The Medcan Clinic is a preventive healthcare clinic focused on identifying health risks before signs and symptoms occur. Medcan provides an array of in-house services, such as diagnostic imaging, genetics, optometry, fitness and nutritional counselling, to customize patients' medical care and optimize healthy outcomes. Since 2005 clients could request a Genetic Risk Assessment, which involves an in-person interview with a masters-trained genetic counsellor and assessment of the family history to identify single gene and/or multifactorial disorders of concern. If there is concern, further genetic testing and/or a consultation with a clinical geneticist is arranged. Since July 2009, the clinic has expanded this service to offer a Personal Genome Testing option. In addition to the Genetics Risk Assessment, the client provides a saliva sample for analysis using the Navigenics platform. Prior to submitting the DNA sample, the client is fully counselled regarding the purpose, limitations, and possible risks of the assessment, including the possibility for insurance discrimination. The results of the array are first conveyed to the client in a personal interview with the genetic counsellor, who reviews the key features of the report. The client is then given a printed copy of the report as well as access to the report on line. Copies of the report are not kept in the patient's file, and are not sent to the patient's physician unless specifically requested by the patient. The client may request follow-up visits with the counsellor if there are any concerns. The array used provides information regarding 27 clinically significant conditions, for which some action is available to reduce lifetime risk. The associations used for the array have been validated in peer- reviewed studies involving independent populations. The combination of pedigree analysis and SNP array screens for both the less common possibility of a Mendelian disorder (e.g. BRCA mutation) and the more common association of SNPs with adult onset conditions. This program combines the benefits of the information available from the SNP array with the value of a family health history review and detailed explanations by a trained genetics professional. In this way, the technology provided in a 'Direct to Consumer' test is made available within the framework of genetics 'best practice'.

1986/F

Personal Genomic Testing - Initial Results of a Genetic Service Combining Family Health History and SNP Array. *L. Velsher, J. Davies, J. Aw.* Dept Gen, Medcan Clinic, Toronto, ON, Canada.

The Medcan Clinic is a preventive healthcare clinic focused on identifying health risks before signs and symptoms occur. Medcan provides an array of in-house services, such as diagnostic imaging, genetics, optometry, fitness and nutritional counselling, to customize patients' medical care and optimize healthy outcomes. Since July 2009, clients can request Personal Genome Testing, which includes a detailed review of their family history and a SNP array using the Navigenics platform. So far, we have provided the service to 284 clients. 242 (85%) of these requested the full genome testing after reviewing the option on the website or speaking to the genetic counsellor or trained sales person prior to their visit. The other 15% were originally seen for a Genetics Risk Assessment, which involves only the pedigree analysis, and decided then to proceed with the genomic SNP test. 4% of the individuals who chose Personal Genome Testing were adopted. Only 3% were referred by their doctors for the service. During the same time period, 73 clients who were seen for the pedigree assessment declined the SNP array. We are compiling a data base of our cases, combining family history and SNP array results for each condition tested by the array. One trend we are seeing is that an increased risk for common disorders based on family history correlates with increased risk by SNP array about 50% of the time. However, the reverse is not true. In most cases with a higher than average risk the family history is negative. We are also conducting a survey of clients, to assess their satisfaction with the test, whether they report changes in their health care or behaviour, and whether clients are experiencing changes in anxiety levels because of the test. Anecdotal trends so far indicate a low level of anxiety and a high degree of satisfaction among those who have had the full Personal Genome Testing. This may be due to the detailed information given by the genetic counsellor before and after the actual test is done. It may also be a function of the select population in the clinic, where most of the clients are highly educated, motivated individuals who are early adopters of new technology and are pro-active about their health.

1987/F

Functional genomic screening to identify novel pathways involved in HIV pathogenesis. *D. Dykxhoorn[1,2], M. Dominska[1], S. Liu[1].* 1) John P. Hussman Institute for Human Genomics, Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Microbiology and Immunology, University of Miami Miller School of Medicine, Miami, FL.

The human immunodeficiency virus (HIV)/AIDS pandemic remains a global health concern affecting millions of individuals world-wide resulting in tremendous pain and suffering. Over a protracted clinical course, HIV attacks the host's immune system leaving the infected individual susceptible to a wide variety of opportunistic infections. HIV susceptibility and disease progression show a substantial level of inter-individual variability. This heterogeneity is influenced by a number of important factors, including the immune status of the infected individual, genetic, epigenetic, viral and environmental factors. The identification of genes that impact susceptibility and resistance to HIV infection is key to unravelling the complexities of HIV-host interactions. Using an unbiased, genome wide RNA interference (RNAi)-based genetic screen, we identified over 250 host factors (HIV-dependency factors (HDFs)) which are required for HIV-1 replication but whose silencing had no overt cytotoxic effects within the context of the screen. Further analysis of these factors have implicated novel roles for factors involved in retrograde Golgi-to-ER trafficking, in viral fusion, and the karyopherin Transportin 3 (TNPO3) in viral integration. Bioinformatic approaches coupled with functional genomic, biochemical and cell biological approaches have been used to identify interactions between HIV and the host cell machinery that are required for early events in the viral life cycle. The characteriztion of these factors will provide novel therapeutic targets for the development of antiretroviral agents that could halt the transmission and spread of this deadly virus.

1988/F

A large-scale neurodevelopmental genomics study with in-depth phenotype-genotype assessment. *H. Qiu[1], M.E. Calkins[2], F.D. Mentch[1], J. Richard[2], D.J. Abrams[1], R.W. Grundmeier[3], R. Chiavacci[1], J. Loughead[2], P.M. Sleiman[1], L. Hermannsson[1], R.C. Gur[2], R.E. Gur[2], H. Hakonarson[1].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Psychiatry, School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Center for Biomedical Informatics, Children's Hospital of Philadelphia, Philadelphia, PA.

Mental disorders are complex, with underlying genetic, epigenetic and environmental factors that are far from being well understood. Symptoms of mental disorders often emerge during childhood and adolescence and undergo changes modulated by processes related to brain maturation and experience. Application of genomic methods to mental illnesses is still hindered by the paucity of information beyond diagnosis pertinent to mental illness. In a recent large-scale genomics study focusing on Neurodevelopmental Genomics and Trajectories of Complex Phenotypes (NGTCP), we aim to fill the information gap by conducting clinical and neurobehavioral phenotypic characterization of a large cohort of 10,000 prospectively accrued community sample, age 8 to 21 years, who were already genotyped using high-density SNP arrays.

Participants undergo a clinical assessment composed of personal and family psychopathology screening interviews, with their electronic health records (EHR) also linked as supplementary information. Computerized neurocognitive battery (CNB) tests are administered to collect measures in the following domains: 1) Abstraction and mental flexibility, 2) Attention, 3) Working Memory, 4) Verbal Memory, 5) Face Memory, 6) Spatial Memory, 7) Language and Reasoning, 8) Spatial Processing, 9) Emotion Processing, and 10) Sensory-motor Processing Speed. In addition, neuroimaging is conducted in 1,000 participants randomly selected using stratified random sampling. The neuroimaging studies include Structual Imaging (sMRI), Diffusion Tensor Imaging (DTI), Functional Imaging (fMRI) and Resting ASL perfusion MRI. For these 1,000 imaged subjects, DNA methylation profiling is performed and EBV cell lines are established for functional-biological studies such as expression profiling and deep sequencing.

This integrated resource of comprehensive phenotypic and genomic parameters will be presented and is anticipated to lay sound foundations for advanced genomic studies to elucidate the neurodevelopmental trajectories of complex mental disorders in the future.

1989/F

Race, Gender, Adiposity and Leukocyte Telomere Length in Healthy White and Black Adolescents. *H. Zhu[1], X. Wang[1], B. Gutin[1], D. Keeton[1], J. Thomas[1], I. Stallmann-Jorgensen[1], V. Bundy[1], H. Snieder[2], P. Harst van der[3], Y. Dong[1].* 1) Department of Pediatrics, Medical College of Georgia, Augusta, GA; 2) Department of Epidemiology, University Medical Center Groningen, University of Groningen, Groningen, the Netherlands; 3) Department of Cardiology, University Medical Center Groningen, University of Groningen, Groningen, the Netherlands.

Objectives: Telomere length, an emerging marker of biological aging, has been investigated in adult populations. However, little is known about the effect of race, gender, adiposity and the adipokines on telomere length in adolescent populations. **Study design:** Leukocyte telomere length (T/S ratio) was assessed cross-sectionally in 667 white and black boys and girls aged 14-18 years (48% blacks, 51% girls) using a quantitative PCR method, which normalized telomere extension product (T) to the amount of extension product of a single copy gene (S). Predictor variables included body mass index, waist circumference, percentage body fat, visceral adipose tissue, leptin and adiponectin. Multiple linear regression analyses were used to determine the effect of race, gender and adiposity on telomere length. **Results:** Significant race and gender difference in telomere length were identified, with black adolescents having longer telomeres than white adolescents (age and gender adjusted T/S ratio ± SE: 1.32 ± 0.01 vs. 1.27 ± 0.01, p=0.009), girls having longer telomeres than boys (age and race adjusted T/S ratio ± SE: 1.31 ± 0.01 vs. 1.27 ± 0.01, p=0.01). None of the adiposity measures or adipokines explained a significant proportion of the variance in telomere length. **Conclusions:** This is the first study conducted in a biracial adolescent cohort showing that (1) race and gender differences in telomere length have already emerged during adolescence; but (2) adiposity and adipokines are not associated with telomere length at this age.

1990/F

MTHFR 677C>T polymorphism in Iranian migranous patients. *M. Ansari[1], S. Saeidi[1], M. Moghadasi[2], A. Ebrahimi[3], F. Abbasi[1], F. Rezaei[4], MS. Fallah[3,4].* 1) Clinical Biochemistry, Tehran University of Medical Sciences, Tehran, Tehran, Iran; 2) Dep't of Neurology, Iran University of Medical Sciences, Tehran, Iran; 3) Kawsar Human Genetics Research Center, Kawsar Genomics & Biotech Center, Tehran, Iran; 4) Aramesh Pain Clinic, Tehran, Iran.

Migraine is a prevalent and debilitating disease affecting a large proportion of the population. MTHFR is suggested to play a role in migraine susceptibility. There are conflicting data on the association between the MTHFR 677C>T polymorphisms and migraine disease. This may have some correlation with the response to the vitamin therapy. This study performed to find the association between the MTHFR 677C>T polymorphism and migraine in Iranian patients. Migrainous patient according to the international headache society criteria entered in the study. Healthy people without any positive history of periodic headache and no family history of migrainous head in the family recruited as control group. MTHFR 677C>T polymorphisms were investigated in cases and controls using PCR-RFLP method. Thirty-nine migrainous patient (9 male and 30 female) and 58 healthy controls (20 male and 38 female) entered in the study. The CC genotype was most frequent in both group (19 (48.7%) and 31 (53.4%) in case and control group respectively) followed by CT genotype in 16 (41.0%) cases and 25 (43.1%) controls. Genotype frequency didn't show any significant difference between groups (chi square test). In this study we didn't find any correlation between MTHFR 677TT genotype and migraine. More studies with more sample is needed in Iranian population.

1991/F

ENCODE Whole-Genome Data at UCSC: Fall 2010 Snapshot. *K.R. Rosenbloom, T. Dreszer, B. Raney, C. Sloan, V. Malladi, M. Cline, G. Barber, L. Meyers, K. Roskin, B. Suh, A. Hinrichs, A. Zweig, P. Fujita, K. Learned, B. Rhead, V. Swing, A. Coelho, R. Kuhn, D. Karolchik, D. Hausler, W.J. Kent, ENCODE Consortium.* Center for Biomolecular Science and Engineering, UC Santa Cruz, Santa Cruz, CA.

The Encyclopedia of DNA Elements (ENCODE) Project is an international scientific collaboration charged with creating a comprehensive catalog of functional elements in the human genome. In September 2007, the pilot project focused on 1% of the genome, was scaled up to whole-genome scale. Two years into production, the participating experimental groups have submitted a wealth of high-throughput epigenomic and transcriptome data to the ENCODE Data Coordination Center at UC Santa Cruz. At the mid-course milestone (January 2010 data freeze), results from 860 experiments in 112 cell lines and tissues had been submitted to the DCC for public release in the Genome Browser. A total of 23 experimental assays were represented, including ChIP-seq of 98 transcription factors and 10 histone modifications, RNA-seq in 8 cellular compartments, DNase and other measurements of open chromatin, chromatin interaction maps, and high-quality gene annotations from the Gencode project. It is anticipated that the number of experiments will have doubled by November 2010. The ENCODE DCC at UCSC provides both raw data (sequence reads and quality scores) and processed data files (alignments, density graphs and peak calls) from the UCSC Download server, data mining via the UCSC Table Browser, and general access to ENCODE information at the UCSC ENCODE Portal (http://genome.ucsc.edu/ENCODE). This year's developments for ENCODE include migration to the GRCh37/hg19 human genome assembly, completion of the first round of integrative analyses, and the addition of 6 new production groups, expanding the project scope to include new experiment types (proteogenomics, epitope-tagged TFBS assays) and inter-species orthology of regulatory elements from ChIP-seq and RNA-seq in mouse cell lines and tissues.

1992/T

Patient-entered, web-based, EMR-compatible, comprehensive cancer family history collection tool: clinical workflow, demographics, and patient satisfaction from pilot study. *M. Doerr[1], B. Leach[1], X. Men[2], J. Moline[1], K. Stanuch[1], E. Edelman[3], C. Eng[1].* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH; 2) Information Technology Division, Cleveland Clinic, Cleveland, OH; 3) National Coalition for Health Professional Education in Genetics, Lutherville, MD.

MyFamilyHealthHistory (MyFHH) is a patient-entered, web-based, EMR-compatible, comprehensive cancer-focused family health history collection tool developed by the Genomic Medicine Institute (GMI) in collaboration with the Information Technology Division, Cleveland Clinic. Clinical Workflow: A specific appointment type automatically triggers a MyFHH invitation email to the patient. The patient logs in via secure web-portal and follows prompts to complete a 3-4 generation pedigree. If not completed, a genetic counselor assistant (GCA) contacts the patient with reminder phone call(s). GCA can also walk the patient through the questionnaire if the patient lacks web access or needs additional support. Demographics: As of June 2010, MyFHH has been piloted with 56 patients (45 women, 11 men) scheduled for cancer genetics appointments at GMI. 5% of participants self-identified as African-American (n=3), the remainder as White (53); 25% (14) reported Jewish ancestry. The average age of participants was 47 years (median = 50, range = 21-68). Consistent with Clinic norms, most (31, 55%) were white women age 40 or older. 45% (25) of patients completed the questionnaire in advance of their appointment without further prompting; 39% (22) completed it after a reminder phone call; 11% (6) required some GCA support (e.g., web-based completion with a GCA helping by phone); and 5% (3) had the questionnaire completed by their genetic counselor (GC). There were no discernable trends in age, race, or gender of those not needing support vs those needing GC/GCA support. Patient Satisfaction: 48 (86%) of the pilot group completed a satisfaction survey following the questionnaire. 81% (39) agreed/strongly agreed that MyFHH was easy to use. 60% (29) of respondents spoke with family members while completing the questionnaire (a “save and come back” feature facilitates information-gathering). 85% (41) felt that the time it took to complete the questionnaire was “just right” (data entry takes 30-60 minutes); 7 respondents (15%) felt it took “a little too long.” Conclusion: MyFHH enables secure, EMR-compatible, comprehensive cancer family history collection prior to genetic clinic visits. 84% of patients were able to complete MyFHH without GC/GCA support; trends were not observed by age, race, or gender. Patient satisfaction with MyFHH is high. Use of MyFHH could potentially streamline counseling sessions and/or allow for the implementation of alternative service delivery models.

1993/T

A genomic and personalized medicine application for population and public health: The Genomically Enabled Elecronic Medical Record - GenE EMR. *W. Cohn[1], S. Jones[1], M. Ropka[1], R. Gaare-Bernheim[1], J. Harrison[1], J. Lyman[1], S. Powell[2], W. Knaus[1].* 1) Public Health Sciences, Univ Virginia, Charlottesville, VA; 2) Internal Medicine, University of Virginia, Charlottesville VA.

The potential public health benefits available from genomics and personalized medicine have yet to be realized. We previously developed Health Heritage, a Web-based family health history application, to provide an easy-to-use tool for consumers to efficiently collect and update their family health history. Combined with evidence-based decision support, Health Heritage can provide recommendations for prevention and risk reduction for 89 conditions in 5 disease areas, based on hereditary and familial risk factors. Our current project, titled “Building a Genome-Enabled Electronic Medical Record (GenE EMR)”, focuses specifically on cancer risk. The project will enhance Health Heritage in three primary ways. First: it will include additional personal and genomic risk factors into the decision support to provide recommendations that are even more personalized. Second: Health Heritage will be integrated into multiple electronic medical records (EMRs) and personal health records, thus increasing ease-of-use and accuracy by both patients and physicians. Third: we will develop ways to, at patient request, securely electronically share information with family members to ease relatives’ burden of compiling and updating health histories. Additionally, we are exploring the economic, ethical, legal and social implications of GenEMR and its features. Although the initial focus is on cancer during this development phase, work with other diseases is planned.

1994/T

Validation of Electronic Health Records in a large scale pediatric genomics study. *F.D. Mentch[1], D.J. Abrams[1], H. Qui[1], S. Ostapenko[2], J.J.M. Connolly[1], A.W. Moy[1], C.E. Kim[1], R.M. Chiavacci[1], L. Hermannsson[1], K. Wang[1], P.M. Sleiman[1], Y. Guo[1], B. Keating[1], S.F.A. Grant[1,3,4], R.W. Grundmeier[2], H. Hakonarson[1,3,4].* 1) Center for Applied Genomics, Children’s Hospital of Philadelphia, Philadelphia, PA; 2) Center for Biomedical Informatics, Children’s Hospital of Philadelphia, Philadelphia, PA; 3) Division of Human Genetics, Children’s Hospital of Philadelphia, Philadelphia, PA; 4) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA.

Electronic Health Records (EHRs) are a rich source of phenotype information for large scale genomics studies. The format and focus of the data, however, can make it challenging to automate validation of purported subject phenotypes on a large cohort with a high degree of confidence. We report initial results of comparing patient interviews, automated EHR phenotype extraction and manual EHR phenotype extraction for an on-going large scale pediatric genomics study conducted at the Children’s Hospital of Philadelpha, including over 35,000 children. Taking the combination of manual abstraction plus self-reporting as the baseline, we find that patient self-reporting in the interview process returns about 50% of the phenotypes of interest; manual abstraction from the EHR database returns 87%; and the automated abstraction process from the EHR database returns 69%. The combination of patient self-reporting and automated EHR extraction return 93%. We propose that automated extraction is a reliable method for validating and enhancing self-reported data and we will test this approach with larger numbers of subjects as the study progresses.

1995/T

Enabling genetically guided patient care through clinical decision support: a systematic review of the literature. *K. Kawamoto.* Department of Community and Family Medicine and Institute for Genome Sciences & Policy, Duke University, Durham, NC.

Computer-based clinical decision support (CDS) has been identified as a critical enabler of genetically guided patient care by various groups, including the U.S. Secretary of Health and Human Services and the Secretary’s Advisory Committee on Genetics, Health, and Society. In order to inform future research in this area, MEDLINE was systematically searched from 1990 through May 2010 using a search strategy adapted from previous systematic reviews of CDS (Kawamoto K et al., BMJ, 2005), genetic health services (Scheuner MT et al., JAMA, 2008), and family history (Wilson BJ et al., Ann Intern Med, 2009). Of 1,892 references screened, 53 manuscripts met the study inclusion criteria. Of the 53 included manuscripts, 36 (68%) were primary research articles, and 17 (32%) were reviews or opinion papers. Two-thirds of the primary research studies focused on CDS for familial cancer syndromes, as did all eight of the identified randomized controlled trials. Of particular note, a large randomized controlled trial conducted across 45 clinics in the U.K. found that the use of a CDS system by primary care clinicians significantly improved the appropriateness of the clinicians’ genetic counseling referrals for familial breast and colorectal cancer (Emery J et al., Br J Cancer, 2007). Beyond hereditary cancer syndromes, investigators have evaluated the use of CDS to support genetically guided care in several other areas, including HIV management, prenatal testing, warfarin dosing, cardiovascular disease risk management, and drug dosing informed by patients’ genotypes for drug metabolizing enzymes. With regard to long-term trends, research in this field is accelerating, with 92% of the manuscripts published on or after 2000. Also, while only 25% of the 36 manuscripts published before 2008 focused on clinical areas outside of hereditary cancer syndromes, 76% of the 17 manuscripts published on or after 2008 focused on additional clinical areas such as pharmacogenetics. Moreover, recent research efforts have focused significantly on the need for a coordinated, cross-institutional approach to CDS that is based on common health information technology standards and is capable of widespread deployment. Future studies will need to address gaps in the current research landscape, including the need for more scalable approaches to genetically guided CDS and the need for rigorous, prospective evaluations of CDS systems in clinical areas beyond hereditary cancer syndromes.

1996/T

Veterans' Response to the Use of Family Health History Online Tool. *N. Arar.* Dept Medicine, Div Nephrology, Univ Texas Health Sci Ctr, San Antonio, TX.

Objective: To assess veterans' satisfaction in using the online Surgeon General family health history (SG FHH) tool, and intentions regarding the utilization of FHH information. Method: A total of 35 veterans visiting the primary care outpatient clinic in San Antonio, TX were invited to complete the online self-administered SG- FHH tool and the study's surveys. Subjects were provided with a printed copy of their pedigree then asked to participate in a short semi-structured interview to assess their intentions regarding the utilization of their FHH information. The modified ACSI survey assessed drivers of satisfaction (content, functionality, look and feel, navigation, and performance) in using the SG-FHH online tool. The semi-structured interviews focused on facilitators and barriers to using FHH information. Semi-structured interviews were content analyzed using qualitative methods. Results: The majority of participants (71%) was male, 78% were over 50 years of age, and described themselves as non-Hispanic White. About 56% indicated that they had completed some technical school. All participants found the SG- FHH online tool very useful. The total time spent in completing the FHH forms was 25 minutes. About 67% of the participants said that they have easy access to a computer or the internet and demonstrated their ability to complete all FHH forms. Most subjects (88%) viewed the functionality, look and feel, navigation, and performance of the NG-FHH tool favorably. Participants also indicated that the tool has met their expectations. Content analysis of the semi-structured interviews showed several barriers to veterans' use of FHH information. These include (1) lack of patients' knowledge regarding the importance of FHH information, (2) concerns about privacy and confidentiality related. Our findings suggest that strategies to improve veterans' knowledge regarding the importance of FHH information and address their concerns about privacy may enhance successful implementation of FHH information into VHA clinical practice. Impact: Promoting the use of online FHH tool [e.g., SG-FHH tool] will have important implications to the primary care providers and their patients. It will also improve screening for common complex diseases and enable providers to focus their resources on developing critically important health behaviors for populations at high familial risk.

1997/T

Health Needs Assessment as a Pre-requisite for Evidence-based Service Development in Developing Countries. *I. Nippert[1], U. Kristoffersson[2], J. Schmidtke[3], A. Kent[4], R. Raouf[5], C. Barreiro[6], A. Christianson[7].* 1) Women's Hlth Res, Univ Muenster, Muenster, Germany; 2) Dept Clin Gen, Univ Hosp Lund, Lund, Sweden; 3) Inst Hum Gen, MHH, Hannover, Germany; 4) GIG, London, UK; 5) Children with special needs Dep, Ministry of Health, Cairo, Egypt; 6) Hospital de Pediatria SAMIC, Buenos Aires, Argentina; 7) Div Hum Gen, Univ Witwatersrand, Johannesburg, South Africa.

Introduction: Many developing countries have yet to confront the issues of developing policies for the provision of medical genetic services and medical genetic testing. Given their resource limitations they need practical approaches that have been proven to work in real settings. Approaches are required that will result in the development of appropriate needs-based services, that are sensitive to specific country contexts, health service patterns, available resources and capacities as well as to legislative factors and cultural and societal norms. *Methods:* An international multidisciplinary working group developed a model approach for capacity building for the translation of genetic knowledge into practice and prevention in developing countries (CAPABILITY, funded by the EC's 6th Framework programme, LSSG-CT-2006-037275). The model is based upon a systematic health needs assessment (HNA) for medical genetic services and was validated via a joint demonstration project in Argentina, Egypt and South Africa. *Outcome:* A validated capacity building approach sensitive to specific health care contexts and service pattern in developing countries including the magnitude of assessed needs, available resources and capacities, service gaps as well as ethical, socio-cultural and legal implications. *Conclusion:* Significant challenges face the development of medical genetic services in middle- and low-income countries. HNA is a systematic approach for planning and providing cogent health services in a setting of finite resources, epidemiological transition, technological advance and changing public expectations. HNA can assist developing countries determine and prioritise their medical genetic health needs and establish well organised and structured services, both clinical and laboratory, appropriate to their needs and resources.

1998/T

An exploratory study of public and professional perceptions on the use of family history and genomic profiling to assess complex disease risk. *B. Wilson[1], D. Castle[2], M. Weir[1,2], D. Jillions[1], K. Morin[2], J. Little[1], D. Avard[3], M. Cappelli[4], J. Carroll[5], T. Caulfield[6], P. Chakraborty[7], H. Etchegary[8], L. Lemyre[9], F. Miller[10], B. Potter[1], G. Wells[11].* 1) Epidemiology & Community Medicine, University of Ottawa, 451 Smyth Rd. Ottawa, ON K1H 8M5 Canada; 2) Department of Philosophy, University of Ottawa, 234-70 Laurier Ave. E. Background Genomic profiling for susceptibility to complex disorders offers the goal of personalizing disease prevention interventions to individual patient risk, e.g. by defining the right age to start a preventive regimen and/or selecting specific interventions. Two genomic profiling approaches are DNA based and family history (FH) based. The former is still a largely hypothetical possibility whereas the latter is part of standard medical practice. Even if genomic profiling by either method can be shown to produce acceptable clinical validity (ability to correctly predict risk), the clinical or public health utility will be influenced by its rate of adoption by health care professionals, and its acceptability to target populations. We report here the results of a pilot study on (hypothetical) DNA-based genomic profiling for colorectal cancer, discuss the lessons learnt, and describe how the issues are being addressed in current research. Pilot study methods and findings We conducted focus groups and semi-structured interviews with community groups representing the target populations for screening, and relevant professional provider groups. We identified the following salient themes: the attraction of a 'clean' alternative to fecal occult blood testing; attitudes towards knowing one's genetic make-up; professionals' framing of DNA based genomic profiling as 'genetic testing'; and professionals' perceptions regarding health service capacity to integrate new technologies into current screening programs. Methodological issues and current research In the pilot study, we noted the difficulty of imparting information on the nature of a hypothetical technology while also assessing participants' reactions. After a broad literature review, we identified over 100 approaches to public engagement but a dearth of published empirical validations. For our main study, we selected an approach designed for technologies which are new or unfamiliar. The technique involves the carefully staged, incremental presentation of information on the topic of interest (including ethical issues), and the use of open and closed questions to gather reactions as progressively more details are provided. We will present preliminary findings from the main study, and report critical details on the way in which the approach was specifically implemented and initial insights into its performance as a way of evaluating unfamiliar technologies.

1999/T

Evaluation of Clinical Diagnostic Potential of Next Generation Sequencing using Hypertrophic Cardiomyopathy as a model. *K. Kaur[1], J. Broxholme[2], R. Copley[2], J. Thistleton[3], S. Reid[3], L. Ormondroyd[4], A. Seller[3], E. Blair[5], I. Ragoussis[2], J. Taylor[1], H. Watkins[4].* 1) Oxford Biomedical Research Centre, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 3) Oxford NHS Regional Molecular Genetics Laboratory, Oxford, United Kingdom; 4) Oxford University Department of Cardiovascular Medicine, Oxford, United Kingdom; 5) Oxford NHS Clinical Genetics Department, Oxford, United Kingdom.

The routine diagnosis of genetically heterogeneous Mendelian conditions is limited by current technologies. Conventional Sanger sequencing is too expensive for parallel screening of multiple genes and mutation detection methods are laborious for this purpose. As a result many conditions go untested or tests do not encompass all known genes. Next generation sequencing has the potential to revolutionise the field of clinical genetic diagnostics, by providing massively parallel sequencing at comparable costs to current technologies. We have developed a workflow for routine diagnosis of hypertrophic cardiomyopathy using the GS-FLX next generation sequencing platform. The sensitivity and specificity of this platform for genes currently tested in the NHS (MYBPC3, MYH7, TNNT2 and TNNI3) has been confirmed. Using a long range PCR approach the number of genes tested has been expanded to 15 and the mitochondrial genome has been included. A bioinformatics pipeline has been developed to ensure that the data can be analysed in a routine diagnostic laboratory without specialist bioinformatics knowledge. Our results on a cohort of more than 150 probands demonstrate the feasibility of using next generation sequencing in a clinical diagnostic environment. The process of translating this to the NHS and the impact of testing on diagnostic accuracy, yield, turn-around times and cost-effectiveness will be discussed. This approach has considerable implications for routine testing of other heterogeneous Mendelian conditions and monogenic forms of complex diseases.

2000/T

Financial Analysis of Genetic Testing for Legius Syndrome in the Neurofibromatosis Type 1 Population. *T.M. Muram-Zborovski[1,2], D.A. Stevenson[3], D.H. Viskochil[3], J.C. Carey[3], R. Mao[1,2], B. Jackson[1,2].* 1) Department of Pathology, University of Utah, Salt Lake City, UT; 2) ARUP Laboratories, Salt Lake City, UT; 3) Department of Pediatrics, University of Utah, Salt Lake City, UT.

Legius syndrome (LS) is a single gene disorder, which clinically overlaps with the pigmentary features of neurofibromatosis type 1 (NF1). LS individuals may meet NIH diagnostic criteria for NF1, creating diagnostic difficulty. Both LS and NF1 individuals may also have macrocephaly and/or learning disabilities. Distinctive manifestations of NF1 appear with age, lending a definitive diagnosis of NF1. These features include neurofibromas, Lisch nodules, optic gliomas, and distinctive bone manifestations (long bone dysplasia, sphenoid wing dysplasia, dystrophic scoliosis). The diagnostic difficulty remains with those individuals with pigmentary findings who do not develop additional manifestations, with or without macrocephaly and learning disabilities. A diagnosis of LS compared to NF1 may provide both peace of mind, because they lack a tumor phenotype, and cost savings due to less aggressive medical monitoring. However, these savings are balanced against the genetic testing costs. Our aim was to identify the most cost-effective age for genetic testing for LS in an NF1 clinic population. Delaying genetic testing beyond a specific age could lower global testing costs, since fewer patients would require testing as the development of distinct NF1 features would eliminate the possibility of Legius syndrome. Prior to this age cutoff however, all individuals would need to be managed as if they had NF1. Using TreeAge Pro 2009 software, we generated a model of the NF1 population of routine NF1 management costs at a typical NF Clinic to determine a population cost-per-individual between the ages of 1.5 and 18 years, using the assumption based on published data that 2% of these individuals meeting NIH diagnostic criteria for NF1 have Legius syndrome. Our model includes annual genetics and ophthalmology examinations and a 10% probability per year for an MRI scan. Over time, the majority of individuals with NF1 will develop age-related manifestations, declaring themselves diagnostically as having NF1. Therefore, as the model adjusts for age, there are fewer individuals without a definitive diagnosis who require genetic testing. We analyzed the cost effectiveness of testing at 2-year age intervals from 4 until 10 years-of-age. Within the NF1 population, for those individuals who do not develop additional manifestations of NF1, it is not only cost-effective but cost-saving to perform genetic testing for LS, provided that one delays until the child is six years of age.

2001/T

A practical measure of workload for molecular genetic diagnostic laboratories. *S. Stenhouse[1], R. Butler[2], A. Curtis[3], J. Deller[4], K. Kelly[5], R. Mountford[6], G. Norbury[7], Clinical Molecular Genetics Society and UK Genetic Testing Network.* 1) Institute of Medical Genetics, Yorkhill Hosp, Glasgow, United Kingdom; 2) Molecular Genetics, Institute of Medical Genetics, Cardiff and Vale NHS Trust, Heath Park, Cardiff. United Kingdom; 3) Northern Genetics Service, Institute of Human Genetics, Central Parkway, Newcastle upon Tyne, United Kingdom; 4) UK Genetic Testing Network, Southside, 105 Victoria Street, London, United Kingdom; 5) Molecular Genetics, Department of Medical Genetics, Polwarth Building, University of Aberdeen, Foresterhill, Aberdeen, United Kingdom; 6) Merseyside and Cheshire Regional Molecular Genetics Laboratory, Genetics Department, Liverpool Women's NHS Foundation Trust, Crown St, Liverpool, United Kingdom; 7) DNA Laboratory, Genetics Centre, 5th Floor Guy's Tower, Guy's Hospital, London, United Kingdom.

There has long been a need for a robust measure of workload for molecular genetic testing. This is required to predict staffing requirements and provide a logical method for pricing genetic tests. A working group from the CMGS and UKGTN was assigned to investigate this and produce a model for pilot studies.

The initial premise was that the measure should be transparent and flexible to allow comparisons between laboratories and to take account of developing technologies. The unit chosen for the measure was the final diagnostic report which is an easily counted unit. As reports can be relatively simple or very complex a weighting system was required. The unit chosen to weight the reports was 'an amplicon'(or equivalent) which is again an easily counted measure. The weights were then assigned to a band from A to G. The weight for any disorder can be decided in a straightforward manner by counting the amplicons tested and assigning it to a band. The basic unit, Band A, is sample reception and DNA extraction with a weight of one. Band G has a weight of 40.

This system was piloted in 6 UK laboratories and the total annual number of units divided into the total annual budget to provide a cost per unit and a guide price for tests. The laboratories varied in size and testing repertoire to ensure a broad base for the trial. Similarly the total number of units can be divided into the number of staff involved in the testing to derive an approximate figure for staff productivity allowing appropriate service planning.

The mechanics of the measure will be described in detail.

2002/T

Integrating parallel sequencing into diagnostic pathways. *G.R. Taylor, R.F. Charlton, P. Roberts, D.T. Bonthron, C.E. Chu.* Genetics, Leeds Inst Mol Med & Leeds Teaching Hospitals, Leeds, United Kingdom.

We have applied clonal sequencing in a diagnostic setting for the detection of mutations and copy number alterations and describe its effect on the performance and cost of a the service. Base-calling was less accurate than by Sanger sequencing, but complete concordance was seen in 110 Sanger sequenced cases and those sequenced using an Illumina GAII provided that the depth of clonal sequencing was greater than 50. This value implies base calling accuracies below the Phred-like scores commonly used and increases the cost of diagnostic testing. Nevertheless the overall cost of BRCA1 and BRCA2 gene testing was reduced by over 50% and this figure will improve as the workflow is refined. We explored he choice of wide (many genes, few patients) versus deep (few genes, many patients) sequencing in a diagnostic setting using gene sets for cardiomyopathy testing and hereditary cancers. Preliminary findings in terms of costs and patient benefits will be presented. We and others have shown that clonal sequencing can be used to provide copy number information. A comparison of the cost and performance of array CGH with copy number counting using whole genome sequencing shows that in many instances, sequencing is a more economical alternative.

