two affected siblings by combination of target enrichment system and next-generation sequencing approach, because of the high number of candidate genes and low throughput of traditional Sanger sequencing. We used SureSelect Target Enrichment System (Agilent Technologies) to capture whole exons in the human genome and sequenced the captured fractions on the Illumina Genome Analyzer 2. Mean sequencing coverage was approximately 20, and more than 99% of the exons were captured and sequenced to sufficient depth. We detected tens of thousands genetic variants in each affected siblings and found approximately 4000 novel variants in each affected siblings by comparing the variants to dbSNP database. We found 269 identical homozygous variants in two affected siblings including missense and nonsense changes, and selected 64 novel variants located in the SNP homozygous regions. Further validation and analysis of these variants are currently underway and will be reported. We conclude that it is likely to identify a candidate gene of an autosomal recessive disorder even with single consanguineous family by combination of SNP-based homozygosity mapping and next-generation sequencing.

Method for testing relationship between SNP probability and adjacent complex multilocus effect. *K. SHIBATA, A. FUJIYAMA.* National Institute of Informatics, Tokyo, Japan.

Next-generation sequencing technology has been useful for identifying variations between individuals. Thus far, base quality values are used to discern true allelic variations from sequencing errors. In practice, however, while sequence generated by next-generation technology has been aligned to some reference, these mapped to reference assemblies vary greatly in there coverage and complex multilocus effect and then are blind to most novel sequences including true individual variants. Here, we have developed a computational tool that tests the relationship between single nucleotide polymorphism (SNP) probability and adjacent complex multilocus effect. The applicability and accuracy of the methods are evaluated using real data from Illumina GAIIx Analyzer.

1856/T

Validation of a mouse model for Usher Syndrome type 1F (USH1F), a hearing loss disorder in humans. *A.A. Torres[1], S.M.G Massironi[2], J.L. Guenet[3], A.L.B. Godard[1].* 1) General Biology Dept, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil; 2) Department of Immunology, Universidade de São Paulo, São Paulo, Brazil; 3) Unit of Mammals genetics, Institute Pasteur, Paris, France.

The mutation *rodador* is an autosomal recessive disorder characterized by hearing loss, circling behavior and balance dysfunction. Examination of cochlear histology revealed abnormal stereocilia and linkage analysis of recombinant animals using microsatellite markers mapped the mutation on chromosome 10, between 29.0 and 49.0 cM. The characterization of the region allowed the selection of Protocadherin 15 (Pcdh15) as a strong candidate gene as it is involved with hearing function, and many mouse models have already been described and show phenotype similar to *rodador*. Pcdh15 is a member of the cadherin superfamily of calcium-dependent adhesion molecules, and is a component of the extracellular filaments that control morphogenesis and function of stereocilia on mechanosensory cells of the inner ear. We aimed to identify the mutation by sequencing Pcdh15 exons. Forty-one exons, including intronic flanking sequences, were sequenced and an AT-to-GC transition was found in intron 25. Three rodador mice were sequenced: all of them showed the same alteration compared to the control animal from the parental BALB/c strain. C57BL/6, DBA and NZB mice were sequenced to exclude the possibility of this alteration being a polymorphism among strains, and they all presented an Adenine at the referred position. This alteration led to a switch of a dinucleotide ApA for ApG at a position close to the acceptor splice-site. Our hypothesis is that it may have created a stronger intronic cryptic splice-site that could lead to the incorporation of 8 bases from the intronic region into the mRNA, altering the ORF and resulting in a truncate protein. Evidence supporting this hypothesis includes: 1) approximately 80% of known mutations caused by ENU are AT-to-TA or AT-to-GC; and 2) 26% of ENU-induced mutations cause abnormal splicing. We intend to validate this mutation by performing Real-Time PCR tests to evaluate the expression levels of Pcdh15 for control and mutated mice, and sequencing the cDNA portion that contains the junction of exons 25 and 26, to verify whether intronic bases were incorporated. Specific primers have been designed, RNA samples collected from the inner ear and cDNA molecules produced. In humans, mutations of PCDH15 cause hearing loss and Usher Syndrome Type 1F (USH1F). The *rodador* mouse might be a good model for studying hereditary hearing loss and may aid in the comprehension of the mechanisms involved with mechanotransduction and hearing function.

1857/T

Draft sequencing of 1,000 genomes to study the genetics of quantitative traits: data production. *F. Busonero[1], B.J. Tarrier[2], E.A. Ketterer[2], G.R. Abecasis[1], C.A. Brennan[2].* 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) DNA Sequencing Core, University of Michigan, Ann Arbor, MI.

Genome-wide association studies, which systematically assess the association between common single nucleotide polymorphisms and a trait of interest, have led to rapid advances in our understanding of complex traits. Although they have been particularly successful, a large proportion of the genetic component of most of the analyzed traits and diseases remains unexplained. This can be attributed to different reasons, including the fact that the assessed variants were restricted to the design of the commercially available chips and to the catalog of HapMap variations. To overcome this issue, we planned a large scale low-pass whole genome sequencing (1,000 individuals at a minimum depth of 2X) from the SardiNIA project. Sequence data production is ongoing at the University of Michigan DNA Sequencing Core (UMDSC), taking advantage of existing laboratory infrastructure. Upon receipt, each sample is genotyped on the Sequenom platform with a set of 40 SNP markers that are known to have minor allele frequencies close to 50% in a variety of populations. These markers are present in the Illumina Metabochip and Affymetrix 6.0 arrays, and these genotypes will allow samples to be tracked through the lab and to be compared to pre-existing array genotype data, where available. Paired-end Illumina libraries are generated for each sample, as described by Quail M.A. et al. 2008, with several improvements, including automation of purification steps. Actual sequencing capacity, 3 Illumina Genome Analyzers IIx, allows for about 400 GB of DNA sequence data to be generated each month. With each run we are able to sequence 8 samples with an average of 2.5X depth, and greater than 6 GB of high-quality mapped de-duplicated bases per lane in paired-end sequencing runs with 120 bp reads. Sample tracking is accomplished by extending the well established database routines and web interfaces in use at the UMDSC: as a sample advances through the processing steps (sample QC, library prep, library QC, sequencing, data extraction, data QC, data transfer), a status code in the tracking database updates to maintain a clear indication of the location and progress of the sample through the process.

A generic algorithm for calling classical HLA alleles from next-generation sequencing data. *P.I.W. de Bakker[1,2], X. Jia[1,2,3], E. Banks[2], R. Erlich[2], N. Lennon[2], M.A. DePristo[2].* 1) Dept Med, Brigham & Women's Hosp, Boston, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Harvard-MIT Health Sciences and Technology, Boston, MA.

Background: Human leukocyte antigen (HLA) typing is an important tool for clinical diagnostics and biomedical research of autoimmune and infectious diseases. We have developed a generic algorithm for calling classical HLA alleles at 4-digit resolution at class I and II loci from next-generation sequencing data. **Methods**: The HLA caller algorithm, developed as part of the open-source Genome Analysis Tool Kit, examines sequence reads aligned to the classical HLA loci taking SAM/BAM formatted files as input, and calculates for each locus the posterior probabilities for all pairs of classical alleles based on three key considerations: (1) population-specific allele frequencies, (2) genotype calls at each base position, and (3) phase information of nearby variants. The output of the algorithm is a list of posterior probabilities for all possible pairs of HLA alleles. **Results**: We used sequence data from 454, Illumina, and SOLiD in two HapMap individuals (CEU and YRI) generated in pilot 2 of the 1000 Genomes Project (with known HLA types). No manual re-alignment or de novo assembly was attempted. The HLA caller determined all the correct alleles at 4-digit resolution in the two daughters with 454 data, except for HLA-A and HLA-DRB1 in the YRI daughter (NA19240). At HLA-A, one of the two alleles in this YRI individual was incorrect at 4-digit (but correct at 2-digit) resolution. At HLA-DRB1, we observed poor alignment (DRB3 reads aligning to DRB1), resulting in incorrect calls. Using the older Illumina and SOLiD data, the algorithm correctly determined 24/32 and 23/32 HLA alleles, respectively, at 4-digit resolution. Poor alignments across the HLA severely decreased the overall accuracy of the HLA calls. More recently, we also applied the HLA caller to Illumina GA-2 data (76, 101 and 151 bp paired-end at ~54X) as well as Illumina HiSeq data (101 bp at ~60X) in the CEU daughter (NA12878). The 4-digit HLA calls from the GA-2 and HiSeq data were completely concordant with the known types in this CEU individual. Although it was not possible from the sequence data alone to distinguish between DQB1*0201 and DQB1*0203, and between DRB1*0301 and DRB1*0311, the correct calls could still be made due to the population allele frequency priors. **Conclusion**: We have developed a generic HLA calling algorithm for next-generation sequencing data, which will be useful for studying diseases where the HLA is implicated.

Integration of a Linear Isothermal Amplification Protocol with a Streamlined Method for Preparing DNA Libraries used in Next-Generation Sequencing. *S. Kain, H. Sethi, L. Turner, J. Magnus, V. Sementchenko, C. Raymond.* NuGEN Technologies, Inc., San Carlos, CA.

Recent advances in Next-Generation Sequencing (NGS) technology have increased both the throughput and capacity of sequencing platforms, calling for increased efficiency in sample preparation and the ability to work with smaller amounts of starting nucleic acid. The streamlined Encore™ library construction protocol, requiring only two purification steps and no agarose gels, results in amplified DNA libraries prepared from double-stranded cDNA or genomic DNA in as little as 3 hours. Further, a novel indexing capability to enable multiplex sequencing of up to 8 libraries per sequencing lane further improves sample throughput and reduces sequencing costs. These four-base index tags are intrinsic to the first sequencing read and are designed to provide equal representation across all nucleotide bases in the first several sequencing cycles. The index sequences are unambiguous, meaning that sequencing errors or deletion errors do not corrupt the code integrity. Data will be presented from the hybridization of a human genomic DNA library to a human genome CGH array, demonstrating the maintenance of relative stoichiometry across 43k+ coding and non-coding sequences. Other data (amplified cDNA expression array or Encore library sequencing data) will be presented that demonstrates the ability to achieve high quality differential expression analysis using NuGEN's linear isothermal amplification process from as little as 500 pg of total RNA using both RNA-Seq and Digital Gene Expression (DGE) systems. Differential expression data from MAQC A and B library samples, analyzed by RNA-Seq and quantitative PCR (qPCR), produce data concordant with the Taqman reference expression assay (R = 0.934) without significant data compression. Highly conserved differential expression data is observed between libraries from RNA-Seq amplified U937 and HeLa cell-line isolated total RNA. Lastly, data will be shown from deep sequencing of genomic DNA using several bacterial species to demonstrate unbiased mapping of reads as a function of coverage, and the ability to accurately segregate sequencing reads based on the index tags. In addition to genomic DNA, RNA-Seq and DGE samples, the Encore library construction method can be equally applied to the full range of NGS applications including ChIP-Seq, exome sequencing, and amplicon sequencing.

SeqBayes: An adaptive Bayesian framework for calling genotypes from next-generation sequence data. *E.H. Powell, D.D. Kinnamon, M.A. Schmidt, E.R. Martin.* Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

Existing techniques for calling genotypes from next-generation sequence (NGS) data use estimated posterior genotype probabilities based on parameter estimates from previous data or the current sample. Because the degree of confidence in previous estimates and the amount of information in a given sample can vary greatly, we sought a principled approach for efficiently combining the two in genotype calling. We derived a binomial likelihood for the observed base read data from unrelated individuals at a single biallelic variant given a nucleotide-read error rate (r) and latent individual genotypes (G_i). Heterozygotes provide no information on r in this likelihood, so an informative hyperprior for r might be useful in some samples. After assigning a prior to G_i and hyperpriors to r and the variant allele frequency (p), posterior probabilities for G_i can be estimated using Markov chain Monte Carlo. The called genotype is then the one with the highest posterior probability. We estimated overall genotype call error in simulations with 10,000 replicates at read depths from 5 to 25, sample sizes from 10 to 500, p from 0.05 to 0.5, r from 0.01 to 0.10, and genotype frequencies both in and out of HWE. SeqBayes was applied assuming HWE, with a flat hyperprior for p, and with an informative scaled Beta(1, 9, 0, 0.5) hyperprior for r. This hyperprior reflects a vague expectation of r around 0.05 based on previous information. We compared these results to those obtained using sample-based maximum likelihood estimates (MLEs) of r and p. SeqBayes with an informative prior reduced the average genotype-call error rate by 20.13% compared to that obtained using the MLEs (0.049 vs. 0.061) for p=0.5 and r=0.01. In scenarios with excess heterozygosity, in which information on r is sparse, this reduction was 23.04% (0.072 vs. 0.093). Not calling variants for which identification of the MLEs was uncertain (18.87%) reduced the error rate in the called variants to below that of SeqBayes, but call rates were unacceptably low (e.g., 6%) in several scenarios with low read depths and excess heterozygosity. Incorporation of even vague prior knowledge can help to overcome identification problems with purely sample-based approaches, such as maximum likelihood, in sparse data. SeqBayes' ability to incorporate sample information also gives it greater flexibility than methods such as MAQ that rely on constants derived from previous data.

Analysis of a South African genome using SOLiD error correction codes. *V. Tadigotla, C. Clouser, T. Weaver, J. Spangler, M. Sikora, J. Healy, C.C. Lee, T. Harkins.* Life Technologies, Beverly, MA.

The Bushmen of southern Africa are known to be genetically divergent from other humans. An individual from that community (KB1) has recently been sequenced using the 454 GS FLX platform to 10.2 fold coverage and a *de novo* assembly was created. Here we present the deep sequencing of KB1 using the latest developments with the SOLiD™ system and ligation-based sequencing. Specifically, recent improvements in paired-end sequencing have allowed us to achieve longer read lengths in both the forward and reverse direction. Novel error correction codes (ECC) for SOLiD™ are based on standard techniques used in modern communication and data storage systems. ECC works by transforming the valuable information and augmenting it with redundancy to make it more resistant to measurement error. Due to ligation based sequencing, the SOLiD system is unique and can employ ECC encoding by using specially-designed probe sets. This allows us to improve accuracy with minimal impact on sequencing time, as well as decode the original sequence using a Bayesian inference. In total, ~30 fold paired coverage of KB1 was achieved by combining longer paired end sequencing reads (75 bp forward, 30 bp reverse) with standard SOLiD™ mate pair libraries (2x50 bp). These libraries have median insert sizes of 250 bp and 1.5 kb respectively. When mapped against hg18 with ECC applied, there is a 40% reduction in uncovered regions in KB1 and a higher number of heterozygous SNPs are called, which are also present in dbSNP. Structural variations as well as the hybrid assembly of the KB1 genome using 454 and SOLiD data will also be discussed.

1862/T

Comparison of Sequence Alignment Algorithms for Targeted Sequencing Studies. *A.A. Van Zeeland[1], T. Phillips[1], M. Shaw[1], P. Hoover[2], W. Pfeiffer[2], M.A. Miller[2], N.J. Schork[1], S. Levy[1].* 1) Scripps Translational Science Institute, La Jolla, CA; 2) San Diego Supercomputer Center, San Diego, CA.

Accurate alignment to a reference genome is one of the fundamental steps in the analysis of human sequence data. All subsequent analyses, from calling single nucleotide polymorphisms (SNPs) and insertion/deletions (indels) to statistical analyses of variants, rely on accurate and high-quality alignment of the sequencing reads. Moreover, alignment results can provide the first measure of the success of the sequencing experiment by determining whether the library preparation, and if applicable, target enrichment, was effective. A multitude of alignment algorithms exist, and the choice of which to use may be influenced by both the sequencing technology and goals of the experimental study. Unlike previous algorithm comparisons that utilized simulated data (Li & Homer, 2010), here we compare the performance of a select number of both hash-based and Burrows-Wheeler transform (BWT) alignment methods using real data from a targeted sequencing study. Specifically, we targeted approximately 1.3Mb of coding sequence found in 150 candidate genes. In order to accurately assess the relative success of each of the alignment algorithms, we focused our analysis on the HuRef DNA sample, which has previously been Sanger sequenced (Levy et al., 2007). By mapping the HuRef reads back to the NCBI36 reference genome, we could compare the resultant variant calls to the known 'gold-standard' Sanger HuRef sequence. Regions were enriched using microdroplet-based PCR (RainDance, Lexington, MA) and subsequently subjected to sequencing by ligation (SOLiD, Life Technologies, Carlsbad, CA). We applied the default settings for each of the different alignment methods under investigation (BFAST, Bowtie, SHRiMP) and called variants with SAMtools (http://samtools.sourceforge.net/). Preliminary results indicate all mapping algorithms attained an acceptable level of mapped reads (range 56.2% - 69.0%), and achieved high levels of concordance (>90%) with the HuRef genome. The computational loads and speed-accuracy trade-offs will be discussed.

Novel Peak region on 2q13 in Autism case control dataset. *J. Jaworski[1], D. MA[1], D. Salyakina[1], R. Martinez[1], I. Konidari[1], P. Whitehead[1], E. Martin[1], S. Williams[2], R. Menon[2], J. Gilbert[1], M. Cuccaro[1], J. Haines[2], M. Pericak-vance[1].* 1) Hussman Institute for Human Genomics (HIHG), University of Miami, Miller School of Medicine, Miami, FLMIHG, Univ Miami, Miami, FL; 2) Center for Human Genetics Research (CHGR), Vanderbilt University Medical Center, Nashville, TN.

Autism is one of the most heritable neuropsychiatric disorders. No single major gene has been identified conclusively suggesting a complex genetic etiology. Previously we have reported an association of common variants from 5p14.1 with autism risk in a family-based dataset of European ancestry. To validate and extend these results we aimed to take advantage of the case control study design. We selected a total number of 1314 ASD cases from our family dataset and performed association testing with a set of unrelated Caucasian pediatric controls (N=647. A subset of controls (310) were between the ages of 3-21 and were screened for birth defects, developmental and language delays, siezures, as well as ADHD and ASD. The remaining 337 controls were derived from newborn cord blood and screened for birth defects. Quality controls procedures were done at both the sample call rate and population stratification level. Analysis was carried out using the model trend test in PLINK. The previously reported region of 5p14.1 showed nominal p values for SNPs RS1330656 (0.001) and RS7704909 (0.03) although the effect size was much smaller. In addition, we identified an interesting region on 2q13 that has not been previously reported. The peak marker RS11123128 had a p-value of 1.54 * 107 and marked a region of 4 interesting SNPS; RS7600843 (p-value 6.67 * 10^7), RS10197919 (1.39 * 10^6) and RS7593053 (2.44 * 10^6). While not previously reported in autism, the region has been noted in a genome wide linkage study for Schizophrenia (Delisi, E et al, 2002). The peak SNP occurs within the TMEM87B gene while the other SNPS are within the FBLN7 gene. In conclusion, our results confirmed our previously established association at 5p14.1. It also suggests a novel candidate region at 2q13 for further validation.

CD28 proximal promoter polymorphisms and systemic lupus erythematosus susceptibility. *A.J.L. Brambila-Tapia[1], I.P. Dávalos[1], J.I. Gámez-Nava[2], L. González-López[3], J. Medina-Díaz[1], A.G. Bernard-Medina[4], M. Salazar-Páramo[2].* 1) Doctorado en Genética Humana, Instituto de Genética Humana, CUCS, Universidad de Guadalajara (UdeG) y División de Genética, CIBO, Instituto Mexicano del Seguro Social (IMSS), Guadalajara, Mexico; 2) División de Investigación, UMAE, HE, UIEC, CMNO, IMSS y Depto. Fisiología, UdeG, Guadalajara, México; 3) Servicio de Reumatología, Hospital General de Zona, No. 110, IMSS; 4) Servicio de Reumatología, Hospital Civil de Guadalajara, Fray Antonio Alcalde.

Introduction: CD28 expression and serum levels are significantly increased in patients with SLE than in healthy controls (HC). Until now, there are not studies of proximal promoter polymorphisms of CD28 gene in SLE. Therefore, our objective was to investigate the polymorphisms present on the proximal promoter of CD28 in a group of SLE and HC and associate the polymorphisms present with the CD28 serum levels of 40 patients and 40 controls. Material and methods: One hundred and seven patients as well as 108 controls matched by age range and genders were included. The 11 ACR criteria were analyzed on the clinical files and the proximal promoter region of CD28 gene were analyzed by direct sequencing of a 489 base pairs fragment. C28 serum levels (sCD28) were measured by ELISA technique in 40 patients and 40 controls. Results: Only two of the 8 reported polymorphisms were found, they correspond to rs35593994 (-372 A/G) and rs56156157 (-145 -/C). The first had a prevalence of 41% and 36% in patients and controls respectively and the second of 1.4% in both groups. None of these polymorphisms were associated to SLE and the polymorphism the -372 A/G was not associated with the clinical features of disease. Likewise, the association with the sCD28 and the genotypes of -372 A/G polymorphism was not significant. Conclusions: The polymorphisms of the proximal promoter of CD28 are not associated with SLE and the polymorphism -372 A/G is not associated with the diagnostic criteria of SLE or the sCD28.

High Throughput Genotyping: Massively parallel sequencing for Hereditary Spastic Paraplegia on the Roche 454 GSFLX System. *N. Schlipf[1], R. Schüle[2], O. Riess[1], L. Schöls[2], P. Bauer[1].* 1) Department of Medical Genetics, Institute of Human Genetics, Tübingen, Germany; 2) Clinical Neurogenetics, Department of Neurology and Hertie-Institute for Clinical Brain Research and German Center of Neurodegenerative Diseases, University of Tübingen, Tübingen, Germany.

The hereditary spastic paraplegias (HSPs) are a genetically heterogeneous group of neurodegenerative diseases characterized by progressive spasticity and weakness of the lower limbs. At least 46 different loci have been mapped, associated with autosomal dominant, autosomal recessive and X-linked mode of inheritance, 17 responsible genes have been identified. For correct diagnosis molecular testing is essential since clinical parameters by itself are not reliable to differentiate HSP forms. The 454 GSFLX System with its massively parallel pyrosequencing promises high resolution HSP genotyping for multiple individuals at multiple amplicons in a single run. The purpose of this study was to determine the sensitivity and specificity of array based amplicon library generation and massive parallel sequencing of pooled DNA samples for the identification of pathogenic mutations. 47 DNA samples from index cases with sporadic or recessive paraplegia were amplified using Fluidigm 48.48 Access Array System. To achieve high throughput genotyping, we have used PCR primers with multiplex identification tags to amplify *CYP7B1* (SPG5) and *SPG7* exons from individual samples, thereby pooling of the amplicons generated from different individuals prior to the emulsion PCR step. The average sequence read length was 250bp which is in accordance with an average PCR fragment length of 310bp. Also sufficient sequence coverage for full length reads was obtained. We identified eight (including two novel) heterozygous mutations in the *CYP7B1*- and *SPG7* gene in 4 patients. Three of these mutations were nonsense mutations (R63X in CYP7B1, and R247X and R398X in *SPG7*), two were missense mutations (R486C in CPY7B1, and G349S in *SPG7*), one variant (A759T), one a splice site mutation (c.1552+1 G>T) and one was a 29bp deletion (353-384X385) in *SPG7*. Additionally, several known polymorphisms were identified in the *SPG7* gene. All mutations, variants and known polymorphisms were detected by the analysis software and got validated by direct Sanger sequencing. In this study, we were able to establish a high throughput genotyping for sporadic and recessive HSP by an array based amplification strategy to generate amplicon libraries followed by sequencing with 454 GSFLX Titanium chemistry. Further studies will implement the GSFLX Titanium chemistry and genotyping software for higher throughput, longer sequence reads, and greater genomic coverage to provide higher resolution in HSP genotyping.

1866/T

Mapping antioxidant response elements and their variants in the human genome by ChIP-seq. *X. Wang, B. Chorley, M. Campbell, S. Kleeberger, D. Bell.* National Institute of Environmental Health Science, National Institutes of Health, Research Triangle Park, NC 27709.

The antioxidant response element (ARE) is a cis-acting enhancer sequence found in the promoter region of many genes encoding antioxidant and Phase II detoxification enzymes/proteins. In response to oxidative stress, the transcription factor NRF2 (nuclear factor erythroid-derived 2-like 2) translocates to the nucleus and dimerizes with other basic leucine zipper proteins such as small Maf proteins to form a transactivation complex that binds to AREs. To date, NRF2 is known to mediate a transcriptional network of approximately 50 responsive genes that modulate in vivo mechanisms against oxidative damage and reactive electrophiles. Our previous studies on Nrf2-knockout mice and sequence analysis suggest that hundreds of genes may be regulated by NRF2. To get an extensive survey of NRF2 binding to AREs and their variants, we have used chromatin immunoprecipitation with parallel sequencing (ChIP-Seq) technology to identify genome-wide NRF2 binding in human lymphoblastoid cell lines in response to the dietary isothiocyanate, sulforaphane (SFN). Using 12 million uniquely mapped 36-base sequence reads of ChIP DNA from 7 SFN-treated cell lines, we found 2647 NRF2-bound genomic regions. *De novo* motif discovery confirmed the top enriched motif matched the core NRF2 binding motif, and 1302 (49%) regions contained one or more putative AREs. Mapping these regions to nearby genes, we observed 2126 (80%) and 732 (28%) regions were within 100-kb and 5-kb of a gene transcriptional start site, respectively. Based on sequence tag count, we designated 328 regions with high confidence and 98% of them contained putative AREs. Many known AREs were identified in those high confidence regions, however the majority were novel. To determine NRF2 dependence, we selected 6 known, 7 putative, and 30 candidate genes, and measured gene expression in two NRF2-silenced cell lines. Expression of all but 2 known/putative and 20 of 30 candidate genes was reduced in both cell lines. We also identified SNPs within ChIP-seq peak regions and explored the impact of SNP on NRF2 binding and transcription by analyzing genotype and gene expression association in HapMap CEU individuals. This study greatly expands the NRF2 transcriptional landscape and reveals new insights into the role of NRF2 in stress response, environmental susceptibility, and disease etiology.

1867/T

GFM1 is not a major gene of hepatic failure associated with mitochondrial respiratory chain deficiency. *M. Beinat[1], L. Galmiche[1,2], V. Vedrenne[1], A. Slama[3], O. Bernard[4], V. Serre[1], A. Munnich[1], A. Rotig[1].* 1) INSERM U781 and Department of Genetics, Hôpital Necker-Enfants Malades and Assistance Publique-Hôpitaux de Paris, Faculty of Medicine, Université Paris Descartes, Paris, France; 2) Department of Pathology, Hôpital Necker Enfants-Malades and Assistance Publique-Hôpitaux de Paris, Faculty of Medicine, Université Paris Descartes, Paris, France; 3) Department of Biochemistry, Hôpital Kremlin-Bicêtre and Assistance Publique-Hôpitaux de Paris, Paris, France; 4) Department of Paediatric Hepato-gastroenterology, Hôpital Bicêtre and Assistance Publique-Hôpitaux de Paris, Paris, France.

GFM1 gene encodes mitochondrial elongation factor G1 required for elongation phase of mitochondrial translation as it catalyzes ribosome translocation during peptide elongation. GFM1 mutations have been rarely reported in human. Indeed, only four patients from two unrelated families presenting liver insufficiency and multiple respiratory chain (RC) deficiency were found to have GFM1 mutation and one patient with infantile encephalopathy also harbored GFM1 mutation. We have studied a large series of 18 patients with liver insufficiency related to multiple RC deficiencies with no quantitative or qualitative mitochondrial DNA (mtDNA) anomalies. In order to establish the frequency of GFM1 mutations in this group of patients, we have sequenced exons and exon-intron boundaries of GFM1 gene in 15 patients. A genome wide scan was performed in the three other patients using the GeneChip Human Mapping 10K 2.0 Array (Affymetrix) and allowed to exclude GFM1 as a causative gene. Only one patient, born to consanguineous parents, presented a homozygous mutation in exon 9 changing a highly conserved leucine into a proline (L398P). Hepatic failure is frequently associated with multiple RC deficiencies. Most of the patients are sporadic cases but few patients born to consanguineous parents suggest that this disease can be autosomal recessive. Indeed, some of these patients also presented severe mtDNA depletion related to mutations in DGUOK, POLG, MPV17 or PEO1 nuclear genes. The genetic origin of the disease in patients with normal mtDNA content is rarely identified. Mutations of TRMU encoding a mitochondrial tRNA 5-methylaminomethyl-2-thiouridylate methyltransferase allowing thiolation of mitochondrial tRNALys, tRNAGlu and tRNAGln were found in several patients of Arab, Maghreb and Yemenite Jewish origin. However, TRMU mutations were never found in European patients. This study therefore confirms the genetic heterogeneity of mitochondrial hepatic insufficiency and highlights the diversity of abnormal mitochondrial functions in these diseases.

1868/T

Whole exome sequencing analysis in siblings with optic atrophy and suspected mitochondrial disease. *M.J. Falk[1], E. Place[1], S. Dingley[1], J.C. Perin[1], E. Pierce[2], E. Rappaport[1], X. Gai[1].* 1) Department of Pediatrics, The Children's Hospital of Philadelphia and University of Pennsylvania, Philadelphia, PA; 2) Department of Ophthalmology, The Children's Hospital of Philadelphia and University of Pennsylvania, Philadelphia, PA.

Next generation sequencing technologies hold the potential to substantially improve the diagnostic yield for heterogeneous disorders, such as mitochondrial disease. Here, we report results of whole exome sequencing in 2 siblings who presented with optic atrophy, chronic fatigue, GI dysmotility, and motor delay. Genome-wide SNP microarray analysis as well as sequencing of *OPA1* and their mtDNA genome revealed no abnormalities. **METHODS:** 3 ug of fibroblast gDNA (Qiagen) was sheared with a Covaris S2 sonicator, end-repaired, and ligated to SOLiD-specific adapters (Agilent SureSelect Whole Exome bead-based kit). 150-200 base pair fragments were isolated and purified. Following emulsion PCR and bead-enrichment, libraries were sequenced on a SOLiD 3plus system using 50 base pair read length. Average whole exome depths of coverage of 100.3X and 41.9X were achieved in a single NGS run. Short reads were aligned by Burrows-Wheeler Algorithm (BWA). SNPs and indels were called with samtools and custom programs to assess variant calls for depth of coverage, variant percentage, affected gene, amino acid changes, previous population reports (dbSNP), and pathogenicity predictions in PolyPhen and SIFT. Variants were flagged by Human Gene Mutation Database annotation and gene set affiliation. Only shared variants were further considered. **RESULTS:** 7,821 total shared coding single nucleotide variants (SNVs) or small indels were identified in the whole exome, of which 3,713 were non-synonymous (including 43 nonsense) mutations. 97 non-synonymous SNVs were identified in the MitoCarta-defined mitochondria gene set. 29 genes had 31 mito SNVs having "probable", "possible", or "uncertain" deleterious predicted effects, half of which were implicated in fatty acid oxidation (10 genes) or mitochondrial translation (4). Although all 9 homozygous mito SNVs were previously reported in dbSNP, 7 of the heterozygous mito SNVs were predicted to be novel in both dbSNP and SeattleSeq within genes involved in fatty acid oxidation (3), mitochondrial translation (2), calcium transport (1), or unknown (1). Functional analyses are underway to assess FAO and translation in the siblings' fibroblasts. Mutation confirmation is underway in the larger kindred. **CONCLUSIONS:** Comprehensive evaluation of the entire exome in affected siblings, with particular focus on mitochondria-associated genes, permits evaluation of a wide range of potential pathogenic etiologies while minimizing expense and bias.

1869/T

Severe neonatal encephalopathy and Leigh syndrome is related to mutations in GFM1 gene encoding a mitochondrial elongation factor. *L. Galmiche[1,2], M. Beinat[1], V. Vedrenne[1], A. Slama[3], Z. Assouline[1], M. Rio[1], V. Serre[1], A. Munnich[1], A. Rotig[1].* 1) INSERM U781 and department of Genetics, Hôpital Necker-Enfants Malades and Assistance Publique-Hôpitaux de Paris, Faculty of Medicine, Université Paris Descartes, Paris, France; 2) Department of Pathology? Hôpital Necker-Enfants Malades and Assistance Publique-Hôpitaux de Paris, Faculty of Medicine, Université Paris Descartes, Paris, France; 3) Department of Biochemistry, Hôpital Kremlin-Bicêtre and Assistance Publique-Hôpitaux de Paris, Paris, France.

Multiple respiratory chain deficiencies represent a common cause of mitochondrial diseases as it accounts for one third of these disorders. These deficiencies are genetically heterogeneous and can be related to various causes such as abnormal mtDNA maintenance, abnormal mitochondrial translation or cardiolipin synthesis. We have studied a patient born to consanguineous parents of North African origin. He presented intrauterine growth retardation, neonatal feeding difficulties, seizures, encephalopathy, microcephaly and developmental delay. He also had hyperlactatemia and hyperlactatorachia. Brain MRI revealed abnormal basal ganglia. Respiratory chain (RC) analysis showed a complex IV deficiency in muscle and complex I and complex IV deficiency in cultured skin fibroblasts. No quantitative or qualitative mtDNA abnormalities could be identified. A genome wide scan was performed using the GeneChip Human Mapping 10K 2.0 Array (Affymetrix) for the two consanguineous parents and the patient. This revealed 12 regions of homozygosity ranging from 9 to 35 Mb. These regions encompassed 68 known genes encoding mitochondrial proteins, 14 of them being involved in mitochondrial translation. The multiple respiratory chain deficiency observed in fibroblasts of the patients could be related to an abnormal mitochondrial translation. Therefore, we sequenced the GFM1 gene included in a homozygous region of chromosome 3 and identified a homozygous mutation in exon 16 changing a highly conserved arginine into a cysteine (R671C). Structural modeling of the mutant protein showed that the new cysteine is located near to another cysteine and could therefore induce the creation of an abnormal sulfur bridge. This mutation was heterozygous in the two parents and absent from a series of 100 controls of the same ethnic origin. Mitochondrial translation defects of nuclear origin represent a growing cause of multiple RC deficiencies. GFM1 gene encodes a mitochondrial translation factor and mutations of this gene have been rarely reported. Two unrelated patients presented neonatal liver insufficiency whereas a third patient had infantile encephalopathy. Identification of a new GFM1 mutation in our patient confirms the clinical heterogeneity associated to mutations in this gene.

1870/T

Whole exome sequencing of autosomal recessive acute necrotizing encephalopathy. *D.E. Neilson, M. Keddache, P. Putnam, D. Fletcher.* Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

The most intriguing aspect of acute necrotizing encephalopathy (ANE) lies in its gene-environment interaction. In children genetically predisposed to this disorder, mild or non-neurotropic viruses produce a fulminant encephalopathy, resulting in damage to the thalamus and brainstem. Three previously healthy brothers developed episodes of ANE; two died from the disorder. These brothers, born of consanguineous parents, did not have mutations in *RANBP2* (which causes autosomal dominant ANE) and likely represent an autosomal recessive form of ANE. Defining the genetic cause in consanguineous families may allow the identification of a predisposing gene for the "sporadic" cases. DNA was available from only one of the three brothers from the kindred. Previously, this would not be enough to pursue further analysis, but the advent and success of high throughput exome sequencing allows the possibility of identifying novel mutations in regions of identity-by-descent (IBD). **METHODS**: DNA from the surviving proband was tested by whole exome sequencing. A DNA library was enriched by hybridization to a Nimblegen Exome SeqCap array and subsequently sequenced using an Illumina GAIIx next generation sequencer. To supplement marker density, data from a 10K Affymetrix SNP chip were merged with data from exome variants. Regions of IBD were identified through runs of consecutive homozygous markers greater than 1Mb. **RESULTS**: 17,637 total variants were identified. 1303 variants (7% of total) defined 239 regions of suspected IBD. The aggregate size of the regions was 461Mb, or 15% of the haploid genomic size. The largest sized segments were 17 and 18 Mb, whereas the average size was 1.9Mb and the median size 1.4Mb. From these regions, 449 known coding variants and 4 novel missense variants were revealed. **DISCUSSION**: Whole exome analysis reduced IBD candidate regions from 15% of the genome to 4 candidate variations. Although this method does not take into account the contribution of rare known SNPs or intronic variants, this process allows for streamlined candidate gene identification. Exome analyses in additional ANE patients may allow better refinement of candidate genes, but potential locus heterogeneity could complicate the process. For rare, idiopathic reactions such as ANE in which pedigree information and patient populations are limited, exome analysis may provide the best insights into pathogenesis for the near future.

Multiplexed Massively Parallel Sequencing for the Prenatal Detection of Fetal Aneuploidy from Maternal Plasma. *T. Zwiefelhofer[1], J. Tynan[1], L. Cagasan[1], D. van den Boom[2], L. Tang[1], Y. Chen[1], C. Deciu[1], M. Ehrich[2].* 1) Sequenom Center for Molecular Medicine, San Diego, CA; 2) Sequenom Inc, San Diego, CA.

Prenatal diagnosis of fetal chromosome abnormalities such as Trisomy 21 currently relies on invasive procedures which may pose a significant risk to the fetus. Analyzing circulating cell free fetal nucleic acids derived from maternal plasma is a potential non-invasive alternative for aneuploidy detection. Multiple groups have shown high sensitivity and specificity in detection of trisomy 21 using a next-generation sequencing approach. Although the results of these initial studies suggest a superior performance to established screening methods, the expense and low throughput nature of the described technologies currently limits their application in a routine analytical setting. Here we explore an implementation of the sequencing approach that relies on multiplexed sample analysis to address these limitations. In multiplexed sequencing, sample-specific barcode tags are incorporated into each molecule along with a universal adapter sequence. Several tagged samples are then combined for analysis with the output sequences later assigned to their respective parent sample using the barcode tag. In this paper we describe the use of 4-plex sequencing. Due to the low quantity of fetal DNA in maternal plasma the sensitivity and specificity of the sequencing method for aneuploidy detection is dependent upon the total number of uniquely aligned sequences per sample. Increasing those uniquely aligned sequence reads heightens the discriminatory power of the assay as a result of the concomitant decrease in statistical noise. Though the analysis of 4 samples in a single reaction decreases the number of sequences aligned per sample, by adopting the latest biochemistry and software updates, our unique counts per sample have only decreased by half. Thus, we maintain the statistical power of the assay and gain a 4-fold increase in throughput. We studied the initial performance of multiplexed sequencing for T21 detection using a sample set of 88 euploid and 8 T21 samples. Libraries were prepared from each sample and then sequenced in 4-plex format using Illumina's Genome Analyzer IIx. A total of 3 flow cells were completed within 1.5 weeks. All 8 trisomy samples and 86 euploid samples were correctly identified (there were 2 false positives). With the increase in sample throughput and associated reduction in cost, these modifications can make the application of next-generation sequencing for chromosomal aneuploidy detection feasible in a routine analytical environment.

Functional Genomic Approaches Unravel Candidate Genes Associated with Mortality of Critical Illness among African Americans. *L. Gao[1], T. Murray[2], N. Rafaels[1], R.A. Mathias[1], J.P. Maloney[3], M. Moss[3], G. Martin[4], C. Shanholtz[5], D.L. Herr[6], J.G. Garcia[7], J. Sevransky[1], P.M. Hassoun[1], T.H. Beaty[2], R. Brower[1].* 1) Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 3) University of Colorado Health Sciences Center, Denver, CO; 4) Emory University School of Medicine, Atlanta, GA; 5) University of Maryland School of Medicine, Baltimore, MD; 6) Washinton Hospital Center, Washington, DC; 7) University of Illinois at Chicago, Chicago, IL.

Rationale: Both acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) are devastating clinical syndromes affecting over 200,000 patients in the United States each year. ALI is a complex pathophysiologic process involving a variety of molecular pathways. Using high-throughput expression profiling, we prioritized a total of 85 candidate genes that showed significant differential expression in mechanical ventilation or LPS-induced ALI models across different species (mouse, canine and human), and subsequently validated these markers in tests of genetic association using patients with severe sepsis and sepsis-associated ALI. Methods: We genotyped a panel of 1536 SNPs using the Illumina GoldenGate platform in a population of 759 African American subjects (195 severe sepsis patients, 158 ALI patients, and 406 controls). Association between outcome of ALI and SNPs were tested with a logistic regression model using PLINK. Pathway analysis was performed using the program Ingenuity Pathways Analysis (Ingenuity Systems: www.analysis.ingenuity.com). Results: Of the candidate genes tested, 11 genes (ABCB1, ADAM28, FGF10, FGFR3, FKBP5, GADD45G, HDAC9, IL8, NFKB1, PIK3CB, TGFBI) were significantly associated with 60-day mortality among African Americans (P = 0.04-0.0003). Variants in the histone deacetylase 9 (HDAC9) gene provided the most compelling evidence (P = 0.016-0.0003). These 11 genes were clustered into a major pathway related to (i) 'cell death'; (ii) 'organismal injury and abnormalities'; (iii) 'cellular growth and proliferation'; and (iv) 'carbohydrate metabolism'. Conclusions: Our findings using functional genomic approaches offer new insights into ALI pathogenesis and could explain to a certain extent the ethnic disparity (i.e., higher morbidity and mortality) noted among African American patients.

1873/T

Sample Quality Control and Troubleshooting for GAIIx Paired-End Sequencing. *B. Craig[1], B. Marosy[1], K. Hetrick[1], D. Mohr[1,2], M. Barnhart[1], S. Griffith[1], J. Goldstein[1], A.F. Scott[1,2], N. Pankratz[3], T. Foroud[3], K.F. Doheny[1].* 1) Center for Inherited Disease Research (CIDR), Johns Hopkins Univ School of Medicine, Baltimore, MD; 2) Genetic Resources Core Facility (GRCF), High Throughput Sequencing Center (HTS), Johns Hopkins Univ School of Medicine, Baltimore, MD; 3) Department of Medical and Molecular Genetics, Indiana University Medical Center, Indianapolis, Indiana, USA.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to common disease. During CIDR's evaluation of the Illumina® GAIIx and Agilent SureSelect™ Target Enrichment systems for a production service, we have developed a workflow to monitor quality control metrics for samples being sequenced following enrichment for regions of interest. These metrics include capture specificity, efficiency of the target capture reaction at 10X coverage, percentage of duplicate reads, percentage of reads mapped to a reference, percentage of variants called in dbSNP129, transition/transversion ratio and concordance of the sequencing data with GWAS SNP genotypes. Following paired-end sequencing, image and base calling analysis are performed using Illumina's real-time analysis software. Base call files for each lane are analyzed via a CIDR developed software package, CIDRSeqSuite. This software converts the base call files to fastq format, aligns the data using BWA, and generates pileup files, variant call files, and reports for these metrics. Using this workflow, we evaluate the metrics to determine sample quality across GAIIx flowcell runs as well as quality across samples within a project. For our initial pilot project, we designed a custom 3.5Mb SureSelect™ bait library and prepared sample libraries to be indexed four per lane. The majority of the results analyzed thus far demonstrate consistent performance. For all pilot samples, the mean percent of duplicated reads is 10%, mean percent of mapped reads using BWA is 98%, mean target capture specificity of 85%, a mean depth of reads captured by the targeted regions of 175X, a mean percent of SNPs in dbSNP129 of 91% and a mean percent of targeted bases captured by 10 or greater reads of 99%. We have used these metrics to determine wet bench processing issues relating to failure of the capture reaction, insufficient yield from the sequencing run, and library complexity issues. When comparing our sequencing SNP calls to GWAS SNP calls, there is a mean concordance rate of 99.7%. A decrease in sequencing SNP call to GWAS call concordance was crucial in identifying a sample that had a low level of contamination from a neighboring sample during library preparation. With this workflow, we can process samples, determine and troubleshoot sample failures and quickly begin reprocessing those samples.

1874/T

Expanding Second-Generation Sequencing Applications Using the Agilent Technologies SureSelectTM Target Enrichment System. *S. Joshi[1], A. Giuffre[1], C. Pabón-Peña[2], B. Novak[2], M. Visitacion[2], B. Buehler[3], J. Ong[1], H. Ravi[1], E. Lin[2], D. Roberts[2], S. Happe[1], E. Leproust[2].* 1) Agilent Technologies, Cedar Creek, TX,78612, USA; 2) Agilent Technologies, Santa Clara, CA, 95051, USA; 3) Agilent Technologies, La Jolla, CA, 92037, USA.

Second-generation DNA sequencing has revolutionized the discovery of rare polymorphisms, structural variants, and novel transcripts. To meet the demand for fast, cost-effective, and accurate genome analysis methods from small scale studies to large sample cohorts, Agilent Technologies has developed the SureSelectTM Target Enrichment System. SureSelect is a highly robust, customizable, and scalable system that focuses analyses on specific genomic loci by hybrid capture of targets of interest. Agilent is continuing to expand its portfolio by increasing the number of applications available to users. We show high performance across Illumina, SOLiD, and 454 platforms, as measured by capture efficiency, uniformity, reproducibility, and SNP detection using DNA derived from cell lines, flash-frozen tumors, or FFPE samples. We highlight the utility of SureSelect across a wide range of target sizes and genome complexity using pre-designed catalog libraries targeting cancer gene sets, sequences encoding the kinome, and both human and mouse All Exon content. We propose a novel approach for variant discovery - using SureSelect catalog designs to uncover candidate variants, followed by the design of smaller focused custom libraries for SNP validation and region profiling. Custom content design is accomplished using the Agilent eArray software with candidate variant coordinates as input. By pooling many samples together per lane or slide, SureSelect kits for Illumina indexing and SOLiD barcoding enables the validation to be performed in large sample cohorts with substantial cost savings. In addition, accurate sample pooling is facilitated by the Agilent Bioanalyzer and QPCR NGS Library Quantification kits to ensure equal representation across samples. Further efficiencies are realized using the Bravo Automated Liquid Handling Platform to meet the need for parallel preparation of multiple indexed libraries. Lastly, we also describe a unique application of SureSelect for depletion of ribosomal RNA from RNA preparations to facilitate transcriptome analyses.

1875/T

SOLiD™ ChIP-seq kit for ChIP and ChIP-Sequencing from low number of cell or tissue samples. *Z. Chen, V. Anest, L. Pickle, K. Clancy, D. Krissinger, N. Mulakken, D. Leon, R. Bennett.* Life Technologies, 5791 Van Allen Way, Carlsbad, CA 92008.

Chromatin Immunoprecipitation (ChIP) assay is the most widely used and powerful method to identify regions of the genome associated with specific proteins. Combined with massively parallel next-generation sequencing technology, ChIP-sequencing provides a high resolution digital solution for genome-wide survey of protein-DNA interactions. We developed a SOLiD™ ChIP-seq kit, which offers an optimized ChIP workflow and an efficient ChIP-seq library construction from relatively low number of cell or tissue samples. ChIP procedure is usually laborious, time consuming, and typically requires large starting cell numbers or large amount of tissue. We use MAGnify™ Chromatin Immunoprecipitation System, which is suitable for fast enrichment of chromatin complexes and DNA recovery, for ChIP workflow in the kit. It is able to use lower starting cell numbers (10,000-300,000 cells) for ChIP thus preserving precious samples such as primary cells, stem cells, biopsies. We also developed a novel sample preparation method for a variety of tissues, such as brain, heart, kidney and liver. This new approach allows faster throughput to investigate different chromatin and transcription time-course events as well as enable antibody screening to determine ChIP compatibility. In addition, we develop a sensitive ChIP-seq library construction procedure which enables users to construct a complex library using as low as 1 ng ChIP DNA. Combining with SOLiD's ultra high sequencing throughput, SOLiD ChIP-seq offers a highly sensitive, hypothesis-neutral approach to accurately characterize protein-DNA interactions at genome-wide scale. Using SOLiD™ ChIP-seq kit, we characterize histone H3 methylation profile in the RSC-1 embryonic stem cells on the SOLiD system. The data demonstrate that SOLiD ChIP-seq kit provides a streamlined, optimized and reproducible assay for the enrichment of chromatin/protein complexes, DNA recovery using magnetic bead capture technology and construction of sequencing library.

1876/T

Single-tube targeted capture of 524 nuclear-encoded mitochondrial genes for DNA sequencing and copy number detection. *P. Shen[1], W. Wang[1,2], S. Krishnakumar[1], C. Palm[1], A. Chi[1], G. Enns[3], R. Davis[1], T. Speed[2], M. Mindrinos[1], C. Scharfe[1].* 1) Genome Technology Ctr, Stanford Univ, Palo Alto, CA; 2) Department of Statistics, University of California, Berkeley, CA; 3) Department of Pediatrics, Stanford University, Stanford, CA.

DNA sequencing costs have decreased rapidly, while applying high quality genome resequencing to many individuals with a suspected mitochondrial disorder has remained impracticable. As an alternative strategy, targeting genomic regions of higher interest, such as nuclear-encoded mitochondrial genes, allows for more cost effective resequencing of a larger number of clinically affected individuals. We developed a robust and reproducible single-tube assay of multiplex amplification of 524 nuclear-encoded mitochondrial genes (5,471 exons) using long capture circularization (LCC) probes. The LCC probes hybridize to sequences flanking a region of interest and capture these sequences of up to 600 bp in length by extension of the probes, followed by ligation to form circular molecules. The captured targets are multiplex-amplified from the common LCC priming sites. We evaluated the sequence capture efficiency through hybridization of a captured PCR sample to custom-designed Affymetrix resequencing arrays, which contain the coding sequences (0.82Mb) of the 524 candidate genes. We reproducible detected 92% of the captured sequences for DNA variant base-calling, while the efficiency increased to 98% for exons with a GC content of 20-65%. In addition, we found that our method preserved the copy number information of the genome in comparative sample analysis. Based on the analysis of array intensity signals, in a child with ornithine transcarbamylase (OTC) deficiency we identified a deletion of 9 out of 10 exons of this gene (the protein product localizes to mitochondria). In summary, the LCC technology uses only a small amount of ~300ng DNA starting material and enables both targeted resequencing and copy number detection in conjunction with array-based data analysis.

Identification and analysis of DNaseI hypersensitive sites using tiling arrays and DNaseI-MLPA. *S.J. White, T. Ohnesorg, S. Eggers, F. Martin, A.H. Sinclair.* Molecular Development, Murdoch Children's Research Institute, Melbourne, Australia.

Open chromatin is a characteristic of genomic loci with regulatory functions, such as promoters, enhancers and silencers. These regions are preferentially digested by DNaseI, and DNaseI hypersensitivity assays are frequently used to identify and analyse regulatory regions. Many currently available methods, however, are either laborious, limited to short stretches of DNA, or require large numbers of cells. We aimed to develop a fast and simple method to overcome these limitations and facilitate the discovery of regulatory regions in the genome. We designed tiling arrays covering ~ 6 Mb of genomic DNA containing genes involved in gonad differentiation and development. DNA obtained from intact nuclei of ~250,000 cultured cells and treated with DNaseI was directly labelled and hybridised to the arrays. Our recently published method of DNaseI-MLPA was used to confirm the identified hypersensitive sites. In a preliminary study using two different testis cell lines (TM3 and TM4), we could identify a number of DNaseI hypersensitive sites, many of which were located close to transcriptional start sites. Interestingly, the few differences in DNaseI hypersensitive sites between the cell lines correlated with variable expression levels of associated genes. We are also using this method to identify and analyse regulatory regions of all members of the SOX gene family in 6 different human cell lines as well as a range of embryonic mouse tissues. We present here a simple and rapid method to identify and analyse DNaseI hypersensitive sites. Using only 250,000 cells we were able to identify many potential regulatory elements in the tested cell lines and tissues. Due to its simplicity, this method should facilitate the discovery and analysis of regulatory regions in the genome.

1878/T

Single Molecule Real-time DNA Sequencing on the Surface of a Quantum-dot Nanocrystal. *J.M. Beechem.* Genetic Systems, Life Technologies, Carlsbad, CA.

A single molecule, long read-length, real-time sequencing-by-synthesis technology has been developed by building a sequencer directly on the surface of a ~ 10 nm quantum-dot nanocrystal. Five-color fluorescence resonance energy-transfer technology (FRET) is utilized for DNA sequence detection, in which signals from the quantum-dot labeled DNA polymerase plus 4 DNA-base-specific acceptor dyes are simultaneously detected. Acting as the FRET donor, the Qdot™-polymerase generates a correlated "photon-dip" for every inserted based (termed the "quantum-correlation-signal"), allowing for more accurate base-calling. Because the sequencer is not physically bound to any solid substrate, it can be exchanged (like a reagent) during mid-sequence runs, effectively replacing damaged non-functioning polymerases mid-reaction. Each exchange cycle lengthens the effective read-length of the sequencer. In this manner, the read-length can be continuously extended without "gaps". Expanding upon this flexibility, after sequencing a particular length of DNA, the newly synthesized strand can be selectively removed. The original genomic DNA strand is then re-primed, Qdot™-polymerase sequencers are rebound, and the identical genomic DNA strand can be sequenced again, greatly increasing the net accuracy and not requiring circularization of genomic templates. In combining these features, the desired accuracy and read-length can be "tuned" by adjusting the number of reagent exchange cycles. Because each sequencing reaction can be completed in minutes, multiple exchange experiments can be performed per sequencing hour. Precisely engineered sequencing-grade Qdot™ nanocrystals are smaller than current commercially available materials (to increase FRET signals), and have an exctinction coefficient ~100X greater than organic-dyes, allowing for very low levels of excitation power to be used while sequencing, yielding an environment more biologically favorable to polymerase activity and template integrity . These Qdot™-polymerase sequencers can also bind to ultra-long DNA segments (>10kb) at multiple positions along the length of the DNA and sequence while moving "horizontally" (parallel to TIRF field), enabling the possibility of "ordered-reads" for long-phased haplotype sequencing. Examples of real-time sequencing of homopolymeric, patterned, and complex templates will be shown.

1879/T

High quality FFPE tumor sample analysis by a simple single-tube exon enrichment technology and high-throughput sequencing. *O. Ericsson[1], H. Johansson[1], M. Isaksson[1], M. Röjmyr[1], F. Roos[1], P. Eriksson[1], J. Stenberg[1], F. Dahl[1], M. Nilsson[2].* 1) Olink Genomics, Uppsala, Sweden; 2) Department of Genetics and Pathology, Uppsala University, Uppsala, Sweden.

We present data describing the application of Selector Technology to successfully enrich and sequence large sets of exons in both fresh frozen and formalin fixed paraffin embedded (FFPE) tumor samples. We also show preliminary data where the Selector Technology has been adapted to incorporate sequencing primers and barcodes during amplification thereby replacing the laborious sequencing sample preparation step with a single PCR. This enables streamlined analysis of large sets of samples. The technology has been scaled to amplify as many as 17,000 specific targets in one single reaction tube. Our data demonstrates an unbiased enrichment of exons for resequencing with more than 95% of reads mapping to amplified regions. Concordance with HapMap genotypes is 99% and the reproducibility (R2) between replicates is 0.98 at the single nucleotide level. High reproducibility provides the possibility to score copy number variations in tumor samples as well as calling copy number neutral loss of heterozygosity. These features are demonstrated using matched tumor-normal breast cancer samples. Conclusively, the Selector Technology is a convenient, high performance exon enrichment technology for analysis of large sets of cancer samples.

1880/T

Development of an automated, high-throughput exome capture and sequencing protocol. *C. Igartua, S.R. Austin, A. Gracien, M. Mynsberge, D.J. Roach, B.W. Paeper, J.D. Smith, E.H. Turner, J. Shendure, M.J. Rieder, D.A. Nickerson.* Department of Genome Sciences, University of Washington, Seattle, WA.

Exome sequencing provides a cost-effective method for the analysis of coding variation across large sample sets. Traditional shotgun library and exome capture methods have several production bottlenecks, reducing scalability and requiring manual sample manipulation. These methods, particularly those relying on a size-selection step, also often result in a low-complexity library that requires additional sequencing to cover the entire target at a depth sufficient for variant calling. We have developed an automated exome capture protocol that generates 96 sequencing libraries per week with no manual sample handling required. 3 ug of input genomic DNA undergoes a quality control test, including a gender check, concentration reading, PCR assay, and genotyping to establish sample quality and identity. Samples are then processed on liquid-handling robots in 96-well plates through shotgun library construction and in-solution exome capture with a custom pool of 2.1M Nimblegen SeqCap probes. No size-selection is required in this process. Throughout the protocol, the bulk of each sample is carried forward to maximize library complexity. Library quality is evaluated after shotgun library construction and after exome capture. With a single lane of Illumina paired-end 76bp sequencing, the 28 Mb exome target is covered >70x, with >90% of the target covered at 8x or greater; at least 80% of the target is covered at >20x. Approximately 15000 SNVs are detected in each sample, with >93% present in dbSNP (build 129); approximately 900 novel SNVs are called. Compared to high density genotyping of the input genomic DNA, the sequencing data shows >99% concordance.

1881/T

Using Lateral Ultrasonic Thrust™ for High-Throughput DNA Fragmentation. *B. Jamieson, K. Dev, V. Vivek, J. Shieh.* Microsonic Systems Inc.

With the continuing advancements in sequencing technologies, next-generation sequencers perform single molecule sequencing in real time and eliminate the need for DNA amplification. This dramatically reduces the sequencing cycle time. This reduction, however, creates a new bottleneck in the sample preparation process prior to sequencing. For either de novo sequencing or re-sequencing, DNA fragmentation is the first step in preparing DNA libraries. Shearing by ultrasonic energy has become a preferred method due to the large dynamic range of the technique, random fragments and the tight distribution of fragment lengths, but the throughput of current ultrasonic shearing methods is limited to one or few samples at a time and can take many hours to shear enough samples to feed next-generation sequencers. To ensure that up-stream DNA fragmentation does not slow down the next-generation sequencing process, Microsonic Systems Inc. is currently investigating the use of its patented Lateral Ultrasonic Thrust (LUT™) technology for rapid and effective DNA shearing. Currently used for compound solubilization, thawing frozen samples, assay mixing and bead and magnetic particle suspension, LUT technology works by using a Micro-Electrical-Mechanical Systems (MEMS) based transducer, which when excited with RF power generates ultrasonic waves. Microsonics has invented new techniques that use ultrasonic waves to enable rapid DNA fragmentation. To evaluate the effectiveness of LUT technology for DNA fragmentation, Lambda phage DNA (48 Kb) was fragmented at different energy settings. These fragmented samples were then analyzed for various lengths using gel electrophoresis. The results showed successful shearing of the whole genome DNA into fragments ranging from 500 bp to 12 Kb in minutes. This finding confirms that our MEMS based LUT technology can be applied to DNA fragmentation, and with its unique parallel sample processing capability, high-throughput DNA fragmentation is now possible at a speed compatible with the speed of next-generation sequencing.

1882/T

Evaluation of Three Targeted Enrichment Techniques on the ABI SOLiD Platform. *S. Linker, T. Guettouche, W.F. Hulme, A. Andersen, A. Diaz, M.A. Pericak-Vance, G. Bademci, J.M. Vance, J.R. Gilbert, D.J. Hedges.* Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL.

Despite the ever-increasing throughput and steadily decreasing cost of next generation sequencing (NGS), whole genome sequencing of humans is still not a viable option for the majority of genetics laboratories. This is particularly true in the case of complex disease studies where large sample sets are often required to achieve adequate statistical power. To fully leverage the potential of NGS technology on large sample sets, several methods have been developed to selectively enrich for regions of interest. Enrichment significantly reduces both monetary and computational costs compared to whole genome sequencing while allowing researchers to take advantage of NGS throughput. Several targeted enrichment approaches are currently available, including molecular inversion probe ligation sequencing (MIPS), oligonucleotide hybridization based approaches, and PCR-based strategies.The majority of data examining the efficiency of these approaches, however, has been obtained from the Illumina GAII NGS platform. To assess how these methods performed when used in conjunction with the ABI SOLID3+, we investigated three enrichment techniques: oligonucleotide hybridization array-based capture, oligonucleotide hybridization solution-based capture, and a multiplexed PCR-based approach. Target regions were selected from exons and Phast-17-way conserved areas throughout the human genome, covering 5 Mb in total. Probe and primer pair design was carried out for all three methods using their respective informatics pipelines. The hybridization approaches were able to target 89-91% of the desired sequence, while the PCR-based strategy achieved 97%. For the capture experiment, hybridization approach A targeted the entire 5Mb and methods B and C (PCR-based) targeted subsets of the 5Mb total. In all, approximately 1.5Mb of target space was identical for all 3 methods. Targeted regions from 16 human individuals were independently enriched with each method and separately sequenced on a single SOLID octet “spot.” The resulting reads were analyzed for several metrics, including consistency of coverage depth, on-target versus off-target efficiency, and genotype concordance with array-based genotyping data. Preliminary results indicate comparable overall peformance from both hybridization-based approaches, with reduced on-target efficiency for the PCR-based method. In contrast, the PCR-based approach could target a significantly larger percentage of desired sequence.

1883/T

Automated Library Construction Using A Digital Microfluidic Device For Next Generation Sequencing Platforms. *N.R. Mushero, M. Weiand, T.K. Sparrow, P.B. Cahill.* Genome Sequencing Platform, Broad Institute, Cambridge, MA.

The emergence of next generation DNA sequencing technologies has shifted most of the manual labor to the sample preparation portion of the process. The potential to run multiple samples together and ability to gain sufficient coverage from minimal sequencing runs has created a potential bottleneck at library construction. In addition to the considerable amount of time and energy needed to process samples, the sample preparation fraction of total sequencing costs becomes larger as sequencing instrument associated costs are reduced. Automating the sample preparation process allows for higher throughput, less sample to sample variation, minimal chance of contamination or sample mix-up, and significant reduction in reagent costs. Here we report on experiments done in collaboration with Advanced Liquid Logic (A.L.L.) using their microfluidic device as an automated method of next generation sequencing library creation. A.L.L.'s technology uses electrowetting to create tiny droplets in a chip, which can be manipulated electronically. The typical droplet size of 300nL allows all library construction reactions to be substantially scaled down, drastically reducing reagent costs. The chip design also makes sample indexing and pooling possible. DNA shearing and fragment size selection take place upstream of this device, but all other library construction steps occur on chip, including PCR and magnetic based reaction cleanup. Recent experiments examine sample input versus yield, bias, and coverage using A.L.L's device in comparison with standard manual library construction.

1884/T

Pair End Sequencing of Human Genomes on the SOLiD™ Platform. *L. Zhang, S. McLaughlin, E. Dimalanta, K. Eusko, D. Dhingra, C. Lee, C. Clouser, J. Spangler, T. Weaver, M. Lyons, H. Peckham, A. Blanchard, K. McKernan.* Life Technologies, Beverly, MA.

The SOLiD DNA sequencing system utilizes stepwise ligation of oligonucleotide probes and enables high fidelity, high throughput sequencing. Previous sequencing protocols for the SOLiD system have only been available in the forward direction (3' to 5'). However, fragment library paired end sequencing (in both forward and reverse directions) is highly desired to maximize sequencing capacity and to meet special research interests such as whole transcriptome and translocation studies. To achieve this using the SOLiD platform, novel ligation chemistries were developed to support 5' to 3' read lengths of up to 35 bases. Utilizing this new chemistry, we sequenced an anonymous Caucasian male to an average depth of coverage of 22.4x (2 SOLiD system sequencing runs) covering 96.55% of the genome. The purpose of any resquencing project is to measure variants against a known reference sequence, so we analyzed this data using our in-house variant detection algorithms to assess data integrity. Approximately 2.97M SNPs were discovered: 1.21M homozygotes (94.4% in dbSNP v129) and 1.76M heterozygotes (73.7% in dbSNP v129). Also detected were 103,027 small indels (73.8% in dbSNP v129). Paired-end sequencing with this novel chemistry presented here is effective at variant-detection in a human genome and these values are similar to variant totals from other large-scale human resequencing.

1885/T

The Association of Biomolecular Resource Facilities (ABRF): Advancing Human Genetics through Research, Communication, and Education. *D. Baldwin[1], T. Hunter[2], M. Detwiler[3], G. Grills[4], K. Sol-Church[5] for the ABRF Research Groups.* 1) Penn Molecular Profiling Facility, Univ. Pennsylvania, Philadelphia, PA; 2) University of Vermont; 3) Roswell Park Cancer Institute; 4) Cornell University; 5) Center for Pediatric Research, NCC-Delaware.

Improvements in cutting edge and emerging technologies, such as the introduction of massively parallel sequencing to biomedical research, have dramatically changed the landscape of genetics and the way genetic research is performed. Today, genetic research is often a collaborative effort that is performed in association with shared resource biotechnology (core) laboratories. These cores represent centers of technological excellence that bridge discovery and translational research by integrating state-of-the-art molecular genetics and proteomics technologies into current research programs. The Association of Biomolecular Resource Facilities (ABRF) is an international society dedicated to advancing biotechnology laboratories through research, communication, and education. ABRF Research Groups conduct multi-institutional studies that focus on comparison and optimization of the state-of-the-arts biotechnologies and methodologies available to biomedical researchers and geneticists. An overview of the aims and results of ABRF Research Group (RG) studies will be presented to illustrate the challenges and opportunities of genetic technologies. For example, the results of an RG gene expression study, based on reverse transcription quantitative real time PCR, underscores the importance of sample quality, optimal priming strategies, qPCR assay location and data troubleshooting. An RG study on microRNA expression highlights the strengths and weaknesses of some of the most popular array platforms and compares data from conventional microarray platforms with Taqman Low Density Arrays (TLDA) and two deep sequencing technologies (Illumina GAII and ABI SOLiD). An RG study on SNP discovery and validation also provides performance comparisons between these two sequencing platforms, and highlights the strengths and weaknesses of these platforms in dealing with allelic discrimination in a diploid organism. This presentation will provide a forum for discussion of cutting edge methodologies and approaches in molecular genetics and will illustrate how they can be used to facilitate human genetics research.