2003/T

The NIH Undiagnosed Diseases Program: New Insights on the Application of Clinical Research Techniques to Unknown Diseases. *D. Adams, C. Tifft, T. Markello, C. Toro, G. Golas, L. Wolfe, W. Gahl.* Undiagnosed Diseases Program, NIH, Bethesda, MD.

The NIH Undiagnosed Diseases Program (UDP) is a pilot program designed to address the needs of persons with debilitating medical conditions for which no diagnosis has been found despite an extensive workup. The goals of the UDP include finding accurate diagnoses, and discovering new diseases that provide insight into human health. In the first two years, over 3000 inquiries have been received, 1192 medical records have been reviewed, 227 people have been accepted and 84 have been referred to other ongoing studies within the NIH. To date, 160 accepted individuals have been brought to the NIH for in-depth, one-week inpatient medical evaluation. Approximately 15% of individuals have received a specific diagnosis and a larger number have generated strong candidates for research follow-up. Most applicants have a multisystem phenotype; many have a preponderance of neurological symptoms. Diagnoses have been made by the UDP team before, during and after admission to the NIH Clinical Center. Diagnoses based on clinical evaluation and clinically-available testing include amyloidosis, Smith-Magenis syndrome, familial ALS and hereditary spastic paraplegia. Diagnoses based on research testing include SCA 28, CDG IIb, and a novel arterial calcification syndrome. Research biochemical screening tools include such techniques as organelle immunocytochemistry (Invitrogen, Carlsbad, CA) and biochemical profiling of cellular respiration (Seahorse Bioscience, North Billerica, MA). Research molecular analyses include SNP array screening for indels, contiguous homozygosity, uniparental disomy, consanguinity, and crossover-delineated linked regions. Whole exome data analysis, involving eight families, is ongoing and has yielded an experimentally-verified, disease-causing mutation in one family. Interim analysis of data derived from studied individuals is being used to refine our diagnostic approach. For example, few patients appear to have uncommon presentations of known conditions, and extensive clinical-hypothesis-driven Sanger sequencing has yielded few useful results. Consequently, we have moved toward earlier use of whole exome sequencing and have defined a set of guidelines for determining which family members' should provide DNA samples to maximize the use of genetic models to filter DNA variants. Future development of the NIH UDP pilot will include expansion of in-house research and collaboration to follow-up the abundant basic research leads arising from UDP cases.

2004/T

Family history in risk assessment for common complex diseases: a critical review of practice guidelines and modeling study. *Q. Hasanaj, B. Wilson, J. Little, Z. Montazeri.* Epidemiology and Community Medicine, University of Ottawa, Ottawa, Canada.

Background: Family history (FH) is a risk factor for many common complex diseases, and provides insights into the effects of shared disease susceptibilities arising from genomic susceptibility, shared environments, and common behaviors. Although it is not a modifiable risk factor, in principle, inclusion of FH in disease risk assessment algorithms might improve the accuracy of disease risk stratification; this, in turn, may lead to better matching of disease prevention interventions to individual risks. Practice guidelines often mention FH in the context of risk assessment. However, in isolation, FH is not highly predictive for complex disease risk, so it is important to examine how it alters the predictive accuracy of other accepted risk factors. **Objectives:** (1) To review how 'positive FH' is defined in disease-specific guidelines, (2) To review how preventive recommendations are revised for people with a positive FH and (3) To calculate the incremental improvement in individual risk prediction which is gained by incorporating FH with other forms of clinical information recommended in guidelines. **Methods:** We performed an environmental scan of chronic disease guidelines currently in use in North America using standard systematic review methods. We extracted data on the definitions of 'positive FH' which were used (if any) and the way in which preventive recommendations were altered according to presence of positive FH. We also evaluated the guidelines using the AGREE instrument. We then used data from a large colorectal cancer case control study to determine the predictive ability of FH and other classical risk factors (e.g. age, sex, selected dietary patterns, etc) individually and in combination. We developed logistic regression models and calculated the area under the receiver operating curve (AUC). **Results:** There was no consistency of definitions of 'positive FH' between guidelines for the same condition and there was a wide range in how preventive recommendations are modified in response. The logistic regression modelling and AUC calculations are currently underway.

2005/T

Simultaneous detection of 26 amino acids in human plasma using 6-aminoquinoly-N-hydroxysuccinimidyl carbamate (AQC) as derivatizing agent. *S. Attri, G. Sharma, P. Kumar, S. Singhi, P. Singhi, I. Panigrihi, S. Sharda.* Pediatrics, Postgraduate Inst Medl Education & Research, Chandigarh, India.

The AQC has been used for the derivatization of primary and secondary amino acids to yield fluorescent derivatives with high sensitivity; however there is need to improve and modify the existing Waters' AccQ.Tag method that can analyze maximum number of amino acids in a single run without compromising the sensitivity. All the reagents used were from Sigma, USA except the AccQ.Fluor reagent kit from Waters Assoc (Milford USA). Separations were carried out using Lichrospher 100 RP-18e (5μm) 250x4.0 mm column connected to 100CN 4.0x4.0 mm guard column on a quaternary HPLC system from Perkin Elmer using modified gradient elution instead of AccQ.Tag column from Waters Assoc. The working eluents were acetate buffer (pH 5.8 and 6.8), acetonitrile and water. A fluorescent detector was used to quantify all the amino acids with excitation at 250nm and emission at 395 nm. The photodiode array detector was used at 248 nm to obtain a better quantification of tryptophan. In the present method all the 26 amino acids were assayed with high sensitivity, accuracy and good reproducibility on very small amounts of plasma samples within 50 min whereas only 18 amino acids were detected using original AccQ.Tag method and 24 amino acids by quaternary eluent systems in hydrolysate samples. High resolution was achieved for a number of important amino acids including glutamine, glycine, proline, homocysteine, tyrosine, ornithine, phenylalanine, lysine and leucine. Linearity of the peak areas for different concentrations, ranging from 2.5-200 picomoles, of individual amino acids was determined. A good linearity ($r2 \geq 0.98$) was achieved in the standard mixture for each amino acid. Recovery of amino acids incorporated at the time of derivatization ranged from 95 to 106%. We have established the normative data of amino acids in plasma for 50 children, the profile being comparable to the western data reported in literature. The present method was highly sensitive, accurate, reproducible and cost-effective for amino acid analysis in metabolic laboratory in pediatric setup.

2006/T

Routine use of CANTAB system for detection of neuropsychological deficits in patients with PKU. *M. Bik-Multanowski, J.J. Pietrzyk.* Chair Pediatrics, Jagiellonian Univ, Krakow, Poland.

Adolescents and adult patients with phenylketonuria (PKU) demonstrate compliance problems often leading to discontinuation of their dietary treatment. In such non-compliant patients neuropsychological abnormalities are often reported. Prefrontal cortex-dependent deficits are considered to be early symptoms of brain dysfunction in these patients. However, no standardized tests for reliable, early detection of such deficits were available until recently. The aim of the study was to assess the usefulness of a battery of standardized, computerized neuropsychological tests application for detection of prefrontal cortex dysfunction in patients with PKU. Methods: A group of 47 patients aged >16 years were tested by means of CANTABeclipse system (Cambridge Cognition Ltd), which includes normative database for assessment of results of the tests used. Neuropsychological tests assessing prefrontal cortex-dependent functions such as attention (Rapid Visual Information Processing - RVP), working memory (Spatial Span - SSP and Spatial Working Memory - SWM), impulsive behavior control (Stop Signal Task - SST) as well as reaction time (Simple Reaction Time - SRT and Choice Reaction Time - CRT) were applied. Results: Differences were observed between a group of 20 patients on well-controlled diet and a group of 27 patients with poor dietary control with regard to the results of the tests. The overall frequency of all results of the individual tests below accepted range (<2SD) in patients with poor dietary control was significantly higher than in the well controlled patients ($p=0.022$; Fisher's exact test). Similarly, working memory deficits were found in the group of patients lacking dietary control (the number of errors observed in SWM was higher; $p=0.006$ in Student's t-test) as well as worse impulsive behavior control was observed (the number of errors in SST was higher; $p=0.021$ in Students t-test). Conclusion: CANTABeclipse system allows for reliable detection of neuropsychological deficits in non-compliant adolescents and adults with PKU. Study was sponsored by government research grant NN402329233.

2007/T

Neurocognitive Findings in Individuals with Phenylketonuria and Treatment with Sapropterin Dihydrochloride (BH4). *D.K. Grange[1], D.A. White[2], S.E. Christ[3].* 1) Div Genetics and Genomic Medicine, Dept. Pediatrics, Washington University, St Louis, MO; 2) Dept. Psychology, Washington University, St Louis, MO; 3) Dept. Psychological Sciences, University of Missouri, Columbia, NO.

Background/Objective: Phenylketonuria (PKU) is a disorder in which phenylalanine (Phe) metabolism is disrupted. The disorder is associated with dopamine disregulation and white matter abnormalities in the brain. Impairments in cognition (particularly executive abilities) are common, even in patients treated early and continuously with dietary Phe restriction. Sapropterin dihydrochloride (BH4) is a pharmaceutical agent that lowers Phe in BH4 responders. We are evaluating changes in brain and cognition that occur following BH4 treatment. Method: Brain and cognition are evaluated in PKU patients at baseline before BH4 treatment (20mg/kg/day) using MRI/DTI (diffusion tensor imaging) and neuropsychological tests focused on executive abilities. For BH4 responders, follow-up evaluation is conducted after 6 months of BH4 treatment. Data collection is ongoing. At this time, participant ages range from 7 to 35 years (M=18; SD=8). Evaluation at baseline has been conducted with 19 PKU patients and 12 controls, and at follow-up with 5 PKU patients and 5 controls. Results/Conclusions: Baseline findings to date indicate that executive performance is significantly poorer for PKU patients than controls across a range of tasks assessing abilities such as inhibitory control (go/no-go, $p=.04$; stimulus-response compatibility, $p=.03$), strategic processing (verbal fluency, $p=.007$; word list learning, $p=.001$), and working memory (2-back, $p=.001$). These results reflect specific and pervasive impairments in executive abilities prior to treatment with BH4. Follow-up findings provide evidence of improvement in executive abilities following treatment with BH4. Baseline findings from newly enrolled patients will be presented, as well as specific findings from the follow-up neuropsychological assessments and MRI/DTI data.

2008/T

A novel splice mutation in CYP27A1 associated with cerebrotendinous xanthomatosis (and pulverulent cataract). *S. Joyce[1], R. Bourkiza[2], E. Meyer[1], A. Reddy[2], H. Patel[2], M. Chan[2], E.R. Maher[1].* 1) Medical & Molecular Genetics, University of Birmingham, Birmingham, United Kingdom; 2) Barts and the London NHS Trust, London, United Kingdom.

Cerebrotendinous xanthomatosis (CTX) is a lipid storage metabolism disorder, inherited in an autosomal recessive manner. CTX is characterized by neurological findings (such as cerebellar ataxia and dementia), premature atherosclerosis, tendon xanthomas and cataracts. It is caused by mutations in CYP27A1, leading to sterol 27-hydroxylase deficiency and abnormal cholestanol tissue deposition. A consanguineous Bangladeshi family with three children with pulverulent cataract and global developmental delay were ascertained. Since learning difficulties could also be observed in two of the other siblings who showed no evidence of cataract, the underlying diagnosis and inheritance pattern was unclear. Genetic linkage studies, employing an autozygosity mapping approach, were undertaken to ascertain the underlying genetic cause. The results showed linkage to the chromosomal region 2q35-q36 which contained the CYP27A1 gene. Direct sequencing of CYP27A1 revealed a homozygous splice mutation in all family members with cataracts. This finding confirms the validity of this approach when identifying genes responsible for disorders, even when the aetiology of the condition and diagnosis are uncertain. It highlights the importance of evaluating if CTX is an appropriate diagnosis when the proband has cataracts, especially since the condition can be treated if identified before irreversible brain damage.

2009/T

Assessment of a high-throughput DNA melting analysis assay for rapid screening of gene variants in the Ornithine Transcarbamylase Gene. *K. Sumner[1], L. Hubley[1], S. Dobrowolski[1], G. Pont-Kingdon[1], R. Margraf[1], H. Best[1,2], E. Lyon[1,2].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) Dept of Pathology, University of Utah School of Medicine, Salt Lake City, UT.

Abstract: Ornithine transcarbamylase (OTC) deficiency is the most common inherited defect of the urea cycle and is caused by mutations in the OTC gene (Xp21.1). Over 450 disease-causing mutations have been reported, most of which are family specific, with the vast majority occurring within the exons and intron/exon boundaries of the OTC gene. All 10 exons in the OTC gene are 154bp or smaller making this an ideal target for exon scanning. **Methods:** Exons and intron/exon boundaries were amplified in the LightCycler 480 Real-Time PCR System (Roche Applied Science, Indianapolis, IN) using the LightScanner Master Mix with LCGreen Plus+ Melting Dye (Idaho Technology Inc., Salt Lake City, UT) and then subsequently melted on the same instrument or they were amplified on the GeneAmp PCR System 9700 (Applied Biosystems, Carlsbad, CA) and melted on the LightScanner System (Idaho Technology, Inc., Salt Lake City, UT). Melting curves were then analyzed for differences in melting signatures. As a control, a redundant genotyping melt was also performed to characterize three common OTC polymorphisms. Melting profiles were obtained for 11 deidentified, normal female samples that were submitted to ARUP Laboratories for unrelated testing. In addition, the OTC gene was sequenced in each of these patients to confirm melting curve results. **Results:** One sample was excluded due to poor amplification. Ninety-nine out of 100 exons analyzed were concordant with their sequencing results. Seven exons from 3 samples had deviant melting curves, 8 exons from the same 3 samples contained sequence variations. One sample with a homozygous polymorphism had a melt similar to wild-type samples when using the LightCycler 480 but was distinguishable from the wild-type samples using the genotyping melt assay when the sample was amplified on the GeneAmp PCR System 9700 and melted on the LightScanner System. **Conclusions:** Ninety-nine out of the 100 exons analyzed were concordant with their sequencing results giving the assay an overall accuracy of 99% (excluding all exons from the poorly amplified sample) when amplified on the LightCycler 480 using the LightScanner Master Mix with LCGreen Plus+ dye and then subsequently melted on the same instrument. In summary, DNA Melting analysis is a rapid and inexpensive method to screen for OTC deficiency.

2010/T

A mutation potentially altering ubiquinone binding of ETF dehydrogenase manifests as mild glutaric aciduria type II with severe complex II-III deficiency in liver and skeletal muscle. *J. Vockley[1,2,3], M. He[4,5], N. Payne[1], K.M. Gibson[1,2,4,6], L.A. Wolfe[1,7].* 1) Pediatrics, Children's Hosp of Pittsburgh of UPMC, Pittsburgh, PA; 2) Department of Pediatrics, University of Pittsburgh, School of Medicine, Pittsburgh, PA; 3) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 4) Department of Pathology, Children's Hospital of UPMC, Pittsburgh, PA; 5) Department of Human Genetics, Emory University, School of Medicine, Decatur, GA; 6) Department of Biological Sciences, Michigan Technology University, Houghton, MI; 7) Undiagnosed Diseases Program, National Human Genome Research Institute, Bethesda, MD.

Purpose: Describe clinical and biochemical features of a male with recurrent hospitalizations for recurrent vomiting associated with mild hyperammonemia and elevated CK. Case Review: A 22-year-old male developed severe hypoglycemia (20 mg/dl) and lethargy during an acute illness at 4 months and subsequently grew and developed normally. At age 4 years he developed recurrent vomiting associated with mild hyperammonemia and dehydration requiring frequent hospitalizations for IV fluids. Glutaric aciduria Type II was suspected based upon biochemical findings and managed with cornstarch, carnitine and riboflavin supplements. He did not experience metabolic crises or hospitalizations between ages 4-12 years. He was noted to experience recurrent vomiting, mild hyperammonemia without hypoglycemia, and generalized weakness, primarily associated with acute illnesses and growth spurts. At approximately age 18 years, he developed exercise intolerance and proximal muscle weakness leading to further evaluation. Methods Used: Retrospective records review, prospective evaluation and clinical biochemical testing identified multiple acyl-CoA dehydrogenase and complex II/III deficiencies in both skeletal muscle and liver. Plasma acylcarnitine analyses at this time were unremarkable, while urine organic acid analysis revealed only moderate and variable levels of hexanoylglcyine (HG). Subsequent molecular characterization of the ETFDH gene revealed novel heterozygous mutations, p.G274X:c.820G>T (exon 7) and p.P534L: c.1601C>T (exon 12), the latter within the iron sulfur-cluster and predicted to affect ubiquinone reductase activity of ETFDH as well as the docking of ETF to ETFDH. These mutations were confirmed in parental DNA samples. Results: Our patient, and his unique alleles, support the concept of a structural interaction between ETFDH and other enzyme partners, and predicts that the conformational change upon ETF binding to ETFDH may play a key role in linking ETFDH to II/III super-complex formation interrelating metabolic pathways.

2011/T

Pilot study to evaluate the effects of Sapropterin on adult individuals with Phenylketonuria with measurable maladaptive behaviors. *S. Yano[1], K. Moseley[1], J. Ottina[1], C. Azen[2], R. Koch[1].* 1) Pediatrics/Gen Div, 1G24, LAC+USC Medical Center, University of Southern California, Los Angeles, CA; 2) General Clinical Research Center, University of Southern California/Keck School of Medicine, Childrens Hospital Los Angeles, CA.

Background: We report 12 month data on a pilot study to evaluate changes in behavior while on sapropterin (Kuvan®), a drug that is used for the treatment of PKU. Kuvan® functions like BH4, a co-factor for phenylalanine (phe), tyrosine, and tryptophan hydroxylases. Kuvan® may affect tyrosine and tryptophan hydroxylases in the brain and affect behavior without a reduction in blood phe levels. Objectives: To evaluate effects of Kuvan® on maladaptive behavior in patients with PKU. Material and methods: Ten subjects (>18 years) with maladaptive behavior were enrolled in a 12-month study. Kuvan® was given at 20mg/kg/day. Baseline and quarterly measures of plasma amino acids, as well as baseline, six-month and 12-month evaluation of the Vineland II Adaptive Behavior Scales (VABS-II) and a PKU Behavior Check List were obtained. Results: Comparison of 12-month data to baseline showed no change in blood phe levels (p=0.33), but increased blood tyrosine levels (p=0.05) and decreased blood phe/tyrosine ratio (p= 0.067). The VABS-II showed no change in communication, daily living skills, socialization, or motor skills, but significant improvement for internal behavior including anxiety, nervousness, and unexplained sadness (p=0.018). On the PKU Behavior Check List, subjects showed significant improvement in the sum of scores over the 15 negative behaviors (p<0.0001). Conclusion: PKU subjects who did not respond to Kuvan in blood phe level, showed significant improvement in maladaptive behavior, may suggest effects of Kuvan in the CNS. Long term evaluation of CNS effects of Kuvan is warranted.

2012/T

Is that mitochondrial has any role in Freidreich Ataxia? *M. Naseroleslami[1], M. Heidari[3], K. Parivar[1], S. Sanjarian[1], M. Houshmand[2,4].* 1) Science and Research branch,Islamic Azad University, tehran, Iran; 2) National Institute of Genetic Engineering and Biotechnology, Tehran,Iran; 3) Faculty of Shahid Sadooghi University,Yazd, Iran; 4) Special Medical Center, tehran, Iran.

Introduction: Friedreich's ataxia (FRDA) is an inherited recessive disorder characterized by progressive neurological Disability. The expansion GAA Repeat cause a sever decrease in the expression of frataxin. A deficiency in the protein frataxin causes this disease and the number of triple repeat GAA in the patients is more than 33 repeats. Frataxin interfere with the mitochondrial oxidative process and enhance iron accumulation .decreased oxidation activity a strong negative correlation with the number of GAA Repeats. In 97% of FRDA patients there is expansion of unstable GAA trinucleotide repeats in intron 1 and 2%-3% patients are heterozygote with point mutations. Materials and Methods: Spectrophotometry, temperature gradient gel electrophoresis (TTGE) and PCR-sequencing methods were used to analysis of DNA sample from 25 FA patients. For study role of mitochondrial and role of oxidative stress in FRDA patients. Results: Biochemical study showed that complex I activitiy and intracellular ATP were significantly reduced in patients compared to controls and we found strong, correlation between complex I activity and intracellular ATP content in FRDA patients, (n=12) and control subjects (n=25). (r = 0.93; P<0.002), This study suggested that a biochemical defect in complex I activity and ATP production, which may be due to iron accumulation in mitochondria, can be involved in age of onset of FRDA. We observed 8.6 and 9 Kb deletions in 9 from12 patient (75%) by multiplex PCR and Southern blot analysis. Our results showed also that NADH dehydrogenase (ND) genes mutations in FRDA samples were higher than normal controls (P < 0.001) and we found statistically significant inverse correlation (r = -0.8) between number of mutation in ND genes and age of onset in FRDA patients. In study by TTGE, for the first time, we detected 26 mtDNA mutations; of which 5 (19.2%) was novel and 21 (80.8%) have been reported in other diseases. Investigation of exons 3 of FRDA in 50 patients with a clinical diagnosis of Friedreich ataxia showed SNP (C 832729 T) in heterozygote and homozygote state. No pathogenic mutation was found in our patient by now but investigation of other exons and also other region of FRDA genes continue in our lab. Discussion: 1) Mitochondria play important role in FA. 2) Mutation analysis needs for patients who had shown expansion in one allel.

2013/T

Evaluation of oral feeding of N-acetylmannosamine-related sugars as therapeutics for a knock-in mouse model of *Hereditary Inclusion Body Myopathy* (HIBM). *C. Ciccone[1], A. Astiz-Martinez[1], L. Vincent[1], M. Lin[1], T. Yardeni[1,2], S. Kakani[1], P. Zerfas[3], W.A. Gahl[1], M. Huizing[1].* 1) Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Graduate Partner Program, Sackler School of Medicine, Tel Aviv University, Israel; 3) Division of Veterinary Resources, Office of Research Services, National Institutes of Health, Bethesda, MD.

Hereditary Inclusion Body Myopathy (HIBM) is a recessive adult-onset neuromuscular disorder, characterized by progressive muscle weakness caused by mutations in UDP-GlcNAc 2-epimerase/ManNAc kinase (*GNE*), the key enzyme in sialic acid biosynthesis. We created a *Gne* knock-in mouse model with the human Persian-Jewish M712T founder mutation. Mutant mice died before postnatal day 3 (P3) of unexpected glomerular disease involving effacement of podocytes and hyposialylation of podocalyxin, a glomerular sialoglycan. Administration of the sialic acid precursor N-acetylmannosamine (ManNAc) partially rescued the renal phenotype and allowed survival beyond P3 in 46% of mutant mice. We evaluated the effects of a variety of ManNAc-related sugars on glomerular disease in our mouse model. Sialic acid, mannose, GlcNAc, galactose, or mannosamine were administered in the drinking water to pregnant and nursing mice (1 g/kg/day). Survival of mutant pups beyond P3 was monitored and renal phenotypes were assessed by histology, western blotting, and electron microscopy (EM). Oral treatment of sialic acid, GlcNAc, mannose, GlcNAc and galactose did not improve survival beyond P3, nor did these sugars restore the hyposialylation in mutant mice. Surprisingly, oral administration of mannosamine proved more effective than ManNAc for survival of mutants beyond P3, achieving 56% survival. Western blotting of mannosamine-fed mutants showed improved sialylation of podocalyxin, and improved podocyte ultrastructure on EM. Further research is needed to elucidate whether mannosamine is converted into ManNAc, which feeds into the sialic acid synthesis pathway, or whether mannosamine rescues the phenotype through another mode of action (e.g., chaperoning GNE, assisting folding). This finding may assist in further elucidating the pathology of the glomerular disease in our mice and the muscle phenotype in HIBM patients. Most importantly, mannosamine should be considered as therapy for patients with HIBM, and may also be beneficial for treatment of glomerular diseases with podocytopathy due to hyposialylation, including certain forms of minimal change nephropathy and focal segmental glomerulosclerosis.

2014/T

Further characterization of Congenital Disorder of Glycosylation IIb in siblings. *G.A Golas[1], L.A Wolfe[1], M. He[2], B. Xia[2], W. Zhang[2], X. Song[3], R. Cummings[3], D.R. Adams[1], S. Yang[1], A. Gropman[1,4], C.J. Tifft[1].* 1) Undiagnosed Diseases Program, NHGRI Bethesda, MD; 2) Department of Human Genetics, Emory University, School of Medicine, Decatur, GA; 3) Department of Biochemistry, Emory University, School of Medicine, Decatur, GA; 4) Department of Neurology, Children's National Medical Center, Washington, D.C.

Purpose: Describe clinical and biochemical features of two siblings presenting to the Undiagnosed Diseases Program (UDP). Case review: Two siblings born to non-consanguineous, Northern European parents with negative family history and maternal hypothyroidism and gestational diabetes were evaluated. The older sibling was delivered at 40 weeks gestation by emergency C-section. Birth measurements were normal. Postnatal course was complicated by hypotonia with poor latch and suck requiring bottle feeding. By 8 months of age, he had global developmental delay. Comprehensive molecular and biochemical evaluations were unrevealing. Evaluation at age 11 by the UDP, revealed mild dysmorphia, moderate hypotonia, joint laxity, normal reflexes, and no organomegaly. Weight was 90th centile and height 10th centile. He was non-verbal and able to sit independently and ambulate with assistance. His sister was delivered at 40 weeks gestation by repeat C-section. Birth measurements were normal. She developed generalized seizures within the first 24 hours. The CK was 592 U/L and ammonia 79 umol/dL. Brain ultrasounds and CT were normal. When evaluated at age 6 by the UDP, she was mildly dysmorphic with nystagmus, severe hypotonia, joint laxity, adducted thumbs bilaterally, normal reflexes, and no organomegaly. Height and weight were both below the 3rd centile, at the 50% centile for a 3-=BD year old. She was non-verbal and unable to sit independently. Methods used: Prospective evaluation and clinical biochemical testing. Evaluations revealed generalized cerebral atrophy, delayed myelination and low NAA by brain MRI/MRS in both sibs, cortical visual impairment with optic nerve atrophy. CSF studies identified cerebral folate deficiency in the younger sibling. Urine oligosaccharides on both sibs demonstrated a tetrasaccharide band. Further investigation, identified it as Hex4 with 3 glucose and 1 mannose. The mannose is at the reducing end. DNA studies on the identified three mutations in the GCS1 gene and single mutations in the mother and unaffected sibling. This gene encodes alpha-glucosidase Ia, a protein described in the Congenital Disorder of Glycosylation type IIB in a single case report in 2000. Results: This case underscores the difficulties of diagnosing complex multi-system disease especially when affected siblings have slightly different phenotypes. It also expands the phenotype of CDGIIb.

2015/T

Somatic mosaicism in Menkes disease suggests choroid plexus-mediated copper transport to the developing brain. *P. Johnson[1], A. Donsante[1], L. Jansen[2], S. Kaler[1].* 1) Molecular Medicine Program, NICHD/NIH, Bethesda, MD; 2) Division of Pediatric Neurology, Seattle Children's Hospital Research Institute, University of Washington, Seattle, WA.

The primary mechanism of copper transport to the brain is unknown, although this process is impaired in Menkes disease, an X-linked disorder caused by mutations in a copper transporter, ATP7A. Potential central nervous system entry routes for copper include brain capillary endothelial cells that originate from mesodermal angioblasts and form the blood-brain barrier, and choroid plexuses, which derive from ectoderm, and form the blood-cerebrospinal fluid barrier. We exploited a rare (and first reported) example of somatic mosaicism for an ATP7A mutation to shed light copper transport into the developing brain. In a 20 month old Menkes disease patient evaluated before copper treatment, blood copper and catecholamine concentrations were normal, whereas levels in cerebrospinal fluid were abnormal and consistent with his severe Menkes phenotype. We documented disparate levels of mosaicism for an ATP7A missense mutation, P1001L, in tissues derived from different embryonic origins; allele quantitation showed P1001L in approximately 27% and 88% of DNA samples from blood cells (mesoderm-derived) and cultured fibroblasts (ectoderm-derived), respectively. These findings imply that the P1001L mutation in the patient preceded formation of the 3 primary embryonic lineages at gastrulation, with the ectoderm layer ultimately harboring a higher percentage of mutation-bearing cells than mesoderm or endoderm. Since choroid plexus epithelia are derived from neuroectoderm, and brain capillary endothelial cells from mesodermal angioblasts, the clinical, biochemical, and molecular (Table) findings

Source	% Normal allele (PCR/ Densitometry)	% Normal allele (Q-RT-PCR)
Blood	77.1 +/- 5.48	68.9 +/- 4.16
Fibroblasts	12.24 +/- 5.24	12.34 +/- 4.71

in this infant support a critical role for the choroid plexus epithelia in copper entry to the developing brain.

2016/T

Social Neuropeptides Oxytocin and Vasopressin are Dysregulated in Williams Syndrome. *J.R. Korenberg[1], L. Dai[1], H. Hossein Pournajafi-Nazarloo[2], U. Bellugi[3], C.S. Carter[2].* 1) Center for Integrated Neuroscience and Human Behavior, University of Utah, Salt Lake City, UT 84108, USA; 2) Brain-Body Center, University of Illinois at Chicago, Chicago, IL 60612, USA; 3) Laboratory for Cognitive Neuroscience, Salk Institute, La Jolla, CA 92037, USA.

The social neuropeptides, oxytocin (OT) and Arg-vasopressin (AVP) are involved in the control of social and reproductive behaviors broadly in mammals but whether they play a role in the internal circuitry regulating human behavior is unknown. Williams Syndrome (WS) is a neurobehavioral disorder that is caused by a ~1.5 Mb deletion of 7q11.23 and is uniquely associated with a gregarious personality, a strong drive to approach strangers and an attraction to music. WS provides an unprecedented opportunity to link genetics, neurobiology, and behavior. We hypothesized that alterations in OT and AVP might in part underlie the increased social behavior and response to music in WS. To test this, we established levels of OT and AVP at two baseline points and at eight points after stimulation with music (a self-defined positive stimulus), followed by a mild stressor (cold pressor). Samples collected beginning 30 mins after placement of an indwelling catheter and analyzed using enzyme immunoassays. The data from 13 subjects with WS and 8 age, gender and ethnicity matched controls revealed altered regulation of OT and AVP in subjects with WS. WS subjects showed 5-fold higher mean basal oxytocin (p is less than 0.001) and 3-fold higher vasopressin (p=0.15) levels vs. controls. Longitudinal changes in OT (expressed as % Δ vs. baseline in the peak response during and immediately following the stimulus) exhibited both greater variability (p=0.025 with music; p=0.007 with cold) and greater average increases in WS subjects vs. controls (30% vs. 9% geometric mean increase, p = 0.21, with music; 21% increase vs. 2% decrease, p= 0.01, with cold). Longitudinal changes in AVP exhibited similar but weaker trends, which did not reach statistical significance, for greater variability and greater average increases in WS subjects vs. controls. The results indicate that a subgroup of WS subjects exhibited amplified peak releases of OT, and possibly AVP, in response to music and cold compared to controls. This is the first direct evidence in humans, showing that endogenous circuitry involving OT and AVP might regulate the response to social-emotional stimuli. Furthermore, the genetic circuits that regulate OT and AVP are largely unknown and the data implicate one or a cluster of genes in the WS region. WS provides a unique genetic model for understanding the neurobiology of human sociality and emotion.

2017/T

Biochemical predictors of outcome in methylmalonic aciduria. *H. Vernon[1], A. Hamosh[1], L. Kratz[2], D. Valle[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Biochemical Genetics Laboratory, Kennedy Krieger Institute, Baltimore, MD.

We performed a retrospective analysis of clinical and laboratory data from 11 patients with methylmalonic aciduria (MMA) seen at Johns Hopkins Hospital over the past 16 years: 5 with mut (0), 3 with B12 responsive MMA, 2 with cobalamin B defect, and 1 with mut (-). There were a total of 219 admissions for these patients: 189 in patients with mut (0), 21 in patients with B12 responsive MMA, 8 in patients with Cbl B defect, and 1 in the patient with mut (-). Of the 8 patients who developed renal failure 5 have mut (0), 2 have cobalamin B defect, and 1 has B12 responsive MMA. Additionally, there were 29 acute adverse events: in the mut (0) group there were 6 episodes of basal ganglia (BG) infarction and 20 episodes of pancreatitis; in the B12 responsive group there were 2 episodes of BG infarction; and in the Cbl-B defect group there was 1 episode of BG infarction. To better understand the pathophysiology of MMA, we analyzed plasma and urine methylmalonate levels, blood urea nitrogen, creatinine, acid/base status, ammonia, amylase, lipase and complete blood counts in each patient over time. In 6 patients, there was sufficient data available to compare inpatient and outpatient methylmalonate levels (a total of 41 hospitalizations). Of the 8 patients with renal failure, 4 showed a lifetime trend of increasing plasma and urine methylmalonate levels. Despite this relationship, acutely increased levels of methylmalonate did not correlate with intercurrent hospitalizations, because after the initial diagnostic admission in each of these patients there was no significant difference between inpatient and outpatient levels of methylmalonate. The number of methylmalonate determinations was not sufficient to allow for a correlation to the acute adverse events. However, since there was no difference between outpatient and inpatient methylmalonate levels, we speculate that intercurrent illness leading to hospitalization may reflect changes in tissue sensitivity to relatively constant concentrations levels of accumulated metabolites. This model predicts that, in addition to reducing metabolite accumulation, therapeutic efforts should be directed at correcting tissue sensitivity.

2018/T

An unusual transferrin glycoform in a patient with developmental delay, failure to thrive, anemia, and dysmorphic features suggests a new type of congenital disorder of glycosylation. *M.F. Walsh[1,2], K.M. Raymond[3,4], H.F. Freeze[5,6], P. HE[5], G.H.B. Maegawa[1,2].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Hospital, Baltimore, MD; 2) Department of Pediatrics, Johns Hopkins Hospital, Baltimore, MD; 3) Biochemical Genetics Laboratory, Mayo Clinic, Rochester, MN; 4) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 5) Sanford-Burnham Medical Research Institute, La Jolla, CA; 6) Sanford Children's Health Research Center, La Jolla, CA.