1886/T

Direct determination of molecular haplotypes by chromosome microdissection. *Q. Song[1], L. Ma[1], Y. Xiao[1], H. Huang[2], Q. Wang[1], W. Rao[1], Y. Feng[3], K. Zhang[4].* 1) Cardiovascular Res Inst, Morehouse Sch Med, Atlanta, GA; 2) Clinical Cytogenetics Laboratory, Department of Pathology, Vanderbilt University Medical Center, Nashville, TN; 3) Department of Pharmacology, Emory University School of Medicine, Atlanta, GA; 4) Section on Statistical Genetics, Department of Biostatistics, University of Alabama at Birmingham, Birmingham, AL.

Haplotype refers to a group of alleles inherited on a single chromosome. Haplotype analysis plays an important role for mapping disease genes, elucidating the population histories, studying the evolutionary genetics, and exploring the cis-interactions in the gene expression regulation. Direct observation of haplotypes is technical challenging. Here we report a method for determination of haplotypes through chromosome microdissection. We demonstrate this technology by accurately (> 98.85%) observing human haplotypes with 24,245 heterozygous single-nucleotide polymorphism (SNP) loci in genome-wide chromosome-range phasing distance. Chromosomal haplotypes will be important for functional interpretations of SNPs in cis-interactions and the integration of genetic and epigenetic datasets along the chromosomes.

1887/T

SyTE, a novel bioinformatics tool for efficient discovery of lens disease genes: Application in identification of a new cataract gene *TDRD7*. *S. Lachke[1], F. Alkuraya[2], G. Kryukov[1], S. Choe[1], A. Tsai[3], S. Al-Fadhli[4], A. AL-Hajeri[4], H. Shamseldin[2], S. Sunyaev[1], A. Drack[5], R. Maas[1].* 1) Division of Genetics, Brigham & Women's Hospital and Harvard Medical School, Boston, MA, USA; 2) Department of Genetics, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia; 3) Department of Pediatrics, University of Colorado-Denver, Aurora, CO, USA; 4) Department of Molecular Biology, Kuwait University, Kuwait City, Kuwait; 5) Department of Ophthalmology and Visual Sciences, The University of Iowa, Iowa City, IA, USA.

Identification of candidate mutant genes within a mapped interval in patients with developmental disorders remains a challenge. We aimed to devise a novel strategy that allows prioritization of candidate genes within a mapped interval. As a proof of principle, to efficiently identify lens cataract genes, we developed Systems Tool for Eye gene discovery (SyTE) that uses a developmental profile of the mouse lens transcriptome generated by microarray analysis of the lens as it transitions from the stage of placode invagination to that of vesicle formation. Using a novel *in silico* subtraction protocol with a developmentally matched microarray dataset representing whole embryo minus ocular tissue, we assigned lens enrichment *p*-values to individual probes, thus identifying candidate lens cataract genes. When SyTE was tested on mapped intervals of 23 previously identified non-syndromic cataract genes, it identified the correct cataract gene in >90% cases by ranking it within the top 5 candidates from around 50 or more genes in each locus. To test its ability to detect novel cataract genes, we studied a juvenile cataract patient who carries the balanced paracentric inversion 46,XY,inv(9)(q22.33q34.11). SyTE predicted *TDRD7* as the most probable candidate among 50 genes within a 5 Mb interval around the q22.33 breakpoint. *TDRD7* disruption and haploinsufficiency in the patient was confirmed by FISH and Western blot analysis. We then recruited a consanguineous family with recessive congenital cataract in which the causative mutation also mapped to 9q22.33. Upon sequencing *TDRD7*, we found a novel three base pair deletion mutation that results in deletion of Valine 618, which is conserved from fish to humans. Furthermore, in chick, *TDRD7* knockdown results in cataract formation, corroborating the assignment of *TDRD7* as the gene responsible for the cataract phenotype in human. Finally, section *in situ* analyses show high lens expression of eight candidate cataract genes, further establishing the validity of SyTE, and human orthologs of two of these (*SlPA1l3* and *PTPRU*) fall within mapped human cataract loci. In conclusion, we report a novel systems tool SyTE, which serves to prioritize candidate genes in mapped intervals and demonstrate its use in the identification of a novel cataract gene *TDRD7*. We anticipate that modified versions of SyTE can be used to efficiently identify causative genes in developmental disorders affecting other organs.

1888/T

Comparison and application of whole exome and genome sequencing on an individual with high risk for atherosclerosis. *J.K. Teer, N.F. Hansen, P.F. Cherukuri, L.L. Bonnycastle, P. Cruz, P.S. Chines, H. Ozel Abaan, E.H. Margulies, E.D. Green, J.C. Mullikin, L.G. Biesecker.* NHGRI, NIH, Bethesda, MD.

Massively parallel sequencing has allowed broader interrogation of genomes for variants that cause disease. Continuing improvements now allow whole human genome sequencing in a relatively short period of time. However, targeted sequencing requires fewer bases than a whole genome, and therefore allows more targeted samples than whole genome samples. We have compared coverage of the CCDS exome in NA18507 (HapMap Yoruba) using three different exome capture kits. We find that genotype sensitivity (% of the CCDS regions covered with high-quality genotype calls) is similar between all methods: 86%-88%. In comparison, previously reported 30x whole genome coverage of the CCDS regions in NA18507 was ~73%. We have also compared a more recent 60x whole genome sequence of a ClinSeq™ individual with exome capture. 60x whole genome sequence covered 86% of the CCDS using 192Gb total sequence, whereas exome capture covered 89% with 6.7Gb total. Both methods showed >99.9% overall concordance with genotype chip calls.

We have implemented a secondary analysis pipeline to realign reads using a gapped aligner, cross_match, and to call genotypes using a Bayesian based program, Most Probable Genotype (MPG). Genotypes are then annotated for coding status and potential detriment using CD_Pred. We have also developed a graphical java tool, VarSifter, to view, sort, and filter the resulting data, allowing investigators to focus on interesting variants. Using these tools we have sequenced and analyzed more than 70 exomes as part of the ClinSeq™ program.

We have performed both whole genome shotgun and exome sequencing on a ClinSeq™ individual at high risk for atherosclerosis. To get the highest coverage, we have merged the two data sets, resulting in 94.9% genotype coverage of the CCDS. Using our analysis tools, we identified 3,719,419 total variants, 22,264 of which were coding. We have examined the variants, and have limited the list by removing variants previously observed in 8 HapMap samples, by including non-synonymous single-nucleotide variants and frame-shifting deletion/insertion variants, and by examining variants within a linkage region. Many variants fit these criteria, and we are currently evaluating which are most likely to be causative.

1889/T

DNA microarray intensity prediction. *Y.A. Jakubek, D.J. Cutler.* Human Genetics, Emory University, Atlanta, GA.

There are several types of DNA microarrays including SNP, re-sequencing, CNV, and expression-profiling arrays. The principle behind these arrays is to hybridize labeled target DNA to probes that are attached to a solid surface. The intensity readings form the probe-target duplexes are used to infer genotype and/or copy number for the target DNA. However, often intensity data from certain probes and from entire chips is difficult to interpret, decreasing the information yield for the experiment. Known problems with microarrays include batch effects, high intensity variance between probes, high background intensity variance between chips, and cross-hybridization. In order to minimize the amount of data discarded and to increase the data quality, we created a detailed model of the probe-target DNA hybridization experiment that includes probe specific and experiment specific parameters. We first estimate expected hybridization kinetic values (Kd's) for all possible probe-target DNA duplexes that can form on the array. Then for each chip we estimate: probe nucleotide incorporation rates, mean fragmentation size, intensity detection curve shape, wash stringency, and target DNA concentrations. We use this information to estimate probe intensity in a model that incorporates cross-hybridization, chip-specific parameters, and probe-target DNA thermodynamics. The algorithm can be used to calculate probe intensity data for any type of DNA microarray experiment. Data from a re-sequencing array experiment consisting of 62 chips was analyzed using this approach. The mean correlation between expected and observed probe intensities for the chips (80,408 probes/chip) ranges from 0.59 to 0.85, with a mean correlation of 0.74 across all the chips. The mean of the estimated incorporation rates for A, C, G, and T nucleotides for the chips are 0.97, 0.92, 0.89, and 0.96 respectively. This intensity prediction model allows for discrimination between the effects of probe sequence, experimental conditions, and genotype on probe intensity.

1890/T

Detecting Mutant Allele Fractions as low as 0.01% by combining Digital PCR, LunaProbes™ and Mutant Allele Amplification Bias (MAAB) Methods. *M.D. Poulson, J.T. McKinney.* Idaho Technology, Inc., Salt Lake City, UT.

Detection of low level mutations has driven development of several intriguing methods. We have combined aspects of three prior techniques: digital PCR, LunaProbes, and Mutant Allele Amplification Bias (MAAB). Digital PCR (dPCR, Vogelstein and Kinzler, 1999) requires many replicates of a sample using template diluted to 1 copy/reaction. A variation on the original dPCR technique was developed for Hi-Res Melting (HRM) using template dilutions of 5 copies/reaction (McKinney, 2007). This dictates the mutant allele, if present, will comprise at least 20% of alleles in a reaction and enable detection of heteroduplexes. Sensitivity of dPCR is 2% or less, depending on number of replicates assayed. LunaProbes enable genotyping by using an unlabeled oligonucleotide in the PCR reaction (Zhou, 2005). Sensitivity has been established at approximately 5% for LunaProbes (Wall, 2007). MAAB utilizes the stability of the LunaProbe to preferentially amplify the mutant allele. MAAB has demonstrated sensitivity of <1% (McKinney, 2009). We hypothesized these methods could be integrated with additive benefits. A SNP in the PAH gene was targeted with a standard LunaProbe assay. Samples homozygous for both alleles were identified, standardized for concentration, and mixed to generate serial dilutions of the mutant allele down to 0.01%. Template dilutions (5 to 100 copies) were made, and 96 replicates of each were run on mutant allele dilutions of 1%, 0.1%, and 0.01% using dPCR, MAAB, and dPCR + MAAB (dMAAB) protocols. Results were analyzed to determine optimal PCR protocols, template dilutions, and replicates/dilution required to achieve the greatest sensitivity. A template dilution of 5 copies was optimal for the dPCR assay. For the MAAB protocol, 100 copies/replicate was optimal. All mutant allele dilutions were successfully detected using the dPCR and dMAAB protocols. The MAAB protocol used 3000 copies/replicate and detected the 1% and 0.1% dilutions. Fewer replicates were required to detect the 1% dilution relative to the 0.1% and 0.01% dilutions. The ability to detect low levels of mutant DNA has multiple applications. Some of these include drug resistant pathogens, fetal DNA, low level somatic mutations, and detection of residual disease from peripheral blood post-therapy. Combining previous methods and adding the use of a LunaProbe increases sensitivity 10-100 fold and allows mutant allele confirmation via specific probe melting profiles.

1891/T

Next Generation Multiplexed Small RNA Sequencing Reveals Differential miroRNA Expression Patterns. *M. Toloue.* Bioo Scientific, Austin, TX.

The demand for preparative steps that deliver fast and unbiased small nucleic acid sequence for investigation cannot be overemphasized. Current isolation, fragmentation, ligation and purification methods lead to bias, require significant preparatory time and are highly inefficient. To circumvent these obstacles we have developed several strategies that not only eliminate small RNA circularization and linker dimers, but allow for cross genome analysis using multiplexed barcodes, improving next gen. sequencing and experimental design. We simultaneously examined microRNA (miRNA) expression from 10 organ tissues by multiplexing the sequencing of these samples on a single flow cell lane. This experiment normally requires ten flow cell lanes. Multiplexed samples were tested for sequence bias and compared to individually prepared samples. The results not only identified the highest expressed miRNAs per sample but also demonstrated that within one sample preparation there was a strong expression correlation, however between different tissues, expression levels of miRNA significantly varied. For the first time, miRNA expression levels of normal versus diseased tissue can be studied in a single sequencing reaction lane. This indexing procedure reduces the number of lanes required for a multiplex experiment, eliminates sequence bias associated with ligation and allows drug and time course studies to be performed using an Illumina sequencing platform. It has become obvious that the use of the same preparatory methods to identify and quantify rare transcripts and perform large scale comparative evolutionary studies is not ideal and that there are clear advantages for particular applications over others. Our recent efforts directed towards the development of new template preparations illustrate this.

1892/T

Genotyping SNPs for Native American Y haplogroup assignment. *A.E. Justice[1,3], N.F. Baldi[1,3], C. Phillips-Krawczak[2,3], J. Gerst[4,5], P. Williams[5], M.H. Crawford[1,3].* 1) Anthropology, University of Kansas, Lawrence, KS; 2) Genetics, University of Kansas, Lawrence, KS; 3) Lab of Biological Anthropology, University of Kansas, Lawrence, KS; 4) Medical Center, University of Kansas, Kansas City, KS; 5) Evogen, Inc., Kansas City, MO.

Efficient single nucleotide polymorphism (SNP) genotyping methods are becoming increasingly common in anthropological genetics for haplogroup assignment and identification of ancestry specific markers. SNPs offer a statistical advantage over STRs, are appropriate for typing Native American populations when performed in a hierarchical fashion, and are more cost effective. As such, there is a need for affordable, efficient and reliable techniques for SNP analysis that are appropriate for both high throughput and smaller laboratories to increase consistency and comparability of data. One such method is developed here using a new probe technology, Hybeacons® (Evogen, Inc.), which addresses these goals. The technique involves a single primer pair to amplify the region of interest, normal PCR reagents, and Hybeacons® in a single PCR reaction. HyBeacons® are high definition fluorescently labeled PCR probes with two flourophores. When a probe binds with the target DNA sequence, the level of fluorescence from the probe intensifies, and is measured through melt curve analysis. The difference among melt curves allows the researcher to differentiate among the wild type and the polymorphic SNPs. Hybeacons® are appropriate for high-throughput laboratories as automated genotyping requires only one reaction per SNP. This new method was authenticated using four common Y chromosome SNPs used for haplogroup assignment (Q-M242, Q-M3, R-M269, Q-P36) in Native American populations from the Caribbean, Guatemala, Nicaragua, and Peru. The results were consistent with those from an independent sequencing of a subset of samples from each population. The Hybeacons® have the potential to be a robust typing tool for both high throughput and smaller labs with a wide range of applications in anthropological and population genetics.

1893/F

LRP4 is associated with fracture and bone phenotypes and interacts with other genes in the Wnt- and BMP signaling pathways. *J. Kumar[1], M. Swanberg[1], F. McGuigan[1], M. Callreus[1], P. Gerdhem[2], K. Åkesson[1].* 1) Clinical and Molecular Osteoporosis Research Unit, Department of Clinical Sciences, Lund University, and the Department of Orthopedics, Malmö University Hospital, Malmö, Sweden; 2) Department of Orthopedics, Karolinska University Hospital, Department of Clinical Science, Intervention and Technology, Karolinska Institute, Stockholm, Sweden.

Osteoporosis is a complex disorder leading changes in the micro-architecture of bone and on increased risk of fracture. It is common in postmenopausal women with an estimated 40 percent of women sustaining at least one osteoporotic fracture during their lifetime. Members of the low-density lipoprotein receptor-related protein (LRP) gene family regulate bone development and physiology through the Wnt signaling pathway. The LRP4 gene has been shown to be important in osteoporotic phenotypes through candidate gene and genome wide association studies. Cross-talk between Wnt and BMP signaling pathways is also known to play a role in the regulation of bone. In the current study, we have analyzed the association of three single nucleotide polymorphisms (SNPs) from the LRP4 gene for their association with bone mineral density (BMD), fracture and other bone related phenotypes. Additionally, we have analyzed interactions of LRP4 with three other genes (LRP5, G protein-coupled receptor 177 (GPR177) and Bone Morphogenetic Protein 2 (BMP2)). LRP5 and GPR177 can modify Wnt signaling while BMP2 is part of the BMP signaling pathway. Analyses were performed in two cohorts of Swedish women differing in age: OPRA (1002 elderly women all aged 75 years) and PEAK-25 (1005 young women all aged 25 years) to determine if age influences the possible associations and interactions of these genes. SNPs from the LRP4 gene were found to be significantly associated with increased BMD (p=0.05), decreased bone loss (p=0.02), improved bone quality (p=0.02) and geometry (p=0.007) along with decreased incidence of fractures (p=0.001) in the elderly women. LRP4 polymorphisms were also found to be significantly associated with increased BMD in young women (p=0.007). Significant gene-gene interactions were observed for LRP4 with the GPR177, BMP2 and LRP5 genes. LRP4-GPR177 and LRP4-BMP2 was associated with BMD and bone loss (p=0.05 to <0.001), while LRP4-LRP5 and LRP4-BMP2 were associated with bone quality in the elderly women (p=0.05-0.02). In the young women, interactions for BMD were observed for LRP4-BMP2 (p=0.03-0.004). In conclusion, SNPs from LRP4 gene showed significant association with several bone phenotypes and fracture in elderly women. Additionally, interactions between genes from the Wnt and BMP signaling pathways contribute to the modulation of bone phenotypes contributing to fracture risk, the clinical endpoint of osteoporosis.

1894/F

Identification of novel mutations in the U87 glioblastoma cell-line by examining exomic multi-nucleotide polymorphisms. *J. Rosenfeld[1,2,4], A. Malhotra[1,2,3], T. Lencz[1,2,3].* 1) Zucker Hillside Hospital, Glen Oaks, NY; 2) The Feinstein Institute for Medical Research, North Shore - Long Island Jewish Health System; 3) Dept. of Psychiatry and Behavioral Sciences, Albert Einstein College of Medicine; 4) American Museum of Natural History, New York, NY.

Genomic sequence comparisons between individuals are usually restricted to the analysis of single nucleotide polymorphisms (SNPs). While the interrogation and analysis of SNPs is efficient, they are not the only form of divergence between genomes. We expand the scope of polymorphism detection by investigating the occurrence of double nucleotide polymorphisms (DNPs) and triple nucleotide polymorphisms (TNPs), in which consecutive nucleotides are altered compared to the reference sequence. These mutations are missed by traditional re-sequencing analysis, since the underlying reads would be rejected for having too many mismatches compared to the reference genome. Before looking at the U87 exome, we first analyzed two complete human genomes and exomes to identify DNPs and TNPs. We observed that, although the overall abundance of DNPs and TNPs in exomes is much less than SNPs, these mutations are more likely to affect two amino acids and could contribute to disease risk. In U87 exome, we identified 53 DNPs and 8 TNPs within the coding regions. The most potentially pathogenic mutations that we identified were a TNP causing a single amino acid change in the LAMC2 oncogene and a TNP causing a nonsense mutation in the HUWE1 gene. The mutation in the LAMC2 gene, L952D was predicted by to be damaging by computational analysis. The HUWE1 nonsense mutation causes the protein to be mRNA to be truncated from 4,374 residues to 1,668 residues in length. Neither of these mutations were identified by the conventional SNP-based exome analysis.

1895/F

Convergence of *CXCL12* and *PHACTR1*: Novel Genome Wide Signals for Myocardial Infarction Regulate Plasma CXCL12 Levels. *NN. Mehta[1,2], D. William[1], M. Li[2], A. Khera[1], L. Qu[2], S. DerOhannessian[1], L. Pruscino[1], L. Shaikh[1], C. Hinkle[1], J. He[2], I. Stylianou[1], H. Hakonarson[3,4], DJ. Rader[1], MP. Reilly[1,2].* 1) Dept Cardiology, Univ Pennsylvania, Philadelphia, PA; 2) Center for Clinical Biostatistics and Epidemiology, Univ Pennsylvania, Philadelphia, PA; 3) Center for Applied Genomics, Univ Pennsylvania, Philadelphia, PA; 4) Children's Hospital of Philadelphia, Philadelphia, PA.

Recent genome wide association studies have shown association between coronary artery disease (CAD) / myocardial infarction (MI) and common variation at locus 10q11 ($8.1x10^{-9}$) downstream from *CXCL12*, an inflammatory cytokine; and at locus 6p24 ($3.1x10^{-8}$) near gene *PHACTR1*, a phosphatase-related enzyme. Genetic variation at 10q11 also relates to plasma levels of CXCL12. However, other factors involved in regulation of CXCL12 are poorly understood. Therefore, we performed a genome-wide association study of plasma CXCL12 levels to better understand the biology and relationship to MI. **Methods and Findings:** We measured plasma CXCL12 levels (ELISA, R&D) in a subset of the angiographic study, PennCath (n=1182, 406 with acute MI, 386 with chronic CAD, 390 angiographically normal controls). Genotyping was performed using the Affymetrix 6.0 chip. All samples & SNPs passed stringent QC; there was no significant population stratification (lambda=1.00085). There were multiple SNPs strongly associated (p value $<10^{-5}$) with plasma CXCL12. These SNPs mapped to chromosome (chr) 6p24.1 (*PHACTR1*, top SNP rs202071, $p=5.14x10^{-7}$, beta-coefficient -0.145), chr 6p21.3 (*HIST1H2BC*, rs13206443, $2.19x10^{-7}$, 0.322), chr 5q11.2 (*ITGA1*, rs10044180, $p=2.29x10^{-6}$,-0.123), and 11q23.2 at (*ZW10*, rs2279996, $p=3.42x10^{-6}$, 0.169). These associations remained robust after adjustment for age, gender, CAD, DM, and HTN. **Conclusions:** We show a number of independent genetic associations with CXCL12 plasma levels, and reveal *PHACTR1* in potential trans-regulation of CXCL12 as well as CAD/MI. Ongoing studies for replicating these associations and to examine how these novel loci relate to CAD/MI and each other may reveal novel regulatory pathways in CAD and MI.

1896/F

dbRIP, a database of retrotransposon insertion polymorphism in humans --- a report of major updates. *P. Liang[1], W. Tang[1], B. Abraham[2].* 1) Department of Biological Sciences, Brock University, St. Catharines, Ontario, Canada L2S 3A1; 2) NIH Graduate Partnerships Program with Boston University, Boston University, Boston, MA, USA 02215; National Heart, Lung and Blood Institute, NIH, Bethesda, MD, USA 20892.

Retrotranspons contribute to almost 50% of the human genome, and they play important roles in shaping the evolution of the genomes. Since members of many retrotranspons families are still active, they have generated genome diversity and continue to do so by transposition-mediated insertions, and such Retrotransposon Insertion Polymorphisms (RIPs) can impose a variety of impacts on gene function. The database, dbRIP, was developed in 2006 as the first database dedicated to the documentation of such types of genetic polymorphism in humans. Since then dbRIP has been recognized as a valuable resource in the retrotransposon community because of its easy-to-use interface, which integrates with the UCSC Genome Browser, and high quality of detailed and manually curated data, and easy access to the full dataset. We have recently performed major updates to dbRIP, which include the addition of substantial new RIP data sets and coverage for HERV polymorphism data, migration to the hg18 and hg19 UCSC genome versions, implementing a stable database identification schema, and addition of a position mapping utility. As of writing, dbRIP contains a total of more than 2,600 cases of manually curated retrotransposon insertion polymorphisms, covering Alus, L1s, SVAs, and HERVs. Future maintenance of dbRIP will be focused on timely updating of newly available RIP data, a lot of which will likely come from analysis of personal genomes. The database is freely accessible at **http://dbRIP.brocku.ca**. (This work is in part supported by grants from the Canada Research Chair program, CFI, OMRI, NSERC and Brock University to PL.).

ALFRED: rapidly growing resource for research and teaching. *H. Rajeevan[1,2], U. Soundararajan[1], A.J. Pakstis[1], J.R. Kidd[1], K.K. Kidd[1].* 1) Dept Genetics,School of Medicine, Yale Univ, New Haven, CT; 2) Center for Medical Informatics, School of Medicine, Yale University School of Medicine, New Haven, CT.

ALFRED (http://alfred.med.yale.edu) is a free, web-accessible and actively curated compilation of gene frequency data for molecularly defined polymorphisms on anthropologically defined population samples with active links to ethnographic and molecular databases, and to the relevant literature. Data sources include published literature, collaborators, high throughput data sources and the host laboratory. In the past year the number of allele frequency tables has increased from 500,000 to 1,452,000, largely through the addition of large datasets. Two such additions are: Illumina 370CNV chip data typed on an Estonian population sample (PMID: 19424496, data contributed by Andres Metspalu) and Illumina HumanHap650Y Beadchip data typed on a Korean population sample. Data currently in curation (650K data on HGDP and Kidd Lab populations) will bring the total number of populations to 77 for this panel of 650,000 markers. ALFRED now contains data on several defined SNP panels (e.g PMID: 16586411, PMID: 19083773) that are searchable through a recently added search function "SNP sets" available from ALFRED's homepage. The markers in each of these SNP sets are annotated with relevant information including the locus name, rs#, fst, average heterozygosity and the number of populations for which there are data available in ALFRED. The SNP sets can be sorted by all these functions as well. Another new feature is the ability to restrict the Fst search by "minimum number of populations" option in addition to the already available options. A new addition to the tabular summaries is the "Populations List" displaying the list of all populations in ALFRED with the geographic region and the number of samples for that population. This table can be sorted by Geographic region/Population/# samples option. Among multiple graphical display modes for allele frequencies for a polymorphism, pie-charts can be viewed on Google Map and Google Earth. These display modes allow users to utilize all the functions available from the Google Map, Google Earth applications. ALFRED is supported by US NSF BCS0840570.

1898/F

Confirmation of Genetic Associations from a Genome-wide Association Scan of the GoKinD Collection Identifies Common Type 1 and Type 2 Diabetic Nephropathy Loci on Chromosomes 11p and 13q. *M.G. Pezzolesi[1,2], G.D. Poznik[1], J. Skupien[1,2], A. Smiles[1], J.C. Mychaleckyj[3], S.S. Rich[3], J.H. Warram[1,2], A.S. Krolewski[1,2].* 1) Section on Genetics and Epidemiology, Joslin Diabetes Center, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA; 3) Center for Public Health Genomics, University of Virginia School of Medicine, Charlottesville, VA.

Objective: Diabetic nephropathy (DN) is a complication that affects 30% to 40% of all patients with either type 1 (T1D) or type 2 diabetes (T2D). In a genome-wide association (GWA) scan of the Genetics of Kidneys in Diabetes (GoKinD) collection, we identified four novel susceptibility loci on chromosomes 7p, 9q, 11p, and 13q that were significantly associated with DN in T1D. To follow-up on our initial findings, we examined whether the leading single nucleotide polymorphisms (SNPs) from each of these loci were associated with the risk of DN in patients from the Joslin T2D DN collection. Research Design and Methods: Six SNPs (rs39075 on chromosome 7p, rs1888747 and rs10868025 on chromosome 9q, rs451041 on chromosome 11p, and rs1411766 and rs9521445 on chromosome 13q) across four distinct susceptibility loci were genotyped in 692 normoalbuminuric (control) and 751 proteinuric or end-stage renal disease (case) subjects of European ancestry from the Joslin T2D DN collection. Results: Significant associations were identified at both the 11p (rs451041: OR=1.21, $P=7.5x10^{-3}$) and 13q loci (rs9521445: OR=1.24, $P=2.5x10^{-3}$) in the Joslin T2D collection. A meta-analysis combining these data with that from GoKinD supported these results (rs451041: OR=1.30, $P=3.3x10^{-7}$ and rs9521445: OR=1.31, $P=9.7x10^{-8}$). SNPs on chromosomes 7p and 9q were not associated with DN in the Joslin T2D DN collection. Conclusions: Our analysis of SNPs identified in a GWA scan of the GoKinD collection confirmed associations at two loci; one on chromosome 11p (near the *CARS* gene) and one on chromosome 13q (in an intergenic region between *MYO16* and *IRS2*). These findings implicate the 11p and 13q regions as common diabetic nephropathy loci in both type 1 and type 2 diabetes.

1899/F

Decoding the Information Content of SNP Haploblocks Associated with Innate Immunity in African Americans. *T.E. Mason[1], L. Ricks-Santi[1,2], P. Kurian[3], W. Hercules[3], J. Lindesay[3], G.M. Dunston[1,3,4].* 1) National Human Genome Center, Howard University, Washington, DC; 2) Howard University Cancer Center, Washington, DC; 3) Department of Physics, Howard University, Washington, DC; 4) Department of Microbiology, Howard University, Washington, DC.

Background: Decoding the functional significance of natural variation in the human genome is at the forefront of translational genomic research. Various studies have shown an association between single nucleotide polymorphisms (SNPs) and common disease which lead to the "common- variant-common-disease" hypothesis. We hypothesize that information encoded in the structure of common variants, such as SNP haploblocks, can elucidate molecular pathways and cellular mechanisms involved in the regulation of host adaptation to the environment. Specifically that the regulation of candidate genes underlying innate immunity are essential to the host's adaptation to pathogens in the microbial environment. We utilized the normalized information content (NIC), a derived metric which is based on SNP haploblock structure for interrogating the biology of candidate genes in the immune response. Methods: SNP haploblocks were constructed (Haploview v. 4.2) for the human Major Histocompatibility Complex (MHC) in the African American population from HapMap Phase III data. NIC scores were derived for these haploblocks and analyzed for functional significance of common variants in the MHC, the master regulatory region of the host immune system. Initial attention was given to an assessment of NIC scores relative to potential regulatory elements using ConSite and miRBase. Results: We found that all 10 of the SNP haploblocks with NIC scores in the lower bound (<0.40 on a scale of 0 to 1; $p<0.05$) contained putative transcription factor binding sites (TFBS) and microRNA (miRNA) motifs, thus leading to the identification of common variants involved in the regulation of candidate gene pathways underlying host adaptive mechanisms, such as the immune response. Conclusion: Using the NIC scores, we were able to translate a biophysical mathematical measure of common variants into a deeper understanding of biochemical patterns in SNP haploblocks. We submit that this new metric, the NIC score, may be useful in decoding the functional significance of natural variation and analyzing the regulation of genes involved in host adaptation to environmental pathogens and positive selection.

Variation in Transcription Factor Binding Among Humans. *M. Kasowski[1], F. Grubert[2], C. Heffelfinger[1], M. Hariharan[2], A. Asabere[1], S. Waszak[3], L. Habegger[1], J. Rozowsky[1], M. Shi[2], A. Urban[2], M. Hong[1], K. Karczewski[2], W. Huber[3], S. Weissman[1], M. Gerstein[1], J. Korbel[3], M. Snyder[1,2].* 1) Yale Univeristy, New Haven, CT; 2) Stanford University School of Medicine, Stanford, CA; 3) European Molecular Biology Laboratory, Heidelberg, Germany.

Differences in gene expression may play a major role in speciation and phenotypic diversity. Although variations in gene expression among individuals have been documented, the origins of these differences are not clear, and studies that directly measure differences in transcription factor binding sites among humans have not been performed. We have examined genome-wide variation in transcription factor binding in different individuals and a chimpanzee using chromatin immunoprecipitation followed by massively-parallel sequencing (ChIP-Seq). The binding sites of RNA Polymerase II (Pol II) as well as a key regulator of immune responses, NFκB, have been mapped in ten lymphoblastoid cell lines derived from individuals of African, European, and Asian ancestry, including a parent-offspring trio. Using a stringent threshold, approximately 7.5% and 25% of the respective NFκB and Pol II binding regions exhibit differences between any two individuals. To understand the underlying basis of the variations, we examined the effect of SNPs and genomic structural variations (SVs) on binding differences among individuals. We find that many binding differences are associated with SNPs and SVs. Comparison of the binding data with gene expression data generated by RNA-Seq revealed that differences in binding often correlate with gene expression differences. Furthermore, comparison of the Pol II human sites with binding sites identified in the chimpanzee suggests a high level of divergence in binding relative to our closest evolutionary neighbor. Our results indicate that many differences in individuals occur at the level of TF binding and provide insight into the genetic events responsible for these differences.

Developing Ethnic-Based Reference Sequences: *CFTR* as a Model. *P.G. Ridge Jr[1], E. Lyon[1,2], K.V. Voelkerding[1,2].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT.

Background: Publically available human genome reference sequences may not be representative of multiple ethnic groups. This creates interpretive challenges in diagnostic resequencing studies as many ethnic specific variations are likely missing or not identified as to ethnicity from current reference sequences. Using the *CFTR* gene as a model, the goal of the current study is to develop an expanded *CFTR* reference sequence that incorporates ethnic specific variant information.

Methods: The database for the current study is comprised of approximately 1,000 *CFTR* full gene Sanger sequences from patients referred for clinical testing for suspicion of cystic fibrosis. Sequencing trace files were sorted by self-reported ethnic background (African-American, Ashkenazi Jewish, Caucasian, Hispanic, Middle-Eastern, Other, and Mixed ethnicity). Traces were aligned and variants called according to *CFTR* transcript (NM_ 000492.3) using the CLC Genomics Workbench. Using custom built Java programs we determined which variants were present in dbSNP and/or the Cystic Fibrosis Mutation Database (CFMD).

Results: In a first subset analysis, we have examined 82, 15, and 15 individuals each for Caucasians, African-Americans, and Hispanics, respectively. In this subset, 569 unique variations were identified; 412 in Caucasians, 127 in African-Americans, and 45 in Hispanics. Between 57.8% and 96.6% of these variants were ethnic specific. In Caucasians and African Americans, respectively, 10.1% and 12.7% of variants were present in at least one of the databases (dbSNP and CFMD). No Hispanic-specific variants were found in either database. In total there were 16 missense variants identified, 14 of which were ethnic specific. Only two variants of these 14 ethnic specific variants were found in CFMD (none in dbSNP), both of which were Caucasian specific. Additionally, 2 nonsense mutations were identified.