Congenital Disorders of Glycosylation (CDG) are a heterogeneous group of disorders of abnormal N-linked oligosaccharides caused by deficiency of specific enzymes in N-linked oligosaccharide synthetic pathway, resulting in a broad clinical spectrum (Sparks, 2009). CDGs were previously termed carbohydrate deficient syndromes (Hagberg, 1993). Nearly all proteins that travel through the endoplasmic reticulum - Golgi conduit are N-glycosylated (Freeze, 2006). Some characteristics include variable degrees of developmental delay, hypotonia, failure to thrive, diarrhea, and electrolyte imbalances (Denecke, 2005). Case Report: We describe a 16-month-old male with failure to thrive, developmental delay, mild dysmorphic features, anemia and watery stools. Child was born full-term via vacuum assisted vaginal delivery and was documented IUGR. Salient features at birth included hypospadias requiring a two staged surgery and testosterone therapy. At 16-months, his weight was 9.35kg (<3%), his height was 78 cm (20-30%), and his head circumference was 46cm (25-50%). On P/E, frontal bossing, hypertelorism, genitourinary anomalies, a sacral dimple, torticollis, and pes plan valgus were noticeable. Failure to thrive investigations included normal testing for: celiac disease, cystic fibrosis, and thyroid disease. IGF levels were borderline low prompting an MRI, which, was normal. Folate, vitamin B12, iron levels and hemoccult testing were normal in assessment of the patient's normocytic anemia. Inherited metabolic investigations were inconclusive. Standard CDG testing performed by Immuno-Affinity Chromatography / Mass Spectrometry revealed an unusual transferrin glycoform. Normally transferrin has 2 N-linked sugar chains and mass of 79551 Da. Our patient also has a prominent, unprecedented transferrin variant of 81701Da, consistent with complete 3 N-glycan chains and loss of 1 Fe. This finding suggests a novel congenital disorder of glycosylation. Conclusion: This patient's diagnosis of a congenital disorder of glycosylation is based on the presence of a novel hyper-glycosylated variant of transferrin. Parental testing is underway to evaluate if the glycosylation pattern is inherited or de novo; mapping is currently in progress to further evaluate the significance of the novel glycoform. Since the transferrin glycosylation pattern has never been previously reported, this may uncover another type of CDG, correlating with the clinical phenotype herein described.

2019/T

Systemic Biomarker Profiling of Metabolic and Dysplastic Skeletal Diseases Using Multiplex Serum Protein Analyses. *D. Wenkert[1], M.P. Whyte[1], D.C. Dwyer[2], D.L. Lacey[2], M. Stolina[2].* 1) Shriners Hosp Children, St. Louis, MO; 2) Amgen, Incorporated, Thousand Oaks, CA.

Understanding of the etiology and pathogenesis of metabolic and dysplastic skeletal diseases has come from both genetic and biochemical investigations. Here, we describe our approach to systemic biomarker profiling using multiplex serum protein analyses in healthy controls and to study age- and disease-mediated changes in patients as well as family members with these disorders. The Research Center at Shriners Hospital for Children, St. Louis, Missouri, serves as a national referral center for inpatient diagnosis, treatment, and investigation of pediatric dysplastic, nutritional, and metabolic bone disorders where collection of fasting blood is routine. At Amgen (Thousand Oaks, California), Luminex-based, micro-bead, multiplex kits are used to assay serum osteopontin, osteocalcin, ligand of receptor activator NF-κB (RANKL), osteoprotegerin (OPG), fibroblast growth factor 23 (FGF23), matrix metalloproteinases (MMP 1, 3, 7, 8, and 13), and cytokines. ELISA kits are used for serum prostaglandin E_2 (PGE_2), bone-specific alkaline phosphatase (BAP), tartrate-resistant acid phosphatase (TRACP 5B), and collagen formation/degradation markers. Serum levels of sclerostin (SOST) and dickkopf (DKK1) were evaluated by custom ELISAs (developed at Amgen, Inc). All sera were obtained after donors fasted for at least 4 hours. To establish reference ranges, we studied 9 healthy children and 18 healthy adults (ages 6-60 yrs). MMPs (1, 3, 7, 8, and 13) correlated positively with age (R^2 = 0.26 - 0.64, $p<0.05$), whereas osteocalcin, BAP, c-terminal propeptide of collagen type I (CICP), and TRACP 5B correlated negatively (R^2 = 0.23 - 0.71, $p<0.05$). The patients represented 30 established and 14 unique diagnoses. Affected family members (dominant disorders) and obligate carriers (recessive disorders) were also studied, comprising a total of 110 individuals. Our analyses revealed that serum concentrations of FGF23 were significantly increased in X-linked hypophosphatemia (XLH), TRACP 5B in osteopetrosis, and RANKL in juvenile Paget's disease, whereas decreases in BAP were documented for hypophosphatasia, validating our array strategy. Hence, our multiplex serum protein analyses could reveal unique markers for specific bone disorders, and enhance understanding for a wide range of skeletal diseases.

2020/T

Mucoployssaccharidosis type IIIB and GalNAc Transferase Double Knockout Mice. *E.E.A. Mohammed[1], E.M. Whitley[2], E.M. Snella[1], M.M. Rutz-Mendicino[1], F.D. Echevarria[1], N.M. Ellinwood[1,3].* 1) Animal Science, Iowa State University, Ames, IA; 2) Veterinary Pathology, Iowa State University, Ames, IA; 3) Veterinary Clinical Sciences, Iowa State University, Ames, IA.

Mucopolysaccharidosis type IIIB (MPS IIIB) is a neuropathic lysosomal storage disorder (LSD) resulting from an inherited deficiency of *N*-acetyl-α-D-glucosaminidase (Naglu) activity, an enzyme required to degrade the glycosaminoglycan heparan sulphate (HS). A deficiency in Naglu activity leads to the lysosomal accumulation of HS as a primary storage substrate, and the gangliosides GM2 and GM3 as secondary storage products. To test the effect on neuropathogenesis of ganglioside accumulation, we bred mice deficient in both Naglu and GalNAcT activity. The latter is the enzyme required for the synthesis of GM2 and other complex gangliosides. Contrary to our expectation and to double knockout (DKO) studies where GalNAcT was knocked out in combination with other LSDs, our DKO mice showed a drastically shortened lifespan (20 ± 3.4 weeks, versus 45 ± 6.9 wks (MPS IIIB), and 45 ± 11.03 wks (GalNAcT)). To confirm that HS storage was the primary element resulting in the accelerated disease in our DKO mice, and not a locus tightly linked to the Naglu gene, we replicated our study with MPS IIIA mice, and found a virtually identical result (26 ± 4.9 weeks, versus 53 ± 2.1 wks). All DKO mice showed motor signs of hind limb ataxia and hyper-extension, which were not seen in the single KO or normal mice. At approximately 5 months of age the MPS IIIB DKO showed a unique pattern of vacuolization and nerve fiber degeneration in the corpus callosum as well as the relatively early intracytoplasmic vacuolation of many neurons and glia, the latter also seen in the MPS IIIB mice. We evaluated motor performance on a rocking Roto-rod beginning at 2 months of age. At five months of age the MPS IIIB DKOs performed far worse (p £ 0.0006) than all other genotypes (139 ± 25 sec (DKO), versus 252 ± 18 sec (MPS IIIB), 270 ± 19 sec (GalNAcT), and 293 ± 14 sec (norm). In conclusion we identified an accelerated form of MPS IIIB within a DKO model system which showed white matter changes, with attendant performance deficits and a drastically shortened lifespan. This was in stark contrast to our expectations of a salutary response to the elimination of GM2. Despite this, the accelerated pathology and clinical signs represent an improved system to study the MPS IIIB response to therapies, and may be important to investigate neuropathogenesis as well as the role of complex gangliosides in normal CNS function. Funded by; CIAG of ISU, the LSDRC, and The Sanfilippo Children's Research Foundation.

2021/T

A successful tool to predict antibodies against therapeutic proteins: Experience from infantile Pompe disease. *S.G. Banugaria[1], S.N. Prater[1], Y-C. Hsueh[2], Y-K. Ng[3], J.A. Kobori[4], R.S. Finkel[5], R.L. Ladda[6], A.S. Rosenberg[7], Y-T. Chen[2], M-J. Hwang[2], P.S. Kishnani[1].* 1) Department of Pediatrics, Division of Medical Genetics, Duke University Medical Center, Durham, NC, USA; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 3) Department of Pediatrics, University of Hong Kong, Hong Kong, China; 4) Genetics Department, Permanente Medical Group, San Jose, CA, USA; 5) Division of Neurology, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 6) Department of Pediatrics, Penn State University, Hershey Medical Center, Hershey, PA, USA; 7) Division of Therapeutic Proteins, Office of Biotechnology Products, Center for Drug Evaluation and Research, United States Food and Drug Administration, Bethesda, MD, USA.

With the advent of enzyme replacement therapy (ERT) with alglucosidase alfa (Myozyme®) for Pompe disease, the clinical course of the disease has changed. We have previously described the poor outcome in cross reactive immunologic material (CRIM)-negative patients secondary to high sustained antibody titers (HSAT) to ERT. More recently, we have also shown that a subset of CRIM positive patients develop HSAT and, in essence, behaved similar to CRIM negative patients. There is emerging data on success of tolerance induction therapies in abrogating the effect of antibodies if started early or ideally in naïve setting. However, once HSAT are formed, tolerization therapy has uniformly failed to lower antibody titers. While CRIM negative status can be easily identified by western blot and mutation analysis, the current challenge is the early identification of patients at-risk for developing HSAT amongst CRIM positive patients. We evaluated a cohort of 31 CRIM positive infantile Pompe disease patients: 11 high-titer CRIM-positive (HTCP) patients and 20 low-titer CRIM-positive (LTCP) patients. Our hypothesis was that HTCP and LTCP patients differed in the immunogenic potential of their underlying epitopes. A 3D model of acid alfa glucosidase (GAA) was derived through homology modeling using ESyPred3D based on the X-ray structure of MGAM (human intestinal maltase-glucoamylase), with which GAA shares 42.8% amino acid sequence identity. Mutational data in the context of the 3D model of GAA was then subjected to epitope prediction by ElliPro, a structure-based B-cell epitope prediction tool. Epitope prediction was made based on a protrusion index (PI), which is a measure of the extent that an amino acid residue protrudes from a protein 3D structure. LTCP mutations tended to be located in the core of GAA protein with a PI<0.5 while HTCP mutations were more externally located with a PI>0.5. Accuracy of ElliPro for these single mutation sites was 80% and 85.7% for HTCP and LTCP mutations, respectively. The approach taken here utilizing patient mutation data provides a useful strategy to identify Pompe patients at risk of developing HSAT. This tool thus allows for recognition of patients that need immune modulation prior to ERT and represents a novel approach in the field of therapeutic proteins. Methods similar to the one presented here could also represent a useful strategy in predicting antibodies in other disorders treated with therapeutic proteins.

2022/T

Gyk cGPD Double Knockout Mice Have a Longer Lifespan Than Gyk Knockout Mice. *N. MacLennan[1], A. Presson[2], M. Bedernik[1], R. Crawford[1], E. McCabe[1].* 1) Dept Pediatrics, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Bio statistics, Univ California, Los Angeles, Los Angeles, CA.

The first two steps of glycerol metabolism involve glycerol kinase (GK/Gyk) glycerol phoshpate dehydrogenase (GPD). Single knockout (KO) mice of each enzyme produce two very different phenotypes. Gyk KO mice model the phenotype of human GK deficiency (GKD) except that the mice die at dol 3-4. Cytoplasmic or cGPD KO mice have no apparent adverse effects on lifespan or reproductive capability compared to wild type (WT). These mice suggest that alternate pathways of energy metabolism are available to cGPD KO but not to Gyk KO mice. Our goal was to further understand the molecular pathogenesis of GKD by generating a double KO mouse line for Gyk and cGPD. We mated the single KO lines for Gyk (G) and cGPD (C) to generate the following KO lines all having a C57BL6/J (Gyk KO strain) and BalbC (cGPD strain) mixed background strain: double WT = CG++, double KO = CG--, cGPD WT and Gyk KO = CG+-, and cGPD KO and Gyk WT = CG-+. We then performed microarray expression analysis on day of life (dol) 1 mouse pup livers and compared their gene expression levels. CG-- mice have a lifespan of 4-5 days (n=10 KO pups, 5 litters) versus CG-+ and CG++ mice that live a normal murine lifespan (about 2 years). CG+- (Gyk KO) mice die at dol 3-4. There was minimal overlap of canonical pathways among the single and the double KO mice. Four significant ($p<0.05$) canonical pathways total were altered in the CG-- mice including glycerolipid metabolism, lysine biosynthesis and glycerolphospholipid metabolism. None of these pathways in the double KO were significantly altered in the single KO data. CG+- and CG-+ mice had 14/16 and 1/3 unique pathways, respectively. Both CG+- and CG-+ revealed only 2 overlapping significantly altered canonical pathways. In contrast to CG--, CG+- and CG-+ mouse gene function profiles included cell death and cell cycle. The majority of mouse gene function profiles in the CG+- and CG-+ mouse cell death networks were related to apoptosis and survival. While both cGPD and Gyk single KO mice were enriched for cell death/cell cycle genes, this enrichment profile was not prominent in the double KO. We speculate that contributions of gene alterations comprising the unique canonical pathways and functional enrichment profiles of the single cGPD and Gyk KO mice may complement each other to partially ameliorate negative effects from the Gyk KO and account for an increase in lifespan of the double cGPD Gyk KO mouse.

2023/T

Bone Mineral Density in Patients with Homocystinuria. *J.L. Brodsky[1], K. D'Aco[1], C. Coughlin[1], C. Ficicioglu[1], R. Pyeritz[2], M.A. Levine[1].* 1) Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Medical Genetics, The University of Pennsylvania, Philadelphia, PA.

BACKGROUND: Homocystinuria is an autosomal recessive disorder characterized by homocysteinemia, homocystinemia,hypermethioninemia, and homocystinuria. Defective cystathionine synthetase leads to an inability to synthesize cystathionine from homocysteine and serine in the methionine pathway. Patients with this disorder develop subluxation of the ocular lens, mental retardation, vascular disease, and osteoporosis. While several studies have reported on bone density deficits using radiographs, there has never been a study published using dual x-ray absorptiometry (DXA) to describe bone mineral density (BMD)in this population. OBJECTIVE: To examine the relationship between clinical factors and BMD in patients with homocystinuria. DESIGN/METHODS: Retrospective chart review of all patients with homocystinuria who underwent DXA from July 2002 through January 2010 during routine surveillance at The Children's Hospital of Philadelphia Clinic for Metabolic Disease and The University of Pennsylvania Center for Connective Tissue Disorders. Data collected from the medical record include patient characteristics, disease course and severity, and DXA results. At the time of DXA, data collected include serum homocystine,homocysteine,methionine,calcium,and vitamin D when available, height, BMI% and age at DXA assessment. Descriptive statistics were generated and Spearman correlation analyses performed. RESULTS: DXA results of the lumbar spine (L1-L4) were available for review in 14 patients (6M/8F; age at initial DXA 3.5-49.2 yrs, mean 17.2yrs) with a total of 25 DXA encounters. Serum homocysteine(97.2 μmol/L), homocystine (10.4 nmol/mL) and methionine (324.7 nmol/mL) were elevated, and patients were non-responsive to vitamin B6. Lumbar spine (LS) Z-score was -1.5 SD for the group, with 36% below -2 SDs. Serum 25(OH)D was 27.1±3.6 ng/mL. LS Z-scores were negatively correlated with serum homocystine($p=0.0026$), homocysteine($p=0.0075$), and methionine levels ($p<0.001$) and age of diagnosis($p=0.004$). CONCLUSIONS: Patients with homocystinuria have significantly reduced LS BMD compared to age- and sex-matched controls. BMD is negatively associated with age of diagnosis and serum levels of methionine, homocystine, and homocysteine. These data refine the skeletal phenotype of homocystinuria, and highlight the association between the metabolic defect and low BMD in this population. We propose that bone density should be assessed in all subjects with homocystinuria.

2024/T

Disease Severity in Children and Adults with Hypophosphatasia (HPP). *A. Skrinar[1], J. Smith[1], C. Patel[2], H. Landy[1].* 1) Clinical Research, Enobia Pharma, Cambridge, MA; 2) University of Texas Medical School at Houston.

Hypophosphatasia (HPP) is a rare inherited form of rickets and osteomalacia caused by inactivating mutations in the gene encoding tissue-nonspecific alkaline phosphatase (TNSALP). Birth incidence of severe patients is about 1:100,000. The biochemical hallmarks of this inborn error of metabolism are low circulating levels of ALP with elevated serum or urine levels of TNSALP substrates. The disease manifests as a broad clinical spectrum. There is no approved treatment although clinical trials of a bone-targeted enzyme replacement therapy are underway. Methods: An online survey was developed to assess disease burden in children and adults with HPP. Translations were available in English, French and German. Respondents were recruited through patient advocacy groups and small donations were made for completed surveys. Data from 90 respondents or their caregivers who reported age at symptom onset are presented. Respondents were stratified into 3 subgroups based on age of symptom onset. Results: Approximately 2/3 of the respondents were adults and 1/3 were children at the time of survey completion. Of the 90 respondents, 46 (51%) reported symptom onset in the first year of life, 27 (30%) in childhood (1-12 years) and 17 (19%) in adolescence/adulthood (over 12 years). The most common first symptoms were premature tooth loss (48%), cranial deformity (26%) and gross motor delay (17%) for those presenting in infancy, premature tooth loss (56%), fracture (26%) and bone pain (19%) for those presenting in childhood and fracture (47%) and bone pain (29%) for those presenting in adolescence/adulthood. Bony deformity and developmental delay were more common in those presenting in infancy, $p<.05$. Poorly healing fractures and wheelchair/walking aid use were more common in those presenting in adolescence/adulthood, $p<.05$. There was no significant difference in the median number of fractures (4-5) or the need for surgical fracture repair among the 3 subgroups. No more than 10% of respondents reported an improvement in their disease course over the past 5 years. Pain and limited mobility were among the top rated symptoms that interfered most with daily function. Mean SF-36 PCS, PF and BP scores were below U.S. general population norms indicating significantly diminished function and increased pain. Conclusion: Findings suggest that HPP is associated with debilitating symptoms, functional disability, pain and impaired quality of life regardless of age at symptom onset.

2025/T

An Attenuated form of Morquio Disease seen in Northern Ireland. *F.J. Stewart[1], K. Tylee[2], A. Cooper[2], J.E. Wraith[2].* 1) Dept Medical Genetics, Belfast City Hosp, Belfast, United Kingdom; 2) Willink Biochemical Genetics Unit, St. Mary's Hospital Manchester UK.

Morquio disease (mucopolysaccharidosis type IV) is a lysosomal storage disorder causing predominantly skeletal manifestations. It is caused by a deficiency of galactose-6-sulphatase and is inherited in an autosomal recessive manner. In the classical form of Morquio disease there is extreme short stature with average height being between 90 and 120 cm. There are marked skeletal deformities and many affected individuals require surgery to stabilise their cervical spine. We have identified 10 individuals in Northern Ireland who have an attenuated form of the disease - four sets of siblings and two single cases. All were found to have glycosaminoglycans (GAG's) in their urine. All were found to have reduced levels of galactose-6-sulphatase consisitent with a diagnosis of MPS type IV Morquio disease. Ages ranged from 27 years to 38 years. Height ranged from 142 cm to 160cm (5th to 50th centile). This form of the disease was initially considered relatively mild. However it is now clear that affected individuals have major problems with their joints and 6/10 patients have had at least one major joint replaced with two having had 3 joints replaced. Two further patients are undergoing orthopaedic assessment with a view to having total hip replacements. Our patients have also shown evidence of osteoporosis with decreased bone density being seen in all cases tested so far. Mutations in the GALNS gene have been characterised in all cases and include p.I113F, p.T312S and p.A241A. These patients were all initially considered to have spondyloepiphyseal dysplasia before the correct diagnosis of MPS IV was made. We believe the diagnosis of MPS IV may not be considered in patients who do not show the classical features including extreme short stature. We believe this diagnosis should be considered in young people presenting with epiphyseal dysplasia and also in young adults presenting with joint problems requiring joint replacement surgery at an early age. A urine sample should be screened for GAG's in the first instance followed up by confirmatory enzyme studies if the presence of keratan sulphate is confirmed. Clinical findings in 12 patients with MPS IV A Nelson J, Broadhead D, Mossman J. Clin Genet. 1988 Feb;33(2):111-20.

Whole Exome Sequencing identifies AFG3L2 homozygous mutations resulting in a novel autosomal-recessive progressive myoclonic epilepsy-ataxia-neuropathy syndrome. *T.M. Pierson[1,2], D.A. Adams[1, 3], F. Bonn[4], P.F. Cheruki[5], J.K. Teer[6], N.F. Hansen[5], P. Cruz[5], N.I.S.C. Comparitive Sequencing Program[7], J.C. Mullikin[6,7], R.W. Blakesley[6], G. Golas[1,3], J. Kwan[8], T. Markello[1,3], C. Blackstone[2,9], A. Sandler[10], K. Fuentes Fajardo[1], C. Tifft[1,3], E. Rugarli[11], W.A. Gahl[1,3], T. Langer[12,13], C. Toro[1].* 1) NIH Undiagnosed Diseases Program, NIH Office of Rare Diseases and NHGRI, NIH, Bethesda, MD; 2) Neurogenetics Branch, NINDS, NIH, Bethesda, MD; 3) Office of the Clinical Director, NHGRI, NIH, Bethesda, MD; 4) Institute for Genetics, University of Cologne, Cologne, Germany; 5) Genome Technology Branch, NHGRI, NIH, Bethesda MD; 6) Genetic Disease Research Branch, NHGRI, NIH, Bethesda MD; 7) National Intramural Sequencing Center, NIH, Bethesda MD; 8) EMG Section, NINDS, NIH, Bethesda, MD, USA; 9) Cellular Neurology Unit, NINDS, NIH, Bethesda, MD; 10) Division of Surgery, Children's National Medical Center, Washington, DC; 11) Biocenter, University of Cologne, Cologne, Germany; 12) Institute for Genetics, Centre for Molecular Medicine (CMMC), Cologne Excellence Cluster on Cellular Stress Responses in Aging-Associated Diseases (CECAD), University of Cologne, Cologne, Germany; 13) Max-Planck-Institute for Biology of Aging, Cologne, Germany.

In neurogenetics, a single gene may be involved in several distinct disorders. Examples of this phenomenon include genes for signaling molecules, cellular membrane trafficking, and energy metabolism. These genes, initially identified with one disease, were "rediscovered" in the context of another. Whole exome sequencing (WES) is used to search for new pathogenic mutations, but it also identifies variants in known genes that lead to variant phenotypes. We used WES to identify new homozygous mutations in the AFG3L2 gene resulting in a novel progressive myoclonic epilepsy-ataxia-neuropathy syndrome. Two brothers presented in late infancy with progressive ataxia, dysarthria, spasticity, and myoclonic epilepsy. Associated features included ptosis, dystonia, and action myoclonus. Cognition was intact. Testing revealed cerebellar atrophy and polyneuropathies. Muscle biopsy uncovered mitochondrial respiratory dysfunction and abnormal structure. mtDNA was mildly depleted. The parents (first cousins) were normal neurologically, except the mother had asymptomatic mild cerebellar atrophy on MRI imaging. The AFG3L2 gene causes autosomal-dominant spinocerebellar ataxia, type 28 (SCA 28), which is phenotypically similar to other progressive late-onset SCAs with dysarthria, eye movement abnormalities, and ataxia. AFG3L2 is a nuclear encoded mitochondrial protein that forms oligomeric m-AAA protease complexes, which play a major role in mitochondria ribosomal assembly and proteome quality control. AFG3L2 forms homo-oligomeric m-AAA complexes, it also forms hetero-oligomeric m-AAA complexes with paraplegin, the protein mutated in autosomal recessive spastic paraplegia, type 7 (SPG7). Paraplegin is unable to form homo-oligomers and requires AFG3L2 to function; lack of activity results in lower extremity spasticity. Our patients' mutation, resulting in a missense Y616C substitution, reduces AFG3L2 enzymatic activity in yeast expression studies, without a dominant negative effect. This mutation also inhibits the functional interaction between AFG3L2 and paraplegin in yeast expression studies. These results indicate the brothers' complex phenotype is likely the combination of abnormal activity of AFG3L2 in cerebellar cells and paraplegin in motor neurons. In summary, WES was used to identify novel homozygous mutations resulting in a new disorder primarily consisting of a combination of the SCA28/SPG7 phenotypes in association with other mitochondrial signs and symptoms.

2027/T

A novel Anderson-Fabry disease mutation in a Greek female patient presented with early-onset dystonia: An unknown Anderson-Fabry cerebrovascular phenotype? *A. Psychogios.* American Genetics Center, Nicosia, Cyprus.

We report on a novel Anderson-Fabry disease mutation identified in a Greek 28-year-old female with negative family history presented in adolescence with dystonic muscle contractions causing posturing of her feet, legs, and arms. Other clinical features included normal cognition, scanning speech, hand muscle atrophy, periumbilical and right leg angiokeratomata, hypohidrosis and severe constipation. Serial renal, eye and heart examination and imaging was normal. Previous TOR1A gene testing for early-onset primary dystonia (DYT1) was negative. Brain MRI revealed white matter changes and whole body MRA identified a moderate right femoral artery stenosis. Serial leukocyte testing for alpha-galactosidase activity was abnormal, < 3.0 % a-Gal A activity. Urine ceramide trihexoside was increased which supports the deficient alpha-galactosidase activity. GLA gene sequencing from peripheral blood leukocytes identified a heterozygous 5' UTR -30G>A alteration of uncertain clinical significance. This alteration has been recently reported to be associated with increased transcription resulting in higher than normal plasma alpha-galactosidase activity in females (Oliveira et al., 2008) and may account for some of the difficulty found in determining carrier status in females. These results support the presence of another alteration such as a deletion or duplication which may be responsible for the diagnosis of Anderson-Fabry disease in this patient. The frequency of cerebrovascular complications in carrier females has been reported as high as 28% for TIAs at a mean age of 52 years and the frequency of cerebrovascular accidents 7% at a mean age of 42 years (Mac Dermot KD et al., 2001). Experts recommend that enzyme replacement therapy (ERT) be initiated as early as possible in all males with Anderson-Fabry disease, including children and those with ESRD undergoing dialysis and renal transplantation, and in females with significant disease. In conclusion, dystonia could represent an unknown Anderson-Fabry disease manifestation and further studies are needed to clarify whether there is such a connection in females with significant cerebrovsacular disease of unknown etiology.

Parkinsonism in Patients with type 1 Gaucher disease in the ICGG Gaucher Registry: Prevalence and Clinical Characteristics. *N. Weinreb[1], M. Balwani[2], J. Bronstein[3], E. Kolodny[4], A. Gwosdow[5], J. Taylor[5], J.A. Cole[5], S. Sathe[4], A. Zimran[6], B. Rosenbloom[7].* 1) Univ Res Foundation, Hollywood, FL; 2) Mount Sinai School of Medicine, New Yotk, NY; 3) University of California, Los Angeles, CA; 4) New York University School of Medicine, New York, NY; 5) Genzyme Corporation, Cambridge, MA; 6) Shaare-Zedek Medical Center, Jerusalem, Israel; 7) Tower Hematology Oncology, Beverly Hills, CA.

PURPOSE: Investigate the prevalence of Parkinsonism among patients with Gaucher disease type 1 (GD1) and evaluate the clinical, genotypic, and phenotypic characteristics. BACKGROUND: An association between Parkinsonism and mutations in the glucocerebrosidase (GBA) gene has been reported. GBA mutations resulting in GBA deficiency cause Gaucher disease (GD). Parkinsonism may occur with a greater than expected prevalence among GD patients. METHODS: GD patients with Parkinsonism were identified through reports to the International Collaborative Gaucher Group (ICGG) Gaucher Registry as of April 2010. A control group was constituted by all GD1 patients enrolled in the ICGG Gaucher Registry with no reports of Parkinsonism. A matched case-control analysis was conducted, whereby patients with and without Parkinsonism were matched by sex and year of birth. Up to 10 control patients were randomly selected and matched to each case patient. Demographics, genotypes and GD-related characteristics were provided for both groups. RESULTS: The matched study cohort comprised of 63 patients with Parkinsonism and 608 patients without Parkinsonism. Demographic and clinical characteristics were similar in both groups; the most prevalent genotype was N370S/N370S (approximately 40%). Patients with Parkinsonism were distinguished by 1) later median age at GD1 diagnosis (42yr) compared to controls (29yr), and 2) median age of reported Parkinsonism onset was 56yr compared to 60yr in the general population (Lancet 2009;373:2055-2066). The prevalence of Parkinsonism in all GD1 patients over 18yr in the ICGG Gaucher Registry was 1.5% (CI 1.1, 1.9). CONCLUSIONS: The clinical phenotype of GD1 patients with Parkinsonism was similar to patients with GD1 alone except the median age of GD diagnosis was older in GD1 patients with Parkinsonism. Older age at Gaucher diagnosis may be attributable to a less severe clinical GD1 phenotype. There is no evidence that severity of the common GD1 clinical manifestations was predictive for onset of Parkinsonism.

2029/T

Alpha-synuclein expression and localization in cultured neurons from glucocerebrosidase-deficient mouse models. *W. Westbroek[1], W. Xiao[1], S.W. Klontz[1], Y.N. Blech-Hermoni[1], M.R. Cookson[2], E. Sidransky[1].* 1) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Laboratory of Neurogenetics, NIA, NIH, Bethesda, MD.

Gaucher disease is an autosomal recessive lysosomal storage disorder caused by mutations in the glucocerebrosidase gene (GBA). In patients with Gaucher disease, deficiency of the enzyme glucocerebrosidase (GCase) leads to accumulation of the glycolipid glucosylceramide in reticulo-endothelial cells in the spleen, liver, bones, and, in neuronopathic forms, the brain. A subset of patients with Gaucher disease develop Parkinson disease, an adult-onset neurodegenerative disease characterized by motor dysfunction due to loss of dopaminergic neurons in the substantia nigra and alpha-synuclein protein aggregation into Lewy body structures in the brain. Recent studies have shown that subjects with Parkinson disease are over five times more likely to carry GBA mutations than controls, but the molecular mechanisms by which the two diseases are related remain unknown. We utilized mouse models of Gaucher disease including both the null allele knock-out and point mutation models to investigate the effect of GCase deficiency on alpha-synuclein expression and cellular localization. Primary embryonic hippocampal cells were cultured from E-18 mice homozygous and heterozygous for the null-allele, as well as embryonic mice with other common mutant GBA alleles. We performed immunocytochemistry on distinct primary neuronal cultures with several anti-alpha-synuclein antibodies, followed by laser scanning confocal microscopy. We found that neuronal cells with deficient or absent GCase activity had increased expression and altered localization of alpha-synuclein.

2030/T

Mechanism of neurodegeneration in ATP7A-related distal motor neuropathy is distinct from Menkes disease and occipital horn syndrome. *L. Yi, S. Kaler.* Molecular Medicine Program, NICHD/NIH, Bethesda, MD.

ATP7A is a copper-transporting ATPase that helps regulate and control cellular copper homeostasis. Defects in ATP7A lead to Menkes disease, or its allelic variants occipital horn syndrome, and isolated distal motor neuropathy, a newly discovered condition. Whereas Menkes disease and OHS share certain clinical and biochemical abnormalities, recently identified subjects with ATP7A-related distal motor neuropathy have normal serum copper, normal copper enzyme activities, normal renal tubular function, no central nervous system symptoms, and no connective tissue abnormalities. Conversely, 3 Menkes disease patients and 2 OHS patients whom we studied recently showed no clinical or neurophysiological evidence for motor neuron dysfunction, including the original OHS patient we reported, now 32, an age by which distal motor neuropathy could be expected to be manifest. Together, these clinical findings imply that the mechanism of disease in the new allelic variant is distinctly different than in Menkes/OHS. To characterize the unique missense mutations which cause ATP7A-related distal motor neuropathy, we expressed several (including P1386S and T994I) in a yeast copper transport knockout, ccc2Δ, as well as in Hek293 cells, in a fibroblast cell line from a Menkes patient with a large ATP7A deletion, and in NSC-34 motor neurons. For mammalian cell transfections, we tagged wild type and mutant ATP7A alleles with Venus-fluorescent protein. The mutant alleles complemented ccc2Δ in a range from 60-100% of normal. Expression in Hek293 cells suggested delayed trafficking of mutant ATP7As in response to copper loading, as noted previously in fibroblasts from affected patients. In addition, we observed baseline accumulation of mutant ATP7As at the plasma membrane. This phenomenon was clearer in transfected neuronal (NSC-34) cells in which mutant ATP7A also showed more diffuse intracellular localization than wild type. These results suggest that aberrant ATP7A trafficking, which may be particularly relevant when transport along lengthy axons is required, may sabotage motor neuron function and underlie this phenotype. Protein misfolding with oligomerization or aggregate formation, chronic deficiency of one or more copper enzyme(s), oxidative injury, and altered synaptic activity of ATP7A remain alternative potential disease mechanisms. Delineation of the problem in this form of distal motor neuropathy will help elucidate the normal role of ATP7A in motor neurons.

2031/T

Molecular analysis of patients with unclassified disorders of lysosome-related organelles. *J.A. Curry, A.R. Cullinane, R. Hess, C. Carmona-Rivera, D. Adams, W.A. Gahl, M. Huizing.* Medical Genetics Branch, National Human Genome Institute, NIH, Bethesda, MD.

Altered biogenesis of lysosome-related organelles (LROs) such as melanosomes, platelet delta and alpha granules, lamellar bodies, and lytic granules has been implicated in human pathologies. We investigated 46 patients at the NIH Clinical Center with rare disorders of LRO biogenesis with Hermansky-Pudlak syndrome (HPS)-like phenotypes. These patients presented with hypopigmentation, a bleeding diathesis, and occasionally other symptoms such as immunodeficiency, granulomatous colitis, neurological symptoms or pulmonary fibrosis. Of this cohort, 14 patients had absent platelet dense bodies (a hallmark for HPS) but carried no mutations in the HPS1-HPS6 genes. The remaining 30 patients had reduced or normal numbers of platelet dense bodies, but no mutations in genes associated with oculocutaneous albinism (OCA1-4). For molecular analysis of candidate genes in this cohort, we first considered genes corresponding to mouse models of 'pigment dilution and storage pool deficiency' for which there is not yet a corresponding human subtype. We began by direct sequencing of genes encoding eight subunits of the biogenesis of lysosome-related organelles complex-1 (BLOC-1), including the HPS-7 and HPS-8 genes, not previously tested in this cohort. Additional murine candidate genes include RABGGTA, Rab38, and VPS33. In addition, genes affected in the Drosophila melanogaster 'granule group' of eye color mutants are excellent candidates; these include VPS18, VPS41, rab32 and AP3 subunits. Other molecules, such as coat proteins, SNAREs, syntaxins, rabs, cytoskeletal proteins, and membrane lipids may also be candidates for causing LRO disorders and will eventually be considered. Apart from direct DNA-sequencing, other techniques such as real-time PCR, immunofluorescence microscopy and western blotting will be employed on patients' cells. Although we detected no defects in the genes screened so far, this candidate gene approach appears feasible for identifying novel LRO-related gene defects. Any novel identified gene defect may not only result in prognostic and therapeutic implications for the patients, but also present an opportunity to further elucidate the mechanisms of biogenesis of lysosome-related organelles.

2032/T

Newly identified cardiovascular complications of Menkes disease and occipital horn syndrome. *J. Hicks[1], T. Shawker[2], S. Kaler[1].* 1) Molecular Medicine Program, NICHD/NIH, Bethesda, MD; 2) Diagnostic Imaging, NIH Clinical Center, Bethesda, MD.

Menkes disease is an infantile neurodegenerative disorder caused by mutations in ATP7A, an X-chromosomal gene that encodes a copper-transporting P-type ATPase. Deficiency of the ATP7A gene product results in abnormal cellular copper transport and reduced activities of numerous copper-dependent enzymes. The classical clinical phenotype associated with mutation at the ATP7A locus includes growth retardation, peculiar hair, and focal cerebral and cerebellar degeneration. Some clinical features of Menkes disease are associated with reduced activities of specific copper enzymes. For example, deficiency of lysyl oxidase, a copper enzyme that normally plays a critical role in formation and repair of extracellular matrix via oxidation of lysine residues in elastin and collagen, has been implicated in the generalized vascular tortuosity evident in patients with Menkes disease. In the absence of normal lysyl oxidase activity, formation of covalent cross-linkages that provide tensile strength to blood vessel walls is markedly reduced. Diminished tensile strength predisposes to formation of aneurysms in the walls of high-flow blood vessels, and aneurysms have been reported in some major internal arteries in patients with Menkes disease. Aortic aneurysms are a prominent feature in one mouse model of Menkes disease, Mo-blotchy. Male mice from the Mo-Tohm strain die prenatally due to embryonic vascular abnormalities. The yolk sac of these mice display hemorrhage and arrested development of blood vessels, irregular attachment between mesoderm and endothelial cells, and disrupted collagen linkage. Mo-Tohm/+ females display fragmented elastin in the descending aorta during the neonatal period. We report on three Menkes disease patients in whom complex congenital heart disease (pulmonic stenosis, transposition of the great vessels, and tetralogy of Fallot) was noted. These patients, all identified within a three-year time frame in the United States, highlight the potential role of ATP7A in normal cardiovascular development. In addition, we have documented progressive internal jugular vein dilation in 9/14 Menkes disease infants followed by serial neck ultrasounds, presuambly a consequence of lysyl oxidase deficiency, and of uncertain clinical importance.

2033/T

Identification and Molecular Characterization of Spectrum of Mutations in Galactosemia genes from Galactosemia Patients: A Study from Tertiary Care Center in North India. *R. Singh[1], G. Kaur[2], B.R. Thapa[3], R. Prasad[1].* 1) Biochemistry, Postgraduate Institute of Medical Education and Research (PGIMER), Chandigarh, Chndigarh, India; 2) Department of Physiology, Government Medical College and Hospital, Chandigarh, India; 3) Division of Pediatric Gastroenterology, Postgraduate Institute of Medical Education and Research, Chandigarh, India.

Introduction: Galactosemia is an autosomal recessive metabolic disorder caused by the deficiency of enzymes involved in galactose metabolism resulting in complications like cataracts, hepatocellular damage and developmental delay. Nonetheless, no report is available on mutations in galactosemia genes from our population. Objective: 1) To determine blood GALT activity in infants with cholestasis and to establish a spectrum of mutations in GALT gene 2) To determine blood GALK activity in infants with congenital cataract and to establish a spectrum mutations in GALK gene Methods: 390 infants (2 days-11 months) with cholestasis admitted in Pediatric Gastroenterology over 3.5 years were evaluated for galactosemia. Basic investigations included hemogram, liver function tests, blood culture, urine culture, urine for non-glucose reducing substances, eye evaluation, abdominal ultrasound, TORCH serology, mebrofenin scan and peroperative cholangiogram were done when indicated. Screening for GALT deficiency was done using Perkin-Elmer neonatal GALT kit. The levels of galactose-1-phosphate were also measured. Apart from this, 115 patients with congenital cataract were screened for the galactokinase (GALK) deficiency. Mutation analysis for most common Q188R and N314D mutations in GALT gene was performed by Restriction Fragment Length Polymorphism (RFLP). Single Stranded Conformational Polymorphism (SSCP) analysis and subsequently DNA sequencing were done for identification and characterization of unknown and novel mutations in GALT and GALK genes. Results: 55 (14.1%) infants were found to have reduced GALT activity with male: female: 37:18, jaundice in 54 (98%), hepatomegaly in 50 (91%), splenomegaly in 32 (58%), coagulopathy in 23 (42%), encephalopathy in 9 (16%), septicemia in 10 (18%) and cataracts in 12 (22%) were observed. Increased galactose-1 phosphate levels were fraternized with reduced activity of GALT. A total of 13 mutations and 3 polymorphisms were detected. 8 were novel mutations. N314D mutation was found in 30 patients. Q188R mutation was detected in three patients. Reduced blood galactokinase activity was found in 8 (7%) patients with congenital cataracts. 4 novel mutations were found in GALK gene. Conclusion: N314D mutation was found to be the most common mutation in our population. 8 and 4 novel mutations were also detected in GALT and GALK genes respectively.

2034/T

Comprehensive Biochemical and Molecular Analysis of Congenital Disorders of Glycosylation. *M. He[1], B. Xia[1], X. Li[1], B. Ng[2], H. Freeze[2], R. Cummings[3], W. Zhang[1], D. Matern[4], K. Raymond[4], T. Wood[5], M. Hegde[1].* 1) Human Genetics, Emory University, Georgia, GA; 2) Burham Instituion for Medical Genetics, La Jolla, CA; 3) Biochemistry, Emory University, Georgia, GA; 4) Biochemical Genetics Laboratory, Mayo Medical College, Rochester, MN; 5) Greenwood Genetics Center, Greenwood, SC.

Congenital Disorders of Glycosylation (CDG) are caused by gene defects in biosynthetic glycosylation pathways. To date, 14 different genetic defects in N-glycosylation, 11 in O-glycosylation and 11 in multiple glycosylation are known. Current diagnostic testing are mostly through serum transferrin analysis. However, with 2-3% of the active human genome thought to be involved in the synthesis and recognition of glycoconjugates, screening CDGs by one single transferrin protein is insufficient and a number of different types and patients remain undiagnosed. To improve the diagnosis and therefore an earlier treatment of CDGs, we have developed and launched comprehensive biochemical and molecular clinical CDG screening panels. For biochemical screening of CDG in serum or plasma, we coupled carbohydrate deficient transferrin test with serum N-glycan and O-glycan structural mapping by MALDI-TOF/TOF. This strategy has been applied successfully to the characterization of glycan profiles in 30 micro liter of the serum/plasma from patients suffering from CDG type II, combined CDG type I and type II or deficiencies in COG subunits. In addition to the biochemical CDG screen in blood, we also have implemented a free glycan/oligosaccharide screening in urine by MALDI-TOF/TOF method. Urinary free glycan/oligo screening not only could be used to diagnose the CDGs that are difficult to detect in the blood, such as CDGIIb, but also it specifically detects glycoprotein storage diseases such as the I cell disease, GM1 or GM2 gangliosidosis, galactosialidosis, Pompe, aspartylglucosaminuria etc. The sensitivity and specificity of this method has far exceeded what traditional thin layer chromatography could achieve. For comprehensive molecular CDG test panels, we have developed and launched the comprehensive 24 gene N-glycosylation disorder whole gene sequencing panel, CDG type I, 14 gene panel and multiple glycosylation, 11 gene panel using fluidigm and raindance library construction system coupled with the next generation sequencing and CGH array to detect single and multi exon deletions and duplications. We have also developed a CDG research library containing a list of putative genes which may be associated with CDG. This library will facilitate identification of novel genes associated with CDGs. Our comprehensive biochemical and molecular analysis of CDG provides new algorithms of the diagnosis of CDG.

2035/T

Genetic variation and an increasingly personalized approach to medicine: the Lysosomal Storage Disorder Registries. *E. James[1], F. Stewart[2], S. Prasad[1].* 1) Genzyme Corporation, Cambridge, MA; 2) Belfast City Hospital, Belfast, UK.

Sequencing of the human genome has heralded a new era in medicine. A better understanding of the relationship between genotype and phenotype, as well as the impact of genotype on disease progression and treatment will afford clinicians new opportunities to consider increasingly personalized approaches to disease management. Knowing the sequence of a gene, however, does not establish its function. Consequently, numerous initiatives have been established to further the understanding of the relationship between genetic variation and human health. Increasingly, disease registries are being used to collect observational, clinical effectiveness data in real-world settings. Registries are particularly important in rare genetic (or 'orphan') disorders, where identifying large numbers of patients to enroll in clinical trials is difficult. For example, disease registries now exist for various lysosomal storage disorders (LSDs), including Fabry disease, Gaucher disease, mucopolysaccharidosis Type I, and Pompe disease. Since the establishment of these registries, the understanding of the natural histories of the diseases, phenotypic heterogeneity, and genotype-phenotype correlations has grown, although much is still to be learned. Also, participants from clinical trials are increasingly being entered into registries, enabling follow-up of long-term treatment effectiveness and safety, thus demonstrating how registry data complement and supplement clinical trial data. As of May 7, 2010, the Pompe Disease Registry, established in 2004, contains data for 847 patients. Genotype data are available for a large number of enrolled patients. As the understanding of the genetics of Pompe disease increases, the Registry should help elucidate regional differences in the disease and symptomology in different subgroups. The methodology of how registries operate and how they can contribute to our understanding of disease continue to evolve with increasing advancements in technology and willingness to engage in such projects. This presentation looks at examples from LSD registries on understanding genetic variation and comments on operational aspects of registries to facilitate this. With genetic diseases such as the LSDs, registries are helping establish relationships between genetic mutations and disease, thereby paving the way for an increasingly personalized approach to the treatment of these rare and serious disorders.

2036/T

The heterogeneity of Pompe disease: early data from the Pompe Registry. *S. Prasad[1], B. Byrne[2], L. Case[3], E. Cupler[4], A. Genge[5], P. Kishnani[3] on behalf of the Pompe Registry Boards of Advisors.* 1) Genzyme Corporation, Cambridge, MA; 2) University of Florida, Gainesville, FL, USA; 3) Duke University Medical Center, Durham, NC, USA; 4) Oregon Health & Sciences University, Portland, OR, USA; 5) Montreal Neurological Institute, Montreal, Quebec, Canada.

Background: Pompe disease, a rare autosomal recessive disease resulting from a deficiency of acid α-glucosidase (GAA), is characterized by progressive myopathy. It is classified as infantile (IO; onset £12 months of age) or late (LO; onset >12 months of age) onset, although a range of disease severity and rate of progression is found. Diagnosis is confirmed by identification of absent or deficient GAA enzyme activity or presence of disease-causing GAA gene mutations in both alleles of the GAA gene. More than 289 different sequence mutations in the gene encoding GAA have been identified; 197 appear to be pathogenic. Disease registries are important in establishing information on pathogenesis, genotypic and phenotypic heterogeneity, symptomatology, and natural history of rare diseases. The Pompe Registry was established in 2004. Data from the Registry have begun to demonstrate the phenotypic heterogeneity of the disease in a relatively large cohort of patients. Methods: A query of the Pompe Registry was performed to determine types of GAA mutations in registered patients. Genotype correlations were attempted. Results: As of September 2009, 742 patients from 28 countries were enrolled. Seventy percent (517/742) had symptom onset >12 months of age; 23% (170/742) had symptom onset £12 months of age. Data are missing for 7% (55/742) of patients. Mutation data are available for 284 patients (83 IO; 201 LO). Of common mutations, the frequency of c.525delT appears similar between IO and LO patients; however, understanding the contributions of the other mutation in a patient to phenotype is important. p.Asp645Glu occurs more in IO patients. The most frequent mutation in LO patients is c.-32-13T>G, the splice mutation; it is not seen in IO patients with cardiomyopathy, appearing more frequently in older patients with a milder disease progression. Nonsense mutations predominate in IO patients with cardiomyopathy. Conclusions: Because mutations may be rare, the Pompe Registry is essential to record the full clinical picture. Although lack of longitudinal disease information and clean genotype information have hindered establishing genotype-phenotype associations thus far, as the Registry grows and more genetic information is collected, it may provide a more complete description of the clinical spectrum of the disease. As a global database with clinical and genetic information available through a centralized source, the Pompe Registry is an ideal means to do this.

2037/T

The Genetics of Hermansky-Pudlak Syndrome. *R. Hess, R. Fischer, W.A. Gahl, M. Huizing.* Medical Genetics Branch, NHGRI/NIH, Bethesda, MD.

Hermansky-Pudlak syndrome (HPS) is a disorder of lysosome-related organelle (LRO) biogenesis, resulting in oculocutaneous albinism, a bleeding diathesis, and occasional colitis or pulmonary fibrosis. Eight human HPS subtypes are identified (HPS1-8). Since an accurate diagnosis of each subtype has important prognostic and therapeutic implications and also provides insights into the cell biology of LROs, we extensively characterized each HPS subtype. We have studied 260 HPS patients at the NIH Clinical Center. Our molecular analyses indicated that HPS-1 (188 patients, 13 HPS1 mutations) comprises the largest group due to a founder mutation in NW Puerto Rico. HPS-2 results from mutations in AP3B1, encoding the beta3A subunit of adaptor complex-3, a coat protein that mediates vesicle formation. We identified 3 HPS-2 patients, harboring 4 different AP3B1 mutations. We also identified 13 HPS-4 patients (10 HPS4 mutations), 22 HPS-3 patients (10 HPS3 mutations; with founder mutations in Central Puerto Rico and in Ashkenazi Jews), 10 HPS-5 patients (13 HPS5 mutations), and 5 patients with HPS-6 (8 HPS6 mutations). We have not identified any HPS-7 or HPS-8 patients and only one patient/family of each subtype has been reported. Our remaining 12 unclassified HPS patients provide opportunities to identify new HPS-causing genes. Several genes, some corresponding to HPS mouse models that manifest both hypopigmentation and a platelet storage pool deficiency, are good candidates. Any new genetic causes of HPS will aid in elucidating the mechanism by which melanosomes, dense bodies, and lysosomes are created. Our extensive molecular studies allowed for genotype-phenotype analysis. We found that that HPS-1 and HPS-4 patients are at increased risk for developing pulmonary fibrosis and granulomatous colitis. HPS-2 patients have persistent neutropenia and had recurrent childhood infections, and may develop pulmonary fibrosis. HPS-3, HPS-5, and HPS-6 patients are clinically milder, with no apparent pulmonary involvement. These findings reiterate that an accurate diagnosis of each HPS subtype has important prognostic implications.

2038/T

Type 1 Gaucher disease: Early Manifestations in Children Homozygous for the N370S Mutation. *K. Desai, R.J. Desnick, L. Bier, M. Balwani.* Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY.

Type 1 Gaucher disease (GD1; deficient acid β-glucosidase), is the most common lysosomal storage disorder, and is particularly prevalent in the Ashkenazi Jewish (AJ) population, in which >70% of affected patients are homozygous or heteroallelic for the N370S mutation (carrier frequency 1 in 17). To date, the clinical manifestations of N370S homozygotes have not been characterized in infancy or early childhood and there are no specific monitoring guidelines for presymptomatic children with this typically later-onset phenotype. Therefore, we analyzed our experience monitoring twenty-one N370S/N370S infants and children diagnosed before age 3 years who were evaluated at baseline and at regular follow up visits. Data from clinical, laboratory and imaging assessments were used to monitor disease progression. The 21 patients included nine females and 12 males aged 3 months to 11.5 years. On review of systems, no symptoms suggestive of GD1 were reported. Physical exam did not reveal any GD1 related manifestations except for a palpable spleen tip in one 2.5 year old patient. There was no evidence of growth retardation; growth ranged from the 10th to 95th percentile for age. Mild speech delay and/or motor delay occurred in 18% of the children. Laboratory evaluation of 20 patients revealed that 10% were mildly anemic (mean hemoglobin 10.1 g/dl) due to iron deficiency and one patient had transient thrombocytopenia (129,000 u/L). Coagulation studies of nine patients revealed 67% had a prolonged aPTT (35.4-39.9 sec) on at least one occasion, and 22% had a persistently prolonged aPTT with normal Factor XI levels. Among the 11 (aged 2.5 - 11.5 years) who had imaging studies, 82% had mild hepatosplenomegaly which was preceded by splenomegaly in two cases. Chitotriosidase activity levels varied markedly among patients and increased in all patients with age (10 months to 11.5 years), reaching 5072 nmol/hr/ml (normal <180 nmol/hr/ml) in a 5 year old male. Angiotensin-converting enzyme levels ranged from 8 to 271 IU/L (normal 8-52 IU/L). Thus, Gaucher disease manifestations in N370S homozygous children can include mild visceromegaly, an abnormal coagulation profile, and biomarker elevation. As newborn screening for these disorders becomes a reality, practical screening and management guidelines are needed for presymptomatic pediatric patients affected with GD1.

2039/T

***AMPD2* plays an important role for regulation of lipid and glucose metabolism.** *T. Morisaki[1,2], J. Cheng[1], K. Toyama[1,2], T. Hirase[1], M. Ikawa[3], M. Okabe[3], H. Morisaki[1].* 1) Dept Bioscience & Genetics, Natl Cerebr & Cardiovasc Ctr Res Inst, Suita, Osaka, Japan; 2) Dept Mol Pathophysiol, Osaka Univ Grad Sch Pharm Sci, Suita, Osaka, Japan; 3) Genome Info Res Ctr, Osaka Univ, Suita, Osaka, Japan.

The regulation of liver energy metabolism in lipid and glucose is crucial for defense to obesity, insulin resistance and type 2 diabetes. AMP deaminase (AMPD) deaminates AMP to IMP and play a key role in stabilization of energy charge. AMPD is expressed at high levels in skeletal muscle, and muscle AMPD (AMPD1) deficiency, which is one of the most common enzyme defects especially in Caucasian, has been reported to be associated with symptoms of a metabolic myopathy, though not all of individuals with this defect exhibit symptoms. In addition to AMPD1, AMPD2 and AMPD3 are known to be expressed in tissues other than skeletal muscle, and AMPD2 gene is widely expressed in non-muscle tissues including liver. The precise function of AMPD2 is not known partly because no AMPD2 deficiency has been reported in human. Recently, we established a murine model for AMPD2 deficiency and found that AMPD2 plays an important role in liver lipid and glucose metabolism. AMPD2 deficient mice exhibited reduced body weight and fat accumulation, down-regulated blood glucose level, and increased insulin sensitivity, but did not show any change of the calorie intake or the spontaneous motor activity. AMPD2 deficient mice also exhibited attenuation of high-fat-diet-induced phenotypes including obesity and insulin resistance. In liver, the decrease of AMPD activity, the increase of AMP, and the increase of the phosphorylated AMP-activated protein kinase (AMPK) and the phosphorylated acetyl-CoA carboxylase were observed. The expression of PPAR gamma, PGC-1beta was down-regulated and the expression of leptin receptor was increased in the liver of those mice. Furthermore, the expression of G-6PC and PEPCK in liver was decreased in those mice. Based on these results, we conclude that AMPD2 is a novel metabolic molecule regulating lipid and glucose metabolism by changing the AMP level, resulting in AMPK phsphorylation and further effects. We hope this gene as a promising target for an effective treatment of obesity, insulin resistance or type 2 diabetes.

2040/T

Variation in STARD13 may contribute to type 2 diabetes and obesity. *L. Bian, R.L. Hanson, Y.L. Muller, J. Perez, B. Kaur, J. Mack, S. Kobes, W.C. Knowler, C. Bogardus, L.J. Baier.* PECRB, NIDDK, NIH, Phoenix, AZ.

The Pima Indians of Arizona have a high prevalence of type 2 diabetes and obesity. To identify genetic variation that contributes to both diseases in this population, we completed a genome-wide association study (GWAS) using the Affymetrix 1-million SNP chip. Three SNPs in genotypic concordance (rs521868, rs523656, and rs2858809) that map within introns of STARD13 were associated with early-onset type 2 diabetes (n = 634, P = 1.2 × 10-5) and BMI (n = 974, P = 5.9 × 10-5). STARD13 encodes StAR-related lipid transfer protein 13 that plays an important role in lipid transport and metabolism. To follow-up on this GWAS observation, the putative promoter, all exons, and exon-intron boundaries of STARD13 were sequenced in 24 Pima Indians; 38 variants were identified and 22 were selected as tag SNPs (using pair-wise r2 ≥0.8 to indicate redundance). Additional tag SNPs (n = 21) across intronic regions were selected from GWAS data. All 43 tag SNPs were genotyped in a population-based sample of 3,501 full-heritage Pima Indians for diabetes/obesity analysis. Six SNPs were associated with type 2 diabetes (P = 0.02-0.0009, OR = 1.16-1.24), 18 SNPs were associated with BMI (P = 0.04-0.0002) and 4 SNPs were associated with both phenotypes. Selected SNPs were genotyped in an additional sample of 3,723 “mixed heritage” Native Americans to assess replication. Comparing these two samples of Native Americans, 2 SNPs replicated for BMI (e.g. rs9536645, had a P = 0.0002 in full heritage Pima Indians, P = 0.04 in “mixed heritage” sample, and P = 0.00003 when samples were combined). None of the diabetes associations independently replicated (P < 0.05) between these 2 Native American samples, although associations remained significant in the combined sample (e.g. rs523656 had a combined P = 0.0009). Among the 6 SNPs associated with diabetes in Pima Indians, 5 were reported in the DIAGRAM meta-analysis for type 2 diabetes in Caucasians and 3 SNPs (rs523656, rs17596576, and rs703232) were associated with diabetes in DIAGRAM (P = 0.002-0.0001, OR = 1.10-1.14). Analysis of rs5236565 in the combined data from Pima Indians, “mixed heritage” Native Americans, and DIAGRAM Caucasians provided the strongest evidence for association with type 2 diabetes (P = 7.4× 10-7, OR = 1.14). We propose that variation within STARD13 modestly increases risk for type 2 diabetes and obesity in Pima Indians, and the diabetes effect may be common to other ethnic groups.

2041/T

Mutations in the SLC22A5 (OCTN2) gene detected in 143 subjects for systemic carnitine deficiency. *F-Y. Li[1], A.W. El-Hattab[1], E.V. Bawle[2], R.G. Boles[3], E.S. Schmitt[1], F. Scaglia[1], L-J. Wong[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Division of Genetic and Metabolic Disorders, Children’s Hospital of Michigan, Detroit, MI; 3) Division of Medical Genetics, Children’s Hospital Los Angeles, Los Angeles, CA.

Systemic primary carnitine deficiency (CDSP) is an autosomal recessive disorder caused by mutations in the SLC22A5 (OCTN2) gene encoding the plasmalemmal carnitine transporter. The severe form of CDSP was the originally known presentation of the disease and is characterized by progressive infantile-onset cardiomyopathy, weakness, peripheral neuropathy and recurrent hypoglycemic hypoketotic encephalopathy. However, the advent of expanded newborn screening has broadened the clinical spectrum of disease to include asymptomatic newborns and mothers. In this study, the entire coding regions of the OCTN2 gene were sequenced in 143 unrelated subjects who were suspected of having CDSP either as a follow-up of an abnormal newborn screening (NBS) result or as part of a diagnostic work-up when symptomatic. In 70 unrelated infants evaluated because of abnormal NBS results, 48 infants were found to have at least 1 mutation/unclassified missense variant. Thus, sequence analysis detects at least one mutation in 69% (48/70) in NBS positive infants. Thirty-three mothers whose infants had abnormal NBS results, including 21 whose infants were not tested for OCTN2 mutations, were molecularly evaluated and in 28 (85%) of them at least 1 mutation/unclassified missense variant was found. A total of 11 asymptomatic mothers whose infants had abnormal NBS results were found to have 2 mutations. Therefore, OCTN2 sequence analysis is recommended for infants ascertained due to abnormal NBS results and for their mothers. Conversely, 52 unrelated subjects were tested due to clinical indications other than abnormal NBS and only 14 (27%) of them were found to have at least one mutation/unclassified missense variant. Custom designed oligonucleotide array CGH analysis revealed a heterozygous ~1.6 Mb deletion encompassing the entire OCTN2 gene and other genes in one subject who was apparently homozygous for the c.680G>A (p.R227H) mutation upon sequence analysis . Thus, large deletions at the OCTN2 locus may also be considered if by sequencing, an apparently homozygous mutation or only one mutant allele is identified.

2042/T

Thiamine-responsive pyruvate dehydrogenase deficiency in two patients with normal development and muscular symptoms. *E. Naito[1], T. Hashimoto[1], T. Kumagai[2], S. Yamashita[3], Y. Kotani[4], S. Kagami[4].* 1) Dept. of Pediatrics, Japanese Red Cross Tokushima Hinomine Rehab., Komatsushima, Tokushima, Japan; 2) Dept. of Pediatric Neurology, Central Hospital, Aichi Welfare Center for Persons, Aichi, Japan; 3) Dept. of Neurology, Kanagawa Children's Medical Center, Kanagawa, Japan; 4) Dept. of Pediatrics, Institute of Health Biosciences, The University of Tokushima, Graduate School, Tokushima, Japan.

The human pyruvate dehydrogenase complex (PDHC) catalyzes the thiamine-dependent decarboxylation of pyruvate. Thiamine treatment is very effective for some patients with PDHC deficiency. Among these patients, nine mutations of the X-linked pyruvate dehydrogenase (E1) α subunit have been published previously: H44R, V71A, R88S, G89S, C101F, F205L, L216F, R263G, and V389fs. As four mutations (H44R, V71A, R88S, G89S) were in exon 3, exon 3 in the E1 α subunit appears to be important in thiamine-responsive PDHC deficiency. We report the biochemical and molecular analysis of two male patients with clinically thiamine-responsive lactic acidemia, normal development and muscular symptoms (generalized hypotonia and weakness). The PDHC activity was assayed using two different concentrations of TPP. These two patients displayed very low PDHC activity in the presence of a low ($1x10^{-4}$ mM) TPP concentration, but their PDHC activity significantly increased at a high (0.4 mM) TPP concentration. Especially, the PDHC activity of one patient increased to within the normal range. Thus the PDHC deficiency in these two patients was due to a decreased affinity of PDHC for TPP. Therefore, in order to diagnose this type of thiamine-responsive PDHC deficiency and to prevent a diagnostic error, it is necessary to measure the activity of PDHC in the presence of a low ($1x10^{-4}$ mM) as well as a high TPP concentration. The DNA sequence of these two male patients' X-linked E1 α subunit revealed a point mutation (L260Q in exon 8 and A349T in exon 11). Treatment of both patients with thiamine resulted in a reduction in the serum lactate concentration and clinical improvement of muscular symptoms, suggesting that these two patients have a thiamine-responsive PDHC deficiency due to a point mutation in the E1 α subunit gene.

2043/T

A STUDY OF WILSON DISEASE MUTATIONS IN SPAIN. *C. Solis-Villa[1], L. Hierro[2], C. Lacambra[3], P. Jara[2].* 1) Genetics, University Hospital La Paz, Madrid, Spain; 2) Hepatology, University Hospital La Paz, Madrid, Spain; 3) Internal Medicine, Hospital Severo Ochoa, Leganés, Madrid, Spain.

A STUDY OF WILSON DISEASE MUTATIONS IN SPAIN Wilson disease (WD) is an autosomal recessive disorder of copper transport, characterized by toxic accumulation of copper in the liver and subsequently in the brain and other organs. The disease is caused by a large number of mutations in the ATP7B. We present the genetic screening results of 320 WD patients and relatives from 146 different families mainly from Spain. Mutation screening of the entire coding region and the intron-exon boundaries was undertaken by direct sequencing. In order to simplify and to avoid allele drop-out, we carried out long-range PCR of exons 6-9 and exons 10-14 and then sequenced exon by exon. The rest of the coding region was amplified exon by exon. Recently, we have implemented high resolution melting (HRM) to screen mutations in exons 15 through 21, with promising results. We have found 14 novel mutations and 30 mutations previously described. By far the most frequent mutation is p M645R, which accounts for 33% of the mutated alleles followed by H1069Q, with 13%. We have found 8 homozygotes for p M 645R and just one homozygote for H1069Q. In some of the patients, either one (10%) or both mutations (15%), could not be identified. Multiplex Ligation-dependent Probe Amplification (MLPA) was performed in order to discard long deletions as the disease-causing lesion, but no alterations were identified The novel mutations are: p Ser59Leu, p Ile161Thr, p Ile381Ser, c523-525 del AA, (exon 2), IVS2(+5) G>A, c1739delA (exon5), p Met665Val, p Met671Val, (exon 7), p Gln799X (exon 9), p Glu847X (exon10) p Asp1289Tyr (exon 18), p Leu1313Arg, p Asn1324Ser (exon 19), p Gly1347-Leu (exon 20). No mutations were found in exons 3, 4 or 11. Our findings corroborate the importance of the genetic testing of Wilson disease, especially for the diagnosis of relatives. More studies are needed to unveil the underlying lesion in those cases where no abnormality was found; perhaps the regulatory regions need to be investigated. Finally, HRM has proven to be a powerful technique to screen for ATP7B mutations inWD.

2044/T

DNA diagnosis of neuronal ceroid-lipofuscinoses (NCLs) in the Czech Republic. Does the novel mutation c.1439T>G (p.V480G) in CLN2 gene lead to the non-classical phenotype? *H. Vlaskova, L. Stolnaya, H. Treslova, H. Jahnova, H. Poupetova, L. Dvorakova, M. Elleder.* Inst Inherit Met Disorders, Charles Univ/1 Fac Med/UnivHos, Prague, Czech Republic.

The neuronal ceroid-lipofuscinoses (NCLs) are a clinically and genetically heterogeneous group of fatal inherited neurodegenerative lysosomal-storage disorders characterized by progressive mental and motor deterioration, and seizures. There are eight types well defined at the molecular level. Fifty seven probands with this diagnosis have been identified during last 35 years in our Institute that serves as a diagnostic center for the Czech Republic and Slovakia (15 mil. inhabitants). The diagnosis was carried out using the classical techniques (histology, electron microscopy) continuously updated by histochemistry, biochemistry and molecular genetics. NCL1 (n=2), NCL3 (n=4), NCL5 (n=1), NCL6 (n=2) represent the minority types, NCL2 and NCL7 being most frequent in the Czech Republic. NCL7 (n=22) has high incidence in the Roma population. Common missense substitution c.881C>A (p.T294K; 36/44 alleles) and splice mutation c.754+2T>A (7/44 alleles) are prevalent in this group. In the NCL2 group (n=26) the prevalent mutation was of the nonsense type c.622C>T (p.R208X) in 32 of 50 mutant alleles. Twenty four patients had the classical late infantile phenotype while two of them displayed atypical phenotype: In the first of the patients the disease course was of a variant juvenile type with onset before age of 6 and prolonged life span until 15 years. He was a compound heterozygote for p.R208X and p.V480G mutations (Elleder et al. 2008: Acta Neuropathol 116: 119). The second patient with disease onset at the age of 8 is alive, but bedridden, aged 25. Because of the mixed ultrastructural pattern in the initial skin biopsy we first analyzed the genes for the variant late infantile forms (CLN5 - CLN7) however, the results were negative. Analysis of the CLN2 gene disclosed the same genotype as in the first patient. NCL2 was proved by deficient activity of TPP I. This suggests that the novel mutation p.V480G is to be associated with atypical protracted phenotype. According to the information from the Rare NCL Gene Consortium (RNGC) the mutation c.1439T>G (p.V480G) is unique in CLN2 gene. Support: VZ MSM CR 0021620806, VZ MZ CR 64165.

2045/T

Expanded Clinical Spectrum and Neonatal Hyperammonemia Associated with Mutations in TMEM70. *J. Wang[1], O.A. Shchelochkov[1,2], F.Y. Li[1], H. Zhan[1], J.A. Towbin[3], J.L. Jefferies[3], L.C. Wong[1], F. Scaglia[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Division of Genetics, Department of Pediatrics, University of Iowa, IA; 3) Departments of Pediatrics, Human Genetics and Cardiovascular Sciences, University of Cincinnati College of Medicine, Cincinnati, OH; 4) 4Department of Pediatrics, Baylor College of Medicine, TX.

Mitochondrial disorders are a large and genetically heterogeneous group of disorders posing a significant diagnostic challenge. Only approximately 10-20% of patients have identifiable alterations in their mitochondrial DNA (mtDNA). The remaining ~80-90% of affected patients likely harbor mutations in nuclear genes, most of which are still poorly characterized, and therefore not amenable to efficient screening using currently available molecular methods. Here we present a patient, who has been followed since birth after presenting with neonatal hyperammonemia, Reye-like syndrome episodes, and ventricular tachyarrhythmia. Initial biochemical work-up revealed mild orotic aciduria and significant amounts of 3-methylglutaconic (3-MGC) and 3-methylglutaric (3-MGA) acids in the urine. Muscle biopsy demonstrated the presence of ragged-red fibers and non-specific structural abnormalities of mitochondria. The activities of respiratory chain enzymes (complexes I-IV) showed no deficiency. Mutational analysis of the entire mitochondrial genome did not reveal deleterious point mutations or large deletions. Long-term follow-up was significant for a later-onset hypertrophic cardiomyopathy, muscle weakness, and exercise intolerance. Although she had frequent episodes of Reye-like episodes in infancy and early childhood, mostly triggered by illnesses, these symptoms improved significantly with the onset of puberty. In the light of recent reports linking cases of type IV 3-methylglutaconic aciduria (3-MGCA) and hypertrophic cardiomyopathy to mutations in TMEM70, we proceeded with sequencing analysis of this gene. We identified one previously reported splice site mutation, c.317-2A>G and a novel, unclassified missense variant, c.494G>A (p.G165D) in an evolutionarily conserved region predicted to be deleterious. This variant was not identified in 100 chromosomes of healthy control subjects and 200 chromosomes of patients with cardiomyopathies. In comparison to the previously reported cases, we note that our patient had normal growth parameters and cognitive development, absence of structural heart defects, no dysmorphic features, improvement of symptoms with age, and persistence of hypertrophic cardiomyopathy.

2046/T

Recombinant human NAGLU-IGF2, a potential enzyme replacement therapy for Sanfilippo B syndrome. *S. Kan, C.S. Sinow, K. Haitz, A.K. Todd, S.Q. Le, L. Troitskaya, P.I. Dickson, B. Tippin.* Medical Genetics, LA Biomedical Research Institute (LA Biomed), Torrance, CA.

Mucopolysaccharidosis type IIIB (MPS IIIB; Sanfilippo B syndrome) is a lysosomal storage disorder (LSD) characterized by the defective degradation of heparan sulfate due to lack of α-N-acetyl-glucosamindase (NAGLU). MPS IIIB-affected individuals exhibit mild somatic symptoms, but severe central nervous system degeneration. Enzyme replacement therapy (ERT) has been successfully applied to treat many LSDs, like MPS I, II and VI, Fabry, Gaucher, and Pompe syndromes. However, attempts to use a similar strategy for ERT of MPS IIIB have failed due to inadequate uptake of poorly phosphorylated recombinant human NAGLU (rhNAGLU) via the insulin-like growth factor/mannose-6-phospate (IGF2/M6P) receptor.

In order to enhance the therapeutic potential of rhNAGLU, a modified construct with a C-terminally fused IGF2 receptor binding site and a c-myc tag was created and expressed in Chinese hamster ovary cells. The rhNAGLU-IGF2 was purified by Concavalin A and c-myc affinity chromatography and its biochemical properties were characterized. The purified rhNAGLU-IGF2 showed significantly higher intracellular uptake into MPS IIIB fibroblasts after 4 hours incubation compared with native urinary NAGLU (K_{uptake} of 47 nM, vs 730 nM, respectively). 80% of the cellular uptake was inhibited by IGF2 peptide and 40% was inhibited by neutralizing anti-IGF2 receptor antibody but no cellular uptake inhibition was observed by M6P, suggesting that rhNAGLU-IGF2 enters cells through the IGF2 binding site of the IGF2/M6P receptor. Moreover, rhNAGLU-IGF2 was taken up by several different human neuronal cell lines by the same mechanism. Further *in vivo* assays in MPS IIIB cells were conducted. The colocalization of rhNAGLU-IGF2 with lysosomes by confocal microscopy confirmed its lysosomal targeting. When taken up by cells rhNAGLU-IGF2 reduced GAG storage by 50% demonstrating its cellular physiological activity has potential to treat diseases

The novel rhNAGLU-IGF2 fusion protein shows high-affinity uptake into cells *in vitro* and, reduces GAG storage in MPS IIIB fibroblasts. Additional *in vivo* studies of the effect of intracerebroventricular rhNAGLU-IGF2 treatment on GAG and ganglioside storage in MPS IIIB mice are underway as well as evaluation the enzyme distribution and its half-life.