Conclusions: In 112 patient samples analyzed to date, multiple unique, ethnic specific variants in the *CFTR* gene were identified. A majority of the identified variants were not present in publically available databases. A complete analysis of the 1,000 patient sample set is ongoing in which identification of additional unique variants is expected. From this, an expanded, ethnic specific *CFTR* database will be developed.

1902/F

Flip-flop associations at common SNPs in HIV-1 controllers of European and African ancestry are due to differing LD patterns with protective class I HLA alleles. *P.J. McLaren[1,2], X. Jia[1,2], S. Ripke[2,3], A.L. Price[4], S. Pollack[4], F. Pereyra[1,5], N. Gupta[2], D.W. Haas[6], B.D. Walker[5], P.I.W. de Bakker[1,2], Intl HIV Controllers Study.* 1) Brigham and Women's Hospital, Boston, MA; 2) Broad Institute of MIT and Harvard, Boston, MA; 3) Massachusetts General Hospital, Boston, MA; 4) Harvard School of Public Health, Boston, MA; 5) The Ragon Institute of MGH, MIT and Harvard, Boston, MA; 6) Vanderbilt University School of Medicine, Nashville, TN.

Purpose: Localization of causal variants can be confounded by apparent heterogeneity in SNP associations in different populations. Understanding the nature of so-called "flip-flop" associations (with effects in opposite directions) should help pinpoint causal variants. Methods: We genotyped a cohort of 857 HIV-1 controllers defined as maintaining viral load <2,000 per mL for at least 1 year, and 2,088 progressors, with median viral load >50,000 per mL, from two ethnic groups (European ancestry and African American). Using data from HapMap and the Type 1 Diabetes Genetics Consortium, we imputed 1.4 million SNPs and classical HLA alleles. For both ethnic groups, we tested SNPs and HLA alleles for association by logistic regression correcting for population structure, and performed meta-analysis. In the combined sample, we also performed an association test (2-df chi-squared) that allows for different odds ratios for African vs. European local ancestry as estimated by HAPMIX. Results: We observed >300 SNPs in the European ancestry sample and >30 SNPs in African Americans with genome-wide significance (p<5E-8), all located in the MHC region. Meta-analysis across the two samples demonstrates substantial effect heterogeneity for a range of SNPs that reached genome-wide significance in either sample. The most extreme example was for SNP rs2596503 that reached genome-wide significance in both samples but with opposite direction (p= 1.3E-9, OR=2.1 in Europeans; p=1.9E-11, OR=0.43 in African Americans; p=0.6 in meta-analysis). For many of the SNPs with apparent heterogeneity, the differences in effect estimates for European vs. African ancestry was statistically significant. A close look at the LD structure reveals that the apparent heterogeneity at rs2596503 can be explained by protective HLA alleles in Europeans (B*57, B*27 and B*14) segregating with the G allele, and protective alleles in African Americans (Cw*18 and B*81) segregating with the A allele. Conclusions: Flip-flop associations can be reconciled by differences in LD patterns between common SNPs and causal variants. For diseases where the MHC is implicated we expect such "flip-flop" associations to occur frequently in this region due to the highly polymorphic nature and broad LD.

1903/F

ELF1 is associated with systemic lupus erythematosus in Asian populations. *J. Yang, W. Yang, Y.L. Lau.* University of Hong Kong, Hong Kong, Hong Kong.

Great progress has been made in revealing the genetic variants that predispose individuals to complex diseases through genome-wide association studies (GWAS). However, the genes discovered so far only explain a small portion of heritability for complex disease such as systemic lupus erythematosus (SLE). Imbalance in the populations studied may have prevented us from identifying the population-specific susceptibility genes. This may be especially true for SLE, which has an apparent population difference in both disease prevalence and severity. Through a multi-stage study including GWAS and replication in several Asian populations, which included a total of 3164 patients and 4482 matched controls, we identified ELF1, an Ets family transcription factor that is involved in T cell development and function, associated with SLE (rs7329174, OR = 1.26, joint P = 1.47X10-8). The SNP also showed more association in patients with renal nephritis comparing to patients without (OR = 1.14, joint P = 0.059). The risk allele for this SNP and other SNPs in LD with rs7329174 has extremely low allele frequencies in populations of European ancestry. Bioinformatics analysis of the ELF1 gene revealed evidence for 3 alternative first exons in a 40 kb region in this gene, indicative of a complex control for its transcription, and SNP rs7379174 was located upstream of the third exon1, E1C. The usage of the 3 distinct first-exons was confirmed in PBMC in all patients and healthy controls examined. Furthermore, a prominent alternative splicing variant coding for a 56 amino acid deletion form of the protein was detected also in both patients and controls, both with abundant expression level. Although direct association of rs7329174 with exon 1 usage or alternative splicing was not established, these findings suggest that ELF1 may play a role in SLE susceptibility and the gene is tightly regulated in expression and alternative splicing.

The Human Variome Project - Pilot Projects and Progress. *R. Cotton[1], F. Macrae[2], M.J. Sobrido[3], A. Lo[4], H. Howard[1].* 1) Genomic Disorders Res Ctr, Melbourne, Australia; 2) The Royal Melbourne Hospital, Melbourne, Australia; 3) Fundacion Publica Galega de Medicina Xenomica, Santiago, Chile; 4) Victorian Partnership for Advanced Computing, Melbourne, Australia.

Cotton R.G.H., Macrae Finlay, Sobrido Maria Jesus, Lo, Alan, Howard Heather Convenor, Human Variome Project; Head, Genomic Disorders Research Centre, Howard Florey Institute; Melbourne, Australia Email: cotton@unimelb.edu.au The Human Variome Project (2007) (www.humanvariomeproject.org) initiated in June 2006 (Ring, Kwok et al. 2006) focuses on the importance of collection and its phenotype, and to develop programs to put this into practice. The project builds on work and concepts of the HGVS over the years (www.hgvs.org) to focus variations associated with disease. It includes those discovering mutations, their effectsand collect the data and make it instantly available to clinical decision-makers and researchers. The HVP and InSiGHT (www.insight-group.org) has developed a major pilot study to develop procedures and systems that allow effortless flow of de-identified data from the patient/clinic/diagnostic laboratory via curated locus or gene specific databases to central databases/genome browsers such as NCBI, UCSC and EBI. The system will be easily adaptable to other genes and to multiple laboratories, states and countries worldwide. A country specific collection pilot is underway in Australia and an International Confederation of these countries has been initiated with Korea and China in the application process. Other pilot studies developed include specific ethical studies on mutation collection, loading of LSDB content to dbSNP, funding of curation of LSDBs, a system of Microattribution/reward for mutation submission. Allele Frequency Spectrum Based Analysis Suggest Sequencing Bias in Pilot 1 Data of 1000 Genomes Project. *z. hou[1,2], H. Siu[1,2], K. T[3], L. Jin[1,2,3], M. Xiong[1,2,4].* 1) Laboratory of Theoretical Systems Biology, School of Life Science, Fudan University, Shanghai, China; 2) State Key Laboratory of Genetic Engineering and MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, China; 3) CAS-MPG Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, China; 4) Human Genetics Center, University of Texas School of Public Health, Houston.

The 1000 Genomes Project is the first project to sequence the whole genome of a large number of people, which is expected to provide a comprehensive resource on human genetic variation. Pilot 1 data, whole-genome sequencing of 180 samples (60 samples in each of the three populations, YRI, CEU and ASI), in this project have been released in several versions, of which the latest two were published in December, 2009 and March, 2010 and were named as Data I and Data II by us respectively. We analyzed the two data sets by calculating two different estimations of the fundamental population genetic parameter θ (Tajima's statistic and Watterson's statistic), and several allele frequency spectrum- based statistics, namely Tajima's D, Fu and Li's F* and Achaz's Y*. We used a sliding window of 100 kb for calculations. Comparisons with previous published works show great differences in both the average of estimations of θ and the distributions of Tajima's D. To investigate their differences, forwards-in-time simulations were carried out with FREGENE, according to the widely used comprehensive demographic models under the condition of neutral evolution. Distributions of all statistics from simulations also illustrate great skew to the left, comparing with empirical data. To find out how the deviations occurred, we found that all the curves of the ratio of minor allele frequency (MAF) of the two data sets to simulated data under neutrality dramatically change with the number of minor alleles when the number of minor alleles is less than 7, which demonstrates that minor alleles of low frequencies are much less than expected. To confirm whether it is generated from sequencing bias or very recent serious population bottlenecks, we simulated a serious bottleneck for each population by slightly modifying the demographic model under neutrality, using a serious bottleneck during which the effective population size decreased to 1% of the previous from recovery of the second bottleneck to 50 generations ago, to instead of last expansion. Comparing with results of simulation under neutrality, such kind of bottleneck does skew the trend to the right, however, the deviation is much less than the one between Pilot 1 data and neutral simulations. This showed that bias is not caused by population bottleneck.

A Modular Pipeline for Detecting Human Genetic Variations from Next-Generation Sequencing Data at NCBI. *C. Xiao[1], A. Ward[3], T. Blackwell[2], A. Mnev[1], W. Chen[2], P. Anderson[2], H. Kang[2], B. Li[2], X. Zhan[2], D. Stewart[3], W. Lee[3], M. Stromberg[3], W. Leong[3], A. Indap[3], D. Barnett[3], R. Agarwala[1], C. Marks[1], J. Paschall[1], T. Sneddon[1], J. Garner[1], D. Church[1], L. Phon[1], M. Shumway[1], D. Preuss[1], E. Yaschenko[1], M. DiCuccio[1], G. Abecasis[2], G. Marth[3], S. Sherry[1], the 1000 Genomes Project.* 1) National Center for Biotechnology Information, National Library of Medicine, National Institute of Health, Bethesda, MD; 2) Department of Biostatistics, University of Michigan at Ann Arbor, 1420 Washington Heights, Ann Arbor, MI; 3) Boston College Biology Department, 140 Commonwealth Avenue, Chestnut Hill, Massachusetts.

With the extremely high throughputs and reduced costs, next-generation sequencing (NGS) technologies have revolutionized genome sequencing and provided researchers with unprecedented opportunities to address many important biomedical problems efficiently. Large-scale resequencing projects, e.g. 1000 Genomes, TCGA, TSP, and Exome Sequencing Project etc, have been initiated to extend our knowledge of single nucleotide polymorphisms (SNPs), short insertions/deletions (INDELs) and structural variations (SVs) and relate these variants to human diseases. The amount of NGS data submitted to public repositories such as the Short Read Archives (SRA) at the NIH National Center for Biotechnology Information (NCBI) is growing exponentially and submissions represent a wide array of technology platforms and sequence collection strategies. To process and analyze these data for variation detection in a uniform manner is a challenge requiring a standardized modular pipeline. In collaboration with investigators at Boston College and the University of Michigan, NCBI continues to develop a framework Variation Discovery and Annotation Pipeline (Gpipe). The pipeline generates quality input sequence data from SRA, checks sample identities, aligns the read data with the human reference genome sequences, refines the mapping of placed reads (base quality recalibration and duplicate mark etc), and calls SNPs, INDELs, and SVs according to data availability and project-specific policies. A centrally implemented pipeline streamlines the data processing workflow for the data generated by next-generation sequencing technologies. Currently, this NIH-based modular pipeline is serving as one of the two pipelines for processing the 1000 Genomes main project datasets.

1907/F

Pooled next generation sequencing to identify mutations and rare variants in diabetes. *W. Xie[1], AM. Patch[2], R. Caswell[2], S. Ellard[2], MI. McCarthy[3], AT. Hattersley[2], TM. Frayling[1], MN. Weedon[1].* 1) Peninsula College of Medicine & Dentistry, Exeter, Devon, United Kingdom; 2) Institute of Biomedical and Clinical Science, Peninsula Medical School, Exeter, United Kingdom; 3) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Churchill Hospital, Headington, Oxford OX3 7LJ, United Kingdom.

Genome-wide association studies have identified ~30 loci where common variants are associated with risk of type 2 diabetes. However, these loci explain <10% of the heritability of the disease, and low-frequency and rare variants, which are not captured well by existing genome-wide association (GWA) studies, are thought to explain a substantial fraction of the "missing" heritability. Next generation sequencing (NGS) technologies provide an opportunity to study this type of variant, but whole exome/genome approaches are still not feasible in the large numbers of individuals required for polygenic disease. We therefore targeted 11 candidate type 2 diabetes genes using a pooled-NGS approach. We amplified these 11 genes plus 1kb of sequence 5' and 3' (a total of 95kb) by long range PCR in 4 overlapping pools of 24 and 48 individuals with diabetes. All these individuals had been part of the WTCCC-T2D GWA study, except for 5 that have diabetes due to a known mutation in one of the 11 genes. We performed 76bp sequencing of the PCR products on the Illumina GA2. After alignment, 95% of the targeted regions were covered at sufficient depth (>10-fold average coverage per individual) to call SNPs and estimate allele frequencies. Where we had sufficient coverage, all 13 of the genotyped SNPs from the GWA study were detected. All the known single nucleotide substitution mutations from the monogenic diabetes samples were also detected, even though the mutation represented just 1 heterozygous carrier in the pools. The correlation between observed and expected allele frequencies was >0.99 in all 4 pools. Of the >500 variants we identified in pools of 24 individuals >90% were also identified in the overlapping pools of 48 individuals suggesting a low false positive rate. Approximately 50% of the variants were not in dbSNP or current 1000 genomes data. We have selected 16 non-synonymous SNPs that had estimated variant frequency <5% and 8 novel non-coding SNPs that are highly conserved across species to genotype in additional case and control samples. This study shows that targeted pooled sequencing is an efficient way to identify low frequency variants for further study. The accuracy of the allele frequency estimates from the pools suggests that extending sequencing to additional pools of cases and controls should provide an efficient screen of candidate genes for low-frequency moderate-penetrance type 2 diabetes risk alleles.

1908/F

Genome-Wide Association Studies in Hong Kong identified Novel Susceptibility Genes for Systemic Lupus Erythematosus. *W. Yang[1], R.J. Li[2], J. Yang[1], D.Q. Ye[2], Y.L. Lau[1].* 1) Paediatrics & Adolescent Med, Univ Hong Kong, Hong Kong, Hong Kong; 2) Department of Epidemiology and Biostatistics, School of Public Health, Anhui Medical University, China.

Systemic lupus erythematosus (SLE) is a prototypic autoimmune disease with complex genetic inheritance. GWAS have identified a number of susceptibility genes for SLE in the last two years. However, the imbalance of the populations studied may have hindered our ability to detect susceptibility genes that are either population specific, or show differences in allele frequencies or linkage disequilibrium. We have conducted GWAS on 620 SLE patients collected in Hong Kong and 2193 controls matched by ethnicity and geography. Replication on 200 selected SNPs on independent sample collections from Hong Kong, Anhui, China, and Bangkok Thailand identified novel susceptibility genes for SLE include ELF1, CD247, and others. We present detailed data on CD247 below. Recently, CD247 (CD3Z) was found to be associated with SLE in populations of Caucasian in associated studies of small sample size. Our GWAS data from Chinese living in Hong Kong identified SNPs in and around CD247 to be associated with SLE risk. Two most significant SNPs were selected for further replication in 3180 Asian patients from Hong Kong, Mainland China, and Thailand, as well as 4626 ethnically- and geographically-matched controls. We confirmed the association of CD247 with SLE in Asian populations (rs704853, odds ratio (OR) = 0. 82, P = 7. 31 x 10-6; rs858543, OR = 1. 104, P = 0.0048). Subphenotype analysis showed that rs704853 is also linked to oral ulcer (OR = 0. 78, P = 0. 047), hematologic disorder (OR = 0. 78, P = 0. 033) and anti-ds-DNA antibody (OR = 0. 76, P = 0. 028). Understanding of the involvement of CD247 in the disease could shed new light on SLE mechanisms and help with development of new treatment paradigms.

1909/F

Characterizing Genetic Patterns of Insertion and Deletion Polymorphisms in 1000 Genomes Project data. *F. Yu, D. Challis, L. Bull, M. Bainbridge, R. Gibbs.* Human Genome Sequence Ctr, Baylor College Med, Houston, TX.

Insertion-deletion polymorphisms (INDELs) are important both because of their abundance in the human genome and their significant association with many diseases. The "1000 Genomes Project" aims to resequence 2500 human individuals collected from more than 20 ethnicities world wide, using second generation sequencing platforms. It has already made unprecedented progress in uncovering a massive number of novel SNPs. Yet many genomic characteristics around INDELs remain unexplored, primarily because INDELs have remained difficult to accurately identify due to the relatively short read length and low accuracy of the sequencing platforms. We have developed an algorithm, Atlas-Indel2, to differentiate between true INDELs and sequencing or alignment errors using a logistic model of pertinent variables, tuned with training data. Our results indicate the p-value successfully separates true INDELs from errors within coding regions. The density for p-values between 0.95 and 1 is 0.28, and 0.11 between 0.5 and 0.95, while the density is 1.88 for p-values below 0.5. Using a 0.95 p-value cutoff which requires at least 5 variant reads, on average 1.5 insertions and 2 deletions are discovered per 10,000 exonic bases per individual. For INDELs above the p=0.95 cutoff, 63% have a non-frameshift length of 3-12 (3, 6, 9, or 12), 36% have a length of 1 and about 1% are a frameshift length 2-11base pairs. Most of the INDELs causing a frameshift are with lower population frequency, possibly reflecting a stronger purifying selection effect. In this study, we apply Atlas-Indel2 to discover INDELs from 1000 Genomes Project data, characterize the linkage disequilibrium patterns around INDELs, and further examine the power of imputing known and novel INDELs. We find the level of single nucleotide variation diversity is elevated around INDELs. The long term goal is to enable applications that incorporate small INDELs in genome wide association studies for integrative disease mapping efforts.

1910/F

Genome-wide association study identifies three ancestral loci shared with Neandertal as important for skeletal muscle volume in young males. *J.M. Devaney[1], E.F. Orkunoglu-Suer[1], B.T. Haron[1], H. Heather Gordish-Dressman[1], P.M. Clarkson[2], P.D. Thompson[3], T.J. Angelopoulos[4], P.M. Gordon[5], N.M. Moyna[6], L.S. Pescatello[7], P.S. Visich[8], R.F. Zoeller[9], E.P. Hoffman[1].* 1) Department of Integrative Systems Biology, Research Ctr Genetic Med, Childrens Natl Medical Ctr, Washington, DC; 2) Department of Kinesiology, University of Massachusetts, Amherst, MA; 3) Division of Cardiology, Henry Low Heart Center, Hartford Hospital, Hartford, CT; 4) Center for Lifestyle Medicine and Department of Health Professions, University of Central Florida, Orlando, FL; 5) Department of Physical Medicine and Rehabilitation, School of Medicine, University of Michigan, Ann Arbor, MI; 6) School of Health and Human Performance, Dublin City University, Dublin 9, Ireland; 7) Department of Kinesiology and Human Performance Laboratory, University of Connecticut, Storrs, CT,; 8) Human Performance Laboratory, Central Michigan University, Mount Pleasant, MI; 9) Department of Exercise Science and Health Promotion, Florida Atlantic University, Davie, FL.

Skeletal muscle is extremely important in many physiological and disease processes, including mobility limitation, osteoporosis, higher risk of fracture, dyslipidemia, obesity, insulin resistance, overall frailty, and increased mortality. Skeletal muscle size is under strong genetic determination with heritability ranging from 52% to 84%. However, the location of gene or regions of the genome associated with muscle size has been limited to candidate genes. Recently, we completed a genome wide association study (GWAS) in 144 males (age=24) that participated in the Functional Polymorphisms Associated with Human Muscle Size and Strength (FAMUSS) study. The FAMUSS study is a cohort of young, healthy individuals that undertook a 12-week resistance-training program on the non-dominant upper arm. Before individuals started the training program, we measured skeletal muscle size of the upper arm using magnetic resonance imaging. We selected six variants from the GWAS results for genotyping in the rest of the males and females that participated in FAMUSS study (n=173 males and n=466 females; age= 24 yrs old). Three of the six variants were confirmed in the larger set of males but none of the loci were significant in the females. Two of the variants are located in the ZNF609 gene, a novel zinc finger protein located on chromosome 15 and the other SNP is located in a non-genic region on chromosome 2. Interestingly, all three alleles associated with skeletal muscle size are ancestral in nature and were the same alleles present in the Neandertal sequence recently published in Science (Green et al. A draft sequence of the Neandertal genome. Science. 2010 May 7;328: 710-22). Neandertals were physically diverse, but in general they were larger boned and more heavily muscled than most modern humans. These genomic regions may be the result of the interbreeding of early modern humans and Neanderthals that occurred 50,000 and 100,000 years ago. In This work needs to be replicated and may have significance in the understanding of the basic biology of muscle.

1911/F

Creation of a comprehensive SNP imputation dataset from individuals of European descent. *A.A. Hutchinson[1,2], K.B. Jacobs[1,2], Z. Wang[1,2], M. Yeager[1,2], M.A. Tucker[2], S.J. Chanock[2].* 1) Core Genotyping Facility, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD 21702, USA; 2) Division of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD 20892, USA.

The NCI Division of Cancer Epidemiology and Genetics (DCEG) has performed numerous genome-wide association studies (GWAS) to detect heritable genetic risk factors for numerous cancer sites. Primarily, genotypes have been generated using Illumina HumanHap BeadChip SNP arrays based on the International HapMap project phases I and II. These products are being superseded by a new "Omni" series of arrays that are based on phase III of the HapMap project and variants discovered from preliminary analysis of data from the 1,000 Genomes Project. While these newer arrays provide additional SNP content that may aid in mapping common diseases, all of the content from the older HumanHap series of arrays was not carried into the newer products. In addition, GWAS data from individuals scanned using the Affymetrix 500K and 6.0 arrays are routinely combined with our Illumina data. As we plan future GWAS projects, we must determine the extent data from subjects genotyped on HumanHap arrays can be combined with those that will be genotyped on the new Omni arrays and Affymetrix arrays. Further, we aim to generate a comprehensive dataset to serve as the basis for genotype imputation across these platforms and is of sufficient size to accurately infer variants with relatively low population frequency (>~2.5%). This dataset is being constructed using 750 well-characterized individuals of European descent from three cohort studies. Genomic DNA samples from these individuals are being genotyped using multiple SNP arrays from Illumina (each on the Human Hap1M-Duo, Human Omni1-Quad, and Human Omni2.5M) and Affymetrix 6.0 arrays. We shall use this dataset to evaluate the extent and accuracy of several genotype imputation algorithms and to combine data across all platforms. The resulting genotype data will be combined with data from the HapMap and 1,000 Genomes projects and formatted for use in several popular SNP imputation programs, including IMPUTE, MACH, and Beagle. Once ready, we shall post these datasets to the NCBI dbGaP portal for use by the broader scientific community. Funded by NCI Contract No. HHSN261200800001E.

1912/F

Korean Genome wide association study for pulse rate identifies 6q22.31c loci. *N. Kim, Y. Kim, Y. Cho.* Center for Genome Science, Seoul, Korea.

Pulse rate has been widely known to be related to cardiovascular diseases, lifespan, arrhythmia, hypertension, lipids, diabetes and menopause. Despite the given impact of this trait on several complex diseases/phenotyes, there have been fewer attempts to identify genetic influence on pulse rate. Here we report the associated loci responsible for the variation of pulse rate in Korea population. We performed a genome-wide association study (GWAS) with 352,228 SNPs typed in 8,842 subjects from KARE (The Korea Association REsource) project and replicated the significant signals in 3,703 subjects from independent population. We identified significant associations between pulse rate and genetic loci in four regions near on chromosome 6q22.31c (p=1.1×10-5, in GJA1), 7p15.1b (1.2×10-5, C7orf41), 1q32.2a (3.8×10-7, in CD46), and 6q22.13c (0.3×10-6, in LOCL644502). CD46 and LOCL644502 were previously reported as candidate genes for pulse rate. In present study, we propose a novel locus related to pulse rate on 6q22.31c (GJA1). The encoded protein by GJA1 is the major protein of gap junctions in the heart that is thought to have a crucial role in the synchronized contraction of the heart and in embryonic development.

Genome-wide association study to identify the genetic basis of alcohol consumption in population-based cohorts. *J. Lee, M. Go, Y. Kim, Y. Cho.* Center for Genome Science, Seoul, Korea.

Alcohol dependence, which is related to high alcohol consumption, causes various common public health problems. Previous studies indicated that individual's alcohol consumption is influenced by not only environmental but also genetic factors. To gain insight into genetic basis of individual's alcohol consumption, we conducted genome-wide association study (GWAS) from population-based cohorts. The amount of daily alcohol consumption was calculated based on the second Korean National Health and Nutrition Examination Survey. Our GWAS was conducted to test 352,228 single nucleotide polymorphisms (SNPs) from 3,951 subjects in population-based cohorts of Korean Genome Epidemiology Study I, (KoGES I). We tested genetic association between SNPs and alcohol consumption by performing linear regression analysis after adjustment of 4 variables (age, sex, area, BMI). We identified significantly associated SNPs with alcohol consumption (P-value < 10-6) from initial GWAS. The replication of these associations will be carried out in the independent population (KoGES III samples of about 5,000 samples). The progress and future works of this study will be presented.

1914/F

IGOR: new software for calling genotypes from Illumina BeadArrays. *W. Zhou[1,2], Z. Wang[1,2], Q. Chen[1,2], M. Yeager[1,2], S.J. Chanock[2], K.B. Jacobs[1,2].* 1) Core Genotyping Facility, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD 21702; 2) Division of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD 20892.

Most algorithms used to call genotypes from BeadArray data have difficulty calling rare alleles and handling outliers, and require complex heuristics or questionable assumptions (such as fitness for Hardy-Weinberg proportion) to compensate. We propose a new software suite to process data from the Illumina BeadArray platform to estimate genotypes states. Our new software, Illumina Genetype Probabalistic Caller (IGOR, pronounced 'ahy-gohr'), begins by reading raw Illumina intensity data files (IDAT), normalized or unnormalized Illumina genotype final reports or binary HDF5 files. For unnormalized intensity data, IGOR uses an algorithm similar to the Illumina normalization method. Probe intensity data can be processed further with optional variance stabilization, local GC/CpG sequence context adjustment, and quantile normalization. Genotype clusters are estimated by fitting two multivariate mixture models: one to probe intensities within each array to estimate prior homozygote and heterozygote probabilities for all SNPs; and the other uses the within-array prior probabilities to stabilize cluster assignments for each SNP across all arrays. This procedure provides accurate and consistent genotype assignments, even for monomorphic loci and for those with extremely rare alleles. A variety of output formats are supported, including those that report the most likely genotype (GLU text and binary, PLINK text and binary, PHASE, VCF, etc.), as well as those that support probabilistic genotype assignments (GLU, WTCCC, VCF, etc.). IGOR is designed to run on modern multi-core CPUs as well as computing clusters, enabling high-throughput and scalable processing. IGOR also has the advantage of not relying on the Illumina GenomeStudio software, since it can process native Illumina data files and includes algorithms for probe normalization and genotype calling. Once validated, IGOR will be released as free and open source software. Funded by NCI Contract No. HHSN261200800001E.

1915/F

High throughput single molecule analysis of genomic DNA integrity in nano-channel arrays. *W. Stedman, M. Akana, S. Das, M. Austin, P. Deshpande, D. Bozinov, H. Sadowski, H. Cao, M. Xiao.* BioNanomatrix Inc, 3701 Market St, 4th Floor, Philadelphia, PA 19104.

Nucleotides in DNA and RNA are frequently modified by exogenous and endogenous damaging factors, leading to single strand, double strand DNA breaks, genomic rearrangements and a broad spectrum of chemical modifications (e.g. formations of cyclobutane pyrimidine dimer, oxidation, etc). These changes can alter gene expression, resulting in genome instability and protein malfunction, that often correlates with diseases. Currently, there are limited available high-throughput and sensitive methods to detect these events without the need of DNA amplification, which can conceal those modifications. We have developed a high throughput assay that can directly image the size distribution of genomic DNA molecules and nucleotide modifications of these molecules in massively parallel nano-channel arrays. Our method starts with enzymatic labeling of specific nucleotide modifications (single strand breaks or chemical modifications) on long genomic DNA molecules with fluorophores. The labeled DNA molecules are then linearized inside the nano-channel array and imaged with high resolution fluorescence microscopy. Double-strand breaks can be detected directly by determining the size distribution of the genomic DNA molecules. By localizing fluorescent labels on the DNA backbone, the structural information of the genome and the distribution of modified nucleotides on individual DNA molecule can be inferred with great accuracy and reproducibility. This highly miniaturized nano-array device together with the flexible and efficient labeling chemistry enables direct image analysis of the whole genome at the single molecule level.

1916/F

How significant is the human genome in determining disease phenotypes. Are post-DNA events the key to understanding disease ontogeny? *B. Gottlieb[1,2], L.K. Beitel[1,2,3], M. Trifiro[1,2,3].* 1) Dept Cell Genetics, Lady Davis Institute for Medical Research, Montreal, QC, Canada; 2) Dept Human Genetics, McGill University, Montreal, QC, Canada; 3) Dept Medicine, McGill University, Montreal, QC, Canada.

Since the beginning of the Human Genome Project and throughout subsequent follow-up studies, it has been assumed that the most important factor governing the ontogeny of both common and rare diseases is the nature of an individual's genotype. This assumption has been the basis for the huge amount of resources applied to projects such as the 1000 genomes, the cancer genome, as well as numerous genome wide association studies. While in a few cases such studies have identified genes that cause rare diseases, identification of significant genes in multifactorial diseases such as cancer and cardiovascular disease has not been that successful, mainly because it has been assumed for the most part, that the genes identified so far have not been rare enough to be truly significant. To test this assumption, we decided to examine the genomics of the androgen receptor (AR) gene, a locus-specific gene, in which mutations are responsible for the rare condition known as androgen insensitivity syndrome (AIS). We examined a total of 140 patients with a clear AIS phenotype, and found that in over 40% a mutation in their AR coding exons could not be identified. Further, similar results have been reported in two other AIS databases. In the absence of any other gene being identified as causing AIS to date, the question arises as to whether post-DNA events may play a critical role in determining AIS phenotype. Over the past few years a number of such events and factors have indeed been identified that can significantly affect the relationship between genotype and phenotype. These include DNA and RNA editing, and alternative splicing. They also include many epigenetic factors such as DNA methylation and interactions involving coactivators and corepressors. In light of all these possible sources of phenotypic variation and the apparent disconnect between genotype and phenotype in many diseased individuals, we will discuss a new model of the genotype to phenotype pathways that reflects the actual complexity of this relationship. We believe that understanding such pathways will be critical in determining the ontogeny of disease phenotypes and help bring about the era of personalized medicine in the treatment of disease, which will be critical to both curing and hopefully preventing multifactorial and rare diseases.

1917/F

Common genetic variants in the Nucleotide-binding Oligomerization Domain-1 (NOD1) gene are associated with asthma in a population of African descent. *C.S. Jackson[1,2], L. Santi-Ruiz[2], T.E. Mason[2], V. Apprey[2], G. Bonney[2,3], G.M. Dunston[1,2,3].* 1) Microbiology, Howard University, Washington, DC; 2) National Human Genome Center at Howard University, Washington, DC; 3) Department of Community Health and Family Medicine, Howard University, Washington, DC.

Background: Asthma is a chronic inflammatory disease affecting approximately 7.5 % of Americans 25 years of age and older. The greatest burden of hospitalization and mortality is mainly observed in ethnic minority populations, thus making asthma one of the leading health disparities in the United States. We hypothesize that genetic polymorphisms in the nucleotide-binding oligomerization domain-1 (*NOD1*) gene are associated with asthma susceptibility in an African American population. Our laboratory analyzes the functional significance of common variants in candidate genes associated with health disparities, like asthma. *NOD1*, which codes for an intracellular microbial pattern recognition receptor, is a candidate gene associated with the pathogenesis of asthma in European populations. **Methods:** We performed a genetic association study in a population of 400 African American asthmatic cases (200) and controls (200) from the Washington, DC metropolitan area to determine single-nucleotide polymorphisms (SNPs) associated with asthma. Eight SNPS (rs2075818, rs2235099, rs2075820, rs2075821, rs2907748, rs5743336, rs2906766, and rs2529444) located in both the regulatory and structural domains of *NOD1* were genotyped using PCR-RFLP and Pyrosequencing. **Results:** By using genetic modeling, the SNPs rs29007748 (p=0.039, OR=0.37, 95%CI 0.13-1.01) and rs5743336 (p=0.016, OR=0.50, 95%CI 0.28-0.89) were found to be associated with asthma in the dominant model when stratified by gender. SNP rs2907748 is located in intron 11, and rs5743336 is located in the 5'untranslated region. **Conclusion:** This study shows that common variants in *NOD1* are associated with asthma in an African American population. In addition, genotype-based diagnosis and targeted intervention may be instructive in the emergence of personalized genomic medicine in diverse populations.

1918/F

The European Genome-phenome Archive (EGA). *I. Lappalainen, J. Hinton, V. Kumanduri, M. Maguire, P. Marin-Garcia, P. Flicek.* European Bioinformatics Institute, Cambridge, United Kingdom.