2047/T

Glycosylation-Independent Lysosomal Targeting of Acid α-Glucosidase Enhances Glycogen Clearance from Muscle Tissue of Pompe Mice. *J.H. LeBowitz[1], J.A. Maga[1], J. Zhou[1], R. Kambampati[1], S. Peng[1], D. Cloutier[2], R.N. Bohnsack[3], A. Thomm[1], S. Golata[1], P. Tom[1], N.M. Dahms[3], B.J. Byrne[2].* 1) ZyStor Therapeutics, Inc., Milwaukee, WI; 2) Powell Gene Therapy Center, College of Medicine, University of Florida, Gainesville, FL; 3) Department of Biochemistry, Medical College of Wisconsin, Milwaukee, WI.

We have used a peptide-based targeting system to improve lysosomal delivery of acid α-glucosidase (GAA), the enzyme deficient in patients with Pompe disease. ZC-701 is a recombinant fusion protein containing the GILT (Glycosylation Independent Lysosomal Targeting) tag fused to the N-terminus of amino acid residues 70-952 of human GAA. The GILT tag is derived from insulin-like growth factor II (IGF-II), a high affinity ligand for the 300 kDa cation-independent mannose-6-phosphate receptor (CI-MPR). This receptor, also known as the IGF-II receptor, shows dual ligand specificity in mammals, binding both IGF-II and proteins containing bis-mannose-6-phosphate (M6P) phosphorylated oligosaccharides with high affinity. We reasoned that the presence of the GILT tag, a high affinity ligand for the CI-MPR, on every ZC-701 enzyme molecule would enable more efficient lysosomal delivery of each ZC-701 molecule to cells possessing the receptor. This should ultimately result in more efficient clearance of the storage product, glycogen, from the lysosome of muscle cells. Our results show that in a cell-based uptake assay, ZC-701 was taken up by L6 myoblasts 25-fold more efficiently than was recombinant human GAA (rhGAA) based on measurement of K_{uptake}, the concentration at which half maximal uptake occurs. Once delivered to the lysosome, the mature form of ZC-701 was indistinguishable from rhGAA and persisted with a half-life indistinguishable from rhGAA. Furthermore, after a four week regimen of enzyme replacement therapy, ZC-701 was significantly more effective than rhGAA in clearing glycogen from skeletal muscle tissue of Pompe mice. The study compared 5 mg/kg and 20 mg/kg doses of ZC-701 and of rhGAA administered in four weekly doses. One week after the last injection, the mice were sacrificed and several muscle tissues were assayed for glycogen content using a biochemical assay. In each tissue, ZC-701 was found to reduce glycogen more effectively than rhGAA. ZC-701 demonstrated a dose response in some tissues but in others, 5 mg/kg was as effective as 20 mg/kg in reducing glycogen. 5 mg/kg ZC-701 cleared more glycogen than did 20 mg/kg rhGAA in all tissues indicating at least four-fold greater potency of ZC-701. We conclude that ZC-701 possesses many characteristics one would desire in an improved enzyme replacement therapy for treatment of Pompe disease patients.

2048/T

Assessment of the utility of globotriaosylceramide as a surrogate marker based on randomized controlled trials in Fabry disease. *R. Schiffmann[1], K. Nicholls[2], A. Mehta[3], J.T.R. Clarke[4,5], R.D. Steiner[6], M. Beck[7], B.A. Barshop[8], W.J. Rhead[9], M. West[10], N. Nair[11], R. Martin[11], P. Huertas[11].* 1) Inst Metabolic Disease, Baylor Res Inst, Dallas, TX; 2) Royal Melbourne Hospital, Parkville, VIC, Australia; 3) Royal Free Hospital and University College Medical School, London, UK; 4) Division of Clinical & Metabolic Genetics, Hospital for Sick Children and University of Toronto, Toronto, Canada; 5) Service de génétique médicale, Centre hospitalier universitaire de Sherbrooke, Sherbrooke, Canada; 6) Oregon Health & Science University, Portland, OR, USA; 7) Center for Lysosomal Storage Diseases, University of Mainz, Mainz, Germany; 8) University of California San Diego School of Medicine, La Jolla, CA, USA; 9) Medical College of Wisconsin, Milwaukee, WI, USA; 10) Department of Medicine, Dalhousie University, Halifax, NS, Canada; 11) Shire HGT, Cambridge, MA, USA.

Background: Fabry disease is an X-linked disorder of glycosphingolipid metabolism caused by a deficiency of the lysosomal enzyme α-galactosidase A. In male Fabry patients, kidney and cardiac dysfunction becomes apparent by the third decade of life, and without treatment often progresses to end-stage disease. Conflicting data exist on the utility of globotriaosylceramide (Gb3) as a surrogate biomarker in studies assessing stage of disease or response to specific therapies such as enzyme replacement. Goal: We present an analysis of the relationship of plasma and urinary Gb3 to the estimated glomerular filtration rate (eGFR) and left ventricular mass index (LVMI) in adult male patients who were enrolled in three prospective, randomized, placebo-controlled, clinical trials of agalsidase alfa and their open-label extension studies. Methods: eGFR was calculated using the Modification of Diet Renal Disease (MDRD) equation in 116 adult male patients. Gb3 was measured by HPLC in 24-hour urine sediment and in plasma. The association between plasma Gb3 and urine Gb3 and estimated glomerular filtration rate [eGFR] and MRI left ventricular mass indexed to height [LVMI]) was assessed by calculating the Pearson correlation coefficients (the strength of linear association between two variables). The resulting estimates were tested for statistical significance at the 0.05 level of significance. The robustness of the results was verified by measuring the Spearman correlation coefficient (rank-transformed data). The Pearson and the Spearman correlations were calculated for both the observed values and the changes from baseline at selected time-points up to month 30. eGFR and change in eGFR or LVMI were analyzed separately as outcome variables. Baseline proteinuria status was investigated as a potential covariate. Results: Current Gb3, baseline Gb3, and absolute Gb3 change were not found to be associated with any of the outcomes. Conclusion: These data indicate that plasma or urinary Gb3 cannot be used as a surrogate for GFR or LVMI in patients with Fabry disease undergoing enzyme replacement therapy.

2049/T

Normal oxidative phosphorylation in intestinal smooth muscle of childhood chronic intestinal pseudo-obstruction. *D. Chretien[1], L. Galmiche[1,2], F. Jaubert[2], F. Sauvat[3], S. Sarnacki[3], O. Goulet[4], Z. Assouline[1], V. Vedrenne[1], N. Boddaert[5], N. Brousse[2], A. Munnich[1], A. Rotig[1].* 1) INSERM U781 and Department of Genetics, Hôpital Necker-Enfants Malades and Assistance Publique-Hôpitaux de Paris, Faculty of Medicine, Université Paris Descartes, Paris, France; 2) Department of Pathology and Tumorothèque; 3) Department of Paediatric Surgery; 4) Department of Paediatric Gastroenterology; 5) Department of Paediatric Radiology.

Chronic intestinal pseudo-obstruction (CIPO) is a severe disease of the digestive tract motility. In pediatric population, CIPO remains of unknown origin for most patients. CIPO is also a common feature in the course of mitochondrial oxidative phosphorylation disorders related for some patients to mutations in TYMP, POLG1, mtDNA tRNAleu(UUR) or tRNAlys genes. We hypothesized that CIPOs could be the presenting symptom of respiratory chain enzyme deficiency and thus we investigated oxidative phosphorylation in small bowel and/or colon smooth muscle of primary CIPO children. We studied 8 children with CIPO and 12 pediatric controls. We collected clinical, radiological and pathological data and measured respiratory chain enzymatic activity in isolated smooth muscle of the small bowel and/or the colon. We also sequenced TYMP, POLG, mtDNA tRNAleu(UUR) and tRNAlys genes. No respiratory chain enzyme deficiency was detected in CIPO children. In myogenic CIPO, respiratory enzymes and citrate synthase activities were increased in small bowel and/or colon whereas no abnormality was noted in neurogenic and unclassified CIPO. Levels of enzyme activities were higher in control small bowel than in control colon muscle. Sequencing of TYMP, POLG, mtDNA tRNAleu(UUR) and tRNAlys genes and POLG gene did not reveal mutation for any of the patients. These data indicate that oxidative phosphorylation deficiency is not a common cause of childhood CIPO. Differences between control small bowel and control colon muscle probably reflect normal distinct motility and metabolic activity.

2050/T

Genetic and intestinal cell-specific contributions to the pathogenesis of necrotizing enterocolitis. *M.H. Premkumar[1], A. Erez[2], E. Munivez[2], S.C.S. Nagamani[2], G. Sule[2], J. Zhang[2], C. Rosales[3], B. Lee[4].* 1) Pediatrics/ Neonatology, Baylor College of Medicine, Houston 77030, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, 77030; 3) Department of Pathology, Texas Children's Hospital, Houston, Texas, 77030; 4) Howard Hughes Medicine Institute.

Necrotizing enterocolitis (NEC) is an intestinal emergency of premature infants with a high mortality and severe morbidity. The etiopathogenesis of NEC is not known. NO (nitric oxide) is one of the important mediators of NEC, but the exact mechanism of the role of NO is unclear. We hypothesize that cell specific dysregulation of NO metabolism in the intestine can differentially contribute to prevalence of NEC. NO is generated by the conversion of arginine to citrulline by Argininosuccinate lyase (Asl), the only enzyme in the body capable of generating arginine. We have previously generated Asl hypomorphic mice which exhibit generalized Asl deficiency, resulting in global deficiency of NO. The phenotype is characterized by severe growth restriction, shortened life span, and increased free radical injury. Via homologous recombination, we generated a conditional null allele of Asl. Cell specific KO of Asl was generated in smooth muscle, enterocyte and macrophage by breeding with transgenic mice expressing Cre recombinase in the respective cells. A double KO of eNOS and smooth muscle Asl was also generated. A mouse model of NEC was established in these mutant and wild type mice by subjecting premature mouse pups to exclusive formula feed, hypoxia and hypothermia. The severity of NEC was graded based on histopathology. Inflammatory mediators, protein and mRNA expression of Asl, nitrites and nitrosylation were measured using standard techniques. **Results**: Asl levels on Western blot and RT-PCR analysis were lower in the tissue specific Asl KOs in smooth muscle and macrophages compared to wild type. The incidence, severity of NEC and survival rates did not differ significantly among smooth muscle Asl Kos and double KOs of eNOS/smooth muscle Asl in comparison to the wild type suggesting that the smooth muscle and the endothelial NO contribute minimally to the pathogenesis of NEC. In macrophage KOs, the in vitro cytokine response to stimulation with lipopolysaccharide (LPS) was significantly blunted compared to wild type suggesting the possible role of iNOS in the pathogenesis of NEC.

2051/T

A rare mutation in GOT1 determines asparate aminotransferase (AST) levels in OOA. *H. Shen, C. Damcott, S. Chai, R. Yang, H. Hu, Q. Gibson, D. Gong, B. Mitchell, A. Shuldiner.* School of Med, EDN, Univ Maryland, Baltimore, MD.

Asparate aminotransferase (AST) catalyzes the reversible conversion between aspartate/alpha-ketoglutarate and oxaloacetate/glutamate, pivotal steps in metabolism of amino acid, glucose, and lipid. We have recently carried out a genome wide association study of serum AST levels in 862 Amish participants of the HAPI Heart Study and identified significant association of AST levels with a cluster of SNPs located on chromosome 10q24.1 (peak association was rs17109512; P value = 5.46E-14), in the vicinity of GOT1, the gene encoding cytosolic AST. The frequency of rs17109512 was rare (MAF = 0.006) The 10 heterozygotes had significantly lower AST levels compared to the 852 homozygotes for the common allele (mean of AST: 10.0+/- 2.8 vs. 18.8+/-5.2). Given the low frequency of the associated SNP, its proximity to GOT1, and the very large effect size of the association, we hypothesized that rs17109512 is tagging a functional SNP in GOT, most likely a mutation affecting the protein sequence of AST. We sequenced the gene and identified an in-frame deletion of three nucleic acids encoding asparagine at position 389 in GOT1 gene. Further genotyping of Del389Asn in other Amish samples (n=1600) identified an additional 20 carriers (MAF = 0.006). The variant was not detected in 647 outbred Caucasians. Asn at codon 389 is conserved among known mammalian cytosolic ASTs. The AST activity of recombinant proteins carrying the Del389Asn mutation was significantly lower than the recombinant protein carrying the wide-type allele. In conclusion, we discovered a rare in-frame deletion in GOT1 gene encoding cytosolic AST enzyme in the Old Order Amish. This finding will help us to understand the biology of AST in human intermediary metabolism.

2052/T

Prevalence of lysosomal storage disorders in India: Our experience. *J. Sheth[1], M. Mistri[1], N. Oza[1], U. Dave[1], P. Gambhir[2], R. Shah[1], F. Sheth[1].* 1) Biochem & Molec Bio, Inst Human Gen, Ahmedabad, India; 2) Sasoon General Hospital, Pune, India.

With the population of 1.2 billion, birth rate of about 29 million per year and consanguineous marriages in many parts of the country storage disorders are considered to be high in India. However, due to overlapping clinical phenotypes, lack of therapeutic options for majority of LSDs, the subject remains an investigative with lesser interest from the clinician. On the other hand recent availability of enzyme replacement therapy for some of the storage disorders there is a growing interest among clinicians in an early diagnosis of these diseases. Present study was carried out in 604 children in the age range of 3 months to 12 years with variable phenotypes like coarse facial features, hepatomegaly, neuroregression, epiphyseal skeletal abnormality, corneal clouding, cherry red spot, impaired motor neuron function/hypotonia, respiratory complications with progressive muscular weakness and regression of learned skill/mile stone. All were investigated for seven mucopolysaccharide disorders, glycolipid and lipid storage disorders (Tay Sachs, NPD, Gaucher), storage of sulphatides (MLD and Krabbe), glycogen storage (Pompe), defects in lysosomal transporters (Sialic acid storage disorder) and lysosomal trafficking protein abnormality (Mucolipidosis and NPD-C). Enzyme study was carried out from leucocytes, plasma and skin fibroblasts using fluorometric and spectrophotometric substrate. 208/604 (34.44%) children wear found to have storage disorders like MPS (36.53%), glycolipid and lipid storage (38.46%), sulphatides accumulation (10.57%), glycogen storage (9.66%), lysosomal transporter abnormality (1.93%) and lysosomal trafficking protein abnormality (2.9%). Impaired motor neuron function/hypotonia and neuroregression were the most common phenotype observed in 58.65% and 42.78% children with storage disorders. While other phenotypes were hepatosplenomegaly (28.36%), coarse facial features (29.32%), cherry red spot(32.21%), regression of learned skill/delayed mile stone (32.21%), skeletal abnormality (17.78%), respiratory complications with progressive muscle weakness (9.6%) and corneal clouding (2.4%). Our study suggests that glycolipid and lipid storage disorders are the most common storage disorders in India followed by MPS and information can be utilized for the national screening programme of storage disorders like Gaucher and NPD A/B to offer an early therapeutic intervention with improved prognostication.

2053/T

A common splicing mutation in Korean patients with classical galactosemia. *G.H. Kim[1,3], B.H. Lee[1,2,3], C.K. Cheon[4], J.M. Kim[3], M. Kang[3], J.H. Kim[3], S.H. Yang[5], J.H. Choi[2,3], H.W. Yoo[1,2,3].* 1) Med Gen Clinic & Lab, Asan Med Ctr, Seoul, Korea; 2) Department of Pediatrics, Asan Medical Center Children's Hospital, Seoul, Korea; 3) Genome Research Center for Birth defects and Genetic Diseases,Asan Medical Center Children's Hospital, Seoul, Korea; 4) Pusan National University, Beomeo-ri, Mulgeum-eup, Yangsan-si, Gyeongnam, Korea; 5) Institute of Metabolism,Green Cross Reference Laboratory, Seoul, Korea.

Classical galactosemia is caused by a galactose-1-phosphate uridyltransferase (GALT) deficiency. Newborn screening programs have been established for the early diagnosis of galactosemia. We describe here four Korean children who were identified during newborn screening and confirmed to have classical galactosemia based on enzymatic and molecular genetic analysis. Patients were followed until the age of 0.9-10.8 years (median, 3.4 years), and all four patients showed normal growth and development. Asians have been reported to have mutations distinct from those of Caucasians and African Americans, indicating that *GALT* gene mutations are ethnically diverse. Our four patients had a total of five mutations, two of which were previously known and three were novel (p.R200X, p.E363K and c.252+1G>A) mutations. Interestingly, c.252+1G>A, which leads to skipping of exon 2, was observed in three of the four patients (3 of 8 alleles), indicating that this mutation may be common in Koreans with classical galactosemia. Screening for classical galactosemia in 158,126 Korean newborns identified only 1 individual (Patient 3). In conclusion, our findings provide further evidence for the ethnic diversity of classical galactosemia, which may be rarer in Koreans than in other populations.

2054/T

A novel mitochondrial tRNA lysine variant, m.8358A>G, associated with exercise intolerance, muscle weakness, and fatigue. *V. Venegas[1], M. Landsverk[1], J. Wang[1], D. Boué[2,4], Z. Sahenk[3,5], L-J. Wong[1].* 1) Dept Mol and Hum Genetics, Baylor Col Medicine, Houston, TX; 2) Department of Pathology; 3) Departments of Pediatrics and Neurology, The Ohio State University, Columbus, OH; 4) Department of Laboratory Medicine, Nationwide Children's Hospital, Columbus, OH; 5) Center for Gene Therapy, Neuromuscular Program, Columbus, OH.

Mutations in the mitochondrial genome contribute to a variety of muscular disorders. More than half of the known mitochondrial mutations are located in tRNA genes, which comprise only 10% of the mitochondrial genome. Here we report a novel mitochondrial DNA variant in tRNA Lys at nucleotide 8358 (m.8358A>G). At the time of testing, the proband was a twelve year old male of European Caucasian decent presenting with muscle weakness, fatigue and elevated creatine kinase (CK) levels. Histology noted fiber type (size) disproportion, with only small type 1 fibers intermixed with essentially normal sized type 2 fibers in the absence of any fiber type predominance, as well as rare (<1%), COX-negative fibers by histochemistry. Analysis of muscle respiratory chain enzymes revealed a reduction of activity for complex I (NADH dehydrogenase) and complex IV (cytochrome c oxidase). Sequence analysis of the entire mitochondrial genome in a muscle specimen of the proband revealed an apparently homoplasmic m.8358A>G variant. Blood samples from the proband's asymptomatic siblings and mother identified heteroplasmic m.8358A>G in his brother and mother, and homoplasmic m.8358A>G in his sister, age 15 at the time of testing. Recently, the great aunt of the proband, age 58, presented with fatigue, muscle spasms, exercise intolerance, headaches and hypothyroidism. Sequence analysis of this individual also showed homoplasmic m.8358A>G. Allele-specific oligonucleotide hybridization and heteroplasmy quantification using ARMS PCR confirmed the results obtained by sequencing. This m.8358A>G variant is located in the acceptor stem of tRNA Lys. The A at nucleotide position m.8358 is normally paired with a U at nucleotide position m.8300 and this variant therefore changes a U:A pairing to a U:G mispairing. Multiple tRNA Lys mutations have been identified in this region. This change has not been reported in either the MitoMap or mtDB databases, and has not been found in any of the individuals in our database whose whole mitochondrial genome was analyzed (>1500). The collective data suggest that the m.8358A>G variant is likely to be pathogenic. However, age at onset of disease appears to vary and the apparent homoplasmy in the proband's asymptomatic sister suggests other factors may affect penetrance. Studies of this variant in other tissues from family members may further elucidate its pathogenicity.

2055/T

Hyposialylation in a novel murine glomerulopathy. *S. Kakani[1], J. Poling[1], T. Yardeni[1], H. Dorward[1], I. Manoli[1], C. Ciccone[1], A. Astiz-Martinez[1], P. Zerfas[2], D. Darvish[3], E. Tian[4], K. Ten Hagen[4], W. Gahl[1], M. Huizing[1].* 1) Medical Genetics Branch, National Human Genome Research Institute, Bethesda, MD; 2) Division of Veterinary Resources, Office of Research Services, National Institutes of Health, Bethesda, MD; 3) HIBM Research Group, Encinco, CA; 4) Developmental Glycobiology Unit, NIDCR, NIH, Bethesda, MD.

Hereditary inclusion body myopathy (HIBM) is an autosomal recessive myopathy associated with mutations in the *GNE* gene, which encodes the bifunctional, rate-limiting enzyme in sialic acid (SA) biosynthesis, UDP-GlcNAc 2-epimerase/ManNAc kinase. Since Gne knockout mice are embryonic lethal, we created a knock-in HIBM mouse mimicking the M712T founder mutation. Over 95% of mutant mice died before postnatal day 3 (P3) with unexpected glomerular disease involving podocyte foot process effacement, glomerular basement membrane splitting, and hyposialylation of podocalyxin, the primary podocyte sialoprotein. Oral intake of the sialic acid precursor ManNAc increased survival of mutant pups beyond P3 to ~50%, with improvements in glomerular architecture and podocalyxin sialylation. We examined the glycosylation status of the renal glycocalyx in this mouse model, which may assist in identification of related human renal disorders due to hyposialylation. Paraffin embedded kidney sections from untreated (embryonic, P2) and ManNAc treated (P6) mice were stained with a variety of lectins and antibodies (WGA-FITC, PNA-FITC, Jacalin-488, HPA-FITC, Podocalyxin). Abnormal, increased podocyte staining in mutant kidneys was found for the lectins PNA (for terminal galactose), Jacalin (for terminal galactose on O-linked glycans), and HPA (for terminal GalNAc). These abnormal patterns were partially restored after ManNAc feeding. Podocalyxin, although hyposialylated in mutant mice, appeared to be correctly localized to podocyte membranes in all samples. The lectin profiles suggested hyposialylation of predominantly O-linked glycans in the glomerular glycocalyx of mutant *Gne* M712T knock-in mice. We hypothesize that when a shortage of SA occurs (i.e., through reduced *Gne* activity), N-linked glycans will be preferentially sialylated over O-linked glycans. Although ManNAc treatment does not completely restore glomerular glycocalyx sialylation, it re-sialylates and restores the glycocalyx sufficiently for survival beyond P3. Hyposialylation has been indicated in some human glomerulopathies, including minimal change nephrosis, membranous glomerulonephritis, focal segmental glomerulosclerosis, and IgA nephropathy. The murine lectin staining panel can now be applied to human samples for identification of glomerular hyposialylation. Moreover, ManNAc might be considered as a future treatment in humans afflicted by these renal diseases.

Targeting mitochondrial disorders with custom array CGH. *T. Lewis, E. Lyon, R. Mao.* R&D, Molecular Genetics, ARUP Instutitue for Experimental and Clinical Pathology, Salt Lake City, UT.

BACKGROUND: Mitochondrial disorders are the most common group of metabolic disorders with an estimated prevalence of 1/5000. Mitochondrial disorders are clinically variable, affect single or multiple organs, present at any age and with any mode of inheritance creating a diagnostic challenge. An estimated 1500 genes encode for mitochondrial proteins; 37 encoded by the mtDNA while the remainder are encoded by nuclear DNA. As mutations can originate in either mtDNA or nuclear genes encoding organelle proteins, determining which of the many genes are responsible for the disease in the patient can be invasive, expensive, time-consuming, and labor-intensive. METHODS: To assist in laboratory evaluation, a custom CGH array was designed to cover 105 nuclear genes involved in mitochondrial biosynthesis as well as the entire mitochondrial genome. Probes were tiled at an average of 15bp throughout each nuclear gene including 500bp of flanking 5' and 3' material and spanning the mitochondrial genome. Nine samples with known deletions or duplications in the genomic regions covered on the array were analyzed using SignalMap2.5. RESULTS: Nine samples with known copy number changes were evaluated with the custom-designed mitochondrial array. In addition to concordant results for the known variations, potential new variant regions were observed. In the MFN2 gene, an 800bp copy number change in the mitofusin 2 (MFN2) gene was observed in two of nine samples (Log2 -0.50 and -0.59, 72 probes) and is of interest as it spans exon 18 encoding for the second coiled-coil domain. Three samples showed a copy number change in intron 3 of the PC gene and in intron 7 of the LARS gene, a deletion was observed in one patient with boundaries that precisely matching a LINE element. Four of the nine samples harbored a previously reported variation in introns 4 of the PDSS1 gene. CONCLUSIONS: A high-density custom array has been designed for detecting copy number changes in 104 nuclear genes implicated in mitochondrial disorders and the mitochondrial genome. The use of targeted array CGH holds great promise as a screening and diagnostic tool for mitochondrial disorders. The ability to examine greater than 100 genes at once, will allow the discovery of copy number changes in genes targeted for their role in mitochondrial disorders.

2057/T

ABCG2/BCRP encodes a high-capacity urate transporter and its common variant increases serum uric acid levels in humans. *I. Hiroki[1], H. Matsuo[1], T. Takada[2], K. Ichida[3,4], T. Nakamura[5], A. Nakayama[1,6], K. Suzuki[7], T. Hosoya[4], H. Suzuki[2], N. Hamajima[8], N. Shinomiya[1].* 1) Dept. Integrative Physiol., National Defense Med. College, Tokorozawa, Japan; 2) Dept. Pharm., Univ. Tokyo, Tokyo, Japan; 3) Dept. Pathophysiol., Tokyo Univ. Pharm. Life Sci., Tokyo Japan; 4) Dept. Intern. Med., Jikei Univ. School Med., Tokyo, Japan; 5) Lab. Math.,National Defense Med. College, Tokorozawa, Japan; 6) Dept. Defense Med., National Defense Med. College, Tokorozawa, Japan; 7) Dept Publ. Health, Fujita Health Univ., School Health Sci., Aichi, Japan; 8) Dept Preventive Med., Nagoya Univ. Grad. School Med., Aichi, Japan.

The ATP-binding cassette, subfamily G, member 2 (ABCG2/BCRP) gene encodes a multi-specific transporter which is expressed on the apical membrane in several tissues such as kidney and intestine. It was also reported that the ABCG2 gene locates in a gout-susceptibility locus (MIM 138900) on chromosome 4q, which was demonstrated by a genome-wide linkage study. Recent genome-wide association study revealed that ABCG2 relates to serum uric acid (SUA) and gout, while its mechanism was still unclear. Since the nucleotide analogs which is exported by ABCG2 is structurally similar to urate, we hypothesized that ABCG2 would be a urate secretion transporter and therefore relate to SUA. Transport assays were performed with the use of membrane vesicles prepared from ABCG2-overexpressing cells, and revealed that ABCG2 is a high-capacity urate transporter in the presence of ATP (calculated Km: 8.24 ± 1.44 mM). ABCG2 mutation with Q141K, a high-frequent variant, reduced its urate transport by approximately half, which could be accounted for by its decreased protein expression. Consequently, quantitative trait locus analysis of 739 Japanese individuals showed that the Q141K variant of ABCG2 increased SUA levels as the number of minor alleles of Q141K increased (P = 6.60 x 10-5), and when adjusted for sex, the corrected P value is 2.02 x 10-6. We also genotyped more than 2,000 individuals from a random sample of Japanese population and found that dysfunctional genotypes of ABCG2 occupied approximately 50% of them. These findings imply that ABCG2 has an essential physiological role to control SUA levels through urate secretion in vivo, and that its common dysfunctional variant increases SUA.

2058/T

Identification of a possible major genetic variant for hypokalemic periodic paralysis among Filipinos. *J.B. Nevado[1], K. Fabular[2], G. Facun[2], M. Falagne[2], J. Firme[2], M. Gabatino[2], D. Gauiran[2], L. Go[2], M. Gomez[2], E. Gonzales[2], L. Gonzales[2], J. Granada[2], P. Grullo[2], C. Hipolito[2], V. Igualada[2], N. Illescas[2], R. Imperio[2].* 1) University of the Philippines-Manila, Manila, Philippines; 2) University of the Philippines College of Medicine, Manila, Philippines.

Hypokalemic periodic paralysis (HOKPP) is a condition characterized by repeating episodes of ascending general loss of motor functions attributed to critically low blood potassium levels with intracellular shifting. Generally prevalent worldwide, the condition is far more common and severe among Southeast Asians, which suggests the presence of different genetic predisposition. Thus, we screened for genetic variations in CACNA1S in Filipinos with HOKPP. We recruited 10 adults with recurrent episodes of HOKPP in the past 3 years, without blood acidemia, and thyroid and renal function. Amplification and sequencing of the CACNA1S exons revealed a consistent deletion in 3 bases within exon 11 that produces frameshift variant present in all patients, but which balances out after 5 codons only. The changes are located in the second ion transport domain and the wild-type neutral-amino acid set (MSIFN from position 278) is replaced with predominantly positive and cysteine-containing set (CHLH), which can increase the channels's resistance to the inflow of calcium cations. Therefore, the described changes in the CACNA1S gene in Filipinos with HOKPP may perturb calcium homeostasis that can result to intracellular potassium retention.

2059/T

Preliminary Fluorometric and Colorimetric Assay in the Diagnosis of Metachromatic Leukodistrophy and Krabbe Diseases in Colombia. *I. Arévalo Vargas[1], M. Jay Garcia[1], P. Guerrero[2], J. Uribe[1].* 1) Universidad de los Andes, Bogotá D.C., Colombia; 2) Neuróloga Pediatra, Hospital Militar Central, Bogotá D.C., Colombia.

Inborn errors of metabolism are a group of hereditary diseases that consist in the storage of metabolites due to deficiency of an enzyme in a metabolic pathway. Specifically, Metachromatic Leukodystrophy (MLD) and Krabbe (KD) diseases are autosomal recessive disorders of sphingolipid metabolism that affect the nervous system, these diseases cause severe demyelination and are characterized by a deficiency of Arylsulfatase A (ASA) and β-Galactosylcerebroside (β-Galsyl) lysosomal enzymes, which generate an accumulation of galactosylcerebroside and sulfatides respectively. The reference values for these diseases in Colombia population are unknown. The aim of this study was to develop a compared colorimetric (COL) and fluorometric (FL) technique for MLD and KD.

We measured ASA activity with para-nitrocatechol sulfate for COL and 4-methylumbelliferyl sulfate (4-MUS) for FL, while β-Galsyl activity with Trinitrophenylamino-lauroylgalactocerebroside (TNPAL-Galactocerebroside) for COL and 6-hexadecanoylamino-4-methylumbelliferyl-β-D-galatoside (HMU-βGal) for FL. We analyzed 50 samples for ASA 38 controls and 12 patients with white matter damage and 23 samples were analyzed for β-Galsyl 18 controls and 5 patients. We use as enzyme control β-galactosidase (β-gal) and all activities were expressed in nmol/mg protein/h.

Activity ASA controls (n=38) ranged 0.8-3.4 for FL assay, while in COL technique ranged 100-500, and of the 12 individuals that were associated with white matter damage 3 showed a lower activity in both assays ranged 0.41-0.47 for FL and 32-55 for COL assay. Results obtained β-Galsyl activity in controls (n=23) in range of 2 to 5 for COL and 0.1 to 3 for FL, and a prospective patient with Krabbe with a lower activity 1.85 for COL and 0.034 for FL. The enzyme control βgal allowed to verify the sample quality, because with this we could confirm that samples weren't deficient in more than one enzyme.

This study established the reference values of controls for high-risk screening in Colombia. Both techniques are reliable for detection and early diagnosis of MLD and KD, nevertheless FL assay is 100 fold more sensitive than COL technique.

2060/T

Treatment Trends for Mucopolysaccharidosis I: Findings from the MPS I Registry. *P. Arn[1], R. Giugliani[2], T. Okayuma[3], F. Wijburg[4] on behalf of the MPS I Registry Board of Advisors.* 1) Division of Genetics, Nemours Children's Clinic, Jacksonville, FL; 2) Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil; 3) National Center for Child Health and Development, Tokyo, Japan; 4) Academic Medical Center, Amsterdam, The Netherlands.

OBJECTIVE: We analyzed how treatment approaches to MPS I have evolved over time in the MPS I Registry (www.mpsiregistry.com), an international observational database that collects data relevant to disease progression, treatment, and outcomes of MPS I patients. METHODS: Data entered into the Registry as of March 2009 were analyzed. Treatment allocation (hematopoietic stem cell transplantation [HSCT], enzyme replacement therapy [ERT] with laronidase, both ERT and HSCT, and neither treatment) was determined overall and in relation to year of diagnosis/treatment. Also analyzed were median ages at diagnosis and at first disease-specific treatment in relation to year of treatment initiation. RESULTS: Among the 227 Registry patients who began treatment <2003 (when ERT became available commercially), 24% received ERT only and 76% HSCT. Among the 535 patients who began treatment ≥2003, 75% received ERT alone and 25% underwent HSCT. The proportion of patients who received neither treatment declined from 16% among patients diagnosed <2003 to 9% among patients diagnosed ≥2003. The proportion of HSCT patients who also received ERT was 6% among patients who began treatment <2003, 62% (34/55) in 2003-2004, 76% (28/37) in 2005-2006, and 93% in 2007-2009 (40/43). Among all transplanted patients, median age at first treatment was under age 2 for all year ranges, and among ERT-alone patients was 12.3 in patients who began treatment <2003 (n=55) and 2.8 for those who began treatment in 2009 (n=16).The median interval between diagnosis and first treatment declined in transplanted patients by 0.4 years and in ERT-alone patients by 5.8 years from <2003 to 2007-2009. CONCLUSIONS: Over time, data from the MPS I Registry show a decreasing proportion of untreated patients, an increasing proportion of transplanted patients also receiving ERT, a decreasing age at first treatment among ERT-alone treated patients, and a decreasing interval between diagnosis and treatment in all patients.

2061/T

Genetic screening study of Niemann-Pick disease type C (NP-C) in adults with neurological/psychiatric signs (ZOOM). *P. Bauer[1], H.H. Klünemann[2], F. Sedel[3], D. Linden[4], J.E. Wraith[5], M.C. Patterson[6], M. Pineda[7], J. Priller[8], A. Muller[9], H. Chadha-Boreham[9], C. Remy[9], D.J. Balding[10].* 1) Medical Genetics, Univversity of Tuebingen, Tuebingen, Germany; 2) Regensburg University Clinic for Psychiatry and Psychotherapy, Regensburg, Germany; 3) Pitié Salpêtrière Hospital, Paris, France; 4) Bangor University, Bangor, UK; 5) Manchester Academic Health Science Centre, St Mary's Hospital, Manchester, UK; 6) Mayo Clinic, Rochester, MN, USA; 7) Hospital Sant Joan de Déu, Barcelona, Spain; 8) Neuropsychiatry, Charité-Universitätsmedizin, Berlin, Germany; 9) Actelion Pharmaceuticals Ltd, Allschwil, Switzerland; 10) Institute of Genetics, University College London, London, UK.