The European Genome-phenome Archive (EGA), a service of the European Bioinformatics Institute, provides a permanent archive for all types of potentially identifiable genetic and phenotypic data. The EGA contains data collected from individuals for the purpose of medical or genetic research and whose consent agreements prevents open, public data distribution. The EGA follows strict protocols for information management, data storage, security and dissemination. Researchers with appropriate authorisation may access data from over 40 studies and 50000 individuals currently provided through the EGA web site at http://www.ebi.ac.uk/ega/. These studies include dense genotype experiments between cases and controls, population based studies or re-sequencing and RNA-seq data from various cancer genomes. The EGA has implemented a distributed data access policy whereby the data access decisions are made by a data access-granting organisation (DAO) and not by the EGA project. The DAO may be the same organisation that approved and monitored the initial study protocol or a designate of this approving organization such as a dedicated data access committee. In a typical case, the EGA will direct users to a project homepage where the user can apply for access that is then managed by the EGA. Accepted data types include genotypes, structural variants and whole-genome sequence which are stored in optimised data structures. In addition, manufacturer-specific raw data formats from array-based genotyping and raw DNA sequence data arising from re-sequencing, transcriptomics or other assays may be deposited for archiving and distribution. The EGA also accepts any phenotype data associated with the samples. All deposited data must have a DAO approved data release policy that provides data access in accordance with the original consent agreements. The EGA also provides an analysis infrastructure to add value to data submitted into our system. Our quality control applies to both samples and experimental data without altering the original data but allowing us to merge data collected using different technologies, phase submitted data or impute unobserved genotypes using public resources such as the 1000 Genomes project. The data are made available together with our partner DAOs in the most widely used formats to those users that have been granted access.

1919/F

Distribution of Deleterious Alleles Across Diverse Populations. *S. Musharoff[1], J. Kidd[1], B. Henn[1], MC. Yee[1], M. Snyder[1], F. De La Vega[2], C.D. Bustamante[1].* 1) Genetics, Stanford University School of Medicine, Stanford, CA; 2) Life Technologies, Foster City CA.

Distributions of deleterious alleles are relevant to the study of human disease prevention and treatment. The recent advancements in sequencing whole genomes have enabled the identification of genome-wide functional changes that can be examined in a population-genetic manner. Here we analyze the distribution of deleterious alleles in the diploid genomes of 12 HapMap Phase 3 human individuals from diverse populations which have been sequenced to high coverage using SOLiD technology and relate the differences in distributions of synonymous vs. benign, possibly damaging, and probably damaging non-synonymous coding variants to demographic history. As two of the individuals analyzed are “admixed” with respect to European, African, and / or Native American ancestry, their “admixture breakpoints” are first fine-mapped using admixture deconvolution methods. Then, functional changes are considered separately within tracts of unique ancestry. We extend this analysis to a select sample of individuals from the Human Genome Diversity Project (HGDP) whose genomes are fully sequenced on another next generation sequencing (NGS) platform and examine the retention of deleterious mutations considering population bottlenecks and other known migration events. Considering distributions of such functional changes in populations in the light of human demographic history is essential in the age of personalized genomic medicine.

1920/F

Factors influencing the success of exome sequencing for gene discovery in mendelian disorders. *S. Ng, obo the National Heart, Lung, and Blood Institute's Exome Sequencing Program (Lung Project Team).* Genome Sciences, University of Washington, Seattle, WA.

Several studies published in the last year have demonstrated the utility of massively parallel sequencing for the identification of genes underlying rare, monogenic diseases. We have shown that our approach - based on sequencing the exomes of a small number (i.e., 4-10) of unrelated individuals and identifying the intersection of genes containing rare, protein-altering variants - can be an efficient and successful strategy for discovering genes for both recessive and dominant disorders (Ng et al. 2009, Ng et al. 2010). However, the factors that influence the success of this approach have yet to be well defined. Using a large dataset of 75 human exomes, we analyze the impact of parameters including sample size, pedigree structure, mode of inheritance, genetic heterogeneity, missing data, and variant filtering based on frequency and function. Capture of these exomes was done using in-solution hybridization probes against a CCDS (2008) target, comprising about 28Mb over 160,000 exons, and sequencing was done to an average of 56X. These exomes are part of the U.S. National Heart, Lung, and Blood Institute's (NHLBI) Exome Sequencing Program, and are from a modifier study of cystic fibrosis (CF). We use the CF cohort to assess the effect of varying the threshold frequency for candidate mutations on the power and specificity to identify the major causal gene, CFTR. This is of interest because the carrier frequency for CF mutations is relatively high (up to 1:25 in populations of European ancestry), and these results will have implications for diseases with moderate prevalence and carrier frequencies. We also use permutation analyses of these exomes to estimate the effect of other factors - including the disease model and presence of heterogeneity - on the power of this approach. Our results identify the strengths and weaknesses of various study designs for exome analysis of mendelian disorders, including both rare syndromes and monogenic subsets of common disease, and may be informative for further analyses on more common, complex disease.

1921/F

Association of the functional CD226 307Ser variant with systemic sclerosis: evidence for a contribution of co-stimulation pathways in SSc pathogenesis. *P. Dieudé[1], M. Guedj[2], M.E. Background. The non-synonymous polymorphism rs763361 of the CD226 gene, which encodes the DNAX accessory molecule 1, involved in T cell co-stimulation pathways, has recently been identified as a genetic risk factor for autoimmunity. Objective. To test the association the CD226 rs763361 polymorphism with systemic sclerosis (SSc) in European Caucasian populations. Methods. CD226 rs763361 was genotyped in 3645 individuals comprising a discovery set (991 SSc patients and 1008 controls) and a replication set (999 SSc patients and 634 controls), all individuals being of European Caucasian origin. Expression of CD226 was assessed on PBMCs obtained from 14 SSc patients and from 10 healthy donors genotyped for CD226 rs763361. Results. The CD226 rs763361 T allele was found to be associated with SSc in both discovery and replication samples providing the following results in the combined populations: OR 1.22 95%CI[1.10-1.34], P=5.69x10-5. The CD226 T allele was also associated with various SSc subsets highlighting a potential contribution in disease severity. The most remarkable associations of the CD226 TT risk genotype were observed with diffuse cutaneous subtype, anti-topoisomerase I antibodies positive and SSc-related fibrosing alveolitis subsets: OR 1.86 95%CI[1.42-2.43], P=5.15x10-6, OR 1.82 95%CI[1.38-2.40], P=2.16x10-5 and OR 1.61 95%CI[1.25-2.08], P=2.73x10-4, respectively. The CD226 expression was significantly linked with CD226 rs763361 genotypes in CD3+, CD4+ and CD56+ cells. Conclusions. Our results establish CD226 as a new SSc genetic susceptibility factor and provide evidence for a functional consequence of CD226 rs763361 by demonstrating an association of the CD226 genotypes with CD226 expression in helper T cells and NK cells.

1922/F

Genome-Wide Association Identifies Novel Loci Impacting Common Variable Immunodeficiency. *J.T. Glessner[1], J.S. Orange[2], K.E. Sullivan[2], E.E. Perez[3], E. Resnick[4], M. Gray[5], C.E. Kim[1], R. Chiavacci[1], J.W. Sleasman[3], H. Chapel[5], C. Cunningham-Rundles[4], H. Hakonarson[1,6].* 1) Ctr Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA; 2) Division of Allergy and Immunology, Children's Hospital of Philadelphia Research Institute, Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA 19104, USA; 3) Division of Allergy, Immunology & Rheumatology, Department of Pediatrics, University of South Florida, Saint Petersburg, FL 33701, USA; 4) Mount Sinai School of Medicine, New York, NY, 10029 USA; 5) Nuffield Department of Medicine, University of Oxford and Oxford Radcliffe Hospital, Oxford, OX3 9DU, UK; 6) Division of Genetics, Department of Pediatrics, The Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA, 19104, USA.

Common variable immunodeficiency (CVID) is a generic term for a group of uncommon heterogeneous immune defects characterized by hypogammaglobulinemia, failure of antibody production, susceptibility to bacterial infections and an array of serious comorbidities. To address the underlying immunopathogeneses of CVID, we conducted the first ever genome-wide association study of patients with CVID. 363 patients were genotyped with 610,000 SNPs. Due to the relative rarity of this group of disorders, the study cohort was recruited at four sites. Patients were randomly divided into a discovery cohort of 179 cases in comparison with 1,917 disease-free controls and a replication cohort of 109 cases in comparison with 1,114 controls, controlled for population stratification. Our analyses detected strong association with the MHC region and uncovered a novel association with a cluster of ADAM genes that was replicated in the independent case cohort. Analysis of the same cases for copy number variation (CNV) revealed 28 disease-associated deletions and duplications, as well as 84 unique rare deletions and 98 duplications suggesting multiple novel genetic etiologies for individual CVID cases. Analysis of CVID comorbidities identified significantly associated SNP genotypes with the major CVID clinical phenotypes. Taken together, our integrative genome-wide analysis of SNP genotypes and CNVs has uncovered multiple novel susceptibility loci for CVID, both common and rare, consistent with the highly heterogeneous nature of CVID. These results may allow for improved diagnosis of CVID and prediction of the CVID clinical phenotypes based upon these unique genetic variations.

1923/F

Two missense variants in UHRF1BP1 are independently associated with systemic lupus erythematosus in Hong Kong Chinese. *Y. Zhang[1], W.L. Yang[1], P.W. Lee[1], J. Yang[1], P.C. Sham[2], Y.L. Lau[1].* 1) Paediatrics, The University of HongKong, HongKong; 2) Psychiatry, The Univeristy of HongKong, HongKong.

UHRF1BP1 is a highly conserved protein with unknown function. Previously, a coding variant in this gene was found to be associated with SLE in populations of European ancestry (rs11755393, R454Q, P = 2.22 x 10-8, OR = 1.17). In this study, by a combination of genome-wide study and replication involving a total of 1230 patients and 2193 controls, we confirmed the association of this coding variant in SLE susceptibility in Hong Kong Chinese, and also identified another coding variant in this gene that independently contributes to SLE susceptibility (rs13205210, M1098T, P = 4.44 x 10-9, OR= 1.49). Unlike rs11755393, rs13205210 association fits better to a dominant model and shows higher effect size than reported in the European populations for this gene. Cross population confirmation establishes the involvement of this locus in SLE and indicates that distinct alleles, possibly coding changes, are contributing to the disease.

1924/F

Validation Of Exome Sequencing Variation Using Orthogonal Methods. *M.J. Rieder, I.B. Stanaway, J.D. Smith, E.H. Turner, B.W. Paeper, D.A. Nickerson.* Dept of Genome Sciences, University of Washington, Seattle, WA.

We performed in-solution capture (NimbleGen SeqCap 2.1 M custom probe set) for the protein coding regions of the human genome (i.e. the exome). Sequences have been produced by Illumina GAIIx to identify variants in 50 population diverse samples derived from the HapMap sample set and/or Coriell collection. These samples were also resequenced using traditional Sanger sequencing methods across 231 candidate genes through the NIEHS Environmental Genome Project (EGP). Additionally, a subset of the samples (n=20) were genotyped using a 1M Illumina genome-wide array. All the GAIIx sequencing data was analyzed using a pipeline composed of the Burrows-Wheeler Aligner (BWA) followed by variant detection using the Bayesian, Unified Genotyper in multi-sample mode from the Genome Analysis Toolkit (GATK). We identified an average of 17,125 variants per exome with a mean coverage depth of 68x. To evaluate the robustness of variant calling, we compared the exome dataset to the 1M genotyping data for overlapping regions resulting in a concordance of 99.5% over an average of 8,390 variants per sample. By comparing discrepant sites, we find that for the remaining 0.5% of variants a significant proportion of the miscalls are due to genotyping errors. The false-negative call rate estimated based on the 1M variants to be approximately 3.4%. From a large Sanger based-sequencing dataset (n=5,340 variants), we determined the false discovery rate is 7.5% and the false negative rate is ~ 8%. By assessing filtering metrics and depth of coverage, false negative rates were reduced to ~2%. Using two orthogonal datasets against the exome sequencing data we have estimated the current error rates inherent in high-throughput human exome analysis using the Illumina platform.

1925/F

Validation of 1000 Genomes Project SNP calls using the Affymetrix Axiom™ Genotyping Solution. *J. Gollub, T. Asbury, J. Bleyhl, Y. Lu, G. Mei, M. Purdy, L. Weng, Y. Zhan, T. Webster.* Affymetrix, Inc., Santa Clara, CA.

We have validated approximately three million novel human SNPs discovered by the 1000 Genomes Project for use with the Axiom™ Genotyping Solution, and examined concordance of array-based genotypes to those in the pilot 1 and pilot 2 releases. This effort focused on a subset of SNPs not found in the HapMap Project or dbSNP (release 130). Polymorphism was observed for each validated SNP in at least two HapMap2 individuals, with very high call rates and concordance with 1000 Genomes Project reference genotypes for individuals genotyped in common.

The March 2010 release of 1000 Genomes Project data contains genotypes for approximately 15 million SNPs, based on low-coverage sequencing and genotype imputation for 180 individuals overlapping the HapMap 2 individuals (pilot study 1), and deep sequencing of two nuclear family trios (pilot study 2). Array-based genotypes of the deep-sequenced individuals are more than 99.5% concordant with the reference genotypes. We find noticeably lower concordance (around 98.4%) with the low-coverage sequencing-based genotypes. Concordance with shallow sequencing-based calls of heterozygous alleles (around 97%) is lower than concordance to homozygous calls (98.5%). We ascribe the difference in part to expected errors resulting from the low-pass sequencing and imputation used for SNP calls in the first pilot study.

1926/F

Genetic modifiers of disease severity in Duchenne muscular dystrophy. *A. Kesari[1], J. Devaney[1], H. Gordish[1], C. McDonald[2], E. Hoffman[1], Cooperative International Neuromuscular Research Group (CINRG), FAMuSS group.* 1) Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) University of California, Davis, CA.

Background: Duchenne muscular dystrophy (DMD) is a monogenic condition caused by loss-of-function mutations in the dystrophin gene. Patients show variability in disease onset, progression, and response to glucocorticoids, suggesting genetic modifiers. Understanding genetic modifiers is particularly important as increasing numbers of potential therapies are moving into clinical trials, yet inter-patient variability complicates interpretation of drug efficacy. The Cooperative International Neuromuscular Research Group (CINRG) conducted a natural history study that included a goal of identifying genetic modifiers and comprised 348 participants. One approach to identify genetic modifiers is to use genome-wide association studies (GWAS) of relevant phenotypes in larger normal volunteer populations. Towards this end, we assessed response to muscle resistance training in 1,300 healthy college-age volunteers (FAMuSS study). Those participants that showed the least and greatest increase in strength after 12 weeks of unilateral upper arm training were studied using GWAS methods (1 million SNPs). The top loci were then utilized as candidates for genetic modifiers of DMD. Methods: 180 DMD participants (of 348 or 51.7%) from the CINRG Natural History Study were genotyped for 9 haptag SNPs from the FAMuSS GWAS study of male strength response. Sequence variations were genotyped by TaqMan allele discrimination assays. Analysis of covariance (ANCOVA) with age and current steroid use as covariates was used to identify statistically significant differences in mean measures of muscle strength among genotypes. Results: Of the 9 GWAS strength loci in healthy male volunteers, 4 showed statistical significance as genetic modifiers of DMD using grip strength as the clinical phenotype. In each case, the direction of change was consistent between normal healthy volunteers and DMD participants. Conclusions: The 4 loci showed a similar genotype/phenotype association in both healthy males and DMD boys (e.g. rare allele = increased strength). Inclusion of genetic modifiers in clinical trials holds the potential of increasing sensitivity and specificity of assessments of drug efficacy.

1927/F

Exploring Regions of Extreme Diversity in the Human Genome. *K.M. Steinberg[1], J.M. Kidd[1], F. Antonacci[1], P. Sudmant[1], T. Graves[2], R.K. Wilson[2], E.E. Eichler[1].* 1) Department of Genome Sciences and Howard Hughes Medical Institute, University of Washington, Seattle, WA; 2) Washington University Genome Sequencing Center, School of Medicine, St. Louis, MO.

Highly divergent regions of the human genome, defined as less than 99.5% identity to the reference genome, are often refractory to next generation sequencing technologies and represent a part of the genome where SNP assignment is questionable and annotation is limited. It is therefore critical to further interrogate and accurately annotate the sequence composition of these regions in order to fully understand the complete spectrum of genetic diversity. Utilizing clone-derived end-sequence data from 16 diverse human genomes, we have identified 385 loci greater than 100kb where four or more clones map to the region but the percent identity between the sample and reference is less than 99.5. The average sequence identity of these regions is 97.9%, and over 88% of these regions overlap with segmental duplications. Almost half of these regions overlap RefSeq genes representing potential sites of functional significance. Genes related to the immune system and response to stimuli are overrepresented in these regions, and, in some cases, these loci are also enriched for structural variants. One particularly dramatic and complex region of variation in the human genome is the 17q21.31 inversion locus. The H2 (inverted) haplotype is found primarily in Europeans where its nucleotide diversity is limited when compared to other H2 haplotypes but increased when compared to the H1 (direct orientation) haplotype suggesting an ancient coalescence. H2 haplotypes do exist in non-European populations; however, neither the distribution of this haplotype nor the nucleotide diversity has been explored. Using capillary-based sequencing and 454 technologies, we have directly resequenced 238 fosmid clones from 46 of these highly divergent regions, including the 17q21.31 locus. The average size of the genomic intervals is approximately 120Kb, and all but 4 of the selected regions overlap a RefSeq exon. Six of the regions were sequenced in 8 of the individuals, and the remaining 40 were sequenced in one or two individuals. We have annotated single nucleotide variants that have not been previously identified by the HapMap or 1000 Genomes projects. Additionally, we present data from genotyping assays used to assess the distribution of these variants across a diverse sampling of populations.

1928/F

Development and validation of genotyping assays for functional SNPs in the FC gamma receptor family genes. *S. Cottrell[1], C-P. Huang[1], L. Young[2], J. Dell'Aringa[1], Y. Pan[1].* 1) Molecular Sciences, Amgen, Inc., Seattle, WA; 2) Molecular Sciences, Amgen, Inc., Cambridge, MA.

Five highly homologous FC gamma receptor genes are located in a 200kb region of chromosome 1 (1q23). The products of these genes are receptors expressed on immune effector cells that bind the FC region of IgG antibodies to direct destruction of target cells. Several of these genes contain polymorphisms that affect receptor function, and the polymorphisms have been associated with incidence of diseases (including systemic lupus erythematosus, rheumatoid arthritis, coronary artery disease, asthma) and response to therapeutic antibodies (including rituximab, cetuximab, and trastuzumab). However, research on the phenotypic effects of the alleles has been hampered by the extremely high homology among the genes, linkage disequilibrium in the region, and a reliance on slow, labor-intensive assays. We have developed and validated allelic discrimination assays for SNPs in FCGR3A (rs396991) and FCGR2A (rs1801274), both of which have alleles encoding high and low affinity versions of the receptors. In both cases, primers were designed to specifically amplify the gene of interest by targeting the rare sequence difference between the gene of interest and family members, and the genotype is interrogated by the probes. The accuracy of the assays was confirmed by sequencing 24 donor samples. The call rate for both assays is greater than 95 percent, and we confirmed that copy number variations were the major cause of failed genotype determinations. Robustness, reproducibility, and sensitivity (DNA input amount) were also included in the assay validation in preparation for analysis of clinical trial samples. We tested the assays on a panel of 166 genomic DNA samples and found linkage disequilibrium between the loci (D'=0.39), with significant non-random association of the allele for the high affinity FC gamma receptor 3A with the allele for the high affinity FC gamma receptor 2A (chi square test, p value <0.0001). In conclusion, we have developed high throughput validated assays for SNPs in the FCGR2A and FCGR3A genes that are suitable for analysis of clinical trial samples. Furthermore, we have demonstrated incomplete linkage disequilibrium between the genes, suggesting that both genes need to be genotyped for assessment of association with the phenotype of interest.

1929/F

Korean Genome-Wide Association Studies for Type 2 Diabetes and its related traits identify two independent loci at 12q24. *M. Go[1], Y. Kim[1], J. Lee[1], B. Han[1], H. Kim[1,2], Y. Cho[1].* 1) Center for Genome Science, Seoul 122-701, Korea; 2) Department of Biochemistry, School of Medicine, Ewha Womans University, Seoul 158-710, Korea.

Type 2 diabetes (T2D) is one of major public health problems with its rapidly rising incidence and prevalence worldwide. Nineteen genetic loci showing strong evidence of association with T2D have been identified to date by linkage, candidate gene and GWA approaches. Most of T2D loci were detected from European samples except KCNQ1 which was from East Asian. In this study, we conducted Korea genome-wide association study (GWAS) to identify susceptibility loci to type 2 diabetes (T2D) in 1,042 cases and 2,943 controls in the Korea Association Resource (KARE) study. Nine promising GWAS signals were replicated in 1,216 cases and 1,352 controls from the independent population. Seven of nine signals have been reported for its association with T2D mostly in European populations, while two located in chromosome 12 are newly identified in our study. T2D association to these loci was corroborated by the strong evidence of association for increased fasting glucose levels and reduced beta-cell function as measure by homeostasis model assessment in combined analysis with a total of 14,232 non-diabetic individuals comprising 7,696 GWA and 6,536 replication study subjects. Interestingly, strong associations of two novel loci with T2D and its related traits were only detected in men but not in women, implying gender-specificity of these loci.

1930/F

A survey of the genetics of gene expression in four metabolic tissues from a morbidly obese cohort. *D.M. Greenawalt[1], R. Dobrin[2], E. Chudin[3], I.J. Hatoum[4], C. Suver[3], J. Beaulaurier[3], B. Zhang[3], V. Castro[4], J. Zhu[3], S.K. Sieberts[3], S. Wang[3], C. Molony[1], S.B. Heymsfield[2], D.M. Kemp[2], M.L. Reitman[2], P. Yee Lum[3], L.M. Kaplan[4], E.E. Schadt[3].* 1) Merck & Co., Inc., Boston, MA; 2) Merck & Co., Inc., Rahway, NJ; 3) Rosetta Inpharmatics, Seattle, WA; 4) Weight Center, Massachusetts General Hospital, Boston, MA.

For individuals who suffer from extreme obesity (BMI > 40 kg/m2) surgical interventions such as Roux-en-Y gastric bypass can have a great effect not only on weight but co-morbidities as well. To characterize the molecular components associated with morbid obesity and response to RYGB, we have performed high-throughput genotyping and gene expression profiling in 4 tissues; liver, omental adipose, subcutaneous adipose and stomach, from approximately 1000 patients undergoing Roux-en-y gastric bypass and collected clinical traits associated with weight loss. This data has not only allowed us to calculate the association between clinical weight traits and genetic polymorphisms from individuals suffering from extreme obesity to identify associations to BMI and leptin; but to also calculate the association between SNPs and gene expression of 4 metabolically relevant tissues, to identify expression SNPs (eSNPs). We successfully identified 24,531 eSNPs corresponding to ~10,000 distinct genes. This represents the greatest number of eSNPs identified to our knowledge by any study to date and the first study to identify eSNPs from stomach tissue. We then demonstrate how these eSNPs provide a high quality disease map for each tissue in morbidly obese patients to not only inform genetic associations indentified in this cohort, but in previously published genome wide association studies as well. eSNP data generated from this study of 4 metabolically relevant tissues will aid in informing current and future GWA studies, and provide a path forward to pinpointing genes and associated gene networks of interest responding to genetic perturbations associated with disease.

1931/F

Genome-wide association study identifies sequence variants associated with hematological traits in Asian population. *Y. Kim, J. Oh, Y. Kim, M. Go, Y. Cho.* Center for Genome Science, Seoul, Korea.

To identify genetic loci influencing hematological traits (such as platelet count, white blood cell (WBC) count, red blood cell (RBC) count, hematocrit and hemoglobin concentration), we conducted a genome-wide association study (GWAS) of 8,842 subjects recruited from population-based cohorts in Korea. Replication from independent population (N=7,861) to validate GWAS results revealed SNPs reaching genome-wide significance for selected hematological traits. We identified significant associations between platelet count and genetic variants in four regions on chromosome 4p16.1 (Pcombined = 1.46 × 10-10, in KIAA0232), 4q25 (Pcombined = 6.68 × 10-12, in or near EGF), 12q24.12 (Pcombined = 1.11 × 10-15, in SH2B3) and 6p21 (Pcombined = 1.69 × 10-7, in BAK1). GWAS for WBC showed strong evidence of genetic association on 17q21.1a (Pcombined = 1.1 × 10-16) which contains CSF3 gene. Blood hemoglobin concentration was significantly associated with one region on 22q12.3d (Pcombined = 2.2 × 10-8) localizing to TMPRSS6 that is required to sense iron deficiency. Two SNPs were detected for their association with RBC from GWAS (RBC data not available in replication subjects). One (P = 8.6 × 10-9) is located on 6p21.1f in MED20 encoding a component of the mediator complex. The other (P = 3.3 × 10-12) localizes to 4q12 surrounded with several genes (CHIC2/GSX2/PDGFRA/KIT). Interestingly, One locus located on 6q23.3a near MYB showed strong association with WBC (Pcombined = 5.7 × 10-7), RBC (P = 3.8 × 10-25) and hematocrit (Pcombined = 5.1 × 10-9). This locus is known to play an important role in proliferation and differentiation of hematopoietic progenitor cells. Our findings might enhance to unravel molecular mechanisms underlying these hematological traits.

1932/F

Novel genetic variants behind blood biochemical traits identified by a large-scale meta-analysis in Korean population. *Y. Kim[1], M. Go[1], C. Hong[1], J. Lee[1], B. Han[1], H. Kim[1,2], Y. Cho[1].* 1) Center for Genome Science, Seoul 122-701, Korea; 2) Department of Biochemistry, School of Medicine, Ewha Womans University, Seoul 158-710, Korea.

During the last decade, there were flood of published documents finding the evidence of genetic influence on the variation of phenotypes. Genome-wide association studies (GWAS) have been very successful for identifying susceptible loci influencing several traits in populations with European ancestry. However, GWAS in populations of Asian or African ancestry have been insufficiently represented. Here we present a large-scale effort to look for the genetic loci responsible for the phenotypic variation in blood biochemical traits. Identifying genes responsible for the variation of blood biochemical traits is beneficial to understand the underlying mechanisms of the complex diseases since the levels of biochemical measurements in blood are highly correlated with several complex diseases. Furthermore, the highly heritable nature of these traits revealed from numerous previous studies makes these traits attractive for genetic association studies of diverse phenotypes. Several SNPs revealed the evidence of association with one or more of 14 quantitative traits related to phenotypes such as plasma glucose level, lipid metabolism and hepatic and renal functions from discovery stage meta-analysis combining two independent GWASs of 12,500 samples. Those SNPs taken forward to replication stage analysis were mostly validated in the independent poplation of 7,500 samples. Replicated signals achieving genome-wide significance (P < 5 X 10-8) from overall meta-analysis comprising about 20,000 Korean individuals include previously known loci from European or Japanese GWASs for blood biochemical traits as well as ones newly identified in this study. Fifteen novel loci locate to CUX2 and C12orf51 for high density lipoprotein cholesterol, ABO for low density lipoprotein cholesterol, SIX2-SIX3 for fasting plasma glucose, PLCXD2 and PSMA1 for renal traits, and CUX2, OAS3 and HNF1A for hepatic traits.

1933/F

Genotype stability of highthroughput genotyping microarray using Epstein Barr Virus-Transformed B-Lymphocyte Cell lines. *J. Oh, Y. Kim, J. Jeon, Y. Cho.* Center for Genome Science, Seoul, Korea.

The highthroughput SNP (single nucleotide polymorphism) genotyping microarray has greatly contributed to genome wide association studies (GWAS) for identifying human disease susceptibility loci. Although primary cells or tissue samples are major resources to collect genomic DNA for genotyping, major problem arises when encounter its limited access to primary cells or tissue samples. Due to the insufficiency of the primary cells or tissue samples, the Epstein-Barr Virus (EBV)-transformed lymphoblastoid cell lines (LCL) are promising alternative choice for genomic DNA extraction. Previously, Herbeck et al. reported fidelity of SNP array genotyping using immortalized cell lines. In this study we aimed not only to confirm Herbeck's findings but also to test genotype stability of LCL at different propagation stages in terms of cell passages. We genotyped peripheral blood mononuclear cell (PBMC) and LCLs at 6 different passages of 20 different individuals using Affymetrix SNP 500k genotyping chips. Six LCL samples were generated from long-term subcultures up to a passage number of 160. We extensively monitored the concordance between PBMC and LCL at each propagation stage in terms of identity-by-state (IBS). Our finding shows no significant difference in genotypes between PBMC and all types of LCL samples, suggesting that LCL samples at any stage of propagation may be the trustworthy DNA source for SNP genotype analysis.

1934/F

Initial results from dense SNP genotyping of the 9q22-q31 CRI in ASP from the NIMH and NCRAD cohorts. *R. Perry[1], H. Wiener[1], R.C.P. Go[1,2].* 1) Dept Epidemiology, Univ Alabama at Birmingham, Birmingham, AL; 2) Pacific Health Research Institute, Honolulu, HI.

Background: Linkage scans of Alzheimer's Disease (AD) families by us and others have identified the 9q22 region as a candidate region. Next to the 19q13 peak where *APOE* is located, the 9q22 signal was the most suggestive from the linkage scan of the NIMH Alzheimer's Disease Genetic Initiative (ADGI) family cohort. Follow-up confirmation of this signal was demonstrated when we genotyped additional microsatellite markers, narrowing the 1 LOD region to 11.5 cm. Four candidate genes located between 2-6 Mb proximal to this peak have been reported from candidate gene and genome wide association studies to be significantly associated with AD. We have confirmed the association of one of these genes, *NTRK*2, in a separate set of families from NCRAD. Methods: In order to confirm and more precisely determine the nature and location of these signals, we have performed dense SNP genotyping of the 9q21-9q31 region. This covers a total of 18 Mb which includes the 9q22 candidate region and the proximal 6 Mb where these four candidate genes are located. Haplotag SNPs and unblocked SNPs were chosen from HapMap. Additional SNPs located in reported CNVs from this region were also identified and chosen, resulting in a total of ~ 5800 SNPs. These were genotyped using the iSelect platform from Illumina. Results: Using Family Based Association Testing, more than one signal reached the level of significance. We are currently validating these signals and determining their functional significance. Additionally, we are investigating suggestive evidence for the presence of CNVs. Conclusion: Dense SNP genotyping of the 9q22 candidate region and six Mb of genome proximal to the candidate region identified signals with significant association to AD in ASP from NIMH and NCRAD cohorts. There may also be suggestive evidence of CNVs present. We are in the process of determining if these signals are valid or if they are in LD with additional variants. Significance of these results and follow-up strategy will be presented at the meeting.

1935/F

dbSNP and dbVar: NCBI Databases of Simple and Structural Variations. *L. Phan, M. Ward, G. Yu, H. Zhang, A. Vinokurov, M. Quintos, M. Kholodov, D. Shao, E. Shekhtman, R. Maiti, J. Lopez, T. Hefferon, J. Garner, A. Mardanov, D. Church, L. Forman, D. Maglott, M. Feolo, S. Sherry.* NCBI, National Institutes of Health, Bethesda, MD.

The National Center for Biotechnology Information (NCBI) creates and maintains a set of databases that archive, process, display and report information related to germline and somatic variants from multiple species. These databases, primarily the Database of Single Nucleotide Polymorphisms (dbSNP), the Database of Genomic Structural Variations (dbVar), and the Database of Genotypes and Phenotypes (dbGaP) are integrated with NCBI resources including Gene, GeneTests, OMIM, PubMed, and Nucleotide. This presentation focuses on dbSNP and dbVar, summarizing current function and highlighting recent improvements. The primary roles of both databases are the archival and processing functions. Each submission is assigned a database identifier (dbSNP ss# or dbVar nsv#/esv#) based either on flanking invariant sequence or locations asserted on reference sequences. These submissions are then processed to aggregate information from multiple submitters (assign rs# in dbSNP) and to calculate locations on each version of a genome, RefSeqGenes (LRG), and other NCBI Reference Sequences (RefSeqs). Because these stable public accessions are citable in publications, they facilitate aggregation of information as diverse populations are tested for variation. Researchers and genetic testers are encouraged to submit their variation data and to cite their submissions in manuscripts and on the web. Once data are accessioned, they are made available in diverse ways: Entrez searches, study-specific reports, annotation on the genome, human gene-specific displays such as Variation Viewer, and ftp transfer. This presentation will highlight recently added search and display options and new variation FTP downloads such as for the Variant Call Format (VCF) reports and human gene-specific reports. dbSNP and dbVar represent millions of human variants, with more than 7 million having minor allele frequency > 0.05 in at least one population and more than 5 million validated by genotyping. They also contain thousands of records with possible 'clinical significance'. Data are integrated from large scale international projects such as the Human Genome Project, International HapMap Consortium, DGV/DGVa, 1000 Genomes Project, and from highly-curated Locus Specific Databases (LSDBs), OMIM, the literature, or other gene-specific resources. Given our ever-increasing need for understanding of human variation, maintenance and effective use of centralized variation databases is critical.

1936/F

Confirmation of *CNTNAP2* as an autism susceptibility gene. *S. Sampath, S.S. Bhat, B. Doan, D.E. Arking, A. Chakravarti.* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

The pathophysiology of autism, a childhood neuropsychiatric disorder, remains largely unknown despite a strong genetic component to disease susceptibility. In a previous genomic study of autism we identified a common sequence variant (rs7794745) in intron 2 of contactin associated protein-like 2 (*CNTNAP2*) that was linked and associated with autism susceptibility. Other independent studies have also pointed to the role of common, rare, and structural variants in *CNTNAP2* in autism susceptibility. To further characterize the role of *CNTNAP2* in autism, we studied polymorphisms at a high density across the »3 Mb of the *CNTNAP2* locus. We genotyped 400 trios each from multiplex and simplex families using a custom genotyping array that included 3,150 SNPs. Because the custom array was designed for allelic rather than dosage discrimination, it precluded the efficient use of raw intensities from each SNP for copy number analysis. For statistical analysis we removed SNPs based on missing data (> 0.10), minor allele frequency (< 0.05), Hardy Weinberg fit ($p < 0.001$), and Mendelian errors (> 0.10). We analyzed 2100 SNPs using a transmission disequilibrium test (TDT). Additionally, the presence of contiguous Mendelian errors within each family was evaluated to identify deletions. TDT analysis performed in either multiplex or simplex families alone did not yield any significant finding. However, combining the data from both multiplex and simplex families yielded two SNPs (rs2710093, $p = 1.1 \times 10^{-5}$; rs2253031, $p = 2.5 \times 10^{-5}$) with significant effects at *CNTNAP2*. Both SNPs were located in intron 14 and are highly correlated with each other ($r^2 = 0.99$). The overtransmission of the rs2710093 'C' allele ($\tau = 0.61$) had a significant parent-of-origin effect from the paternal than maternal side ($\tau_{pat} = 0.66$, $\tau_{mat} = 0.56$, $p = 0.0043$). rs2710093 is »57 kb downstream of, and in a different LD block from, SNPs rs2710102 and rs17236239 that have shown significant effects in two previous studies of association to the autism endo-phenotypes of language QTL (age at first word) and specific language impairment. We are currently genotyping additional autism families to confirm this finding. Analysis of large contiguous Mendelian errors within each family did not indicate any segregating deletions or duplications. Cumulative evidence from this and previous autism studies now confirm that multiple common, rare, and structural variants in *CNTNAP2* play a significant role in autism.

1937/F

Evaluation of the performance of genomic DNA from saliva collected with Oragene®•DNA for the purpose SNP discovery on various Illumina technologies. *M.A. Tayeb[1], R.M. Iwasiow[1], P. Hu[2], R.F. Wintle[2], S. Scherer[2].* 1) DNA Genotek Inc., Ottawa, ON, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada.

Genome-wide association studies allow for rapid scanning of markers across entire genomes. The Illumina Human610-Quad and Human1M-Duo BeadChips include more than 600,000 and 1.1 million markers for single nucleotide polymorphism analysis per sample, respectively. The current study evaluates the use of gDNA from saliva collected with Oragene•DNA on the Illumina Human610-Quad Human1M-Duo BeadChips. Oragene•DNA simplifies sample collection by providing an alternative to blood, eliminating phlebotomy cost and complexity and facilitating collection from subjects dispersed throughout the general population. Oragene•DNA is a non-invasive, self-collection device intended for collection of large quantities of high-molecular weight genomic DNA (gDNA) from saliva. DNA is stabilized at room temperature for extended periods enabling sample collection and transport via regular mail and flexibility to process in batches. Two saliva samples were collected from each of four donors on two separate days using the Oragene•DNA kit and the gDNA extracted from each of these collections was analyzed. Performance of the gDNA from saliva was assessed by evaluating the SNP calls from each sample. Reproducibility of the data was determined by comparing the results from two separate collections from the same donor (Human1M-Duo BeadChip only). We report QC call rates >98.8% on the Human610-Quad and >99.8% on the Human1M-Duo. The standard deviation of log R ratio (SDLRR) of all saliva samples was <0.4 for the Human610-Quad and <0.2 for the Huaman1M-Duo. Concordance between separately-collected saliva samples was >99.8% (Human1M-Duo). Concordances between blood and saliva samples from the same donor were >99.9% and >99.8% on the the Huaman610-Quad and Human1M-Duo, respectively. The results indicate that gDNA isolated from saliva collected with Oragene•DNA is a suitable substitute for gDNA from blood for use on Illumina SNP discovery technologies.

1938/F

A common variant on chromosome 5q33.3 is associated with susceptibility to systemic lupus erythematosus in Chinese Han population. *Y. Ren[1,2], Y. Li[1,2], Z. Zhang[1,2], J. Han[1,2], L. Sun[1,2], S. Yang[1,2], X. Zhang[1,2].* 1) Key Laboratory of Dermatology (Anhui Medical University), Ministry of Education, China, Hefei, Anhui 230032, China; 2) Institute of Dermatology and Department of Dermatology at No.1 Hospital, Anhui Medical University, Hefei, Anhui, China.

Background: Systemic lupus erythematosus (SLE) is a systemic autoimmune disease characterized by the presence of autoantibodies and by the anatomical and functional damage of multiple organs. The pathogenesis of SLE is complex and involves a combination of multiple genetic and environmental factors. During the past 20 years, many studies have identified multiple genetic factors related to SLE. However, these studies were mainly conducted on European popu=AClations and less performed in other ethnic populations. In fact, the genetic heterogeneity between ethnic populations has been suggested to be important in SLE risk. For example, the single nucleotide polymorphism (SNP) rs2431697T on chromosome 5q33.3 has been shown to be associated with SLE in European populations, but not been studied whether being a risk factor in other ethnic populations. Objective: To investigate whether the SNP rs2431697 on 5q33.3 is also a risk factor for SLE of Chinese Han. Method: EDTA anticoagulated venous blood samples were collected from all partici=ACpants (1,993 SLE cases and 4,770 controls). Genomic DNA was extracted from peripheral blood lymphocytes by stand=ACard procedures using FlexiGene DNA kits and was diluted to concentrations of 15-20ng/ul for the validation study. The SNP was genotyped using the Sequenom MassArray system. The SNP rs2431697 was tested for significant deviation from Hardy-Weinberg equilibrium in controls and it passed the test with P-values >0.05.The association between the SNP rs2431697 and disease susceptibility to SLE was assessed using the Chi-square test with 2×3 and 2×2 contingency tables. Result: The SNP rs2431697T on 5q33.3 was found to be associated with SLE (P=6.27×10-11, odds ratio (OR) = 1.43 on the major allele, 95% confidence interval (95% CI): 1.28-1.59). Conclusion: We confirmed that the SNP rs2431697T on 5q33.3 was also associated with SLE in Chinese Han population, which suggested that it might be a common susceptibility factor for SLE within different populations.

1939/F

Follow up study identifies two novel susceptibility loci for systemic lupus erythematosus in Chinese Han population. *S. Yang[1,2], Y. Li[1,2], Z. Zhang[1,2], J. Han[1,2], L. Sun[1,2], X. Zhang[1,2].* 1) Key Laboratory of Dermatology (Anhui Medical University), Ministry of Education, China, Hefei, Anhui 230032, China; 2) Institute of Dermatology and Department of Dermatology at No.1 Hospital, Anhui Medical University, Hefei, Anhui, China.

Background: Systemic lupus erythematosus (SLE) is an autoimmune disease characterized by dysregulated immune responses mediated by T and B cells, leading to increased production of pathogenic autoantibodies, against several self antigens. The etiology of SLE might include genetic and environmental factors. In past two years, six genome wide association study (GWAS) of SLE have been published, which identified more than 30 susceptibility genes or loci for SLE and confirmed some of genes found by candidate gene study. In 2009, we have completed a GWAS of SLE in Chinese Han population, and identified 9 new susceptibility loci, as well as confirmed 8 reported ones in previous study. Objective: To investigate additional potential genetic variants for SLE in Chinese Han population. Method: We re-analyzed the GWAS data and selected 72 SNPs, which were genotyped in 3,152 cases and 7,050 controls of Chinese Han using the Sequenom MassArray system. For the each replication study, 72 SNPs were analyzed using the logistic regression (gender as a covariate). The joint analysis of the combined GWAS and replication samples was performed by using logistic regression (gender and sample cohorts as covariates). Results: Two susceptibility loci were validated and surpassed genome-wide significance in combined analysis with GWAS data, which located at 16q11 (P=1.352×10-9,) and 2p23 (P=3.91×10-8). Conclusion: By follow up GWAS dataset, this study identified two novel loci (16q11 and 2p23), which should expand the catalog of genetic factors for SLE and throw new insights into the pathogenesis to the molecular level.

1940/F

Follow up study identifies six novel susceptibility loci for psoriasis in Chinese Han population. *X. Zhang[1,2], L. Sun[1,2], Z. Wang[1,2], H. Cheng[1,2], S. Yang[1,2].* 1) Key Laboratory of Dermatology (Anhui Medical University), Ministry of Education, China, Hefei, Anhui 230032, China; 2) Institute of Dermatology and Department of Dermatology at No.1 Hospital, Anhui Medical University, Hefei, Anhui, China.

Background Psoriasis is a chronic inflammatory hyperproliferative skin disease influenced by multiple genetic factors. The exact etiology of psoriasis is not fully clear so far. In the past several years, genome-wide association study (GWAS) plus linkage and association studies have implicated many genomic regions in the pathogenesis of psoriasis, not all of which have been confirmed. Previously, we have completed a first large GWAS of psoriasis in Chinese Han population, in addition to validating the established susceptibility loci major histocompatibility complex (MHC) and IL12B, we identified a novel susceptibility locus within the late cornified envelope (LCE) gene cluster. Objective To further explore additional susceptibility loci for psoriasis and investigate disease heterogeneity. Methods A follow-up study of psoriasis was performed within multiple populations including 6,634 cases and 10,868 controls in Chinese populations, 539 cases and 824 controls in Chinese Uygur, and 823 cases and 1840 controls of European population. Results Six new susceptibility loci (Pcombined Chinese Han £ 3.78 × 10-8) were identified and one previously reported one for psoriasis (P < 4.55 × 10-18) was validated in Chinese Han. Conclusion Our findings increase the number of genetic risk factors of psoriasis, some of which have also been implicated in other autoimmune diseases. Our results also highlight novel and plausible biological pathways in psoriasis, suggest additional genetic factors that may contribute to its age at onset, and provide insight into genetic heterogeneity of psoriasis across different ethnic populations.

1941/F

Lack of association of telomere length and type-2 diabetes(T2D). *Y. Liu[1], Q. Shen[2], Z. Zhang[2], L. Cao[1], L. He[1].* 1) Institutes Biomedical Sci, Fudan Univ, Shanghai, China; 2) Institute for Nutritional Sciences, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, PR China.

Telomeres are structures at the ends of eukaryotic chromosome and engaged a lot in genomic stability.High oxidative stress potentially leads to accelerated telomere shortening and consequent premature cell senescence,which implicated in type 2 diabetes (T2D) development. Therefore, we conducted association study of leukocyte telomere length (LTL) with the presence of T2D in Chinese Han population.We measured mean telomere length in 1936 patients and 2080 controls using an established and validated quantitative PCR-based technique. In this study, we analysed the LTL adjusted by age,gender,smoking and drinking, telomere length declined by 0.00673 T/S per year (r2 = 0.036, P<0.0001), and is longer in woman than man(r2=0.01,p<0.0001),while no association of T2D presence with telomere length when adjusted (p=0.151). In conclusion, telomere length is unlikely to play a major role in the susceptibility of T2D.

1942/F

High-throughput resequencing of human LINE-1 insertion sites suggests both inter- and intra-individual genetic variation in L1 content. *A.D. Ewing[1], S.R. Richardson[2], J.L. Garcia-Perez[3], J.V. Moran[2,4], H.H. Kazazian, Jr.[1].* 1) Department of Genetics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania 19104, PA; 2) Departments of Human Genetics and Internal Medicine, University of Michigan Medical School, Ann Arbor, Michigan 48109, USA; 3) Andalusian Stem Cell Bank, Center for Biomedical Research, Avda Conocimiento s/n, University of Granada, 18100, Spain; 4) Howard Hughes Medical Institute, Chevy Chase, Maryland 20815, USA.

We previously have reported a high level of inter-individual variation of dimorphic L1 insertions in human genomes, using a technique that locates human-specific L1 insertions by selectively resequencing their 3' genomic flanking regions. Further analysis, aided by cross-referencing with the results of an algorithm that identifies L1 insertions from whole-genome resequencing data, now reveals more extensive L1 variation than recognized previously. We have identified ~500 non-reference L1 insertions present in a collection of 25 individuals (15 of whom are unrelated), after including insertions generated via both techniques. These data represent a substantial addition to a previous report of 367 non-reference L1 insertions in the same cohort.

In addition to inter-individual variation in L1 content, we report evidence for intra-individual somatic variation due to L1 retrotransposition. These data come from two lines of evidence: analysis of cultured cells, including human embryonic stem cells (hESCs), and analysis of trios consisting of a proband and both parents. In cultured cells, we thus far have discovered six L1 insertions that appear to be present in only one clonal line from pairs that were established and propagated from the same parental cell line. Thus, the L1 retrotransposition events likely occurred from endogenous L1 progenitor loci while the cells were in culture. Three L1 insertions are present in clonal PA-1 ovarian embryonic carcinoma lines, whereas the other three insertions are present in clonal H13B hESCs. Two of the three insertions in H13B cells likely are present at less than one copy per genome, as nested PCR was required to amplify the 'filled' insertion sites. Moreover, we uncovered evidence for a sub-genomic insertion in placental tissue derived from a stillborn proband. This L1 insertion was identified by nested PCR in placental DNA derived from the proband, but not from blood-derived genomic DNA samples from either parent. This putative somatic insertion was identified from one of only two studied stillborn trios. Thus, these data suggest that L1 retrotransposition contributes to both inter- and intra-individual human variation.

1943/F

Comparison of tagging and imputation for HLA allele prediction and association testing. *J. Shen[1], S. Leslie[2], S. Bacanu[1], J. Whittaker[3], G. McVean[2], M. Nelson[1].* 1) Genetic, R&D, GlaxoSmithKline, Research Triangle Park, NC, 27709; 2) Department of Statistics, University of Oxford, Oxford Ox1 3TG, UK; 3) Genetic, R&D, GlaxoSmithKline, Harlow, UK.

The major histocompatibility complex (MHC) includes the genes that encode the human leukocyte antigens (HLA) involved in adaptive immune response. HLA genotyping by sequencing is the gold standard, but is expensive and requires relatively large quantities of DNA. Making inferences about HLA associations using SNPs offers a promising alternative. Both tagging and imputation methods have been proposed for HLA allele prediction from SNPs. However, there remains considerable uncertainty regarding the reliability with which these methods can infer HLA alleles from SNPs and the extent to which power to detect HLA associations is eroded when imputation or tagging is used. We compare the ability of single-SNP tagging, single-SNP imputation and multi-SNP hidden Markov model (HMM) imputation to predict high resolution alleles of HLA-A, B, C, DQA1, DQB1 and DRB1 in subjects of European background and the potential power loss in a case-control association testing framework. We find that multi-SNP HMM imputation generally performs better on both common and rare HLA alleles than single-SNP methods. As expected, rare alleles are more difficult to predict by all three methods, requiring standard methods of high resolution typing when such are of pivotal research interest. For some HLA alleles, lower tag SNP predictive values may be offset by relatively high HMM imputation no-call rates, suggesting that a mixed approach to analysis may be most powerful. Overall, we conclude that when sufficient training data are available, exploratory HLA analysis can be carried out using HMM imputation on SNP genotypes with little loss of power. This has considerable importance for the design and analysis of association studies where HLA alleles are believed likely to be important, for instance in pharmacogenetics.

1944/F

Linkage Disequilibrium mapping: why coverage is so much more important than sample size. *W. Lau, N. Maniatis.* Genetics Evolution & Environment, Univeristy College London, London, United Kingdom.

Over the recent years, association mapping of disease genes has developed into one of the most dynamic research areas of human genetics. Establishing the Linkage Disequilibrium (LD) structure of the Human Genome was extremely important for the effective application of association mapping. It was also instrumental for the advancement of genome wide association scans. From the International HapMap Project and other sources, millions of SNP genotypes are now available for constructing high resolution LD maps. Here we compare the maps in LD units that were constructed from the 60 CEU individuals of the Phase II HapMap data and the combined 17,000 individuals from the Welcome Trust Case Control Consortium (WTCCC). We investigate the importance of high resolution and sample size on the genome wide patterns of LD and find that SNP resolution is the main factor in obtaining smaller error variance and finer localization of LD hot and cold spots. These results may have important implications in association mapping.

1945/F

Relationship between fine-scale recombination and Linkage Disequilibrium maps in the human genome. *N. Maniatis, W. Lau.* Genetics Evolution & Environment, University College London, London, United Kingdom.

Recombination is essential for correct chromosome segregation and for increasing haplotype diversity within populations. It is the main determinant of Linkage Disequilibrium (LD) patterns in the genome, which influences our ability to map disease-related loci. The small number of informative meioses in pedigree studies has limited the resolution of linkage maps. A recent study has mapped crossovers in nuclear families using a high-density SNP typing. However, even a much higher resolution profiles of recombination can be obtained from linkage disequilibrium maps based on SNP data from the International HapMap Project. In this study we compare two linkage maps from previous studies that vary on resolution and family size with the maps in LD units (LDU). We investigate the nature of recombination hotspots and the quantitative relationship between cross-over frequency and LDU distance.

1946/F

Admixture mapping of fasting glucose: Identification of a candidate locus associated with T2D. *G. Chen[1], D. Shriner[1], J. Zhou[1], A. Doumatey[1], H. Huang[1], N. Gerry[3], A. Herbert[4], M. Christman[3], G. Douston[2], M. Faruque[2], Y. Chen[2], A. Adeyemo[1], C. Rotimi[1].* 1) CRGGH/NHGRI/NIH, NIH, Bethersda, MD; 2) National Human Genome Center, Howard University, Washington DC 20060 USA; 3) Department of Genetics and Genomics, Coriell Coriell Institute for Medical Research, Camden, NJ 08103 USA; 4) Department of Genetics and Genomics, Boston University School of Medicine, Boston, Massachusetts 02118 USA.

Elevated fasting blood glucose is a feature of type 2 diabetes and insulin resistance. We have carried out a search for novel loci associated with fasting blood glucose (FBG) among African Americans using the mapping by admixture linkage disequilibrium (or “admixture mapping”) approach. Using an ancestry informative marker (AIM) panel comprising 1800 SNPs, the genomes of 619 non diabetic and non hypertensive unrelated African Americans from the Howard University Family Study (HUFS) were screened for regions with elevated ancestry proportions from either of the ancestral populations (reference HapMap YRI and CEU). The mean proportion of African ancestry in the study sample was 0.81 ± 0.10. An increased fasting glucose was associated with increasing proportion of European ancestry with β = 0.087 and p value = 0.044. Using ADMIXMAP, we identified a ~12.36 Mb region (46.49 - 59.85 Mb) on Chromosome 14q22 - 23 associated with FBG with the best p value 6.4x10-5 (rs12895262). Ten AIMs in this region showed Bonferroni corrected p values < 0.05. Repeating the analysis with the STRUCTURE program yielded the similar results. In a follow up fine mapping study, 800 SNPs in this region (average density 9.8 kb) present on the Affymetrix 6.0 SNP array were tested for association with FBG. The best p values were 3.38x10-6 (rs10146136, position 51079426bp, ATL1) and 3.23x10-5 (rs11570807, 50830141bp, CDKL1).In summary, we found that increasing percent of European ancestry was associated with increasing FBG among African Americans. We identified a new locus on chromosome 14q22-23 that influences FBG levels and fine mapping confirmed this association.

1947/F

Direct Assessment of Multiple Testing Correction in Case-Control Association Studies with Related Individuals. *Z. Wang.* Division of Biostatistics, Yale University, New Haven, CT.

Genome-wide association studies typically test large numbers of genetic variants for association with trait values. It is well known that linkage disequilibrium (LD) between nearby markers tends to introduce correlation among association tests. Failure to properly adjust for multiple comparisons can lead to false positive results or miss true positive signals. The Bonferroni adjustment, which ignores dependence among test statistics, is generally conservative in the presence of LD. The permutation procedure, although has been widely employed to adjust for correlated tests, is not applicable when related individuals are included in case-control samples. When relatives are sampled, the dependence among relatives’ genotypes can contribute to the correlation between tests. We present a new method P_{norm} to correct for multiple hypothesis testing in case-control association studies with related individuals. The adjustment with P_{norm} simultaneously accounts for two sources of correlations of the test statistics: (1) LD among genetic markers (2) dependence among genotypes across related individuals. Through simulation studies, we demonstrate that it is more accurate in terms of error rate and more powerful than some of the recently developed methods. We apply the method to a genome-wide association study of alcoholism in the GAW 14 COGA data set and detect genome-wide significant association.

1948/F

Global exon expression analysis of alternative splicing during aging in mice. *S. Rodriguez, M. Eriksson.* Karolinska Institutet, Department of Biosciences and Nutrition, Karolinska University Hospital, Novum, SE-141 83 Huddinge, Stockholm, Sweden.

The severe segmental premature aging disease Hutchinson-Gilford progeria syndrome (HGPS or progeria) is caused by a *de novo* point mutation in exon 11 of the *LMNA* gene. The mutation leads to the activation of a cryptic splice site that removes 150 nucleotides from the prelamin A mRNA and thus results in a truncated prelamin A protein, commonly known as progerin. Recent reports have identified low levels of progerin in normal tissues and that these levels increases during cell aging in cells from both progeria patients and in unaffected controls. We hypothesize that during normal aging, mis-splicing events such as the cryptic splicing seen in progeria could become more widespread all over the genome possibly as a result of a general decline in the stringency of the splicing machinery. To test this hypothesis we have used GeneChip® Mouse Exon 1.0 ST Arrays which provide a unique ability to interrogate global gene expression at the exon level to analyze alternative splicing during aging of C57BL/6 wild-type mice. RNA was extracted from several tissues including skin, skeletal muscle, bone, thymus, and white adipose tissue. Samples were obtained from three different ages of mice, 4, 18, and 28 months. Hybridization data was analyzed using the Partek® Genomic Suite™. Preliminary results have identified a considerable number of genes displaying significant differential alternative splicing with age in all mouse tissues analyzed. Our results suggest that alternative splicing might be affected during tissue aging. As far as we know, this is the first analysis of alternative splicing to be performed on normal aging of animal tissues and highlights the importance of global genome analysis to increase the understanding of genetic mechanisms during aging.

1949/F

Using mouse models for Potocki-Lupski and Smith-Magenis syndromes to study the impact of CNV on behavioral phenotypes. *M. Heney[1], W. Gu[1], C. Spencer[1], R. Paylor[1], J.R. Lupski[1,2,3].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's hospital, Houston, TX.

Many microdeletion/microduplication syndromes are associated with specific abnormal behavioural phenotypes. Potocki-Lupski syndrome (PTLS; MIM #610883) is associated with microduplication in chromosome 17p11.2, and it is characterized by autistic or ASD-like phenotypes, congenital and neurobehavioral abnormalities, and developmental delay. The reciprocal 17p11.2 microdeletion is associated with Smith-Magenis Syndrome (SMS; MIM #182290), a multiple congenital anomaly disorder with neurobehavioral features including aggression and self-injury, as well as mental retardation. We previously generated mouse models for PTLS, *Dp(11)17/+*, and SMS, *Df(11)17/+*, that harbor either a duplication or deletion of a ~2 Mb region syntenic to the PTLS/SMS region. These mouse models recapitulate some of the physical and neurobehavioral phenotypes seen in patients, including abnormal social interactions, motor, and learning defects. This unique mouse model system allows the systematic study of copy number variation (CNV) in relation to specific physical and neurobehavioral phenotypes because *Df(11)17/+*, *Df(11)17/Dp(11)17*, *Dp(11)17/+*, and *Dp(11)17/Dp(11)17*, mice can be analyzed to evaluate the effect of one, two, three, and four copies, respectively, of the SMS/PTLS critical region. In addition, we have developed mouse strains with a point mutation in the major dosage-sensitive gene, RAI1/Rai1, as well as different sized deletions, which allow us to also observe the effect of flanking regions on the CNV manifestation, perhaps through chromatin structure alteration. Utilizing these mouse models, the behavioral phenotypes were studied with a battery of behavioural tests, including the tube, partition, hotplate, 3-chamber, rotarod, conditioned fear, Morris water maze, open field analysis, light-dark, and hotplate tests to determine how CNV of the SMS/PTLS critical region can be linked to behavioural phenotypes. In this study, we confirm previously published results and extend these studies to include new tests and other mouse strains with different-sized deletions. Furthermore, copy number normalization in *Df(11)17/Dp(11)17* mice is examined to determine whether it is able to partially correct the phenotypes examined. Our results indicate that both dosage of RAI1/Rai1 and possibly other modifier genes or elements result in neurobehavioral anomalies, suggesting the presence of gene(s) functioning in the regulation of neurobehavioral pathways in this region.

1950/F

Specific detection of single-stranded DNA in the presences of double-stranded DNA in ChIP-Seq data improves recognition of meiotic hotspots of recombination. *P. Khil[1], F. Smagulova[2], K. Brick[1], I. Gregoretti[1], S. Sharmeen[1], R.-D. Camerini-Otero[1], G. Petukhova[2].* 1) Genetics and Biochemistry Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD 20892; 2) Department of Biochemistry & Molecular Biology, Uniformed Services University of the Health Sciences, 4301 Jones Bridge Road Bethesda, Maryland 20814.

The absence of simple and reliable methods to map recombination hotspots on a genome-wide basis presents a major block to further research on the mechanisms of meiotic recombination in mammals. Existing methods, such as sperm genotyping, do not scale well to allow analysis of whole genomes. One powerful approach for the mapping of protein-bound sequences is chromatin immunoprecipitation followed by next-generation sequencing (ChIP-Seq). We have devised an extension to ChIP-Seq that uses molecular features uniquely found in meiotic hotspots to significantly improve the efficiency of the procedure. Following DSB formation, recessed single-stranded DNA ends are formed at the hotspots. These ssDNA strands are covered with Dmc1 and/or Rad51 proteins. Thus, in the first step we use immunoprecipitation to isolate Dmc1- or Rad51-bound sequences. To improve the specificity of hotspot detection we developed an approach to distinguish single-stranded DNA from double-stranded DNA in sequencing data. The rationale for the method is the following: In the process of library preparation for sequencing single-stranded DNA can form hairpins with 5' overhangs which are extended and filled-in by polymerase. The newly added sequence differs in sequence from genomic DNA but is identical to the reverse complement of the sequence from the other end of the fragment. Thus, the presence of a 5-10 nt transferred sequence indicates that the fragment of the DNA was single-stranded rather than double-stranded. A specific single-stranded DNA signature originates from the hotspots whereas background DNA is largely double-stranded. Compared to standard ChIP-sequencing without an ssDNA detection step, both the sensitivity and specificity can be improved more than ten-fold. We applied our method to map hotspots in the mouse and find that if we use this ssDNA signature, we can map more than 10 thousands hotspots in each of two mouse strains. Another important advantage is the ability to gain insights in the molecular structure of the hotspots. For example, we can distinguish hotspots where DSBs are formed at a single location versus several locations clustered together and precisely define the location of initiating DSBs. In addition to mapping meiotic hotspots, this approach can also be extended to other applications where the detection of single-stranded DNA intermediates is necessary.

1951/F

Acute myeloid leukemia 1 over-expression improves muscle pathology in mdx mice. *SH. Lai[1], R. Shi[1], M. Sutherland[2,3], S. Muger[3], R. Marathi[1], N. Kumari[1], YW. Chen[1,2].* 1) Center for Genetic Medicine Research, Children's National Medical Center, Washington , DC; 2) Department of Integrative System Biology and Department of Pediatrics, George Washington University, Washington DC; 3) Center for Neuroscience Research, Children's National Medical Center, Washington DC.

Duchenne Muscular Dystrophy (DMD) is an X-linked muscle disorder caused by mutations in dystrophin gene. Our previous study showed that acute myeloid leukemia 1 (AML1) was up-regulated in non-symptomatic patients with DMD but not in patients with advanced disease. We hypothesized that AML1 was involved in a compensatory mechanism at the early stage of DMD. To study the role of AML1 in the skeletal muscle and DMD, a tet-repressible muscle-specific Aml1 transgenic mouse model (mCK-tTA/TRE-Aml1) was generated. Over-expression of Aml1 in skeletal muscle does not cause an abnormal phenotype. The mice were then crossed with mdx mice which is a widely used animal model of DMD to generate mCK-tTA/TRE-Aml1/mdx mice. Aml1 over-expression was induced at 2 weeks of age and the muscles of the mCK-tTA/TRE-Aml1/mdx mice were collected 4 weeks afterwards. The muscles of mCK-tTA/mdx littermates were used as controls. To evaluate the pathological changes, Hematoxylin and Eosin staining was performed followed by quantifying the different changes (necrotic fibers, myofibers with centralized nuclei and inflammatory foci). Anti-laminin antibody was used to identify the membrane boundaries when measuring the minimal Feret's diameter. The results showed that the mdx muscles over-expressing Aml1 had fewer myofibers with centralized nuclei than their control littermates ($p < 0.05$). The small-calibre regenerating fibers were less abundant and fiber size variability was reduced in the mice over-expressing Aml1 in both gastrocnemius and diaphragm ($p < 0.05$). To investigate the mechanism, we studied proliferation and differentiation of primary myoblasts from the mice over-expressing Aml1. The results indicated that Aml1 promotes both cell proliferation and differentiation in primary myoblasts.

1952/F

Constitutively Nuclear *Foxo3* in Oocytes of Primordial Follicles Promotes Conservation of Ovarian Reserve. *E. Pelosi[1], S. Omari[1], M. Michel[1], A. Forabosco[2], D. Schlessinger[1], C. Ottolenghi[3].* 1) Laboratory of Genetics, NIA/NIH-IRP, Baltimore, MD, USA; 2) Unita' di Genetica Medica, Universita' di Modena, Modena, Italy; 3) Université Paris Descartes, Paris, France.

During female reproductive life, the number and state of ovarian follicles depends on initial numbers of oocytes and follicles and the subsequent balance of activation, maturation and atresia. By age 50 numbers are depleted, and menopause ensues in women, with the cessation of ovarian function. *Foxo3* is a transcription factor that is required to maintain follicles in a quiescent state. FOXO3 is active in the nucleus, but when phosphorylated, it exits the nucleus and becomes inactive. We made a construct in which critical regulatory sites of *Foxo3* were mutated, so that a transgene would remain constitutively active. The transgene was put into mice under the control of a c-kit promoter, in order to drive its expression preferentially in the oocytes of quiescent follicles. We then tested for effects of the transgene with forced nuclear localization on follicle dynamics. In mouse ovaries 3 days post natum, the activation of primordial follicles was delayed and lesser in extent in the presence of the transgene, accounting for a significantly larger pool of primordial follicles at puberty. This was accompanied by an up-regulation of expression of early follicle genes, and a down-regulation of maturation markers. In transgenic peri-menopausal ("old") mouse ovaries we also observed significant down-regulation of aging-associated markers. At the morphological level, relative follicle counts showed a larger number of primordial and still growing follicles in the old transgenic ovaries. We infer that the transgenic ovaries retained some active folliculogenesis. The transgene was then introduced into knockout (*Foxo3-/-*) mice, i.e., where it is the only *Foxo3* allele present. At 14dpn, a stage at which all primordial follicles had disappeared from *Foxo3-/-* ovaries, ovaries from the mice with the transgene still exhibited primordial follicles. Consistent with a rescue of quiescent follicles, ovaries of the *Foxo3-/-* animals harboring the transgene appeared globally younger in their gene expression profiles, assessed by microarray analysis, than did ovaries from age-matched knockouts. Our study supports proposals that *Foxo3* is a guardian of the primordial follicle reserve, and creates a model that could help evaluate and characterize the function of genetic variants putatively involved in the determination of female reproductive lifespan.

1953/F

Genome & Transcriptome Analysis of Human Genomes: Maximising the Benefits of Next-Generation Sequencing using latest Technologies. *K. Stangier, U. Schoeck.* GATC Biotech AG, Konstanz, Germany.