A gene sequencing analysis recently found an NP-C prevalence of 6.4% among undiagnosed adolescent and adult psychiatric patients. To investigate further the extent to which adult psychiatric patients might be affected by NP-C, an international genetic screening study has been designed to evaluate NP-C in patients with psychosis or early-onset dementia.

The first phase of this multicentre observational study is cross-sectional, aimed at evaluating the prevalence of NP-C in selected psychiatric patients who will be recruited from around 50 psychiatric and neurological reference centres across the EU and USA. Consecutive adult patients aged 18-50 years will be included according to five criteria, which specify different combinations of psychosis and/or early-onset dementia plus pre-defined neurological or visceral symptoms. Psychosis is defined according to ICD-10 and DSM-IV criteria. Blood samples will be collected from all recruited patients for *NPC1* and *NPC2* gene mutation analysis (direct sequencing and multiplex ligation-dependent probe amplification). Data on patients' clinical status and history will be captured electronically by secure web-based reporting. As well as evaluating NP-C prevalence, analyses of the cross-sectional data will assess NP-C phenotypes and possible genotype-phenotype associations. Next, a retrospective case-control phase will explore non-genetic predictors of NP-C that may be useful as diagnostic tools.

This screening study will provide valuable data on the prevalence of latent NP-C among adults with neurological/psychiatric signs, and will strengthen knowledge of the clinical manifestations of adult NP-C.

2062/T

Effect of miglustat on disease progression in Niemann-Pick disease type C (NP-C): a multicentre retrospective observational cohort study. *R. Giorgino[1], M.C. Patterson[2], M. Pineda[3], F. Sedel[4], C. Luzy[1], J.E. Wraith[5].* 1) Actelion Pharmaceuticals, Allschwil, Switzerland; 2) Mayo Clinic, Rochester, MD, USA; 3) Hospital Sant Joan de Déu, Barcelona, Spain; 4) Hôpital Pitié Salpêtrière, Paris, France; 5) Manchester Academic Health Science Centre, St Mary's Hospital, Manchester, UK.

NP-C is a rare and devastating genetic disorder characterized by a range of progressive, disabling neurological manifestations. A clinical trial demonstrated that miglustat stabilized key parameters of neurological disease progression in children and adults with NP-C over 24 months. We present data from a subset of miglustat-treated patients who were included in a previous observational cohort study assessing the natural history of NP-C.

Physicians managing patients with NP-C in clinical practice settings were asked to retrospectively assess patients' neurological disease progression using a disability scale at diagnosis and up to 4 follow-up visits, including both pre- and post-treatment evaluations. The disability assessment[1] evaluated patient function on 4 key parameters of disease progression (ambulation, manipulation, language and swallowing), rated on a modified scale from 0 (best) to 1 (worst). Individual disability parameter scores and a composite score (including all 4 parameters) were assessed.

A total of 19 miglustat-treated patients were included in the observational cohort. The mean±SD patient age was 13.6±5.9 years at diagnosis and 18.7±8.0 years at miglustat initiation. The mean±SD period between diagnosis and treatment was 4.9±4.1 years. The median (range) duration of miglustat therapy was 1.2 (0.2-3.0) years. Mean (95%CI) composite scores increased (indicating disease progression) from 0.18 (0.13,0.23) at diagnosis to 0.48 (0.39,0.57) at last pre-treatment visit. After miglustat treatment, the mean (95%CI) score was 0.44 (0.34,0.35), indicating stabilization. Similarly, individual parameter scores for ambulation, manipulation, language and swallowing increased between diagnosis and last pre-treatment visit, and were consistently reduced after miglustat therapy.

These data indicate continuous neurological disease progression in NP-C patients before treatment and stabilization of disease-specific neurological parameters after miglustat therapy.

Guidelines for the evaluation and management of children with Fabry disease. *R.J. Hopkin[1], M. Banikazemi[2], D.P. Germain[3], M. Mauer[4], A. Tylki-Szymanska[5], D.G. Warnock[6], W.R. Wilcox[7].* 1) Department of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Clinical and Molecular Genetics, Columbia University College of Physicians and Surgeons, New York, NY; 3) University of Versailles, Hôpital Raymond Poincaré, Garches, France; 4) Department of Pediatrics, University of Minnesota Medical School, Minneapolis, MN, United States; 5) The Children's Memorial Health Institute, Warsaw, Poland; 6) Department of Medicine, University of Alabama at Birmingham, Birmingham, AL; 7) Medical Genetics Institute, Cedars-Sinai Medical Center Los Angeles, CA.

Fabry disease is an X-linked lysosomal storage disorder, characterized by decreased or absent activity of lysosomal α-galactosidase A. As a result of this enzyme deficiency, globotriaosylceramide (GL-3) and other glycosphingolipids accumulate within various tissues and eventually impair vital organ function, putting patients at risk of developing renal failure, cardiovascular dysfunction, and stroke. The initial signs and symptoms of Fabry disease, including neuropathic pain in the extremities, hypohidrosis, angiokeratomas, and gastrointestinal discomfort, generally appear during childhood. More serious complications of Fabry disease can also occur during childhood, including proteinuria, valvular dysfunction, conduction abnormalities, left ventricular hypertrophy and arrhythmia. In view of the growing recognition that significant manifestations of Fabry disease can occur during childhood, an international group of physicians who have pediatric patients enrolled in the Fabry Registry developed a set of specific guidelines for assessing Fabry disease in children based on evidence from the Fabry Registry and published literature. A summary of the general types of recommended assessments is shown below.

Summary of Recommended Pediatric Assessments

Medical and Family History	Measured Glomerular Filtration Rate
Enzyme Activity and Genotype	Albuminuria and Proteinuria
Physical Exam	Quality of Life, Fatigue, Pain
Cardiac, Audiologic, Cranial MRI	Antibodies, Plasma GL3 Levels

This new Pediatric Minimum Recommended Schedule of Assessments will increase the medical community's awareness of the burden of Fabry disease in children, assist with monitoring , and improve the outcome for these young patients.

2064/T

Glucocerebrosidase alternative promoter has features and expression characteristic of housekeeping genes. *M. Hrebicek[1], E. Svobodova[1], L. Mrazova[1], O. Luksan[2], L. Stolnaja[1], M. Jirsa[2], L. Dvorakova[2].* 1) Institute of Inherited Metabolic Disorders, Charles University, Prague, Czech Republic; 2) Laboratory of Experimental Hepatology, Institute of Clinical and Experimental Medicine, Prague.

Glucocerebrosidase deficiency is the cause of Gaucher disease. Glucocerebrosidase transcripts show alternative splicing at their 5' ends, suggesting that a fraction of the transcripts originates at an alternative upstream promoter (P2) located 2.6 kb upstream of the first ATG. Currently, there are five alternative GBA transcripts in the databases, one of which is transcribed from the downstream (P1) promoter and four others apparently from the P2 promoter. The alternative transcripts from the putative upstream promoter contain one or two extra exons (exon -2 or exons -2, -1, respectively), but the first ATG codon and predicted amino-acid sequence are the same as in the transcript from the downstream P1 promoter. Our goal was to confirm that the putative P2 functions as a promoter and to study its properties. The in-vitro Dual-Luciferase Reporter Assay (Promega) was used to verify that the region 1 kb upstream of exon -2, which contains the presumed P2, can function as a promoter. The constructs with the sequence of P1 promoter exhibited the highest activity of luciferase (17, 82 ± 1,1 relative luciferase units) in HEP-G2 cells, while the P2 construct reached 3, 01 ± 0, 43 relative luciferase units. Four constructs carrying serial deletions of P2-containing construct pGL4 -353/-1509 were created to delineate the P2 promoter. The region from -1311 bp to -1509 bp (counted from the first ATG) likely contains a negative regulator of transcription activity. Three major initiation sites (328, 361 and 394 bp upstream of the first ATG) were identified by 5'RACE. Although faint RT-PCR products, which may represent promoter upstream transcripts (PROMPTs), were amplified up to position -481 bp, quantitative RT-PCR using TaqMan probes (Applied Biosystems) confirmed that the -328, -361 and -394 positions are the main transcription initiation sites. The expression of P2-originating transcripts measured by quantitative RT-PCR in twenty different tissues revealed similar levels relative to two known housekeeping genes, as well as to transcripts from P1. The P2 contains an unmethylated CpG island, multiple Sp-1 consensus binding sites and unlike P1 does not contain a TATA-box and CAAT boxes. Together with its expression pattern these features underscore the housekeeping character of the P2 promoter of GBA gene. Whether the promoter may play a role in the pathogenesis of Gaucher disease remains to be elucidated. Supported by GAUK 121407, VZ MšM ČR 0021620806.

2065/T

Wolman Disease (LIPA p.G87V) Genotype Frequency in Patients of Middle Eastern Descent. *D. No[1,2], Y. Valles-Ayoub[1], S. Esfandiarifard[1], P. Sinai[1], Z. Khokher[1,2], G. Lee[1], D. Darvish[1].* 1) HIBM Research Group, Reseda, CA; 2) Los Angeles Mission College, Sylmar, CA.

Wolman disease is a rare inherited condition caused by Lysosomal acid lipase (LIPA, LAL) deficiency. Infants with Wolman disease are healthy and active at birth but develop symptoms of severe malnutrition in the first few months of life. Harmful amounts of lipids accumulate in the spleen, liver, bone marrow, intestine, adrenal glands, and lymph nodes. Almost all affected infants die before the age of one. Although worldwide incidence is estimated at 1/350,000 newborns, Wolman disease seems to occur at a higher frequency in the Middle Eastern community of the Los Angeles area. Identifying high risk populations for this rare genetic disease may have significant impact for those working on gene therapy targeting lysosomal enzyme deficiencies. As a validation study, we analyzed 165 DNA specimens of Middle Eastern origin by automated sequencing of Exon 4 of LIPA, in search of p.G87V (ggc>gtc). This mutation is also described as p.G66V due to post-translational modification of the LAL protein (coded for by LIPA) that cleaves off the first twenty-one amino acids. For LIPA p.G87V, a heterozygous frequency of 3/165 (1.82%) was discovered. Thus, we estimate that as high as 1 in 12,100 newborns of Middle Eastern couples may be at risk. Additional studies are required to confirm and further validate the higher frequencies seen in our sample pool, and to determine if people of Middle Eastern descent have a higher risk for Wolman disease.

Updated results from a Phase 2 study of eliglustat tartrate, a novel, investigational oral compound for Gaucher disease type 1 (GD1). *J. Peterschmitt[1], E. Lukina[2], N. Watman[3], E.A. Arreguin[4], G. Pastores[5], M. Iastrebner[6], M. Dragosky[6], H. Rosenbaum[7], M. Phillips[8], M. Kaper[1], T. Singh[1], A.C. Puga[1].* 1) Genzyme Corp, Cambridge, MA; 2) National Research Center for Haematology, Moscow, Russia; 3) Hospital Ramos Mejia, Buenos Aires, Argentina; 4) Instituto Mexicano del Seguro Social Hospital de Especialidades, Col. La Raza, Mexico; 5) New York University, New York, USA; 6) Instituto Argentino de Diagnostico y Tratamiento, Buenos Aires, Argentina; 7) Rambam Medical Center, Haifa, Israel; 8) Sha'are Zedek Medical Center, Jerusalem, Israel.

Introduction: Eliglustat tartrate (Genz-112638) is a novel oral inhibitor of glucosylceramide synthase under investigation for the treatment of GD1. Aim: Report updated 2-year efficacy and safety data from an ongoing Phase 2 study. Methods: This open-label, uncontrolled, multicenter Phase 2 clinical trial of eliglustat tartrate (50 or 100 mg bid depending on plasma level) enrolled 26 untreated adults with GD1. Efficacy results included changes from baseline in spleen and liver volumes, hemoglobin and platelet levels, bone mineral density (BMD) and other skeletal findings (reviewed centrally), and achievement of GD1 therapeutic goals for anemia, thrombocytopenia and organomegaly. Results: New 30-month hematologic, visceral and biomarker data will be available for presentation. Data are currently available for up to 20 patients who completed 2 years of treatment. Mean hemoglobin level increased by 2.1±1.5 g/dL and platelet count by 81.5±56.0%; mean spleen volume decreased by 52.4±10.7% and liver volume by 23.9±12.8% (all P<0.001). No bone crises or reductions in mobility were reported. Bone marrow infiltration by Gaucher cells was reduced (8/18 patients) or stable (10/18 patients). There were no new lytic lesions or bone infarcts. Existing lytic lesions remained stable; of 7 existing infarcts, 1 improved and 6 remained stable. Mean lumbar spine BMD increased by 7.8±10.6% (P= 0.010), DXA T-Score by 0.6±0.8 (P=0.012), and DXA Z-Score by 0.6±0.7 (P=0.003), with major gains among osteoporotic/osteopenic patients. After 2 years, most patients met short-term therapeutic goals published by Pastores et al (*Semin Hematol* 2004). Overall, 85% (17/20) of patients met established therapeutic goals for ≥3 of 4 parameters. Eliglustat tartrate was well tolerated. The most common adverse events (AEs) through 2 years were viral infections (6 patients), and urinary tract infections, increased blood pressure, and abdominal pain (3 patients each). Eight drug-related AEs, all mild, occurred in 6 patients. Discussion: In the Phase 2 study, eliglustat tartrate has shown promising efficacy and safety as a potential oral substrate-reduction therapy for GD1 with continued improvements in hematologic, visceral, and bone parameters after 2 years. Two controlled Phase 3 registration studies are underway in untreated patients (ENGAGE) and in patients switching from enzyme replacement therapy (ENCORE). Another Phase 3 study will compare different dose frequencies of eliglustat (EDGE).

2067/T

The emerging phenotype of long-term infantile Pompe survivors. *S.N. Prater, S.G. Banugaria, L.E. Case, J.F. Mackey, M.M. Canfield, S.L. DeArmey, P.S. Kishnani.* Duke University Medical Center, Durham, NC.

The natural history of untreated infantile Pompe disease is limited as the median age of death in this lethal disorder is approximately 12.7 months. With the advent of enzyme replacement therapy (ERT) with alglucosidase alfa (Myozyme®), the clinical course of the disease has improved significantly. Improved survival has also led to a number of unanswered questions regarding the clinical course of treated disease. Currently, there is a paucity of data in the published literature pertaining to the physical and cognitive phenotype of older infantile Pompe survivors. Herein we report a series of 9 (7 M, 2 F) of the oldest infantile Pompe survivors treated with ERT ranging from 4 to 10 years of age. All patients had symptom onset within the first 6 months of life with the presence of severe cardiomyopathy. Median age at start of ERT was 4.6 months (range 0.3 - 6.3 months). Patients received alglucosidase alfa at 20 - 40 mg/kg biweekly and all patients tolerized to ERT. At most recent follow-up, all 9 patients were ambulatory and none required invasive ventilation. The majority of patients had some residual motor weakness (neck flexor and dorsiflexor weakness, myopathic facies). Additional notable findings included ptosis, hypernasal speech, velopharyngeal weakness, sensorineural hearing loss and osteopenia. Despite hypernasal speech and some expressive language delays, these children are cognitively intact. Although there are some phenotypic similarities to late-onset patients, there also exist key distinguishing features. This series represents the largest cohort of long-term survivors of infantile Pompe disease. It provides a contextual basis for the emerging phenotype and relevant issues in clinical management. Data obtained thus far are encouraging. Continued systematic follow-up is needed, however, to better characterize this emerging phenotype and to allow for improved patient management.

2068/T

Evaluation of the apoptotic effect of globotriaosylceramide (Gb3)on normal mononuclear cells: implication for Fabry disease. *P. Rozenfeld, N. De Francesco, C. Fossati.* Dept Immunolgia, Univ Natl de La Plata, Buenos Aires, Argentina.

Fabry disease is an X-linked lysosomal storage disorder (LSD) due to deficiency of the enzyme alpha-galactosidase A, resulting in intracellular deposition of globotriaosylceramide (Gb3). Plasma Gb3 concentration in Fabry disease patients varies between 2 to 50 μM, while in normal individuals values are below 1,2 μM. In order to analyze a possible pathophysiologic role of Gb3 in Fabry disease, we aim to investigate weather addition of Gb3 on normal cells induces apoptosis. Peripheral blood mononuclear cells (PBMC) from normal control individuals were treated in culture with different concentrations of Gb3 (range: 0 a 40 μM) during different times (0 to 48 hs). Apoptosis levels were analyzed by Annexin V and TUNEL by flow cytometry. Moreover, mithocondrial membrane depolarization by the reagent JC-1 was measured. The treatment of PBMC with Gb3 at different times resulted in an increase of apoptosis, with maximum levels at 6hs. The dose response curve with Gb3 showed a positive effect on apoptosis. These results show a direct effect of pathological Gb3 levels on PBMC. This result would suggest a causal relationship on apoptosis in Fabry disease that could be related to pathophysiology of this disorder.

International disease registry for Niemann-Pick disease type C: preliminary data. *B. Schwierin[1], E. Mengel[2], F.A. Wijburg[3], M. Pineda[4], J.E. Wraith[5], M.T. Vanier[6], A. Muller[1], M. Silkey[1], R. Giorgino[1], M.C. Patterson[7].* 1) Actelion Pharmaceuticals Ltd, Allschwil, Switzerland; 2) Villa Metabolica, University of Mainz, Mainz, Germany; 3) Academic Medical Centre, University of Amsterdam, Amsterdam, The Netherlands; 4) Hospital Sant Joan de Déu, Barcelona, Spain; 5) Manchester Academic Health Science Centre, St Mary's Hospital, Manchester, UK; 6) INSERM Unit 820, Lyon, France; 7) Mayo Clinic, Rochester, MN, USA.

A disease registry was started in Europe in September 2009 to evaluate the long-term disease course of Niemann-Pick disease type C (NP-C) in clinical settings.

All patients with a diagnosis of NP-C are eligible for inclusion irrespective of treatment. Demographics, disease characteristics and treatment data are collected. Patients are monitored using a disability scale (Pineda et al. Mol Genet Metab. 2009;98:243-9) that evaluates ambulation, manipulation, language and swallowing; rating from 0 (best) to 1 (worst).

Eighteen patients (median age [range] 13.8 [1.9-46.3] years; 50% female) were enrolled as of March 2nd 2010. Seventeen patients were confirmed as receiving miglustat therapy (mean exposure 1.83 years). Early visceral involvement was recorded in 4/9 (44%) evaluable patients. Most patients (15/18 [83%]) were diagnosed by biochemical or biochemical/genetic testing. Age at diagnosis ranged from 1.7-44.2 years. All patients had neurological manifestations at enrolment. Median ages at first neurological manifestation were: 0.4 years in early-infantile (aged 6 months to <2 years, n=1), 4.9 years in late-infantile (2 to <6 years, n=3), 10.1 years in juvenile (6 to <15 years, n=10), and 39.6 years in adolescent/adult patients (≥15 years, n=3). The median (95%CI) composite disability score among 15 evaluable patients was 0.35 (0.23, 0.55) at enrolment. Low numbers of patients had normal ambulation (2/15 [13%]), language (3/15 [20%]) and manipulation (3/16 [19%]) at enrolment; 7/16 (44%) had normal swallowing.

This registry will provide valuable information on the long-term progression of functional neurological impairments and treatment outcomes in NP-C.

2070/T

MCP-1 deficiency reduces macrophage infiltration and aggravates demyelination and paralysis in mouse model of Krabbe disease. *J.S. Shen[1, 2], X.L. Meng[1, 2], S. Kawagoe[3], K. Shimada[4], Y. Eto[3], T. Ohashi[2, 3].* 1) Institute of Metabolic Disease, Baylor Research Institute, Dallas, TX; 2) Department of Gene Therapy, Jikei University School of Medicine, Tokyo, Japan; 3) Department of Genetic Diseases & Genome Science, Jikei University School of Medicine, Tokyo, Japan; 4) Department of Anatomy, Jikei University School of Medicine, Tokyo, Japan.

Krabbe disease is a severe demyelinating disease caused by genetic deficiency of a lysosomal enzyme β-galactocerebrosidase. Infiltration of PAS positive macrophages in the nervous system is the hallmark of Krabbe disease. However, the exact role of these microglia/macrophages in pathogenesis of this disease remains to be elucidated. Monocyte chemoattractant protein-1 (MCP-1) is upregulated significantly in the brain of animal models of Krabbe disease, suggesting that MCP-1 may contribute to cell infiltration. To assess the role of microglia/macrophages in Krabbe disease, twitcher mice, the murine model for Krabbe disease were mated with MCP-1 knockout mice to generate MCP-1 deficient twitcher mice. Compared to MCP-1 intact (+/+) twitcher, MCP-1 deficient (-/-) twitcher mice showed worsened clinical symptoms including general motor functions and muscle strength. The onset of paralysis of hind limbs also occurred earlier in MCP-$1^{-/-}$ twitcher than MCP-$1^{+/+}$ twitcher. There was significant reduction of the number of PAS^+ macrophages and Mac-1 (a marker of monocyte/macrophage)-immunoreactive cells in MCP-1 deficient twitcher mouse brain. Consistent to the worsened neurological symptoms, immunohistochemistry and quantitative RT-PCR showed significantly reduced myelin basic protein and other myelin related proteins in both the central and peripheral nervous systems in MCP-$1^{-/-}$ twitcher compared to MCP-$1^{+/+}$ twitcher mice. This study demonstrated that MCP-1 plays important role in recruitment of macrophages to demyelinating lesions and that microglia/macrophages infiltration plays protective, rather than pathogenic, role in Krabbe disease.

2071/T

Hypodontia of mandibular permanent canines and long with curved tooth roots are newly recognized finding of Mucopolysaccharidosis type VI. *P. Tanpaiboon[1], P. Dejkhamron[2], P. Kantaputra[3].* 1) genetics and metabolism, children's national medical center, Washington, DC; 2) Department of Pediatrics, Faculty of Medicine, Chiang Mai university, Chiang Mai 50200 Thailand; 3) Division of Pediatric Dentistry, Department of orthodontics and Pediatric Dentistry, Faculty of Dentistry Chiang Mai University, Chiang Mai 50200 Thailand.

Mucopolysaccharidosis VI (MPS VI) is a very rare autosomal recessive lysosomal storage disease caused by deficiency of the enzyme Arylsulfatase B. Lacking or decreasing enzyme activity leads to accumulation of dermatan sulfate. Phenotype is highly variable and involves multiorgan systems. Oral manifestations have been reported including thick lips, high-arched palate, enlarged alveolar process, gingival hyperplasia, opened mouth and enlarged tongue. The previously reported dental anomalies consist of delayed tooth eruption, enamel hypoplasia, malocclusion, multiple dentigerous cysts, and malformed teeth. Here, we report a Thai MPS VI with new dental findings. A 17 yr-old girl was referred to genetics clinic due to coarse facies and short stature. She also had symptoms of left sided heart failure. She is a freshman and can live independently. Her medical problems were first brought to medical attention when she was 9 yr-old. From the medical record at that time, she had short stature, joint stiffness, and cloudy cornea. The time line of each problem was unclear and she had not received any diagnosis or treatment. Family history was significant with a 9 yr-old brother who also had similar clinical phenotypes but with less stiffness of joints and no heart problems. Both parents were healthy and denied consanguinity. Physical examination showed body weight 20 kg, height 102 cm, macrocephaly, coarse facies and cloudy cornea. Mitral stenosis, aortic stenosis murmurs were detected. She had umbilical hernia, hepatosplenomegaly, limitation of spine-joints movement and claw hands. Skeletal survey demonstrated dysostosis multiplex. Echocardiography showed severe mitral valve stenosis and mild aortic stenosis. Enzyme analysis indicated Arylsulfatase B deficiency confirming diagnosis with MPS VI. Oral manifestations consist of congenital missing of the mandibular permanent canines, maxillary constriction, posterior crossbite, anterior openbite, long and curved tooth roots, and widening of alveolar process. Hypodontia and long tooth roots have never been described in patients with MPS VI. In conclusion this is the first time that hypodontia and long tooth roots are reported in a patient with MPS VI. It is noteworthy that mutation of Arylsulfatase B which led accumulation of dermatan sulfate subsequently caused hypodontia and long tooth root in this patient. These findings have raised the question of the role of dermatan sulfate in tooth development.

2072/T

TNFα contributes to inflammation in the pathogenesis of Sandhoff disease. *E.J. White[1], H. Abo Ouf[1], S.A. Igdoura[1,2].* 1) Department of Biology; 2) Department of Pathology & Molecular Medicine, McMaster University, Hamilton, Ontario, Canada.

Mutations in the hexb gene can produce a deficiency in the lysosomal enzymes beta-hexosaminidase A and beta-hexosaminidase B, which leads to the accumulation of GM2 ganglioside and related glycolipids in neurons. The hexb-/- mouse provides a model of the inherited human disorder, known as Sandhoff disease, with progressive neurodegeneration leading to paralysis and seizures. In addition to the GM2 storage disorder that is intrinsic to disease progression, increases in pro-inflammatory immune cell function are hypothesized to contribute to the pathogenesis with TNFα signaling playing a key role. Previous work has demonstrated that the ablation of TNFα delays the onset of neurodegeneration in hexb-/- mice. The contribution of innate and adaptive immune responses in the onset and progression of Sandhoff disease is still unclear. The first aim of this study is to examine the impact of hexb deficiency as well as hexb and TNFα combined deficiencies on the immunophenotypes of peripheral inflammatory cells. In addition, the second aim is to examine cytokine production in bone marrow derived macrophages (BMDMs) from wild type, hexb-/- and hexb-/-tnfα-/- mice in response to treatment with LPS, poly I:C or GM2 ganglioside. Our findings indicate that hexb and TNFα combined deficiencies result in an increase in the frequency of peripheral blood $CD19^+$ B cells, $CD8^+$ cytotoxic T cells as well as $NK1.1^+$ NK and $NK1.1^+CD3^+$ NKT cells when compared to hexb deficient and wild type mice. Interestingly, hexb-/- mice show an overall decrease in all examined immunophenotypes of peripheral blood cells when compared to wild type mice. Furthermore, BMDMs from hexb-/- and hexb-/-tnfα-/- mice produce significantly lower levels of MCP-1 and IL-10 in response to LPS whereas IL-1β levels are only reduced in BMDMs from hexb-/-tnfα-/-. On the other hand, IL-12p70 expression was elevated in BMDMs from hexb-/- mice. These data point to an effect of TNFα on the abundance of peripheral blood cells during neuroinflammation. In addition, the LPS response observed in BMDMs reflects a role for both hexb and TNFα as modulators of macrophage function. Our data highlights the importance of TNFα during the robust neuroinflammatory cascade in Sandhoff disease.

2073/T

Few females develop anti-α-galactosidase A IgG antibodies in response to agalsidase beta treatment: data from the Fabry Registry. *W.R. Wilcox[1], D.J. Gruskin[2], D.G. Warnock[3].* 1) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Genzyme Corporation, Cambridge, MA; 3) Department of Medicine, University of Alabama at Birmingham, Birmingham, AL.

Fabry disease results from a genetic deficiency of lysosomal α-galactosidase A (αGAL). The lack of αGAL enzymatic activity impairs the catabolism of globotriaosylceramide (GL-3) and other glycosphingolipids, which then accumulate within various cell and tissue types. Enzyme replacement therapy (ERT) with agalsidase beta, a form of recombinant human αGAL, is administered via intravenous infusions. Like all therapeutic proteins, agalsidase beta can potentially cause immunogenicity. Seroconversion status and peak anti-αGAL immunoglobulin G (IgG) antibody titers were evaluated in patients enrolled in the Fabry Registry. As of April 2, 2010, a total of 827 Fabry Registry patients who were treated with agalsidase beta as their only source of ERT had reported post-baseline anti-αGAL IgG titer data. Four hundred sixteen of 573 males (73%) eventually developed anti-αGAL IgG antibodies, with a median peak titer value of 3200 (minimum 100, maximum 819200). In contrast, only 31 of 254 females (12%) seroconverted and their median peak titer value was 200 (minimum 100, maximum 6400). Males were less likely than females to have tolerized (defined as being seronegative after seroconversion, at time of the most recent anti-αGAL IgG test); only 47 of 416 males tolerized (11%, 95% CI: 8%-15%), compared to 17 of 31 females (55%, 95% CI: 36%-72%). There were no statistically significant differences in endogenous (in vitro) levels of plasma or leukocyte αGAL enzyme activity between patients who had seroconverted and patients who had not. However, only a subset of patients who had seroconverted reported corresponding plasma or leukocyte αGAL enzyme activity data (222 of 416 males [53%] and 15 of 31 females [48%]). Genotype data were available for 27 of the 31 females who seroconverted. Most genotypes were unique and there were no clear similarities in genotype among the females who seroconverted. In summary, relatively few Fabry Registry females developed antibodies against agalsidase beta. Those females who did develop antibodies had much lower peak titer values than males and were likely to tolerize.

2074/T

Clinical phenotype in a mother and her son with a novel mutation for Fabry disease. *S. Yang, K. O'Brien, C. Tifft.* NHGRI, National Institute of Health, Bethesda, MD.

Fabry Disease (FD) is an X-linked lysosomal storage disease caused by mutations of the alpha-galactosidase A (GLA) gene resulting in a deficiency of the alpha-galactosidase A (alpha-GAL-A) enzyme. Male hemizygotes with classical Fabry disease often show the complete spectrum of symptoms beginning in mid childhood while female heterozygotes demonstrate a variable phenotype ranging from that seen in male patients to asymptomatic. We describe the case of a 45-year-old African American female with 12 year history of hypertension who developed rapid elevation in serum creatinine with insignificant proteinuria leading to renal biopsy for a diagnosis. The biopsy showed distended cytoplasm, myelinoid fibures, and zebra bodies in the podocytes consist with Fabry disease. At the time of her initial genetic evaluation, she denied any clinical symptoms of Fabry disease and there were no findings on physical exam to support the diagnosis. The family history was likewise negative. However, the molecular analysis of the GLA gene revealed a novel missense mutation in exon 6 (c806 T>A; p.Val269Glu) of unknown clinical significance. A detailed workup at the NIH Clinical Center was initiated which revealed multi-organ system involvement including left ventricular hypertrophy, increased Gb3 (globtriaosylceramide) excretion, whorl-like corneal opacities (cornea verticillata), hypohidrosis, and possible mild acroparesthesias (peripheral neuropathy). The patient's 23-year-old asymptomatic son was also tested and found to carry the V269E mutation. His AGA activity of 5.6 pmol/punch/hr was well within the range for patients with Fabry disease (2.0-12.0). Our findings conclude that the V269E mutation may be associated with a milder clinical course; however, close clinical monitoring remains important. Enzyme replacement therapy (ERT) has been discussed and offered to both patients.

2075/T

A missense variation in human Fibroblast Growth Factor 23 (FGF23) gene that induces functional alteration and shows association with renal phosphate leak in calcium nephrolithiasis. *T. Esposito[1], G. Mossetti[2], D. Rendina[2], G. De Filippo[2], A. Perfetti[3], S. Magliocca[1], P. Formisano[3], F. Gianfrancesco[1], P. Strazzullo[2].* 1) Inst Gen & Biophysics, Italian Natl Res Council, Naples, Italy; 2) Dep. of Clinical and Experimental Medicine, Federico II University Medical School, Naples, Italy; 3) Dip. di Biologia e Patologia Cellulare e Molecolare, Università di Napoli "Federico II", Naples, Italy.

Approximately 20% of patients with calcium nephrolithiasis and normal parathyroid function show a reduced rate of renal tubular phosphate reabsorption and reduced serum phosphate concentration (i.e. renal phosphate leak). We have previously demonstrated that in these patients circulating levels of fibroblast growth factor 23 (FGF23), a hormone regulating phosphate homeostasis, were significantly higher compared to stone formers without renal phosphate leak and to healthy controls. We detected a C716T (T239M) non-synonymous change in the FGF23 gene in stone formers with renal phosphate leak. The C716T allele and genotype frequencies were significantly higher compared to controls [C vs. T allele frequencies (p= 0.03), genotype frequencies (p=0.007)], and to stone formers without renal phosphate leak (p=0.024 and p=0.002, respectively). In the study population as a whole, subjects carrying the T239M missense variation showed levels of serum phosphate and TmPi/GFR significantly lower compared to subjects without the variation. The major intracellular signaling pathway of FGF was shown to be the Ras/MAPK pathway. FGF-23 was found to significantly phosphorylate ERK, and then we tested the ability of FGF23 wt and FGF23-239M to induce ERK phosphorylation. Our data clearly showed that both proteins (wt and 239M) induced dose dependent activation of ERK protein, and that the mutated protein (FGF23-239M) gives higher activation when compared to wt protein. These data could suggest that in presence of the mutated protein (FGF23-239M) there is a major inhibition of the sodium-phosphate co-transporter operating in the proximal tubule, resulting in renal phosphate leak that we observed in our patients. Our results highlight a novel significant association between the T239M missense variation in the FGF23 gene and calcium nephrolithiasis with renal phosphate leak.

2076/T

Generation and Characterization of a Mouse Model of Polyglucosan Body Disease. *H.O. AKMAN, W.J. CRAIGEN.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Background: The synthesis of glycogen is catalyzed by the sequential actions of two enzymes: (i) glycogen synthetase, which attaches glucosyl units to linear chains of glycogen; and (ii) glycogen branching enzyme (GBE), which attaches a short branch of glucosyl units to a linear chain. Glycogen storage disease type IV (GSD IV) (OMIM 232500) is an autosomal recessive disorder caused by GBE deficiency, leading to the accumulation of an abnormal amylopectin-like polysaccharide (polyglucosan) in multiple tissues, including liver, heart, skeletal muscles, and the central nervous system. A late-onset clinical variant, known as adult polyglucosan body disease (APBD), causes a neurodegenerative disorder simulating amyotrophic lateral sclerosis (ALS). The two naturally occurring animal models of this disorder, American quarter horses and Norwegian forest cats, are not practical laboratory animals. The mechanism for polyglucosan associated pathology is poorly understood and there are no treatment strategies for the disease. Method: We have developed a mouse model for APBD by introducing a common adult disease allele, Y329S, into the mouse GBE1 gene by homologous recombination in embryonic stem cells. In addition, we have generated a null allele by deleting exon 7 of the GBE gene. Results: GBE1 activity in muscle and liver is decreased to 6% and 30% of control values in mice homozygous and heterozygous, respectively, for the Y329S mutation. The Y329S mutation does not cause polyglucosan accumulation in heterozygous animals, and they appear otherwise normal, however homozygous animals have severe polyglucosan accumulation in muscle and liver, and to a lesser extent in peripheral nerves. Conclusion: Introduction of the Y329S mutation associated with APBD into the mouse GBE1 gene has generated a mouse model for polyglucosan body disease. This animal model is suitable for investigating the pathogenesis and possible novel treatments of polyglucosan accumulation.

Getting to the heart of the matter: Cardiac involvement in Glycogen Storage Disease type III. *S.L. Austin[1], A.D. Proia[2], J. Butany[3], S.B. Wechsler[1,4], P.S. Kishnani[1].* 1) Div of Medical Genetics, Dept of Pediatrics, Duke Univ Med Ctr, Durham, NC; 2) Dept of Pathology, Duke Univ Med Ctr, Durham, NC; 3) Dept of Pathology, Toronto General Hospital, Toronto, Canada; 4) Div of Cardiology, Dept of Pediatrics, Duke Univ Med Ctr, Durham, NC.

Cardiac involvement is a feature common to several glycogen storage diseases (GSD) such as GSD II, III, and IX. A significant amount is known about extent of cardiac involvement in Pompe disease (GSD II) where glycogen accumulation affects both the structure and the function of the heart. We are beginning to better recognize the level of cardiac involvement in the other GSDs, particularly GSD III. GSD III is a rare disease of variable clinical severity affecting primarily the liver, heart, and skeletal muscle. It is caused by deficient activity of glycogen debranching enzyme which is a key enzyme in glycogen degradation. Unlike other GSDs, glycogen accumulation in GSD III is structurally abnormal, which is thought to cause liver fibrosis/cirrhosis. Cardiac involvement in GSD III is typically thought of as left ventricular hypertrophy (LVH) with very slow progression. Life threatening cardiac arrhythmias have been occasionally reported and there are a few cases of cardiac transplant. Given the improved long term survival of this population, cardiac symptoms continue to be revealed. We recently reported on cardiac wall thickness and left ventricular mass as measured by echo over time in individuals with GSD III. To further our understanding of the impact of glycogen accumulation on heart structure and function in this group, we examined cardiac tissue of three individuals with GSD IIIa: two after cardiac transplant (27 yrs and 40 yrs) and one deceased (unknown cause; 36 yrs). In the individuals with cardiac transplant, cardiac function was greatly impaired prior to transplant. Histology revealed fibrosis. There was marked LVH as well as right ventricular hypertrophy. In contrast, the individual who died of an unknown cause only had minimal LVH. However, heart tissue may provide a clue for the possible cause of death. The cardiac conduction system was abnormal with glycogen accumulation within the specialized muscle cells of the SA and AV nodes, the penetrating bundle of His, and the right bundle branch. The degree of glycogen accumulation within the conduction system was less than in the cardiac myocytes. The glycogen accumulation in the conduction system could have served as a substrate for a lethal arrhythmia. Additional cardiac pathology findings will be presented. The lessons learned from carefully studying these individuals will lead to better clinical management for our patient population with GSD III.

2078/T

Brain function in individuals with PKU treated with Kuvan: Evidence from functional magnetic resonance imaging. *S.E. Christ[1], D. Peck[2], A.J. Moffitt[1], R. Hillman[2].* 1) Psychological Sciences, University of Missouri, Columbia, MO; 2) Child Health, University of Missouri School of Medicine, Columbia, MO.

Background: Phenylketonuria (PKU) is a genetic disorder characterized inefficient metabolism of phenylalanine. Early and continuous dietary control prevents the severe neurologic and cognitive consequences once associated with PKU. Kuvan (sapropterin dihydrodichloride, BH4) represents a new supplemental pharmacologic treatment for PKU. In the present study, the researchers utilized functional MRI to examine neurocognitive functioning in individuals with and without PKU. The potential impact of Kuvan treatment on neural activity in PKU was also explored.

Methods: Brain imaging data was collected from 7 individuals with early-treated PKU (mean age = 21.9 years) immediately before treatment with Kuvan and then again after 4 weeks of Kuvan treatment. For comparison purposes, data was also collected from 5 non-PKU individuals (mean age = 20.0 years). At each timepoint, neural activity was recorded during performance of a working memory task.

Results: Analysis of the pre-treatment data revealed PKU-related irregularities in neural activation in prefrontal cortex (PFC) and other brain regions, $F(1, 10) > 5.53$, $p < .05$ FDR-corrected. At the 4-week evaluation, two participants had responded to Kuvan with a >20% reduction in phenylalanine levels. Both also showed improved activation for a region in orbitomedial PFC. Findings for other brain regions were mixed.

Conclusion: The present results provide evidence of brain dysfunction in individuals with early-treated PKU. Whereas the initial findings on Kuvan treatment are promising, additional data is needed to fully evaluate its benefits for brain function in PKU.

2079/T

The Different Protein Functions of Glycerol Kinase are Important in Metabolism and Adipocyte Formation. *K.M. Dipple[1,2], L.S. Parr[1], G. Sriram[3].* 1) Dept Human Genetics, UCLA, Los Angles, CA; 2) Dept of Pediatrics, UCLA, Los Angeles, CA; 3) Dept of Chemical and Biomolecular Engineering, University of Maryland, College Park, MD.

Glycerol kinase (GK) catalyzes the phosphorylation of glycerol and is at the interface of carbohydrate and lipid metabolism. GK is the causative gene for GK deficiency (GKD), an X-linked inborn error of metabolism for which there is no genotype-phenotype correlation. GK also has alternative protein functions including the ATP-stimulated translocation promoter (ASTP). GK also plays a role in adipogenesis and the N288D mutation in GK has been associated with obesity and diabetes. We hypothesize that investigating the roles of GK in other metabolic pathways and understanding its alternate functions will explain the complexity of GKD as well as its role in obesity. In order to examine this, we performed metabolic flux analysis in lipid and central carbon metabolism in GK-overexpressing H4IIE cells. In addition, we examined the GK ASTP activity and the ability of the cells to differentiate into adipocytes in Gyk (mouse GK ortholog) knockout (KO) mouse embryonic fibroblasts (MEFs) infected with mouse Gyk, E. coli GK, or the N288D Gyk mutant. Metabolic flux analysis showed that GK-overexpressing H4IIE cells had significantly altered fluxes through central carbon and lipid metabolism. This included flux thru the pentose phosphate pathway and increased production of lipids including stearic acid. Oil Red O staining confirmed the higher lipid reserves. There was an equal contribution of glycerol to carbohydrate metabolism in all cell lines, suggesting that GK's alternate functions are important for these observations. In MEFs, the E. coli GK lacks ASTP activity but retains the enzymatic activity; and do not differentiate into adipocytes (similar to Gyk KO MEFs,). Additionally, the N288D mutation, loses phosphorylation activity, retains ASTP activity, and cells differentiate similar to wild type preadipocytes. Therefore the GK phosphorylation activity does not play a role in adipogenesis while the ASTP activity does. In conclusion, GK overexpression globally affects both carbohydrate and lipid metabolism in rat liver cells and GK is required for normal adipocyte differentiation. In addition, the ASTP function appears to play a greater role in adipocyte differentiation and lipogenesis than the phosphorylation activity. This work shows the importance of understanding all of the cellular protein activities of GK, in order to understand the variability in the GKD pathogenesis.

2080/T

Linking cholesterol biosynthesis and human behavior. *C. du Souich[1, 2, 3], M.J.M. Nowaczyk[4], A. König[5], F.L. Raymond[6], K.W. McLarren[2, 3], R. Larstone[7], J. Livesley[7], R. Friedlander[7], M.A. Marra[8], C.F. Boerkoel[1, 2, 3].* 1) Medical Genetics, Children's and Women's Health Centre of BC, University of British Columbia, Vancouver, BC, Canada; 2) The Rare Disease Foundation, Vancouver, BC, Canada; 3) Child and Family Research Institute, Vancouver, BC, Canada; 4) Pathology & Molecular Medicine and Pediatrics McMaster University, Hamilton, ON, Canada; 5) Universitätsklinikum Gieβen und Marburg GmbH, Standort Marburg, Marburg, Germany; 6) Cambridge Institute for Medical Research University of Cambridge, UK; 7) Department of Psychiatry, University of British Columbia, Vancouver, BC, Canada; 8) BC Cancer Agency Genome Sciences Centre, Vancouver, BC, Canada.

INTRODUCTION: Several epidemiological studies have established an association between cholesterol levels and human behavior. The molecular bases of human behavior however, have largely eluded identification in part due to the type of diagnostic criteria used. Disorders of behavior are amalgams of symptoms and signs that are the product of several underlying causal mechanisms. Therefore, dissection of human behavior into unidimensional, homogenous traits should facilitate identification of causation.

METHODOLOGY: Testing this, we identified an X-linked disorder of cholesterol biosynthesis with intellectual and behavioral abnormalities that establishes this link. CK syndrome presents in affected males with intellectual disability, microcepahly, seizures, cortical malformations and dysmorphism. Affected females have normal intellect and physical appearance but segregate high levels of callousness, an important trait of psychopathy. To establish this link further, we extend these results to other disorders of cholesterol biosynthesis including Smith-Lemli-Opitz syndrome and Congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD) syndrome.

RESULTS: Partial loss-of-function mutations of NSDHL (NAD(P)H steroid dehydrogenase-like) cause abnormal personality traits. Findings in other cholesterol metabolism disorders support the link between cholesterol and human behavior and shed light on a possible biological mechanism causing psychiatric disease.

CONCLUSION: We establish a genetic link between human behavior and cholesterol biosynthesis, a long recognized epidemiological association. We also demonstrate that dissection of human behavior into homogenous traits allows ready identification of genetic factors modulating behavior and offers insight into a possible mechanism of disease.

2081/T

HUMAN ARGININOSUCCINIC ACIDURIA IS A HUMAN MODEL OF NITRIC OXIDE INSUFFICIENCY. *A. Erez[1], S. Nagamani[1], M. Premkumar[1], Y. Chen[1,7], O. Shchelochkov[1], P. Campeau[1], A. Mian[1], T. Bertin[1,7], J. Black[2], H. Garg[6], H. Zeng[3], Y. Tang[6], M. Summar[3], W. O'Brien[1], W. Mitch[4], J. Aschner[3], J. Marini[5], N. Bryan[6], B. Lee[1,7].* 1) Baylor College of Medicine, Houston, TX; 2) Department of Pathology, Texas Children's Hospital, Houston, TX; 3) Department of Pediatrics and Center for Human Genetics Research, Vanderbilt, University Medical Center, Nashville, TN; 4) Department of Medicine and Division of Nephrology, Baylor College of Medicine, Houston, TX; 5) Department of Pediatrics/ Nutrition, USDA/ARS Children's Nutrition Research Center, Baylor College of Medicine; 6) Brown Foundation Institute of Molecular Medicine, University of Texas - Houston Health Science Center; 7) Howard Hughes Medical Institute, Houston, TX.

Nitric Oxide (NO) is an essential signaling molecule for diverse physiological and disease processes. In humans, the urea cycle disorder argininosuccinic aciduria (ASA) caused by deficiency of argininosuccinic acid lyase (ASL) shows systemic features that in part reflect global dysregulation of NO homeostasis due to deficiency of intracellular arginine synthesis and inability to utilize extracellular arginine. We generated and characterized a novel Asl hypomorphic mouse model in which endogenous, intracellular Arginine production is impaired resulting in decreased NO production and a multi system dysfunction. We used this mouse model to understand the mechanism underlying human ASL deficiency phenotype and to assess new treatment modalities. We found that ASL is essential for a novel complex assembly necessary for NO synthesis. We next verified our mouse studies in a case study of patients with ASL deficiency. ASA patients have decreased biochemical markers and dynamic measures of NO production despite elevated arginine level resulting from their treatment. In addition, ASA patient's fibroblasts cannot utilize extracellular arginine for NO synthesis. Hence, we hypothesized that supplementing ASA patients with NO donors as a direct replacement of the NO deficiency, will have a beneficial effect. We further studied a 15 year old boy diagnosed with ASA complicated by hypertension for more than ten years. He was unresponsive to multiple anti-hypertensive regiments including diuretics, ACE inhibitors, calcium channel blockers, and beta-blockers. Recently, he proceeded into a hypertension crisis. As a proof of principal to our recently described novel role of ASL in nitric oxide synthesis, we treated the patient with Isosorbide dinitrate as an NOS independent NO donor. The patient showed a dramatic clinical response with normalization of the blood pressure over a three day treatment with weaning of all other anti-hypertensive medications. This case highlights the central role of ASL in nitric oxide regulation, demonstrates that ASL deficiency is a human genetic model of NO insufficiency, and provides a potential novel therapy for these patients that need to be further studied in controlled trials.

2082/T

ETFDH mutations are the major cause of myopathy with multiple acyl-CoA dehydrogenase deficiency (MADD). *C. Gellera[1], B. Castellotti[1], V. Pensato[1], C. Antozzi[2], B. Garavaglia[1], G. Uziel[3], S. Di Donato[1], M. Rimoldi[1], F. Taroni[1].* 1) Unit of Genetics of Neurodegenerative and Metabolic Diseases, IRCCS Carlo Besta Neurological Institute, Milano, Italy; 2) Unit of Neurology and Neuromuscular Disorders, IRCCS Carlo Besta Neurological Institute, Milano, Italy; 3) Department of Child Neurology, IRCCS Carlo Besta Neurological Institute, Milano, Italy.

Glutaric Aciduria type II (GAII) and Multiple Acyl-CoA Dehydrogenase Deficiency (MADD) include a wide spectrum of autosomal recessive diseases caused by defects in mitochondrial electron transfer system and fatty acid catabolism. The clinical presentation range from a severe encephalomyopathy of childhood to a mild myopathic form of adult frequently responsive to riboflavin treatment (RR-MADD). These disorders can be due to defects of Electron Transfer Flavoprotein (ETF) or ETF dehydrogenase (ETFDH) but for some cases an as yet unidentified riboflavin metabolism alteration is also supposed. We have studied 23 index cases, in which the biochemical profile, a characteristic pattern of medium- and long-chain esterified carnitines in plasma, and the clinical presentation were suggestive of MADD. The onset was variable from childhood to adult age including severe and very mild presentations. Five patients had a positive familial history for the presence of an affected sibiling. Acyl-CoA dehydrogenase activities for short-, medium- and long-chain fatty acids were markedly reduced in the analyzed cases (10/23) showing a residual activity between 10% and 50%. A pathological pattern of urinary dicarboxylic acids was detected during metabolic crisis. About 50% of patients showed a marked improvement of clinical conditions and the normalization of biochemical parameters after treatment with riboflavin. ETFDH gene analysis demonstrated the presence of 15 different mutations (13 missense, 1 nonsense, and 1 splicing mutation) on both alleles either in homozygous or in compound heterozygous form, in 16/23 patients (70%). The large majority of mutations (13/15) were novel. Four out of 23 patients resulted negative for the analysis of ETFDH, ETFA and ETFB genes indicating genetic heterogeneity, albeit limited. In 3/23 index cases, we identified mutations on one allele only and we excluded the presence of intragenic rearrangements. Interestingly, in two of these families, which carried the same mutation, segregation of the mutation with the disease in two generations indicated an autosomal dominant transmission. These results would suggest that a dominant-negative mechanism might underlie the disease in a subgroup of patients. Our study indicates that (1) mutations in ETFDH gene are the major cause of MADD, (2) MADD myopathy may present as an autosomal dominant trait, and (3) other genes are likely to be implicated in the pathogenesis of this rare metabolic disease.

2083/T

2,4-dienoyl CoA reductase deficiency: a novel neurometabolic disease. *M. Gucsavas-Calikoglu[1], D. Frazier[1], S. Young[2], D. Millington[2].* 1) Pediatrics, University of North Carolina School of Medicine, Chapel Hill, NC; 2) Biochemical Genetics Laboratory, Duke University Medical Center, Durham, NC.

Mitochondrial 2,4-dienoylCoA reductase is a key enzyme for the beta-oxidation of unsaturated fatty acids. A deficiency of this enzyme was reported in 1990 by Roe et al. in a black female infant with hypotonia, hyperlysinemia, hypocarnitinemia, and decadienoylcarnitine in urine and blood. She died of respiratory acidosis at age four months. We now report a second case in a Hispanic male. Our patient presented at age 8 weeks with failure to thrive, microcephaly and central hypotonia. Plasma and urinary 2,4-decadienoylcarnitine(C10:2); plasma, CSF and urine lysine(LYS); blood and CSF lactates were elevated. Urine organic acids showed increased methylmalonic, glutaric and urine amino acids showed increased LYS. Incubation of skin fibroblasts with C18:2 showed an accumulation of C10:2 six fold greater than control cells. Very long chain fatty acids and CSF neurotransmitters were normal. Treatment consisted of dietary LYS restriction, caloric support, provision of medium chain fatty acids and carnitine. At age 6 mos, he had social smile but did not sit. At age 18 months, he had nystagmus and abducens palsies, hypertonia and clonus. He developed choreoathetosis and intermittent lactic acidosis with minor illnesses. At 30 mos, he had pancreatitis. He developed gram negative sepsis after gastric tube placement and experienced further neurological decline. At 36 mos, he had renal tubular acidosis. At 4 =BD years, he had severe encephalopathy, dystonia, spastic quadriplegia, cortical blindness, epilepsy and episodic central apnea. He died at age 5 with aspiration pneumonia. Multiple MRIs were consistent with progressive leukodystrophy, generalized cerebral atrophy, ventriculomegaly, and bilateral basal ganglia T2 abnormalities. Autopsy showed ventriculomegaly and severe white matter gliosis particularly in frontal lobes and basal ganglia. The biochemical etiology of this disorder is currently unknown and the relationship between elevated C10:2 and LYS is unclear. Dietary LYS restriction was not successful in preventing neurological decline. Progressive encephalopathy, dystonia, RTA, intermittent lactic acidosis, the presence of leukodystrophy and basal ganglia lesions on MRI and gliosis on autopsy suggest that 2, 4-dienoyl CoA reductase deficiency results in a neurometabolic disease. Possible mechanisms may involve mitochondrial dysfunction with oxidative damage and disturbed lipid peroxidation. The disorder may be incompatible with survival.

2084/T

Molecular confirmation of VLCAD deficiencies in newborns. *M. Landsverk, F. Scaglia, L-J. Wong.* Dept of Mol and Hum Genetics, Baylor College of Medicine, Houston, TX.

Acyl-CoA dehydrogenases catalyze the initial step in the beta-oxidation of fatty acids in the mitochondrial matrix. Deficiencies in acyl-CoA dehydrogenases are autosomal recessive disorders that result in a decreased ability to oxidize fatty acids, thereby leading to metabolic dysfunction. Very-long chain acyl-CoA dehydrogenase (VLCAD) targets 14 to 20 carbon long-chain fatty acids. VLCAD deficiency (VLCADD) can generally be grouped into three phenotypes: a severe, early-onset, form with a high incidence of cardiac and multiorgan failure; a milder childhood form usually presenting with hypoketotic hypoglycemia; and an adult myopathic form with intermittent rhabdomyolysis, muscle cramps and exercise intolerance. Early detection through newborn screening (NBS) by measuring acylcarnitines using tandem mass spectrometry has increased the number of patients identified with VLCADD, and has allowed for the identification of milder clinical phenotypes. An increase in acylcarnitine C14:1 is suggestive for VLCADD. However, acylcarnitine profiles alone cannot confirm a diagnosis since initial elevations of C14:1 on NBS may also reflect neonatal stress. Conversely, normal biochemical testing on follow-up of abnormal NBS for VLCADD does not rule out the disorder since C14:1 levels tend to normalize over time. Molecular identification of deleterious mutations in the ACADVL gene is necessary to confirm the diagnosis. From January 2007 to October 2009 we analyzed 175 individuals, ages 6 months and younger, presenting with abnormal NBS or clinical indications suggestive of VLCADD for mutations in ACADVL. We identified previously reported mutations as single heterozygotes in 36 individuals, compound heterozygotes in nine, and homozygotes in 5. An additional 13 individuals harbored known mutations as compound heterozygotes with unclassified variants. We also identified 6 novel frameshift mutations leading to premature stop codons, 1 novel indel, 1 novel in-frame deletion, and 4 novel splice-site mutations, all heterozygous. Unclassified variants were found as single and compound heterozygous in 21 and 8 individuals respectively. However, we found no known mutations or unclassified variants in the coding exons of ACADVL in 66 (38%) individuals tested for VLCADD. These results underscore the necessity of mutation analysis of the ACADVL gene when VLCADD is suspected in children under the age of 6 months based on suggestive clinical indication or positive NBS results.

2085/T

Mechanistic study for mucopolysaccharidosis VII using induced pluripotent stem (iPS) cells. *X. Meng[1, 2, 4], J. Shen[1, 2, 4], Sh. Kawagoe[2], T. Ohashi[1, 2], R.O. Brady[3], Y. Eto[2].* 1) Department of Gene Therapy, The Jikei University School of Medicine, 3-25-8 Nishi-Shinbashi, Minato-Ku, Tokyo, Japan 105-8461; 2) Department of Genetic Diseases & Genome Science, The Jikei University School of Medicine, 3-25-8 Nishi-Shinbashi, Minato-Ku, Tokyo, Japan 105-8461; 3) National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD 20892; 4) Current address: Institute of Metabolic Disease, Baylor Research Institute, 3812 Elm Street, Dallas, TX 75226.

Mucopolysaccharidosis VII (MPS VII) is a genetic metabolic disorder, caused by a genetic defect for a lysosomal enzyme, β-glucuronidase (GUSB). The substrates of the enzyme, glycosaminoglycans (GAGs), accumulate in multiple tissues. Affected patients show dysostosis multiplex such as skeletal dysplasia, hepatosplenomegaly and mental retardation. Hydrops fetalis occurs frequently suggesting presence of abnormalities in prenatal development in this disease. The pathogenesis of this disease is largely unknown. MPS VII mouse is a naturally-occurring murine model of MPS VII, having null mutation in GUSB gene causing biochemical and pathological abnormalities closely resemble that of MPS VII patients. Percentage of MPS VII mouse newborns born from heterozygote mating is significantly lower than expected 25%, suggesting intra-uterine loss of some affected embryos. To study the pathogenesis of MPS VII, we generated induced pluripotent stem (iPS) cells from MPS VII mouse (MPS VII-iPS) by retrovirally transduction of Oct3/4, Sox2 and Klf4 into tail tip fibroblasts. Generated iPS cells express ES cell marker genes and were pluripotent as demonstrated by in vitro differentiation study and teramota formation in nude mice. Notably, MPS VII-iPS cells showed markedly impaired ability to from embryoid bodies (EBs) in vitro compared with normal mouse derived iPS cells. MPS VII-EBs exhibited elevated level of hyaluronan and its receptor CD44, and markedly reduced expression levels of E-cadherin and cell-proliferating marker. Partial correction of enzyme deficiency in MPS VII-iPS cells led to improved EB formation and reversal of aberrant protein expression. These data indicate a potential mechanism for the partial lethality of MPS VII mice in utero and suggest a possibility of abnormality in embryonic development of human MPS VII. Our observations shed new light on the effect of defective lysosomal enzyme on embryogenesis and demonstrated the unique promise of iPS cells for studying the pathogenesis of genetic disorders.

2086/T

Quality of Life in Adults with Glycogen Storage Diseases I and III. *C.M. Milleson, S.L. Austin, P.S. Kishnani.* Division of Medical Genetics, Department of Pediatrics, Duke University Medical Center, Durham, NC.

Glycogen storage diseases (GSD) are an inherited group of conditions resulting in glycogen accumulation in various organs. The liver, kidney, and intestines are most affected in GSD I, while the liver, heart and skeletal muscles are affected in GSD III. With increasing survival rates, individuals with both disorders have chronic, long term complications and a significant disease burden. Despite the severity of these diseases, there has been no previous research published on quality of life (QOL) in adults with GSD I or III. Our objective was to examine QOL in adults with GSD I and III, to determine if there are notable differences between the groups. The Short-Form Health Survey (SF-36) was used to measure physical, mental, and social functioning. The sample consisted of 21 individuals with GSD I (19-48 yrs, mean=31 yrs) and 11 individuals with GSD III (23-56 yrs, mean=40 yrs). Descriptive statistics were calculated for the demographics and the eight scale scores. A Mann-Whitney test was used to compare the medians of the GSD I and III scale scores. Scores were also compared to a normed US population. Individuals with GSD III reported poorer quality of life than those with GSD I or the general US population. In physical domains, individuals with GSD III were greatly impaired, while those with GSD I were only minimally impaired. In mental and emotional domains, individuals with GSD I and III fared well—better than the general US population. Additionally, social functioning was significantly affected for individuals with GSD I and III when compared to the general US population. QOL in adults with GSD III was more impaired in physical domains than GSD I, possibly due to the additional symptom of muscle involvement in GSD III. The mental or emotional QOL domains are not impaired by the diseases, but rather, may suggest protective coping mechanisms. Despite positive emotional health, social functioning is an area of concern for individuals with GSD I and those with GSD III. This may be due to the frequency of their feeding schedule or due to other disease-related factors. Areas of future research interest include exploring whether there are protective benefits from having GSD I or III that facilitate positive emotional outcomes, examining if the physical and emotional outcomes of individuals with GSD I and III change over time, and determining if there are additional or improved ways in which individuals GSD I and III can be supported by medical providers.

2087/T

Detection of ACADVL and SLC22A5 Deletions and Duplications by MLPA. *M. Procter[1], K. Tuin[3], R. Mao[1,2].* 1) ARUP Laboratories, Salt Lake City, UT; 2) University of Utah Department of Pathology, Salt Lake City, UT; 3) MRC-Holland, Amsterdam, The Netherlands.

Background: Very long-chain acyl-coenzyme A dehydrogenase deficiency (VLCAD) and Primary Carnitine Deficiency (PCD) are fatty acid oxidation disorders that prevent the body from converting certain fats to energy, proving particularly problematic in times of fasting. VLCAD is caused by pathogenic variations in the ACADVL gene. PCD is caused by defects in the SLC22A5 gene, which encodes the protein OCTN2. Both disorders are autosomal recessive and 80-85% of cases of each disorder are caused by mutations in the respective gene. However, the remaining 15-20% of cases show no mutations and are presumed to be caused by complete or partial deletions of the ACADVL gene (for VLCAD) or the SLC22A5 gene (for PCD). We evaluated a Multiplex Ligation-dependent Probe Amplification (MLPA) assay for detection of deletions and duplications in ACADVL and SLC22A5 for use in our molecular laboratory. Methods: An MLPA assay for ACADVL and SLC22A5 was developed by MRC-Holland at the request of ARUP. MLPA is a semi-quantitative multiplex PCR approach to determine the relative copy numbers of each of 20 ACADVL exons and 10 SLC22A5 exons. Genomic DNA was hybridized overnight with probe mix, probes were ligated, and the fragments were amplified using universal dye-tagged primers. PCR products were subjected to fragment analysis by capillary electrophoresis and results analyzed by GeneMarker v1.85 software. To determine accuracy, DNA from 21 whole blood samples was collected from volunteers who denied any personal or family history of VLCAD or other metabolic disorders. DNA was extracted from the whole blood using MagNAPure extraction and tested using this MLPA assay. Additionally, because samples with deletions were not available for validation, we used amplicon mapping to ascertain the specificity of the MLPA probes. This was done by combining amplicons for exons together and testing them in MLPA reactions in place of genomic DNA. Results and Conclusions: All 21 accuracy samples gave no deletion MLPA results, with excellent between-run and within-run specificity for each probe data point. For individual probe specificity, one ACADVL MLPA probe and 3 SLC22A5 MLPA probes lay outside the amplicon boundaries and could not be immediately tested for specificity. The remaining 26 probes were detected in the appropriate exon amplicons. Our evaluation showed this assay to be reliable and robust in the detection of deletions and duplications in each exon of the ACADVL and SLC22A5 genes.

2088/T

Mutational screening of ALG(Glycogen Debranching Enzyme) gene in glycogen storage disease type III. *CF. Sargin Ozkaya[1], AE. Manguoglu[1], V. Uygun[2], R. Ertan[2], G. Luleci[1], S. Berker Karauzum[1].* 1) Department of Medical Biology and Genetics, Akdeniz University Medical Faculty; 2) Department of Pediatric Gastroenterology, Antalya, Turkey.

Ten patients who were followed in Akdeniz University Medicine Faculty Department of Pediatric Gastroenterology Hepatology and Nutrition, and diagnosed as GSD type 3 with liver biopsy and enzymatic analyses in Erasmus University Clinical Laboratory of Genetics in Rotterdam (Holland) were participated to the study. The age, consanginuity, residency, somatic development data, clinical, biochemical and echocardiographic data were compared with enzimatic activity of the patients. Mutation analyses resulted with a missense mutation in exon29 c.13428 A>G (Gln-Arg) in one patient, a missense mutation in exon 6 c.1628 G>T (Gly-Val) in three patients, a missense mutation in exon 6 c. 1646 A>T (Tyr-Phe) in the two of the same three patients, a nonsense mutation in exon31 c.15047 C>T (Gln-Stop) in one patient, a polymorphism in two patients in exon31 c.14956 G>A (Val-Val) that does not cause any change in protein production. Two splice site mutations were found in the first base of exon 12 c. 4362G>A in one patient and in intron 16 c.6970 A>G in an other patient. In this study, we followed ten patients with GSD type 3 which can be referred for Turkish people. We observed no serious clinical problem in these cases. Mutation analyses resulted with three missense mutation, one nonsense mutation, two splice site mutations and two silent mutations which were accepted as polymorphism. A further study is necessary to state these findings as mutation.

Tyrosinemia type II (Richner-Hanhart syndrome, RHS; MIM 276600) is a rare autosomal-recessive disorder characterized by keratitis with photophobia, palmoplantar hyperkeratosis, variable mental impairment, and elevated blood tyrosine levels. The disorder results from deficiency in the liver-specific enzyme tyrosine aminotransferase (TAT). The 11 kb *TAT* gene at 16q22 encompasses 12 exons encoding a 454 amino acid protein. Starting with our initial publication (Natt et al., PNAS 89:9297, 1992), *TAT* mutations have up to now been identified in 18 RHS families totalling 18 different mutations: one deletion, three frameshift, three splice, three nonsense, and eight missense mutations. We now identified 15 missense mutations and two identical R297X nonsense mutations in 14 RHS families from 10 different countries. Of the 15 missense mutations, one (R119W) has been described previously, three recurred twice, and one was observed in three families from Las Palmas, Canary Islands, not known but likely to be related. The nine novel missense mutations are: L76Q, A147V, T209I, A237P, K280R, M375R, D389N, P406L, R417Q. The 17 different TAT missense mutations known thus far all affect conserved amino acid residues and highlight their importance for transaminase function. Notably, the K280R substitution affects the lysine residue to which the cofactor pyridoxal phosphate binds during catalysis. Comparison of the clinical, biochemical and molecular findings for all RHS patients with identified *TAT* gene mutations does not reveal any clearcut genotype-phenotype correlation. Our study raises the number of different mutations in the *TAT* gene to 28, emphasizing the great mutational spectrum in this rare metabolic disorder.

2090/T

Diagnostic tests for hereditary renal hypouricemia. *I. Sebesta[1,2], B. Stiburkova[2].* 1) Institute of Clinical Biochemistry; 2) Institute of Inherited Metabolic Disorders, Charles University, First Faculty of Medicine, Prague, Czech Republic.

Introduction: Primary hereditary renal hypouricemia is a genetic disorder characterized by defective renal urate reabsorption with complications such as nephrolithiasis and exercise-induced acute renal failure. The known causes are: defects in the SLC22A12 gene, which encodes the human urate transporter 1 (hURAT1), and also impairment of the recently identified voltage urate transporter (URATv1), encoded by SLC2A9 (also called GLUT9) gene, which plays probably a major role in urate homeostasis as was revealed by recent study of knockout mice. Diagnosis is based on two markers: hypouricemia (< 119μmol/l) and increased fractional excretion of uric acid (> 10%). Therapy requires alkalization of urine, drinking plenty of water, and abstention of strenuous exercise. To date, the cases with mutations in hURAT1 gene have been reported in East Asia only. More than one hundred Japanese patients have been described and this number is unique worldwide. Hypouricemia is sometimes overlooked, therefore we have set up the flowchart for this disorder. Methods: The patients were selected for molecular analysis from 620 Czech hypouricemic patients. These cases were found from 3 600 blood and urine samples. Serum and urinary uric acid and creatinine were determined. The sequence analysis by automated DNA sequencer (Applied Biosystems 3100) of the coding region of SLC22A12 and SLC2A9 genes were performed after informed consent. Results: The proposed scheme was as follows. Secondary causes of hyperuricosuric hypouricemia were excluded as the first step. The estimation of :1) serum uric acid , 2) excretion fraction of uric acid, 3) and analysis of hURAT1 and URATv1 genes follow then. Using this flow chart we were able to find 3 transition and 4 deletions in SLC22A12 gene, yet unpublished, in 6 Czech patients. In addition, one family with one nucleotide insertion in URATv1 gene was found. Three patients were suffering from acute renal failure and urate nephrolithiasis. Conclusions: Our finding of the defect in URATv1 gene gives further evidence that SLC2A9 is a causative gene of primary renal hypouricemia and supports the important role of SLC2A9 in regulation of serum urate levels in humans. Hereditary renal hypouricemia is still unrecognized condition and probably not wide spread in Japan and Korea only. (Supported by grant VZMSM0021620806, Czech Republic).

2091/T

Biotinidase Analysis: The Quest Diagnostics Experience. *R. Sharma[1], D. Salazar[1], R.M. Lobo[1], W. Sun[2], C.M. Strom[1,2], J.A. Neidich[1].* 1) Biochemical Genetics, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA; 2) Molecular Genetics, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

Biotinidase deficiency is an autosomal recessive disorder that manifests with central nervous system symptoms including seizures and mental retardation and skin symptoms such as dermatitis. Biotinidase is the enzyme involved in releasing biotin from biocytin and biotinyl peptides, the products of carboxylase degradation. Biotin is a cofactor for 4 biologically important carboxylases: propionyl CoA carboxylase, β-methylcrotonyl CoA carboxylase, pyruvate carboxylase, and acetyl CoA carboxylase. These enzymes are involved in gluconeogenesis, fatty acid synthesis, and amino acid catabolism. Since August 2008, we have analyzed more than 1600 patient samples for biotinidase. From studies of enzyme activity alone, 22 patients were identified as deficient, 21 as partially deficient, and 26 as possible carriers. Mutation analysis was performed on 4 of 22 patients identified as deficient: 2 patients were homozygous for the H447Y mutation; 1 patient had Q456H in conjunction with both A171T and D444H; and the fourth patient had A171T in conjunction with both D444H and the novel mutation R538S. Mutation analysis was also performed on 9 of 23 patients identified as partially deficient; each patient was found to have a mutation previously associated with partial enzyme deficiency. All 9 patients had the D444H partial-deficient mutation, along with either the Q456H mutation (3 patients) or D444H, D444H-A171T, 97_104delinsTCC, 459G>A, R5538C, or R157H (the remaining 6 patients, respectively). Out of 27 patients identified as possible carriers, mutation analysis was performed on 6: 5 patients had either the K176N, R538S, R157H, or D444H mutation; 1 patient had both the D444H and R538C mutations. In our sample group, D444H was the most common mutation associated with apparent partial enzyme deficiency. We suggest that mutation analysis in conjunction with biotinidase enzyme analysis may be helpful in the diagnosis and subsequent treatment of patients with biotinidase deficiency.

A new case of *cblF* disease detected by newborn screen and a follow up on a 14-year-old patient. *M. Shinawi[1], D.S. Rosenblatt[2], D. Watkin[2], L. Spreitsma[1], D. Dietzen[1,3], O. Oladipo[3].* 1) Pediatric, Genet. & Genomic Med., Washington Univ, St. Louis, MO; 2) Department of Human Genetics, McGill University, Montreal, Qc, , Canada; 3) Department of Pathology and Immunology, Washington University School of Medicine, St. Louis, MO.