The Illumina HiSeq 2000 provides the industry's highest sequencing output and quality at fastest data generation rate. This can be optimally used in combination with different paired end and mate pair libraries as well as enrichment strategies. **Genome Re-Sequencing** Illumina sequencing data can be generated by using paired end and mate pair data to identify InDels and SNPs simultaneously in whole human genome sequencing, which is especially useful in cancer research. GATCs prorietary tagging system allows barcoding of samples for the combination of any number of samples with any size of targeted region. Depending on size and number of samples, different enrichment technologies can be applied to sequence a specific subset of the human genome. **Transcriptome Sequencing** Enrichment kits for exons can be customised to target all exons including additional specific regions of interest. Using a proprietary tagging protocol it is possible to multiplex samples for sequencing on Illumina sequencing technologies in order to generate expression profiles from several samples in a cost effective way. For both applications, special bioinformatics analysis tools are used. We will show a variety of visualised results generated from different technical approaches and analysis tools. **Conclusion** High quality results will be achieved when optimally combining several library preparations and Next Gen technologies with state-of-the-art bioinformatics.

1954/F

A secure repository for human sequencing data with rich phenotypes. *M.F. Shumway, E. Yaschenko, S. Sherry, R. Agarwala, M. Feolo, L. Hao, M. Kimelman, G. Godinskiy, C. O'Sullivan, A. Sturcke, A. Mnev, J. Ostell.* National Center for Biotechnology Information (NCBI), National Library of Medicine, Bethesda, MD.

NCBI has developed a controlled access repository for detailed genetic information including sequence and alignment data. This system builds on the existing Genotype and Phenotype archive (dbGaP) infrastructure [1] by placing inside it an instance of the Sequence Read Archive (SRA) [2] specially designed for archiving human sequencing datasets under privacy control, usage restrictions, or ethical constraints. Controlled Access SRA will acquire and distribute data to approved users via dbGaP using existing mechanisms. An important difference between dbGaP and open SRA submissions is that study, subject, and sample metadata and phenotypes must be submitted before sequencing data can be accepted. Controlled Access SRA will archive and distribute human clinical and research sequencing data gathered under subject consent. Controlled Access SRA will also house human meta-genome datasets where a level of human contamination may exist. These datasets can be optionally screened to remove human contaminants and exported to open SRA. The presentation will review the experience of Controlled Access SRA in the context of the first phases of sequencing and alignment data from The Cancer Genome Atlas (TCGA) project [3] and the Human Microbiome Project (HMP) [4]. 1955/F

Accurate imputation and phasing for paired-end read sequencing data with low coverage. *E. Eskin, B. Han.* Dept Computer Sci, Univ California, Los Angeles, Los Angeles, CA.

Many methods have been developed for imputing uncollected genotypes based on the microarray technology, but few methods are available for imputation based on the sequencing technology. To our knowledge, the only imputation method that currently supports sequencing data is MACH. However, MACH uses the simple model that "decouples'' sequence reads into SNP-wise information. This way, if a read or paired-end read covers multiple SNPs, the information that the observed alleles came from the same chromosome, or the partial phasing information, is ignored. If the coverage is low, the partial phasing information can substantially affect the accuracy. The challenge is that it is very difficult to incorporate partial phasing information into the traditional hidden Markov model (HMM). We solve this challenge by introducing a new model, rotating hidden Markov model (RHMM). The key idea is to place the multiple alleles from a read to the one of two chromosomes in the model to keep the partial phasing information, and then allow two states corresponding to the two chromosomes to freely "rotate'' so that no phasing information is imposed between two separate reads. In our simulations using 1x coverage paired-end read data, the imputation accuracy of RHMM is the same as that of HMM, but the phasing accuracy of imputed genotypes dramatically increases from 48% to 87% by an almost 2-fold change. Similarly to the other imputation methods, our method can utilize information from the sample data as well as from the reference data. Our method IMPERS (IMputation for Paired-End Read Sequencing) is publicly available for research community.

1956/F

Resequencing of a patient with inflammatory bowel disease and subsequent evidence-based treatment. *A. Franke[1], I. Thomsen[1], M. Schilhabel[1], P. Rosenstiel[1], S. Schreiber[1,2].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University Kiel, Kiel, Germany; 2) Department of General Internal Medicine, University Clinic S.-H., Kiel, Germany.

Resequencing entire individual patient genomes has become technologically and economically feasible. While several projects have so far demonstrated the successful application of genome resequencing in the field of cancer genetics as well as monogenic diseases, much (>50%) of the heritability for complex (polygenic) chronic inflammatory diseases remains to be discovered. Hence, we have started to resequence the entire genome of a patient with inflammatory bowel disease using the SOLiD system. The patient has not yet responded to any available treatment for the disease and has undergone multiple surgeries. Based on the first genetic findings and subsequent studies, an individual treatment was designed that later proved to be successful. The full experiment with the final sequencing data will be presented at the conference.

1957/F

Re-sequencing of the entire HLA region for informative polymorphism detection and haplotype map construction. *K. Hosomichi, T. Shiina, T. Wang, S. Suzuki, H. Inoko, I. Inoue.* Molecular Life Science, Tokai University School of Medicine, 143 Shiokasuya, Isehara, Kanagawa, Japan.

The human leukocyte antigen (HLA) super-locus on the chromosomal position 6p21 includes six classical HLA genes and at least 132 protein coding genes that play important roles for the regulation of the immune system as well as some other fundamental molecular and cellular processes. This small segment of the human genome associates with more than 100 kinds of diseases including common diseases such as diabetes, rheumatoid arthritis, psoriasis, asthma and various other autoimmune disorders. Furthermore, the HLA region strongly associates with some drug hypersensitivities. Primary aim of the HLA re-sequencing is to provide reference sequences of the most common representative HLA haplotypes in the Japanese and other populations. The 3.8-Mb entire HLA region from *MOG* to *KIFC1* were amplified by using 447 long-range PCR (LR-PCR) primer sets. We performed the LR-PCR reactions using genomic DNA of seven Japanese HLA homozygous cell lines - AKB, TOK and T182 (A24-B52-DR15), HOR (A33-B44-DR13), SA (A24-B7-DR1), LKT3 (A24-B54-DR4) and TAB089 (A2-B46-DR8) representing the highest (8.2%), second highest (5.2%), third highest (3.6%), fourth highest (2.3%), and fifth highest (2.2%) haplotype frequency, respectively, within the Japanese population. The PCR amplified products were sequenced by Genome Analyzer (Illumina). Paired end DNA library preparation and sequencing-by-synthesis methodology followed the manufacturer's instructions (Illumina). Reads were mapped to UCSC hg18 (NCBI Build 36) human reference genome and the chr6 alternate haplotype sequences (PGF, COX) in the Wellcome Trust Sanger Institute MHC Haplotype Project. Average depth of the genome coverage on the seven HLA homozygous cell lines (AKB, TOK, T182, HOR, SA, LKT3 and TAB089) was 178x, 122x, 136x, 64x, 301x, 91x and 220x, respectively, and percentage of the genome coverage was 98.2%, 89.7%, 91.1%, 95.6%, 95.6%, 94.6% and 95.9%, respectively. Data derived from each genome were sorted to lists of sequence variants (SNPs and short indels) in basis on score values as a measure of SNP call accuracy. Identification of the variants relating to common disease susceptibility is critically depended on general informative polymorphism and haplotype map information. Our future aim is to produce these critical data and to develop them publicly available as a general resource for the HLA-linked disease studies.

1958/F

Genotyping and resequencing identified *HLA-DPB1* locus as a susceptibility to non-obstructive azoospermia in Japanese patients. *S. Suzuki, K. Hosomichi, T. Wang, T. Cui, S. Mitsunaga, H. Inoko, T. Shiina, I. Inoue.* Molecular Life Science, Tokai University School of Medicine, 143 Shimokasuya,Isehara, Kanagawa, Japan.

Worldwide, approximately 15% of couples attempting pregnancy meet with failure. Male factors are thought to be responsible in 20-50% of all infertility cases. Azoospermia, the absence of sperm in the ejaculate due to defects in its production or delivery is common in male infertility. In this study, we focused on non-obstructive azoospermia (NOA) because the etiologies of obstructive azoospermia are well studied and distinct from those of NOA. Microdeletions of the Y chromosome are thus far the only genetic defects known to affect human spermatogenesis, but most cases of NOA are unsolved. Thus far, we reported significant associations between NOA and *HLA* (human leukocyte antigen) *-DQB1*0604* with odds ratio 3.58 in a relatively small sample size. In the current study, we performed the HLA genotyping (*HLA-A*, *-C*, *-B* and *-DRB1*, *-DQB1*, *-DPB1*) between 355 NOA patients and 544 male controls. As a result, we identified a strong association with *HLA-DPB1* locus locating 409kb upstream of *DQB1*: the strongest association was observed with *DPB1*0401* (P=5.15x10^{-7}) having the highest odds ratio (OR=2.42). We are uncertain whether *DPB1*0401* is a true causality of NOA or merely a surrogate because of the high linkage equilibrium. Therefore, we further resequence the locus with the next generation sequencer (illumina Genome Analyzer IIx) to identify a variation that could be an authentic causality of NOA. We used genomic DNA extracted from six NOA patients who harbor *HLA-DPB1*0401* as a heterozygote. We specifically amplified the loci spanning *HLA-DQB1* to *KIFC1* (750 kb) using a long PCR method. As a result, we detected a total of 828 variations (42 in exons, 314 in introns, 55 in untranslated regions, and 417 intergenic) from six patients. Among those, there were 117 variations (9 in exons, 39 in introns, 7 in UTR, and 62 in intergenic) that could be on the same haplotype with *DPB1*0401* (minor allele frequency > 30%). Six nonsynonymous substitutions of nine SNPs in exons were detected but all of them were known variations. We also detected 16 novel variations, however, they were not located on exon (one in intron, three in UTR, and 12 in intergenic). In conclusion we identified *HLA-DPB1*0401* as a susceptibility allele to NOA that may play a decisive role in the pathogenesis of NOA. Further replication study in different populations for confirmation is needed.

1959/F

ANNOVAR: functional annotation of genetic variants from high-throughput sequencing data. *K. Wang[1], M. Li[2], H. Hakonarson[1,3].* 1) Center Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA 19104, USA; 2) Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA 19104, USA; 3) Department of Pediatrics, University of Pennsylvania, Philadelphia, PA 19104, USA.

High-throughput sequencing platforms are generating massive amounts of genetic variation data for diverse genomes , but it remains a challenge to pinpoint a small subset of functionally important variants. To fill these unmet needs, we developed the ANNOVAR tool to annotate single nucleotide variants (SNVs) and insertions/deletions, such as examining their functional consequence on genes, inferring cytogenetic bands, reporting functional importance scores such as SIFT scores, finding variants in conserved regions, or identifying variants reported in the 1000 Genomes Project and dbSNP. ANNOVAR can utilize annotation databases from the UCSC Genome Browser or any annotation dataset conforming to Generic Feature Format version 3 (GFF3). We also illustrate a "variants reduction" protocol on 4.7 million SNPs and indels from a human genome, including two causal mutations for Miller syndrome, a rare recessive disease. Through a stepwise procedure, we excluded variants that are unlikely to be causal, and identified 20 candidate genes including the causal gene. Using a desktop computer, ANNOVAR requires ~4 minutes to perform gene-based annotation and ~15 minutes to perform variants reduction on 4.7 million variants, making it practical to handle hundreds of human genomes in a day. ANNOVAR is freely available at http://www.openbioinformatics.org/annovar/.

1960/F

Exome resequencing in a densely affected multigenerational SLE pedigree. *G. Wiley[1], C.P. Lin[1], I. Adrianto[1], J. Kelly[1], K.L. Moser[1], K.K. Kaufman[1,2,3], J.B. Harley[2,3], C. Gray-McGuire[1], P.M. Gaffney[1].* 1) Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) The University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) Oklahoma City VA Medical Center, Oklahoma City, OK.

Systemic lupus erythematosus (SLE) is a complex autoimmune disease that has heretofore been the subject of intense genetic scrutiny. While genome-wide association studies in SLE have successfully identified approximately 30 new risk loci the low odds ratios of associated loci leave a substantial portion of the estimated heritability of SLE unexplained. By comparison, the high odds ratios of highly penetrant rare polymorphisms (e.g. *TREX1*, OR=25) suggest the possibility that some of the missing heritability of SLE may exist in the form of rare variants. To begin to explore the role of rare variants in SLE susceptibility we resequenced the exome in a unique, densely affected multigenerational SLE pedigree with 7 affected individuals. A densely affected pedigree was specifically chosen with the assumption that rare variations conferring higher SLE risk are more likely to be represented within such a family as opposed to the general population. The entire exonic region for the individuals within this family were captured through the use of the Agilent SureSelect sequence capture system and sequenced to 15x coverage using an Illumina GAIIx second-generation sequencer. Assembly of sequence to reference, variant calling, and other analysis were carried out using the CLC Genomics Workbench bioinformatics suite. Variants were verified with Illumina Omni1 Quad genotyping assays. Identified variants were screened using effect on protein function as determined by the SIFT algorithm. Over 1700 coding variations were identified as shared between all case subjects within the family with approximately 40% encoding a nonsynonymous amino acid change. Of these amino acid changes approximately 7% are predicted to be damaging to the encoded protein. We have identified several nonsynonymous changes in proteins previously associated with SLE (*TNIP1*) as well as in loci not previously implicated in SLE including *NFKBIL1* and *NOTCH1*.

1961/F

Candidate Gene Identification for Distinct Mendelian Disorders Using Exome Resequencing. *V. Schaibley[1], W. Peng[1], J. Xu[1], J. Bedoyan[2], C. Keegan[1,2], D. Martin[1,2], J. Li[1].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Pediatrics, University of Michigan, Ann Arbor, MI.

The Online Inheritance in Man database describes the phenotype for thousands of Mendelian disorders. However about 60% of the diseases with established loci do not have known causative genes. If the disease is sufficiently homogeneous and if causative variants are of high enough penetrance, whole-exome sequencing can be an effective strategy for candidate gene identification. Several recent studies have demonstrated the ability of whole-exome sequencing to identify genes for both autosomal dominant and recessive Mendelian disorders. We applied whole-exome capture (Agilent SureSelect) followed by next-generation sequencing (Illumina GAII) to study two Mendelian disorders in which the underlying genetic cause is unknown. The two disorders include a rare Mendelian disorder characterized by congenital sensorineural hearing loss and mental retardation and another where affected individuals exhibit a well-defined constellation of severe birth defects. These disorders not only represent a diverse spectrum of phenotypes, they also show distinct transmission patterns, specifically X-linked recessive and *de novo* autosomal dominant. We generated high quality exome sequence data of >20X coverage for 7 individuals: 1 with the hearing loss and mental retardation syndrome and 6 with the severe birth defect complex. To analyze the novel variants found in each of these diseases we applied a combination of bioinformatic filters, incorporating previous information on haplotype sharing or regions of homozygosity, functional annotation, and candidate gene sharing between multiple unrelated affected individuals. We were able to narrow the number of candidate genes for each disorder from thousands to a small set, highlighting several candidate genes for future in-depth investigation. While each condition brought different challenges in data analysis, interpretation, and functional follow-up, our experience demonstrates the feasibility of using high-throughput whole-exome sequencing to accelerate gene discovery for a wide array of Mendelian disorders.

1962/F

Application of exome resequencing with targeted analysis for autosomal dominant disorders with positional information. *L. Huang[1], L. Racacho[2], L. McDonell[1], S. Douglas[3], D.E. Bulman[2], K.M. Bycott[1].* 1) Children's Hospital of Eastern Ontario Research Institute,Ottawa, ON, Canada; 2) Ottawa Hospital Research Institute, Ottawa, ON, Canada; 3) Faculty of Medicine, University of Toronto, Toronto, ON, Canada.

Next-generation sequencing technologies have dramatically accelerated the sequencing of genes that have been implicated in human disease. Two strategies can be employed for DNA enrichment prior to sequencing: capture of a specific region (contiguous or gene-specific); or capture of the human exome with analysis limited to the region(s) of interest. The latter strategy has the benefit of significant cost savings but the potential disadvantage of less coverage. For example, Agilent's SureSelect Human All Exon Kit covers the genes in the NCBI Consensus CDS Database but not hypothetical genes. To evaluate this further we used exome resequencing to identify variants in two patients from two families with autosomal-dominant disorders that have prior positional information based on linkage analysis. A novel locus for autosomal dominant hereditary spastic paraparesis was mapped to a 2.4 Mb region on chromosome 3 in a large Canadian family. The critical region contains 16 genes, 9 of which are covered by the Agilent's SureSelect Human All Exome Kit. The captured whole exome was sequenced using an Illumina GAII sequencing system with a 72bp read length. Twenty-four of 31 million reads were of good quality and were aligned to the human reference sequence (NextGENe). The average sequence coverage was 7x. Four unreported single nucleotide alterations within the coding sequence of four genes in the critical region were identified. Confirmation of these changes using Sanger sequencing is underway. In a smaller family with autosomal dominant spinocerebellar ataxia, three candidate regions of 3.6, 1.9 and 1.2 Mb in length were identified on chromosomes 10, 11, and 19, respectively. The Agilent's SureSelect human all exome kit covers 23/29, 17/22, and 36/40 genes in the three regions, respectively. Twenty-six of 33 million reads were of good quality and were aligned to the reference sequence. The average sequence coverage was 11x. Fourteen unreported single nucleotide alterations within the coding regions of 12 genes were identified. Confirmation of these changes using Sanger sequencing is underway. Our studies demonstrate that exome sequencing coupled with targeted analysis may be an efficient and cost-effective way to quickly identify mutations associated with human disease.

1963/F

Accurate Variant Detection within Targeted Genomic Regions across Unamplified and Whole Genome Amplified HapMap Families using MicroDroplet-based PCR and SOLiD Sequencing. *J.B. Warner[1], A. ELSharawy[2], J. Brayer[1], M. Forster[2], P. Rosenstiel[2], S. Schreiber[2], A. Franke[2], J. Olson[1], D. Link[1].* 1) RainDance Technologies, Lexington, MA; 2) Institute of Clinical Molecular Biology (ICMB), Christian-Albrechts-University of Kiel, Germany.

Many hypothesis driven studies such as Genome Wide Association Studies or Candidate Gene Studies require the ability to efficiently target specific regions of the genome to detect sequence variations across a population of samples. With the increased sequence capacities offered by today's 'Next Generation' sequencing platforms, investigators are now able to generate massive amounts of sequence data. The ability to target specific regions of the genome allows researchers to screen larger numbers of samples against regions relevant to their research. In this study we will present the use of RainDance's microdroplet-based PCR and ABI SOLiD sequencing to specifically target 383 exons. This targeted approach leverages the sensitivity and specificity of the Polymerase Chain Reaction (PCR) to efficiently capture and represent the sequence context from these regions.

There are several advantages with this approach to targeted resequencing. The PCR based approach allows a high degree of stringency and flexibility to design to the targets of interest. Also, the sequence coverage is uniform across all of the amplicons allowing for efficient use of sequencing capacity. This allows for sample indexing strategies, reducing the sequencing cost per sample.

In this study we evaluated six HapMap samples from two family trios from the 1000 genomes project. One of the trios was also evaluated after whole genome amplification (WGA). All samples were evaluated with several barcoding strategies at different stages of the ABI SOLiD workflow. Genotyping data for all samples were compared back to their reference genotypes and across the different sample treatments to determine the concordance of the variant detection. Family structure was also evaluated to confirm Mendelian patterns of inheritance within each family trio. Each sample was barcoded and sequenced under the following conditions: 1) one sample per octet, 2) samples were pooled pre-emulsion PCR (emPCR) and 3) samples were pooled post-emPCR.

SNP detection was performed for each sample and compared with the reference genotypes for each HapMap sample. The average genotype concordance maintained across all of the samples was 99.5%. We also did not detect any errors in the Mendelian patterns of inheritance of genotypes between the parents and offspring within each trio.

1964/F

Performance Comparison of Three Commercial Softwares for Analysis of Illumina Genome Analyzer Next Generation Resequencing Data. *J. Durtschi[1], P. Ridge[1], S. Dames[1], W.L. Wooderchak[1], P. Bayrak-Toydemir[1,2], K.V. Voelkerding[1,2].* 1) 1ARUP Institute for Clinical & Experimental Pathology, Salt Lake City, UT; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT.

Background A key bioinformatic requirement for NGS sequencing is accurate analysis software. The current study evaluated the performance of three commercial software packages that have features, flexibility, ease of use, and customer support attractive for clinical application. **Methods** Variant calling ability in exons and processing speed at a range of software settings was compared for DNAStar Seqman NGen, SoftGenetics NextGene, and CLCBio Genetic Workbench. Illumina Genome Analyzer data sets included; 1) 76 base, single end read data from 9 genes of a Long Range-PCR enriched hypertrophic cardiomyopathy (HCM) panel; 2) 76 base, single end read data from the same HMC genes enriched on a Febit capture chip and; 3) 36 base, pair end read data from an Agilent SureSelect X chromosome capture enrichment. Software parameters were adjusted for each software to improve performance. Some targeted regions were Sanger sequenced providing variant confirmation. **Results** The LR-PCR data set generated average coverages of over 1000. The high coverage and enrichment specificity of the LR-PCR data yielded perfect exon variant calling in the three softwares using typical variant parameters of 25 read percentage and minimum 20 coverage (in addition to software specific limits). The Febit data included problematic co-capture leading to 12, 14 and 14 Sanger disputed exon false positives in *ACTC1* from DNAStar, CLCBio and SoftGenetics, respectively. Alignment to the whole human genome, currently relatively easy with CLCBio and SoftGenetics, greatly reduced this problem. Other exon regions in the Febit data yielded 2, 3 and 3 incorrect calls from DNAStar, CLCBio SoftGenetics, respectively in low complexity exon regions of *MYBPC3* and *TPM1*. X chromosome data was Sanger sequenced only in a cross-homologous gene, *ABCD1* indicating one true variant in exon 6 that was identified by all softwares. Each software also identified more than 10 false positive exonic variants in this region. **Conclusions** Our ongoing comparison of these three softwares with clinical target data shows that each performs comparably with respect to variant calls. Each also has specific advantages including processing and display features. The differences in alignment and variant detection methods between softwares cause some marginal differences in accuracy of difficult variant calls, specifically low coverage, low complexity and high homology regions.

1965/F

Establishment of two different targeted re-sequencing workflows and a benchmark of whole-exome approaches. *A. ElSharawy, M. Forster, B. Stade, M. Schilhabel, I. Thomsen, P. Rosenstiel, S. Schreiber, A. Franke.* Institute of Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany.

Next generation sequencing (NGS) has revolutionized throughput and cost per base call, but bottlenecks exist at the front-end, especially the targeted sequencing of specific genomic regions in large numbers of samples. Until the whole-genome re-sequencing of large numbers of individuals becomes feasible, targeted re-sequencing of both whole-exomes and a complete set of specific genomic loci present the next logic attractive options. Here we established two different targeted next-generation re-sequencing workflows on the SOLiD NGS system, using microarray-based and PCR-based enrichment technologies. In both protocols, we employed molecular bar-coding and pooling strategies to increase throughput, reduce cost per base, and make the identification of variant carriers more efficient. In the microarray-based workflow, we analyzed the data with different software tools, benchmarking against the known HapMap, dbSNP, and whole genotypes derived from re-sequencing an entire genome. The results showed high enrichment key measures and that SNP discovery depended strongly on chosen tools, suggesting a combination of target region matching, SNP backmapping and a final manual inspection as a convenient approach to attain more confident results. In the PCR-based workflow, we evaluated the performance of different pooling schemes on whole-genome amplified and un-amplified genomic DNA HapMap samples. The results of the latter approach showed efficient parallel detection of both homozygous and heterozygous SNPs in all tested samples. Given the fact that most of the known relevant somatic mutations that deliver the development of cancer in human are populated at protein-coding regions (and given that around 90% of all monogenic diseases derive from mutations in the coding sequence or splice sites), we also evaluated the performance of leading whole-exome re-sequencing approaches on different NGS technology platforms. We evaluated many enrichment measures as well as SNP concordance and overlap between different technologies using the generated re-sequencing data in addition to that of whole genome sequencing and dbSNP. At the conference, we will present a state-of-the-art-summary of our benchmarks and the targeted enrichment field.

1966/F

In-Run QC for Paired-End Sequencing with the Illumina GAIIx. *K.N. Hetrick II, B.D. Craig, M.W. Barnhart, S.M.L. Griffith, B.A. Marosy, K.F. Doheny.* CIDR, Johns Hopkins Univ, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to common disease. CIDR is currently evaluating the Illumina® GAIIx sequencer and Agilent© SureSelect™ enrichment technology for use in providing our investigators with a next-generation sequencing service. We initially relied on Illumina's real-time analysis (RTA) reports, CASAVA pipeline post-run reports as well as our own post-run analyses in order to determine sequence data quality, enrichment efficiency, and sample-prep library complexity which, for a paired-end (PE) run, could take 10 to 14 days from the start of the sequencing run. In order to cut this time in half, we have designed an in-run QC analysis workflow that uses only the first read of a PE sequencing run, treating it as a single-end (SE) run. Using Bowtie, this workflow aligns the first read to a reference genome and produces a SAM/BAM output file. The Bowtie output allows us to estimate the percentage of reads mapped to a reference genome, the proportion of map-able bases that aligned to the targeted enrichment regions, sequence depth coverage summary statistics and library complexity for each individual experiment. When compared to our PE final results for 24 samples using a custom Agilent Sure-Select bait pool targeting 3.5 Mb (using BWA as the aligner for the PE run); the mean difference between the percent of mapped reads for Bowtie and BWA was 0.8%, the Bowtie SE analysis flagged a mean of 3.4 times more reads as molecular duplicates per experiment than BWA (BWA mean 10%, bowtie mean 32%), a mean difference of 6.7% of map-able bases aligning to target (BWA mean 65.5%, Bowtie mean 58.8%) and a 1.7% mean difference of targeted bases with 10x or greater coverage. This in-run QC analysis process can save CIDR half the instrument time used by alerting us to catastrophic target enrichment failures so that we can cancel the sequencing run. This process also enables us to flag potentially sub-optimal experiments during the sequencing run allowing us to reprioritize samples that need to be redone in subsequent experiments. This method of in-run QC analysis workflow has been automated in the CIDRSeqSuite (refer to Barnhart, et al.) which can allow us to analyze the experiments in a few hours and determine if we should continue on with the sequencing run.

1967/F

Custom Design of Library Target Selection for Next Generation Sequencing. *B. Marosy[1], N. Pankratz[2], B. Craig[1], K. Hetrick[1], M. Barnhart[1], S. Griffith[1], D. Snyder[1], J. Romm[1], T. Foroud[2], KF. Doheny[1].* 1) CIDR/IGM, JHU-SOM, Baltimore, MD, USA; 2) Dept Medical and Molecular Genetics, IU-SOM, Indianapolis, IN, USA.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to common disease. CIDR has begun to evaluate Next Generation Sequencing in conjunction with targeted library selection as a future service. Genome Wide Association and linkage studies that identify a chromosomal region may require additional follow-up sequencing in order to find one or more causal variants that contribute to the genetic trait. The Agilent© SureSelect™ Target Enrichment method was used to capture specific regions of interest and was followed by paired end sequencing using the Illumina® GAIIx. Baits were custom designed to capture genomic features within a previously identified 19Mb linkage peak. Using the UCSC genome browser genes, hESTs, conserved regions, sno/miRNAs and predicted first exon/promoter regions were identified for inclusion in the target design. GALAXY was used to import tracks/bed files from UCSC and provided tools to extract exons, add flanks, merge or subtract regions, and provide base coverage information. In the final design, 150bp flanks were added to each exon and 3kb/2kb flanks were added upstream/downstream to each gene. Secondary regions containing additional known causative genes were also included in the design. Regions containing CIDR's SNP barcode panel were added to confirm sample identity and provide QC to identify potential problems, such as contamination. These regions were then submitted in two passes to the Agilent eArray website, which provided additional parameters such as tiling and repeat masking for bait design. The first pass included 2x justified tiling with a 20bp 'avoid overlap' and masking using Repeat Masker. After the first pass any portion of the targeted regions not covered by baits was then resubmitted in a 2nd pass in an attempt to provide complete coverage across the regions of interest. The 2nd pass included 2x centered tiling with a 40bp 'avoid overlap' and masking using Window Masker. By resubmitting these 'missed' regions, 4% of exonic bases were recovered with 7% of exonic bases not covered in the final design. A total of 57,680 baits were designed covering 3.46Mb. Subsequent sequencing data shows an average capture specificity of 66.5% of all regions and 85% for regions targeted within the 19Mb linkage peak. At 1X and >10X depth, >99% and >98% of the targeted bases are covered, respectively.

1968/F

DNA capture and massively parallel sequencing to identify novel alleles for recessive non-syndromic hearing loss. *H. Shahin[1], T. Walsh[2], M.K. Lee[2], A.M. Thornton[2], A. Abu Rayyan[1], S. Loulus[1], A.S. Nord[2], K.B. Avraham[3], M-C. King[2], M. Kanaan[1].* 1) Dept of Life Sciences, Bethlehem University, Bethlehem, Palestine; 2) Depts of Medicine and Genome Sciences, University of Washington, Seattle. WA; 3) Dept of Human Molecular Genetics and Biochemistry, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

In studies of genetics of deafness, families with inherited hearing loss have been extremely valuable, providing paths to discovery of genes essential to mechanisms of hearing. Until now, such studies have depended on Sanger sequencing of genes in candidate genomic linkage regions. Constraints of PCR-based sequencing have largely limited gene discovery to conventional mutations in known genes in relatively small regions of linkage. The advent of DNA enrichment techniques coupled with next generation sequencing technology has the potential to dramatically accelerate the pace of gene discovery. We have applied in-solution DNA capture and massively parallel sequencing to identify the causative alleles from two large Palestinian families that map to recessive non syndromic deafness loci. We designed cRNA oligonucleotides to capture all RefSeq and CCDS annotated exons from the DFNB83 locus: 45MB on chromosome 9, and the DFNB85 locus: 11MB on chromosome 17. We captured 1823 exons from germline DNA of an affected individual from the DFNB83 family and 1372 exons from an affected individual of the DFNB85 family. Each captured library was sequenced on an Illumina Genome Analyzer IIx to a >100x depth. We filtered DNA variants against publicly available databases and categorized the remaining rare and private variants for predicted severity on gene and protein function. We did not observe any rare truncating alleles in the captured exons. We are currently evaluating conserved missense mutations, intronic variants distant from known exons that may alter splicing and read depth data for copy number variants such as deletions and duplications.

1969/F

Buyer beware: limitations of whole-exome sequencing capture methods and the search for rare, Mendelian variants. *K.B. Jacobs[1,2], M. Yeager[1,2], M.G. Cullen[1,2], X. Zhang[1,2], J. Boland[1,2], J. Bacior[1,2], V. Lonsberry[1,2], C. Matthews[1,2], D. Roberson[1,2], Q. Chen[1,2], L. Burdett[1,2], I. Menashe[2], X.R. Yang[2], L.R. Goldin[2], M.L. McMaster[2], N.E. Caporaso[2], P.R. Taylor[2], M.T Landi[2], J. Sampson[2], N. Chatterjee[2], M.L. Nickerson[3], K. McGee[3], M. Dean[3], J. Khan[4], M.A. Tucker[2], S.J. Chanock[2], A.M. Goldstein[2].* 1) Core Genotyping Facility, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD 21702, USA; 2) Division of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD 20892, USA; 3) Laboratory of Experimental Immunology, CCR, NCI, NIH, Bethesda, MD 20892, USA; 4) Oncogenomics Section, Pediatric Oncology Branch, CCR, NCI, NIH, Bethesda, MD 20892, USA.

New technologies such as 'whole'-exome sequencing capture methods have led to renewed excitement about discovering rare, Mendelian, high-risk susceptibility gene variants in humans. To assess the currently available sequence capture approaches with respect to coverage across the exome, we evaluated the content and the empirical performance of the currently-available 'whole'-exome sequence capture methods [NimbleGen Sequence Capture 2.1M Human Exome Array; Agilent SureSelect Human All Exon Kit] on three sequencing platforms [454 FLX Ti (4 runs); ABI SOLiD (1 quadrant); Illumina GA II (2 lanes)]. The protein coding sequences (CDS) reported in the RefSeq database (build 36.3) served as the gold standard for our assessment. NimbleGen capture probes target 77% of CDS bases and Agilent capture probes target 83% of CDS bases. We observed 21.5 Mbps (65%), 25.0 Mbps (76%) and 23.4 Mbps (71%) of the 33.0 Mbps of CDS with ≥8x sequence depth for Nimblegen/454, Agilent/SOLiD, and Agilent/Illumina, respectively. Since identification of rare gene variants requires high per-gene coverage, we also computed the proportion of genes with >90% of CDS bases covered with ≥8X sequence depth. Only 42%, 55%, and 45% of genes were covered by Nimblegen/454, Agilent/SOLiD, and Agilent/Illumina, respectively. Since coverage across the gene CDS is incomplete, failure to identify a causal mutation should be interpreted cautiously. It is notable that many characterized genes are not included in this first generation whole-exome capture products and that only 40-50% of genes are well covered across all known exons with the amount of sequencing performed. Our results underscore the limitations of current 'whole'-exome capture products and have important implications for designing studies in families and unrelated populations. In spite of the limitations, these products may still be useful to screen for disease variants within exons that are satisfactorily covered. The design of future 'whole'-exome capture products will likely be more expansive and performance will likely improve, however careful attention must be paid to coverage in practice. Funded by NCI Contract No. HHSN261200800001E.

1970/F

Analysis of GBA mutations in a French-Canadian Parkinson's disease cohort. *A. Noreau[1], J.-B. Riviere[1], S. Diab[1], P. Dion[1], S. Chouinard[1], M. Panisset[1], N. Dupre[2], G.A. Rouleau[1,3].* 1) The Centre of Excellence in Neuromics, CHUM Research Center and the Department of Medicine, University of Montreal, Montreal, QC, Canada; 2) Faculty of Medicine, Laval University , Department of Neurological Sciences , CHA - Enfant-Jésus, Quebec City, Qc, Canada; 3) Sainte Justine Hospital, Montreal, Qc, Canada.

Background: Gaucher disease is a rare mendelian disorder characterized by accumulation of the lysosomal enzyme glucocerebrosidase (GBA), mainly cause by mutations in the GBA gene. Pedigree analysis revealed an increase incidence of Parkinson's disease (PD) in relatives of patient's with Gaucher disease. Recently, a multicenter analysis of the Glucocerebrosidase gene (GBA) reported that a higher frequency of missenses mutations could be observed PD patients by comparison to healthy controls individuals. Moreover this result was even more significant when making a separate GBA mutation rate examination of the Jewish descent individuals within the cohort; this subgroup presented a 15 % mutation for two specific missenses (L144P and N370S) which is five times higher than what can be observed in Jewish-healthy controls. In that study, they also present an increased rate of mutations in the non-jewish population, less impressive but significant as 3% in PD patients match up to less than 1% in controls. The main goal of our study was to evaluate the possible involvement of the GBA mutations in a french-canadian PD cohort. **Methods**: We completely resequenced the GBA gene in a cohort of 213 French-Canadian patients with a clear PD diagnosis and 190 healthy-age-match French-Canadian controls. PCR and sequencing primers were designed using the chromosome 1 genomic contig sequence (NT_029419) enabling PCR of all 11 coding exons. Primers were designed enabling preferential amplification of GBA over the GBA pseudogene, located on the same chromosome, 16 kb upstream. **Outcomes**: The resequencing success rate reach more than 99 % and we observe an increased amount of GBA mutations in Parkinson's patients. Heterozygotes mutations was found in 10,8 % of the Parkinson's patients compare to 5,8 % in ethnically-healthy controls. This study provides evidence that GBA is probably involved in PD in the French-Canadian population.

Development of new HLA-B*3505 genotyping method using Invader assay. *N. Hosono[1], S. Chantarangsu[1], K. Kiyotani[1], S. Takata[1], Y. Tsuchiya[1], S. Mahasirimongkol[2], W. Chantratita[3], T. Mushiroda[1], N. Kamatani[1], Y. Nakamura[4], M. Kubo[1].* 1) Center for Genomic Medicine, Riken, Japan; 2) Center of International Cooperation, Minstry of Public Health, Thailand; 3) Ramathibodi Hospital, Mahidol University, Thailand; 4) Human genome Center, University of Tokyo, Japan.

OBJECTIVE: Several pharmacogenetic studies have revealed strong genetic associations between specific human leukocyte antigen (HLA) alleles and the susceptibility to drug hypersensitivity. Recently, we reported HLA-B*3505 as a strong genetic biomarker for the prediction of the nevirapine (NVP)-induced skin rash in a Thai population. Due to its high specificity and positive predictive value, HLA-B*3505 genetic test will facilitate pharmacogenetic study to avoid a subset of the NVP-induced skin rash. METHODS: We developed a new HLA-B*3505 genotyping method by a combination of the Universal Invader assay and sequence-specific primer PCR method. We performed the assay using an ABI-7500 system, and total reaction time was 50 minutes. We tested the assay using 324 Thai individuals and the results were compared with the data obtained by the sequence-based typing method. RESULTS: From the sequence alignment of HLA Class I alleles detected in the Thai population, we selected the most discriminative SNP (rs1140412) as a target SNP for the Invader reaction and rs4997052 for a sequence-specific reverse primer site. When we performed the assay, the fluorescence intensities of HLA-B*3505-positive samples rapidly increased. Meanwhile, the intensities of HLA-B*3505-negative samples were apparently low. At the endpoint of the reaction, our assay could easily determine the presence or absence of HLA-B*3505. Our assay detected HLA-B*3505 for 100% concordance with the results obtained by a sequence-based typing method. CONCLUSION: Our assay is simple, rapid, and closed-tube homogeneous format. We believe our method will be a useful tool for pharmacogenetic testing of the NVP-induced skin rash in Thailand.

1972/F

A new sequencing primer and workflow increase 5' resolution and throughput on HLA sequencing. *P. Ma[1], SC. Hung[1], S. Berosik[1], M. Wenz[1], S. Schneider[1], A. Chhibber[3], T. Agostini[2], D. Berchanskiy[2], D. Dinauer[2].* 1) Genetic Systems, Life Technologies, Foster City, CA; 2) Applied Market, Life Technologies, Brown Deer, WI; 3) Dept of Bioengineering and Therapeutic Sciences, UCSF, San Francisco, CA.

High quality and high accuracy are the hallmarks of Sanger re-sequencing projects. We have developed a new sequencing primer and workflow that improves 5' sequence resolution, increases throughput, and reduces hands-on time. The novel sequencing primer chemistry produces high quality bases from base 1 on POP-7™ that previously only could be resolved on the slower POP-6™ polymer. The new primer chemistry and workflow also eliminates the need for a separate PCR clean-up step. These improvements reduce the entire workflow from PCR to finished sequence data to under 5 hours, compared to 8 hours for the standard workflow. We used our enhanced sequencing primer and workflow to investigate Human Leukocyte Antigen (HLA) polymorphisms on twelve DNA samples by using the Invitrogen SeCore® HLA-DRB1 primer set and Group Specific Sequencing Primers. Sequencing reactions generated with the traditional sequencing primer and with the new sequencing primer were electrophoresed on Applied Biosystems 3500xl™ Genetic Analyzer using POP-7™. For each sequencing primer, we compared 5' resolution and basecalling accuracy and quality. On average the traditional primers produced high quality readable bases by base 25 after the sequencing primer while the new primers produced high quality bases by base 5, and by base 1 in many cases. Because of improved resolution, basecalling accuracy was increased. This simplified process without a separate PCR clean-up step reduced the overall workflow time by 40%. For HLA genes, obtaining readable sequence within 5 bases of the primer offers improved polymorphism detection and more efficient use of allele specific sequencing primers for heterozygous ambiguity resolution. In conclusion, the novel primer chemistry and workflow generates data superior in quality relative to other currently used solutions and offers significant time savings as well.

1973/F

Multi-sample pooling and Illumina Genome Analyzer sequencing to determine gene sequence variation for database development. *R.L. Margraf[1], J.D. Durtschi[1], S. Dames[1], D.C. Pattison[1], J.E. Stephens[1], K.V. Voelkerding[1,2].* 1) ARUP Institute for Clinical & Experimental Pathology, Salt Lake City, Utah; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, Utah.

Multi-sample pooling and Illumina Genome Analyzer (GA) sequencing is a cost effective way to sequence many samples to determine sequence variation within a population. Determination of sequence variation within a genetic locus is essential for developing clinically relevant databases, which are critical for molecular assay design and clinical test interpretation. In this study, multi-sample pooling combined with Illumina GA sequencing was investigated using the *RET* proto-oncogene as a model. All samples were also Sanger sequenced for *RET* exons 10, 11, and 13-16. Based on a preliminary experiment where a 10 sample pool was sequenced on the Illumina GAII using 36 base reads; we predicted £30 samples (or a minimum 1% variant reads for singletons) could be pooled to reliably detect singleton variants by Illumina GA sequencing without needing additional confirmation testing. A second experiment using a 30 sample pool and 50 sample pool was performed to test the predicted pooling limit and also to test the recent Illumina GAIIx upgrades and 76 base length reads. The automatable SequalPrep™ method was used to normalize PCR products before pooling. For comparison, a single 'control' sample was run in a different flow cell lane. Data was evaluated using an established variant detection method (% variant reads) and a new subtractive correction method utilizing the control sample. In total, 59 variants were detected in the pooled samples, which included all the Sanger identified variants. Both the 30 and 50 pool had 17 known singleton variants due to Sanger sequencing. These 17 singleton variants in the 30 pool had 1.70±0.53% average read frequency (expected 1.67% allele frequency), while these same variants within the 50 pool had 1.13±0.23% average frequency (expected 1%). A total of 12 novel intronic variants (not in NCBI dbSNP) were detected within all the Illumina GA sequenced samples and four of the novel variants were within 200bp of the exons, at potential areas of primer design. These data sets confirmed the predicted maximum 30 pool limit for reliable singleton variant detection (all singleton variants were above 1.3% read frequency), since some singleton variants in the 50 pool would be difficult to distinguish from background sequencing errors if the singleton variants were unknown. These pooling protocols and data analysis can be used for other genes for development of locus-specific databases and to facilitate molecular diagnostic test design.

1974/F

Mutation screening of 95 patients with bilateral sensorineural hearing loss using HybSelect and massively parallel sequencing - experience of a clinical diagnostic laboratory. *A. Santani[1], X. Gai[2], M. D'Arcy[2], M. Grauer[2], A. Caruso[3], H. Wu[3], T. Tischler[1], A. Keller[4], V. Boisguerin[4], L. Francey[5], D. Clark[5], I. Krantz[5], C. Stolle[1].* 1) Dept of Path & Lab Med, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Bioinformatics Core Facility, The Children's Hospital of Philadelphia, PA; 3) febit Inc, Lexington, MA; 4) febit Biomed gmbh, Heidelberg, Germany; 5) Dept of Genetics, The Children's Hospital of Philadelphia, PA.

Hearing loss is the most common birth defect, affecting 1 of every 500 newborns with bilateral sensorineural hearing loss (BLSHNL). More than 50% of affected individuals have a genetic etiology. Over a decade of research in this field has revealed extensive genetic heterogeneity, with more than 40 genes known to date. The universal newborn hearing screening program, together with notable progress in the elucidation of the genetic basis of hearing loss, have resulted in an increased demand for detecting the molecular basis of hereditary hearing loss through DNA testing. Diagnostic testing for BLSHNL is offered as a panel of tests in different centers around the world including the molecular genetics diagnostic lab at CHOP. However, diagnostic testing can be time consuming and expensive. Targeted capture and resequencing of multiple genes can significantly reduce the time and expense to that comparable for a single gene disorder. Here we report the use of a multiplex approach to simultaneously capture and resequence 95 patients with BLSHNL using the microfluidic Geniom biochips approach. Of the 95 patients, 13 patients had a confirmed molecular diagnosis. We enriched and then sequenced 138.8 kb of the human genome encompassing the coding regions of 35 genes implicated in BLSHNL. DNA samples were captured first with HybSelect technology and then sequenced using the SOLiD platform, in either 1-plex, 4-plex, or 8-plex. We captured on average 92.6% (range:69.2%-98.6%) of the targeted regions at an average coverage depth of 13.5X (range: 2.1X-44.6X). We assessed this method's performance in detecting homozygous and heterozygous variants and found 75% concordance with previously reported data. Of the 1545 non- synonymous SNPs or indels, ~196 variants were unique. To date, potentially disease causing mutations were identified and confirmed by Sanger sequencing in 20 previously undiagnosed patients. 4 nonsense mutations and 19 missense variants were identified. 19 mutations were previously reported in the Human Genome Mutation Database & 4 were novel variants. Although the multiplex capture was highly specific, we found that a key issue was non-uniform capture that will require additional optimization to be suited to the performance requirements of a clinical molecular laboratory. Nonetheless, our results demonstrate the utility of this multiplexed capture approach for efficient and cost effective screening of multiple genes implicated in disease pathways.

1975/F

Phenotype driven next generation sequencing of X-linked intellectual disability genes. *E. Chin[1], C. Alexander[1], J. Sun[1], A. Tanner[1], L. Tribble[2], M. Friez[2], M. Hegde[1].* 1) Dept Human Gen, Emory University, Atlanta, GA; 2) Greenwood Genetic Center, Greenwood, SC.

X-linked intellectual disability (XLID) is a common, clinically complex and genetically heterogeneous collection of conditions arising from mutations in genes on the X chromosome. It affects approximately 1/1000 males with females affected to a much lesser degree. Research has identified >100 different XLID genes, affecting a wide range of cellular processes. Many X-linked genes remain undiscovered, especially for non-syndromic forms of XLID. Approximately 11%; of genes located on the X chromosome are implicated in XLID; most, however, contribute individually to only <0.1%; of the total landscape. In recent years, progress has been made in delineating the clinical features associated with some forms of XLID, yet it remains virtually impossible to accurately predict the causative gene in non-syndromic cases that predominate in this group of disorders. For most genes very few clinical cases have been reported so the precise clinical phenotype is not clear. We have chosen 93 genes with a clearly established association with XLID to be a part of a next generation resequencing panel. We have validated the use of highly multiplexed PCR by simultaneously resequencing all 93 XLID genes using 24 positive controls. Highly multiplexed PCR using a customized RainDance Technology primer library designed to capture the genes of interest was used to enrich the target genes. We describe here for the first time evaluation of the highly multiplexed PCR technology in a clinical laboratory setting using XLID as a model. A web-based tool is available for users to input clinical information which allows a more refined selection of genes in smaller panels of 30 or 60 genes. This web-based tool will also allow further characterization of the phenotype associated with mutations in these genes. The combination of highly multiplexed PCR and next generation sequencing allows high resolution analysis capable of detecting coding and non-coding point mutations as well as deletions and duplications. The Collaboration Education and Test Translation (CETT) Program has provided support for this project which also includes development of educational materials to assist clinicians in utilizing testing for this large set of genes.

1976/F

Leber's hereditary optic neuropathy associated with Multiple Sclerosis like picture in a man. *R. Cittadella[1], V. Andreoli[1], P. Valentino[2], F. Trecroci[1], M. Caracciolo[1], O. Gallo[1], G. Di Palma[1], A. La Russa[1].* 1) Inst Neurological Sci, CNR, Cosenza, Italy; 2) Institute of Neurology, University "Magna Graecia", Catanzaro, Italy.

Purpose: Leber's hereditary optic neuropathy (LHON) is the most common mitochondrial disease, and it is characterized by degeneration of the retinal ganglion cells with demyelination and atrophy of the optic nerve. The primary LHON mutations 3460, 11778, and 14484 are found only in LHON pedigrees and putatively play a genetic role in its pathogenesis. Multiple sclerosis (MS) is a multifocal demyelinating central nervous system disease in which genetic susceptibility factors and non-genetic factors are postulated to be involved, most likely all with a small contribution to the overall risk. Here we report a male patient with LHON homoplasmic T14484C and heteroplasmic G15257A mutations who developed an MS-like picture. Methods: The patient is a 35-year-old young man who developed a sudden episode of paresthesia and weakness of the legs and feet bilaterally. There was no family history of neurological disease or loss of vision. Neurological examination revealed a gait disturbance with hypostenia and hypoesthesia of lower limbs bilaterally. Somatosensory evoked potentials with stimulation of the posterior tibial nerve at the ankle were absent bilaterally. Pattern visual evoked potentials revealed a delayed response bilaterally. Brain MRI revealed sparse areas of demyelination along the periventricular white matter without gadolinium enhancement. Spinal cord MRI showed diffuse demyelinating lesions extending from D6 to D11 with gadolinium enhancement. Spinal fluid examination showed oligoclonal bands.Total leukocyte DNA was extracted using standard protocols. DNA was screened for the LHON nt-3460, nt-11778, nt-14484, and nt-15257 mitochondrial DNA (mtDNA) base changes using polymerase chain reaction and restriction enzyme fragment length polymorphisms analysis. Mutations were confirmed by directed sequencing. Summary of results: Analysis of mtDNA revealed a homoplasmic T14484C change and heteroplasmic for the G15257A, which are common mutations causing LHON. Conclusion: Here we report one additional male patient displaying LHON and MS like picture (Harding's syndrome). Similarly to previous reports of LHON and MS in men, distinguishing MRI features were the major involvement of the spinal cord, while only sparse demyelinating lesions were seen on brain MRI. On this basis, screening for the Leber's mutations in male MS patients who display such features might be considered, as this has important prognostic and genetic implications.

1977/F

Single nucleotide polymorphism in the MMP-9 gene is associated with susceptibility. *A. La Russa[1], E. De Marco[1], P. Valentino[2], V. Andreoli[1], F. Trecroci[1], M. Caracciolo[1], G. Di Palma[1], R. Cittadella[1].* 1) Institute of Neurological Sciences,National Resear, Cosenza, Cosenza, Italy; 2) Institute of Neurology - Magna Graecia - Catanzaro, Italy.

Purpose: Multiple sclerosis (MS) is a chronic autoimmune disease of the central nervous system (CNS). It is characterized by the presence of demyelinated plaques or multifocal inflammatory lesions caused by autoreactive immune cells migrating through the damaged blood-brain barrier (BBB) into the CNS during the active stage of the disease. MMPs, and especially MMP-9, seem to play a role in the influx of inflammatory cells into the CNS and in the breakdown of the BBB and have been demonstrated to cleave human myelin basic protein in vitro. MMP-9 is higher in the cerebrospinal fluid and serum of patients with MS, compared to healthy controls and represents a useful marker for the evaluation of the clinical type, disability and severity of the disease. The transcriptional activity of the MMP-9 gene is influenced by two polymorphisms identified in the promoter region. These are a (CA)n microsatellite polymorphism from position -90 and a single nucleotide polymorphism at position -1562. In this study we wished to investigate the role of the MMP-9 gene in patients MS Methods: The functional -1562C/T and -90 (CA)n repeat polymorphisms were analyzed in 243 patients with MS and 173 healthy sex and age matched controls. All patients and controls were Caucasian and were born in Italy. All gave written informed consent prior to participation in the genetic studies. Genomic DNA was extracted from peripheral blood leukocytes of patients and controls using a standard procedure. The C/T polymorphism at position -1562 of the MMP-9 gene promoter was genotyped by PCR-restriction fragment length polymorphism analysis. To determine the numbers of the CA repeats in the MMP-9 promoter region, PCR products were generated using already published primers. Capillary electrophoresis was used to separate the amplicons. GENESCAN™ software was used to determine allele size. Summary of Results: A significant increase of the -1562T allele carriers was found in patients with MS compared to controls. Moreover, haplotype analysis showed that the haplotype formed by the -1562T allele and the L allele ((CA)£20) was overrepresented in patients with MS versus controls. Conclusion: Our study suggests that the MMP-9 gene is implicated in the susceptibility to MS. This result, together with that obtained in a distinct ethnic population with MS reporting association with disease progression, supports the hypothesis of an important role played by this gene in MS.

1978/F

An integrated analysis identifies several factors influencing the expression of CDKN2A and CDKN2B in glioblastoma. *J. Feng, W. Liu, S. Kim, J. Kim, J. Sun, Z. Zhang, Y. Zhu, J. Sun, J. Xu.* Center for Cancer Genomics, Wake Forest University School of Medicine, Winston-Salem, NC.

Glioblastoma multiforme (GBM) is the most prevalent primary brain tumor and is among the deadliest of all human cancers. CDKN2A and CDKN2B are two tumor suppressor genes encoded at 9p21.3 that have established roles in GBM. Germline polymorphisms at 9p21.3 and somatic variations such as deletions, mutations and DNA methylations at CDKN2A/CDKN2B are associated with GBM susceptibility, development and prognosis. Despite these reports, these events are only isolatedly documented, and their functional connections and relative contributions to the disease phenotype remain yet to be characterized. In order to obtain a comprehensive view of these genomic and cellular events related to GBM, we have performed an integrated analysis by leveraging the full spectrum of GBM data available from the Cancer Genome Atlas (TCGA) Research Network. Our univariate analysis indicated that the expression of CDKN2A and CDKN2B was strongly affected by copy number variations (CNVs, p=2.01 × 10-44 and 5.91 ×10-37, respectively). DNA methylation may also have an influence, with that on one CpG site (cg10210238) significantly associated with CDKN2B expression levels (p=0.029), and that on another (cg17449661) marginally associated with CDKN2A expression (p=0.079). However no correlations were found between the germline or somatic polymorphisms with their mRNA levels. Through multivariate analysis, we further found that CNVs accounted for a significant proportion (25.6% and 29.5%, for CDKN2A and CDKN2B respectively) of the total variations of the expression levels of CDKN2A/CDKN2B, whereas DNA methylation variations made a small but significant contribution (3.67% and 6.06%, respectively). Taken together, these analyses indicate that CDKN2A/CDKN2B expression is predominantly influenced by copy number variations, and to a less extent by DNA methylation at specific CpG sites. The fact that the majority of the variances (69.4% for CDKN2A and 61.6% for CDKN2B) remain still unexplained suggests that there are yet other factors that strongly affect the expression of CDKN2A and CDKN2B but await further identification.

1979/F

Utility of autopsy-derived tissue for gene expression studies. *S. Gupta, G.M Hilton, M.K Halushka, D.E Arking.* Johns Hopkins University School of Medicine, Baltimore, MD.

Gene expression studies are currently used to identify differentially expressed transcripts between cases and controls, and to identify functional genetic variants (eQTLs). While many of these studies are performed in blood or lymphoblastoid cell lines, the majority of eQTLs are tissue specific, and thus, gene expression studies will need to be conducted in the relevant tissue for a disease. One major technical concern about using autopsy-derived tissue is how representative it is of physiologic conditions because of the effect of postmortem interval on tissue degradation. This study evaluates the variability of RNA message in autopsy-derived tissues. Heart tissues were obtained from a cardiac transplantation and a rapid autopsy. Tissues were allowed to autolyze in a simulation of standard autopsy conditions. Hearts were initially maintained at 37°C, and then cooled at 1°C / hour for 12 hours, after which they were cooled at 2-3°C/hr (to 4°C). This simulated a body cooling at room temperature for 12 hours, before transportation and storage to a cold room in the morgue. Twenty-one tissue samples were harvested from each heart at time points 0,6,12,18 and 24 hours. These heart samples, along with 2 HeLa RNA controls were run on the Affymetrix 1.0 ST Exon arrays. Exon arrays have 1.4 million probesets that map to over a million exon clusters. We analyzed expression data from ~200,000 core probe sets that were supported by putative mRNA from RefSeq. The gene intensities were quantile normalized and summarized by using Robust Multi-Array Analysis. The probes were filtered to retain those flagged as present (DABG<0.05), at at least one time point. Approximately, 163,000 probes mapped to ~14,000 transcripts. Comparing the 0 hour explant and autopsy tissues to the later harvest time points, we observed that only <0.5% of genes were differentially expressed (FC > 2 and p<0.05), which was similar to results observed comparing technical replicates (HeLa 1 vs HeLa 2). Our data also demonstrated biologically relevant expression differences between the two hearts. For example, CTGF, a secreted protein that is strongly induced in human and experimental heart failure, was 5-fold higher in the transplant heart (p=0.011). These results demonstrate that RNA from autopsy-derived tissue, even after 24 hours of autolysis, can be used to identify biologically relevant expression pattern differences, thus serving as a practical source for gene expression experiments.

1980/F

***ABCA13*: the naming of a gene.** *R. Seal, S. Gordon, M. Lush, M. Wright, E. Bruford*. HUGO Gene Nomenclature Committee (HGNC), European Bioinformatics Institute, Hinxton, Cambridgeshire, United Kingdom.

The HUGO Gene Nomenclature Committee (HGNC) aims to approve a gene symbol and name for every human gene. Standardisation of gene symbols is important as it allows researchers to refer to the same gene without ambiguity and facilitates data retrieval. The primary rule of the HGNC is that every approved gene symbol must be unique. Gene symbols should also be acceptable to researchers to ensure their widespread use, and should be based on structure, function or homology wherever possible. The HGNC encourages the development of a common root symbol for members of a gene family, with a hierarchical numbering system to distinguish the individual members, as this is an efficient way to name large numbers of related genes and makes each family member instantly recognisable. We provide individual web pages on our site for many established gene families and have over one hundred specialist advisors that help us to accurately maintain these families. Here we describe the naming of one particular gene family member, *ABCA13* (full name: ATP-binding cassette, sub-family A (ABC1), member 13). We explain how and why the gene was named and how the symbol has subsequently been used. The first step was the development of the ABC (ATP-binding cassette) gene superfamily and sub-family nomenclature scheme, following in depth discussions between the HGNC and the ABC research community. This was followed by the identification and naming of *ABCA13* as part of this family, its appearance in the biomedical literature and databases, its adoption for the mouse and rat orthologs as *Abca13*, and its subsequent breakthrough into the international media. For further information on human gene nomenclature, please email us at hgnc@genenames.org, or visit http://www.genenames.org/. The work of the HGNC is supported by the NHGRI and the Wellcome Trust.

1981/F

Long segment Hirshprung's disease and bifid epiglottis in a patient with a denovo mutation in the GL13 gene. *H.H. SHUHAIBER, K. Surapaneni, E. GUZMAN, K. ANYANE-YEBOA*. Columbia University Medical Centre, New York, N.Y.

Pallister-Hall syndrome (PHS) is a pleiotropic disorder first described in 1980 and characterized by hypothalamic hamartoma, central or postaxial polydactyly, hypopituitarism, and variable visceral anomalies1.In 2005, mutations in the zinc-finger transcription factor gene (GLI3) on the chromosomal locus 7p13 were found to be the causative factor in 95% of patients with clinically suspected PHS. We describe a neonate who was the product of an uncomplicated pregnancy and normal spontaneous vaginal delivery at 34 4/7 weeks to an otherwise healthy 19 year old G1P1 with an initial birthweight of 3105 grams. On newborn exam, the patient was found to have bilateral polydactyly, microphallus and hypospadius. On day of life three, the patient was found to have bilious emesis .Resected bowel pathology was consistent with a long-segment Hirschprung's disease. Further evaluation showed patient's karyotype to be 46XY, with low growth hormone and testosterone. MRI imaging demonstrated a large nonenhancing prepontine mass causing superior displacement of the optic chiasm and mildly deforming the ventral pons. Molecular DNA analysis showed that patient was heterozygous in the GLI3 gene for a framshift mutation defined as c.2400delA and predicted to result in premature protein truncation p.Ala801-ProfsStop8. The presence of a hypothalamic hamartoma is the primary clinical feature of PHS that helps in differentiating it from other genetic polydactyly syndromes with overlapping features. Additional major findings in PHS aside from central polydactyly include a bifid epiglottis, GI anomalies (Hirschprung's disease and imperforate anus), renal abnormalities, panhypopituitarism, and dysplastic nails. Two studies have reported finding a bifid epiglottis in 50-58% of patients diagnosed with PHS (Azzam and Ondrey). The association between polydactyly and bifid epiglottis in PHS patients may possibly be secondary to the developmental observation that the hand and foot plates, digital rays, and epiglottis develop between 32 and 46 days of gestation. It has been shown that haploinsufficiency of GLI3 causes GCPS while protein truncation mutations in GLI3 are associated with PHS, which may partly reflect the absence of bifid epiglottis in GCPS patients. The characteristic finding of a bifid epiglottis and a hypothalamic hamartoma seem to be key differentiating features of PHS from other genetic polydactyly syndromes.

1982/F

Sequence interpretation challenges for mutation detection for congenital muscular dystrophy - a complex multigene panel. *C.A. Valencia, K. Gokhale, C. Alexander, E. Chin, S. Bhide, M. Yau, M. Hegde*. Department of Human Genetics, Emory University School of Medicine, Decatur, GA.

Congenital muscular dystrophies (CMDs) are a group of genetically and clinically heterogeneous hereditary myopathies characterized by congenital hypotonia and muscle weakness, contractures, and delayed motor development. Given the recent improvement of molecular technologies, the classification of CMDs has significantly changed from phenotype driven towards a more molecular based categorization. So far up to twelve genes are known to cause various forms of CMD, including *COL6A1*, *COL6A2*, *COL6A3*, *ITGA7*, *FKTN*, *FKRP*, *POMGNT1*, *POMT1*, *POMT2*, *SEPN1*, *LARGE* and *LAMA2*. Single gene sequencing is effective when a single missing protein is identified by a muscle biopsy and loss of that protein fits the phenotype. However, a comprehensive gene sequencing panel is necessary when ambiguous results arise or when muscle biopsies are difficult to obtain. To overcome these difficulties, clinical laboratories are now pursuing novel strategies to perform large scale mutation detection such as cost-effective targeting of a specific fraction of the genome. We have developed a next generation panel for CMD using highly multiplexed PCR using RainDance and SoLiD. We have used previously identified eleven positive controls in different CMD associated genes which consist of point mutations and indels. Analysis performed using Softgenetics, NextGene software, permitted the successful detection of all mutations and polymorphisms. The CMD panel genes are highly complex and extremely polymorphic which create challenges for interpretation and classification of variants. As genomics is rapidly moving towards clinical whole genome sequencing, the CMD next generation sequencing serves as a good model in understanding the interpretation challenges we will be facing.

1983/F

A preliminary comparison of the distal gut microbiome in HIV-infected subjects before and after HAART. *L.M. Bull[1], B. Youmans[2], Y. Shang[2], S.K. Highlander[1,2], J.F. Petrosino[1,2], K. Worley[1], Q. Xiang[1], R.A. Gibbs[1]*. 1) Human Genome Sequencing Ctr, Baylor College Med, Houston, TX; 2) Molecular Virology and Microbiology, Baylor College of Med, Houston, TX.

The importance of the gastrointestinal tract's commensal bacteria in the maintenance of the mucosal barriers has become evident. In acute HIV infection the primary site of T cell depletion is from the (GI), and HIV viral replication plays a fundamental role in perpetuating microbial translocation, suggesting that the microbiome may have significant impact on HIV disease progression. To examine the relationship between HIV infection and the distal colon's microbiome, we conducted a pilot study to evaluate the difference in microbial community structure and diversity in treatment naïve HIV infected patients (CD4 cell count <250 cells/mm^3), before and after HAART. All subjects were matched by sex and race to HIV negative controls. 16S rDNA from fecal samples was amplified and sequenced using standard Sanger and 454 FLX Titanium, and the taxonomic groups were compared. We found that in all samples, the predominant bacterial classes were the Clostridia (Phylum Firmicutes) and Bacteroidetes (Phylum Bacteroidetes). There was greater variation in the number of minor groups found in the controls which were not identified in the HIV-infected cases. We also found that in all case groups there was an average reduction of the Bacteroidetes to half of the community membership representation that was observed in the controls. Most significantly, there was a clear shift in phylum membership between the cases and the controls that trended with severity of the immune depletion. While all cases showed changes at the phylum level compared to the controls, the most advanced disease (CD4 =118cells/mm^3) case showed the greatest reduction in Bacteroidetes and a greatest increase in Firmicutes. The shift in the higher bacterial taxa either completely or partially reversed after 6-12 months on HAART. Principal component analysis using bacterial families differentiated between the cases before and after HAART for participants that were compliant on medication. Our pilot study suggests that the shift in the GI microbial structure maybe correlated with HIV viral load in a dose-dependent manner, and that upon partial restoration of immune system on HAART, the higher taxa composition is significantly different and likely to cluster with the HIV negative controls. This is the first study to examine the relationship between HIV infection and the human distal colon's microbiome, and the first to report a possible association between HIV viral load and key microbial community membership.

1984/F

Genetic Variants in the promoter region of the gene encoding C-Reactive Protein (CRP) are associated with serum CRP levels in African Americans. *A. Doumatey, G. Chen, A. Adeyemo, H. Huang, J. Zhou, C. Rotimi.* Center for Research on Genomics and Global Health, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Purpose: C-reactive protein is an acute phase reactant protein produced primarily by the liver and associated with diabetes, hypertension, and cardiovascular diseases. Its level is also influenced by other factors such as obesity, smoking. Multiple studies have reported significant association between serum CRP levels and polymorphisms within the CRP gene; however these associations explain only a small proportion of the reported heritability. Thus, it was hypothesized that genetic effects on CRP are certainly present outside its locus. Genome-wide approach has been used in other populations mainly in Europeans to identify other loci that may control serum CRP level. The aim of this study was to identify genetic variants that influence serum CRP in African Americans and to replicate the findings of previously published GWAS in other populations. Methods: A total of 836 unrelated African Americans recruited through the Howard University Family study (HUFS) were genotyped using the Affymetrix 6.0 fixed SNPs array. After quality controls, the analyses focus on 2,366,856 genotyped and imputed SNPs. CRP levels were measured using a clinical auto analyzer (COBAS Integra 400 plus, Roche Diagnostics). The associations were assessed under the additive model with adjustment for proportion of African ancestry, age, gender and BMI. Results: We found significant associations with serum CRP on chromosome 1 at CRP locus (rs3093058, p= 5.20E-10; rs9628671, p= 9.09E-10) and on chromosome 5 near MAN2A1 locus (rs25913, p= 2.58E-06; rs31610, p= 5.61E-06 and rs25915, p= 6.02E-06) Conclusion: In this study, we observed associations at CRP locus with serum levels of CRP as reported in populations of European ancestry. Importantly, we observed a novel locus that may be influencing CRP levels in African Americans.