BACKGROUND: The *cblF* defect is due to disturbed lysosomal release of cobalamin (Cbl) into the cytoplasm. The disease is very rare and the *cblF* patients have variability in age of onset, presenting symptoms, response to treatment, and long-term complications. The *LMBRD1* was identified as the causative gene for *cblF* and it has been shown that the majority of mutated alleles carry the deletion c.1056delG. **METHODS:** Clinical and biochemical characterization of a new patient with *cblF* and a follow up of a 14-year-old patient with *cblF* who initially presented with failure to thrive (FTT) and feeding difficulties. We compare the clinical findings in our patients with previously reported cases. **RESULTS:** The new patient had C3 elevation on newborn screen. Confirmatory tests revealed hyperhomocysteinemia, hypomethioninemia, methylmalonic aciduria, decreased serum Cbl, and complementation analysis showed *cblF* defect. The patient was small for gestational age (SGA), exhibited dysmorphic features and mild developmental delays, and had trigonocephaly and ventricular septal defect. There was complete biochemical normalization within 2 weeks of parenteral Cbl treatment and her feeding difficulties and FTT improved. The other patient presented at 4 weeks of life and was homozygous for the 1056delG mutation. She has not been regularly followed by a metabolic service and was treated only with monthly cyanocobalamin shots. The patient has never experienced metabolic decompensation. Her height was at 1st percentile. She was an average 8th grade student with no behavioral concerns and had regular menstrual cycles. Her hyperhomocysteinemia and methylmalonic aciduria significantly improved after switching to weekly hydroxycobalamin. **CONCLUSIONS**: Patients with the *cblF* defect exhibit variable expressivity and long-term outcomes. Of the 14 *cbl*F confirmed patients, 8 showed FTT, 5 were SGA, 5 developed feeding difficulties, 5 were reported with congenital heart defects, 6 had low serum Cbl at presentation, and 4 presented with elevated C3 on newborn screen. 3 of the 14 died during first year of life (2 due to cardiac surgery complications and one was an unexpected death) and 7 exhibited variable degrees of developmental delays. The SGA and increased incidence of birth defects are intriguing features and suggest a prenatal effect. The thorough investigation of additional *cblF* patients will shed light on the clinical course, neurological outcome, and efficacy of treatment.

2093/T

Methylmalonic acidemia and optic nerve atrophy: reversal of sub-acute loss of visual function with anti-oxidant therapy. *J.L. Sloan[1], N.S. Hauser[1], I. Manoli[1], W.M. Zein[2], K. Bowles[2], K. O'Brien[3], B.P. Brooks[2], C.P. Venditti[1].* 1) Genetics and Molecular Biology Branch, NHGRI, Bethesda, MD; 2) Ophthalmic Genetics and Visual Function Branch, NEI, Bethesda, MD; 3) Medical Genetics Branch, NHGRI, Bethesda, MD.

Isolated methylmalonic acidemia (MMA) results primarily from a defect in the mitochondrial enzyme methylmalonyl-CoA mutase (MUT). Patients present with recurrent metabolic crises and multisystemic complications including growth retardation, chronic renal failure, pancreatitis and developmental delay despite optimal management. Studies in MMA knock out mice and patient tissues have suggested that mitochondrial dysfunction plays a significant role in the pathophysiology of MMA. Optic nerve atrophy (ONA) has been described as a rare complication of the disorder, and the pathophysiology is unknown. Patients with isolated MMA evaluated through NIH study 04-HG-0127 (clinicaltrials.gov identifier: NCT00078078) "Clinical and Basic Investigations of Methylmalonic Acidemia and Related Disorders" underwent comprehensive ophthalmologic evaluation. We report four *mut^0* patients with ONA out of the 56 with isolated MMA followed in our protocol. All four patients were males, and presented with a decreased visual acuity at the ages of 7, 22, 23 and 24 years. Vision loss was bilateral but asymmetric and the progression was variable. Best-corrected vision ranged from 20/40 to 20/800 and in two patients visual evoked potentials were severely diminished and delayed. There were no apparent biochemical or environmental triggers shared by the patients and none had an acute metabolic decompensation during the onset of the symptoms. Each carried two mutations in the MUT gene. Two patients were negative for the Leber Hereditary Optic Neuropathy mitochondrial mutations. Patient 4 was a 24 year-old male, 4 years status-post cadaveric kidney transplantation, whose vision progressively worsened from 20/20 to 20/40 OS and 20/125 OD over a 4-week period. Daily oral coenzyme Q10, vitamin E, ascorbic acid, thiamine, and intravenous infusions followed by oral N-acetylcysteine were employed. The patient's visual acuity improved to 20/25 OD and 20/20 OS over one month, although the nerve fiber layer thickness remained decreased. Our experience suggests that 1) ONA is a late onset complication of isolated MMA and therefore all patients should have periodic thorough ophthalmologic evaluation and counseling about the symptoms of ONA. 2) Anti-oxidant therapy can be used to at least partially reverse the functional visual effects of optic nerve pathology in MMA patients in the acute setting.

2094/T

Evidence of a Frequent 2-Methylbutyryl-CoA Dehydrogenase (ACADSB) Mutation Among Somalian Immigrants in the USA and Questions About its Role in Autism Spectrum Disorder. *E.H. Smith[1], D. Gavrilov[1,2,3], K. Raymond[1,3], P. Rinaldo[1,3], S. Tortorelli[1,3], D. Matern[1,3], D. Oglesbee[1,2,3].* 1) Biochemical Genetics Laboratory, Mayo Clinic, Rochester, MN; 2) Molecular Genetics Laboratory, Mayo Clinic, Rochester, MN; 3) Department of Medical Genetics, Mayo Clinic, Rochester, MN.

Background. 2-methylbutyryl-CoA dehydrogenase (2MBD) deficiency is an autosomal recessive disorder of L-isoleucine metabolism that is detectable by elevated 2-methylbutrylcarnitine (C5) levels in bloodspots through newborn screening (NBS) by tandem mass spectrometry. Previous studies described a mutation, c.303+3A>G, in the 2MBD gene (ACADSB), in four children of East African descent. Of these, two unrelated children from Somalia were homozygous for this alteration and displayed autistic features. Minnesota is home to the largest Somalian population in the Western hemisphere and autism rates in this group are three times that of the general population. **Methods.** In order to assess a possible correlation between 2MBD deficiency and autism, we surveyed cases of 2MBD deficiency identified by NBS between 2004-2009 for Somalian ancestry and retrospectively analyzed a subset of negatively screened cases from 2009-2010 for the presence of c.303+3A>G. **Results.** Molecular analysis confirmed homozygosity for c.303+3A>G in four newborns and two carriers of the mutation, all of whom were of Somalian descent. Two infants (one carrier and one c.303+3A>G homozygotic individual) were retrospectively identified from negatively screened NBS cases. Significant overlap was observed for C5 levels between confirmed carriers of this mutation and homozygotic individuals. Clinical follow up is available for only one infant, who is developmentally normal at two months of age without treatment. **Conclusions.** From previous observations, and from our identification of six additional unrelated infants, the c.303+3A>G mutation is common to the Somalian population within the USA. Current cut-off values for NBS C5 levels are insufficient to detect all cases of 2MBD deficiency due to c.303+3A>G homozygosity. While the question of whether 2MBD deficiency is a contributor to autism spectrum disorder remains to be elucidated, ongoing studies on the natural history of this metabolic condition, and mutation analysis of autistic patients with Somalian ancestry, will aid in determining the proportion of c.303+3A>G in autism.

2095/T

A mouse model of creatine deficiency: Effects on growth and metabolite levels. *C. STROMBERGER[1], H.O. AKMAN[2], W.J. CRAIGEN[2].* 1) Department of Radiotherapy and Radiological Oncology, Charité University Medicine, Berlin, Germany; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston TX 77030.

Creatine deficiency is a recently recognized inborn error of metabolism that can be diagnosed either by magnetic resonance spectroscopy or by measuring analytes in blood and urine. It can be caused by defects either in creatine biosynthesis or transport. Two enzymes catalyze creatine synthesis from arginine and glycine; arginine glycine amidinotransferase (AGAT) and guanidinoacetate methyltransferase (GAMT). Each exhibits intellectual impairment, and in the latter case epilepsy, but it is surprising that a lack of creatine phosphate, an energy reservoir in high concentration in brain and muscle, is otherwise a viable deficiency state. In order to better understand the requirement for creatine and the underlying mechanisms that may account for the intellectual disability associated with its deficiency, we generated a knockout model of AGAT deficiency using a conditional knockout strategy that allows for the tissue specific deletion of the gene. Mice globally lacking the AGAT activity are live born and survive to adulthood, but exhibit growth retardation. Deficient mice are fertile, but blood amino acid levels demonstrate a severe reduction in creatine levels, and, surprisingly, arginine concentrations in blood are reduced, suggesting that the AGAT activity provides a net contribution to arginine stores during development. This mouse model will be valuable in defining the neurologic phenotypes in AGAT deficiency, and may provide novel insights into the role of creatine in other tissues such as myocardium and skeletal muscle.

2096/T

Novel HADHB mutations, including an exonic deletion, in a neonate with mitochondrial trifunctional protein deficiency. *S.F. Suchy[1], H. Shuhaiber[2], R. Busin[1], S. Aradhya[1], W.K. Chung[2].* 1) GeneDx, Gaithersburg, MD; 2) Columbia University, New York, NY.

The mitochondrial trifunctional protein is a multi-enzyme protein that catalyzes the last three steps of beta-oxidation. It is comprised of 4 alpha and 4 beta subunits encoded by the *HADHA* and *HADHB* genes, respectively. Mitochondrial trifunctional protein (MTP) deficiency leads to a wide clinical spectrum of disease ranging from severe neonatal/infantile cardiomyopathy, acute hepatic dysfunction and early death, to mild chronic progressive sensorimotor polyneuropathy with episodic rhabdomyolysis. Mutations in *HADHA* are more common than *HADHB*. An affected male was delivered to G1P1 mother at 28 weeks gestation via emergency section due to mother's acute fatty liver of pregnancy, oligohydramnios and increased decelerations in the fetus. The baby's birth weight was 867 g, birth length was 34 cm, and head circumference was 25 cm. His Apgar scores were 6 and 8 at 1 and 5 minutes, respectively. The newborn screen was abnormal with elevated C16-OH (0.99 μmol/L, normal< 0.1 μmol/L) and C18:1-OH (1.23 μmol/L, normal< 0.1 μmol/L), consistent with LCHAD/MTP deficiency. Follow-up plasma acylcarnitine profile revealed an elevated C12-C18 hydroxylated and non-hydroxylated acylcarnitine. In vitro interrogation of beta-oxidation in fibroblasts with radiolabeled palmitate demonstrated significant elevations of C14, C16, C16-OH and C18 suggesting either LCHAD or trifunctional protein deficiency. Molecular testing failed to identify a mutation in HADHA. Sequencing *HADHB* revealed that the patient was heterozygous for a novel IVS4-1 G>T mutation. Deletion/duplication testing by exon-level array CGH identified a deletion of exon 4 in *HADHB*. This is the first report of an exon deletion in *HADHB*. Spiekerkoetter et al. (2003) described the largest series of 15 patients from 13 families with *HADHB* mutations and demonstrated that the most common mutations are missense mutations. Our patient has two novel, uncommon mutations: a splice site mutation and deletion of a single exon. This case demonstrates the value of exon-level deletion/duplication analysis, and highlights the significance of maternal history of acute fatty liver disease of pregnancy in patients carrying a fetus with MTP deficiency.

2097/T

NSDHL deficiency and disease: methyl sterols or cholesterol? *J. Trinh[1, 3], M. Morimoto[1, 3], G. Hendson[2, 3], K. McLarren[1, 3], C. du Souich[1, 3], C.F. Boerkoel[1, 3].* 1) Department of Medical Genetics, University of British Columbia, Child & Family Research Institute, Vancouver, BC, Canada; 2) Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada; 3) Rare Disease Foundation, Vancouver, BC, Canada.

BACKGROUND: NAD(P)H steroid dehydrogenase-like (NSDHL) is an X-linked gene that encodes for a 3β-hydroxysteroid dehydrogenase in the cholesterol biosynthetic pathway. Loss-of-function mutations of NSDHL cause CK and CHILD syndromes. CK syndrome patients have syndromic intellectual disability. Their dysmorphic features include microcephaly, thin build, a long and thin face, epicanthic folds, almond-shaped eyes, upslanting palpebral fissures and micrognathia. Their intellectual disability can be attributed to cortical malformations and seizures. A thorough examination of the expression of NSDHL in human tissues has never been done making delineation of the cell autonomous and non-autonomous aspects of NSDHL deficiency difficult. HYPOTHESIS: NSDHL deficiency causes the features of CK and CHILD syndromes by cell autonomous and non-autonomous mechanisms. METHOD: We profiled NSDHL expression in human male and female tissues by immunohistochemistry, qRT-PCR, and immunoblotting. We also compare this expression profile to that of the mouse Nsdhl and other enzymes in the cholesterol biosynthetic pathway. RESULTS: Our preliminary results show expression of NSHDL in steroidogenic, epithelial, and neuronal cells. CONCLUSION: This expression profile suggests that NSDHL loss-of-function mutations have both cell autonomous and cell non-autonomous effects. Based on comparison of NSDHL expression to that of other enzymes in the cholesterol biosynthetic pathway, we propose that some features of CK and CHILD syndromes are caused by the accumulation of methyl sterols rather than cholesterol deficiency alone.

2098/T

Reliable determination of phenylketonuria genotypes predictive of sapropterin dihydrochloride response. *J. Utz[1], C. Pham Lorentz[1], D. Markowitz[1], K.D. Rudser[2], C.B. Whitley[1].* 1) Adv Therapies, Pediatrics, Univ Minnesota, Minneapolis, MN; 2) Biostatistics, Univ Minnesota, Minneapolis, MN.

Background: Sapropterin dihydrochloride (SAP), a synthetic tetrahydrobiopterin (BH4), works as a chaperone of the phenylalanine hydroxylase enzyme (PAH) in phenylketonuria (PKU) by facilitating folding of PAH into its most active conformation and stabilizing the active conformation. No standard pharmacogenetic tests exist to identify responsive genotypes. Previous studies have failed to identify genotypes that consistently predict response, but they were weakened by varied: 1) SAP/BH4 doses; 2) response definitions; 3) duration; 4) phenylalanine (PHE) test times at varied protein catabolic states; 5) control of dietary PHE. START (sapropterin therapy actual response test) protocol is a double-blind, placebo-controlled, 4-week clinical diagnostic test that obviates the confounders aforementioned. START results were evaluated for response-genotype correlates and trends in molecular characteristics. Results: Sixty PKU patients completed START, with 44 patients' mutations known and 35 different genotypes represented. Thirty patients (50%) were responsive to SAP. Alleles singly associated with response include Y414C (7/7 patients, 5 genotypes) and I65T (8/8 patients, 5 genotypes) . Mutant allele R408W, located at the crux of a strategic hinge site for activating folding in the wild type, is associated with non-response in 16/20 (80%)patients and 11/15 (73%) genotypes. Straight-chain amino acids substituted with aromatic amines had low residual activity and were associated with non-response in 16/20 (80%) patients, 11/15 (73%) genotypes. Substitution with lower molecular weight amino acids was associated with high residual activity and responsiveness in 23/26 (88.5%) patients. Conclusions: The START protocol provides a consistent pharmacogenetic test to reliably identify genotypes associated with SAP responsiveness and augments understanding of the chaperone role of SAP/BH4. To date, START has identified 22 genotypes predictive of response. Response trends were associated with mutant locus at activating PAH fold sites and spatial folding changes incurred by substituted amino acid size and configuration. Substitution with aromatic amines is associated with non-response. Ongoing study of BH4 response via START protocol will provide a reliable pharmacogenetic test for improving understanding of how PKU mutations impact PAH protein folding dynamics and will enhance understanding of PKU disease and its management.

2099/T

Niemann-Pick Type C Disease in Australia: Data From Four Decades of Diagnosis. *M. Walterfang[1,2], M. Fahey[3,4], D. Bratkovic[5,6], M. Fietz[5,6], D. Velakoulis[1,2], E. Storey[7,8].* 1) Neuropsychiatry Unit, Royal Melbourne Hospital, Parkville, Victoria, Australia; 2) Melbourne Neuropsychiatry Centre, University of Melbourne, Parkville, Victoria, Australia; 3) Department of Neurology, Monash Children's, Monash Medical Centre, Clayton, Victoria, Australia; 4) Department of Pediatrics, Monash University, Clayton, Victoria, Australia; 5) Metabolic Unit, Women's and Children's Hospital, Adelaide, South Australia, Australia; 6) SA Pathology, Adelaide, South Australia, Australia; 7) Neurology Unit, Alfred Hospital, Prahran, Victoria, Australia; 8) Department of Neurology, Monash University, Clayton, Victoria, Australia.

Niemann-Pick type C (NPC) disease is a well-characterised protean neurovisceral disorder that is caused by mutations to NPC1 and NPC2, whose products function as intracellular sterol chaperones. NPC presents from neonates to adults, with presentations ranging from cholestatic jaundice in infancy to mental retardation, seizures, ataxia, psychiatric illness and dementia through childhood and adulthood. Australia's sole lysosomal storage disease reference laboratory serves the Asia-Pacific region; diagnosis via filipin staining and esterification began in the 1990s and stored samples were retrospectively analysed for biochemical characterisation. Data from all patients diagnosed since 1980 (n=84) were analysed; the majority (n=60) of patients were from Australia. Age of diagnosis ranged from the neonatal period to 49 years of age, with "classical" biochemical phenotypes diagnosed at a mean age of 7 and "variant" phenotypes at a mean age of 25. Over four decades, there was a year-on-year increase in the rate of diagnoses, with 40 patients diagnosed in the last decade, particularly the adult-onset form. There was a significant correlation between esterification rate ($r^2=0.3$, $p<0.001$) and filipin staining percentage ($r^2=0.3$, $p<0.0001$) and age of diagnosis. In patients genotyped, I1061T was the most common causative mutation, and seen in patients up to the age of 30; S954L was associated with later-onset disease. This analysis presents a large regional cohort diagnosed through a single laboratory and illustrates the wide phenotypic variation of disease, but suggests that there are correlations between genotype, biochemical and clinical phenotypes. Increased recognition of the disease, particularly adult-onset forms, appears to be responsible for the increasing proportion of variant illness diagnoses.

2100/T

SECONDARY BIOTIN DEFICIENCY OBSERVED IN TWO JAPANESE INFANTS DUE TO CHRONIC USE OF HYPOALLERGIC INFANT FORMULA. *Y. Watanabe[1,2], T. Ohya[2], T. Ohira[2], T. Fukui[3], T. Watanabe[3], T. Inokuchi[1], M. Yoshino[2], T. Matsuishi[1,2].* 1) Research Institute of Medical Mass Spectrometry, Kurume University School of Medicine, Fukuoka, Japan; 2) Department of Pediatrics and Child Health, Kurume University School of Medicine, Kurume, Japan; 3) School of Human Science and Environment, University of Hyogo, Himeji, Japan.

Background: Biotin is a water-soluble vitamin and is widely distributed in many foods. Biotin functions as a cofactor for acetyl-CoA carboxylase (AC), methylcrotonyl-CoA carboxylase (MCC), propionyl-CoA carboxylase (PCC), and pyruvate carboxylase (PC), and is important in fatty acid synthesis, amino acid metabolism, and gluconeogenesis. Symptoms of biotin deficiency include dermatitis, hypoglycemia, characteristic organic acidemia, seizures, and developmental delay. Although biotin deficiency is believed to be rare, there have been several reports of symptomatic infants with secondary biotin deficiency in Japan because biotin is not supplemented in infant special formula such as hypoallergenic infant formula including lactose free formula. Objectives: To raise awareness of importance of supplementing biotin in infant special formula by reporting infants diagnosed with biotin deficiency due to the typical biochemical profiles consistent with biotin metabolism defects including biotinidase deficiency and holocarboxylase synthetase deficiency (HCS). Case report: Patient 1 is an 8-month-old Japanese female, ex-33 week premature infant, with seizures and history of idiopathic gastric rupture. Hypoallergenic formula was implemented since age 20 days. Her physical exam was unremarkable. Laboratory studies including lactic acidemia, a low free and a high C5OH carnitine, and elevated urine 3-hydroxyisovaleric acid and 3-methylcrotonylglycine, prompted us to study biotin metabolism defects. Biotinidase and HCS were measured normal. Plasma and urine biotin were measured below the reference ranges: plasma: free 0.3 ng/ml ref. 0.4-1.1; urine < 2 ref: 4-25. Patient 2 is an 11-month-old, ex-33 week premature, Japanese male. He was solely fed with lactose free hypoallergenic formula until 7 months when small solid foods were started. His physical exam was unremarkable but mild metabolic acidosis was noted. Laboratory studies including plasma and urine biotin levels, plasma acylcarnitines and urine organic acids were consistent with biotin deficiency. The enzymes related to biotin metabolism were normal. Conclusion: Hypoallergenic infant formula has recently been more commonly used. Pre-symptomatic infants with biotin deficiency might be not rare in Japan. Supplementation of biotin in hypoallergenic infant special formula is essential to promote infant's well-being.

2101/T

DPM1 mutations in a patient with dystrophic muscle and abnormal alpha-dystroglycan. *A.C. Yang[1], B. Ng[2], S.A. Moore[3], J.S. Rush[4], K.M. Raymond[5], C.J. Waechter[4], H.H. Freeze[2], L. Mehta[1].* 1) Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Sanford Children's Health Research Center, Sanford-Burnham Medical Research Institute, La Jolla, CA; 3) Department of Pathology, The University of Iowa, Iowa City, IA; 4) Department of Molecular and Cellular Biochemistry, Chandler Medical Center, College of Medicine, University of Kentucky, Lexington, KY; 5) Department of Laboratory Medicine and Pathology, Mayo Clinic School of Medicine, Rochester, MN.

Type I congenital disorders of glycosylation (CDG) are rare autosomal recessive diseases involving a spectrum of defects in post-translational modification of proteins via attachment of carbohydrate chains. Patients with CDG type I typically present with neurological manifestations including seizures, psychomotor retardation, cerebellar atrophy, hypotonia, and microcephaly. Other associations include liver disease and coagulation abnormalities. Such disorders result from N-linked glycosylation defects. Patients with severe forms of dystroglycanopathy typically present with muscular dystrophy, brain and eye abnormalities that arise from reduced O-linked mannosylation of alpha-dystroglycan. We describe an infant who initially presented with hypotonia, camptodactyly, severe motor delays, elevated CK, and borderline microcephaly. A muscle biopsy showed necrotizing myopathy and a mosaic pattern of reduced alpha-dystroglycan immunostaining with glycoepitope antibodies suggestive of dystroglycanopathy. Carbohydrate deficient transferrin testing was abnormal and consistent with CDG type I. Phosphomannomutase and phosphomannose isomerase activities were all within the normal range ruling-out CDG-Ia and Ib. No mutations were found in DPM2 or DPM3, but sequencing of DPM1 (dolichol-P-mannose synthase subunit 1) revealed a heterozygous splice site mutation (c.563G/A = R188K) that leads to a premature stop codon as well as a homozygous novel Gly>Val change (c.455 G>T = G152V) of unknown pathogenicity. Enzyme analysis showed a 75% deficiency in DPM1 activity while Km was normal suggesting a decrease in the amount of enzymes. The DPM complex, composed of 3 protein subunits, has previously been shown to have roles in both N-glycosylation and O-mannosylation. There has been only one case reported in the literature that links CDG with dystroglycanopathies: a girl with a homozygous DPM3 mutation who has a mild muscular dystrophy and dilated cardiomyopathy (Lefeber et al, 2009). We present another case of apparent CDG type I with clinical and muscle biopsy findings consistent with dystroglycanopathy. DPM1 mutations are being investigated as the cause. Previously reported patients with DPM1 mutations, classified as CDG-Ie, have been described to have elevated CPK, but have not been evaluated for a dystroglycanopathy. In the future, such investigations will expand the phenotypic spectrum of these rare disorders.

2102/T

Development of Models of Succinyl-CoA Ligase Deficiency and mtDNA Depletion in Mouse and Fruit Fly. *T.R. Donti[1], N.K Hawkins[1], M. Ge[1], K. Eldin[2], B.H. Graham[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pathology, Texas Children's Hospital, Houston, TX.

Mitochondrial diseases associated with depletion of mitochondrial DNA (mtDNA) have emerged as an important subset of mitochondrial diseases over the past few years. Mutations in subunits of Succinyl-CoA Ligase (Synthetase), a component of the citric acid cycle, have been associated with mitochondrial encephalomyopathy and mitochondrial DNA depletion. *SUCLA2*, encoding the ADP-specific beta subunit, and *SUCLG1*, encoding the alpha subunit, have both been demonstrated to be mutant in cases of mitochondrial disease with mtDNA depletion. The goal of this project is to develop model systems of Sucinyl-CoA Ligase deficiency to study disease pathogenesis and biology of mtDNA maintenance. A gene trap allele of *Sucla2* (*Sucla2*^{SA}β*geo*) has been isolated in mouse embryonic stem (ES) cells and used to generate transgenic animals. *Sucla2*^{SA}β*geo* homozygotes exhibit recessive lethality with most mutants dying late in gestation (e18.5). Histological analysis of mutant placenta reveals increased mineralization and mutant embryos are approximately 25% smaller than wild type littermates. Mutant placenta and embryonic brain, heart and muscle show varying degrees of mtDNA depletion (20-60%), while there is no appreciable mtDNA depletion in mutant liver. Mouse embryonic fibroblasts (MEFs) derived from e12.5 embryos show a 50% reduction in mtDNA content after five passages for mutant compared to wild type. In *Drosophila*, a deletion mutant of *Scsalpha* (*CG1065*, *SUCLG1* ortholog) has also recently been isolated through imprecise excision of a P-element inserted next to the gene. Preliminary analyses of this mutant reveal that they are homozygous viable but exhibit neurological dysfunction manifested through increased sensitivity to mechanical stress (increased bang sensitivity). Quantification of mtDNA in these mutants is currently being performed. The characterization and exploitation of models of Succinyl-CoA ligase deficiency promise to provide insights into the pathogenesis of mitochondrial diseases with mtDNA depletion as well as into the biology of mtDNA maintenance.

2103/T

Deoxyguanosine kinase (*DGUOK*) deficiency presenting as neonatal hemochromatosis. *N.A. Hanchard[1], O. Shchelochkov[1,2], E. Brundage[1], E. Schmitt[1], A. Roy[3], M. Finegold[3], L. Wong[1], F. Scaglia[1].* 1) Human and Molecular Genetics, Baylor College of Medicine, Houston, TX; 2) Division of Genetics, Department of Pediatrics, University of Iowa Hospitals and Clinics, Iowa City, IA; 3) Department of Pathology, Baylor College of Medicine, Houston, TX.

Mutations in the nuclear gene deoxyguanosine kinase (*DGUOK*) can result in mitochondrial DNA (mtDNA) depletion, which may present as neonatal liver failure. *DGUOK* deficiency as the underlying diagnosis in the severe hepatic failure of neonatal hemochromatosis (NH), however, is poorly described in the literature and under-recognized in clinical practice. We report an African American female neonate born at term to non-consanguineous parents, who failed her newborn screen for tyrosinemia (tyrosine 800 μmol/L; upper cut-off 500 μmol/L). By two weeks of age she was hospitalized with severe, progressive liver failure and an elevated serum lactate (9.4 mMol/L). Urinary succinylacetone was not observed and plasma amino acids were consistent with hepatic failure. Further evaluation revealed an elevated ferritin (1627 ng/ml; upper limit 391 ng/ml), which, in conjunction with an abdominal MRI suggestive of hepatic siderosis, led to a presumptive diagnosis of NH. Despite intensive treatment, her hepatic dysfunction and coagulopathy worsened, leading to death on day of life 44. Subsequent autopsy demonstrated significant hepatic siderosis as well as extrahepatic iron deposition sparing the spleen, consistent with the diagnosis of NH. The abnormal newborn screen, severe liver dysfunction, and elevated lactate prompted evaluation for a hepatic mtDNA depletion syndrome. Sequencing of the nuclear genes *POLG1*, *MPV17* and *DGUOK* in blood revealed an apparent homozygous change c.572A>G (p.Y191C) in the *DGUOK* gene. This missense variant is predicted to disrupt enzyme function and has been reported in a neonate with the hepatocerebral form of DGUOK-related mtDNA depletion syndrome. Oligonucleotide arrayCGH targeted to genes involved in metabolic and mitochondrial disorders revealed a significant reduction of mtDNA content in blood (approximately 45% of age and tissue matched control). Parental samples were unavailable for analysis; however, a high resolution SNP-array demonstrated an 8 mb region of absent heterozygosity encompassing the *DGUOK* gene, confirming homozygosity of *DGUOK*. The etiology of NH is unclear, but autosomal recessive inheritance is implied; we are thus evaluating other NH cases for evidence of MtDNA depletion. This report underscores the importance of considering *DGUOK* deficiency as a cause of NH, highlights mtDNA depletion in the differential diagnosis of neonatal tyrosinemia, and broadens the ethnic profile of *DGUOK* mutations to include African Americans.

2104/T

A Drosophila model of mitochondrial complex 1 deficiency. *V. Hegde[1,2], B. Duboff[1,2], R. Vogel[2], M. Feany[1,2].* 1) Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School.

As a group, mitochondrial respiratory chain disorders are one of the most common inborn errors of metabolism. They frequently causes a devastating encephalomyelopathy of infancy, Leigh's disease. Mitochondrial complex 1 deficiency is the most common cause of respiratory chain dysfunction. The pathophysiology of complex I deficiency is poorly understood, at least in part due to the absence of adequate animal models. Here we demonstrate that complex 1 deficiency can be modeled in Drosophila by post-transcriptional silencing (knockdown) of a critical subunit of complex 1. Knockdown flies show many of the features of human mitochondriopathies including a shorter life span, locomotor dysfunction, histological evidence of neurodegeneration, reduced complex 1 activity and electron microscopy findings of large dysmorphic mitochondria. Our results demonstrate that many of the clinical features of mitochondrial complex 1 disease can be modeled in Drosophila, a powerful model organism to study genetic pathways and disease pathophysiology.

Mitochondrial-Genetics Diagnostic Clinic Two-Year Experience at the Children's Hospital of Philadelphia. *E. Place, M. Falk.* Division of Human Genetics, Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA.

The Mitochondrial-Genetics Diagnostic Clinic at the Children's Hospital of Philadelphia was established in 2007 to facilitate the often complicated diagnostic process for the heterogeneous class of mitochondrial diseases. Here, we review our 2-year clinical experience, focusing on the number and type of diagnoses made. **METHODS**: Since June 2008, 79 new patients ranging in age from 6 weeks to 82 years were evaluated in this Clinic. 2/3 of referrals were for abnormal laboratory results (13), family history (10), seizures (10), GI problems particularly dysmotility (8), developmental delay (6), and muscle weakness (6). All patients underwent clinical evaluation including physical and dysmorphologic examination, medical and family histories, and metabolic screening studies. Genetic diagnostic testing and more invasive testing such as tissue biopsy, LP, and neuroimaging studies were obtained based on individual presentation. **RESULTS**: 14 individuals were found to have genetically-confirmed primary mitochondrial DNA (mtDNA) cytopathies: a boy with severe multi-systemic disease including retinitis pigmentosa, cataracts, and cardiomyopathy (*tRNA-SER(AGY)* C12264T); a mother and 2 daughters with complex I deficiency due to two LHON mutations (*ND4* G11778A heteroplasmy and *ND6* T14484C homoplasmy); 6 individuals with progressive myopathy (*tRNA-LEU* A3288G); 2 siblings with COX deficiency (*tRNA-TRP* 5537_5538insT); and mother and daughter with MELAS (*tRNA-LEU* A3243G). mtDNA mutations of uncertain pathogenesis were identified in 5 individuals (*tRNA-TYR* A5836G, *ND2* C4936T, and *ATP8* C8472T plus *ND2* C4960T). 3 patients had myopathy, global delay, and abnormal respiratory chain studies of unclear genetic etiology. 1 individual had severe mtDNA depletion in skeletal muscle of unknown genetic etiology. Non-mitochondrial diseases subsequently diagnosed in this cohort included central dopamine deficiency, Ulrich muscular dystrophy, myotonia congenita, *CPT II* deficiency, *SEPN1*-related myopathy, Fabry's disease, and Gitelman syndrome. 4 chromosomal abnormalities were diagnosed including *IL1RAPL2* deletion, *MEFC2* deletion, a three-way unbalanced translocation, and isochromosome Xp. **CONCLUSIONS**: The diagnosis of mitochondrial disease is a complex but navigable process. Retrospective review of a 2-year dedicated outpatient experience highlights the wide range of heterogeneous conditions that must be considered in patients for whom mitochondrial disease is suspected.

2106/T

Creation of a Mouse Model for Lowe Syndrome and Dent Disease 2 by Humanizing a Paralogous Modifier Gene. *R. Nussbaum[1,2], E. Chan[1], I. Bernardini[3], Y.-M. Kuo[1], W. Gahl[3], S. Bothwell[1].* 1) Medicine, UCSF, San Francisco, CA; 2) Institute for Human Genetics, UCSF, San Francisco, CA; 3) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD.

The Lowe OculoCerebroRenal syndrome (OCRL) is a pleiotropic X-linked human disorder characterized by congenital cataracts, cognitive disability, and proximal renal tubular dysfunction, particularly low molecular proteinuria and often aminoaciduria, phosphaturia and bicarbonaturia. OCRL is caused by loss-of-function mutations in the *OCRL* gene encoding Ocrl, a type II phosphatidylinositol bisphosphate 5-phosphatase. Mutations in *OCRL* can also cause a proximal tubular disorder known as Dent Disease type 2, in which the disease is limited to the proximal renal tubules. A first attempt to create a mouse model for OCRL/Dent 2 failed when we found that *Ocrl*-mice are unaffected. We reasoned that the disparate phenotype between humans and mice with loss-of-function mutations in *Ocrl*/*OCRL* resulted from differences in how the two organisms cope with loss of the enzyme rather than in differences between the two species in the function of the enzyme itself. We hypothesized that *Inpp5b* and *INPP5B*, which also encode a type II phosphoinositide 5-phosphatase in mice and humans, respectively, might underlie the disparate phenotype in the two species because (1) they are the closest paralogs to *Ocrl* and *OCRL* in the respective genomes of mice and humans, (2) *Inpp5b* has overlapping function in vivo with *Ocrl*, and (3) the two species differ in a number of important ways in how *INPP5B* and *Inpp5b* are expressed. We used a bacterial artificial chromosome containing *INPP5B* to create transgenic *Ocrl*-;*Inpp5b*-/-mice expressing *INPP5B*. All showed reduced post-natal growth, low molecular weight proteinuria, and aminoaciduria when hemizygous for the *INPP5B* insertion but not when homozygous for the insertion. Ophthalmological abnormalities were not present. We have created the first animal model for OCRL/Dent Disease 2 by humanizing a modifier paralog in mice carrying the mutant disease gene.

2107/T

Cytoskeletal alterations in the bladder from male mice with cystinuria. *A. Sahota[1], K. Johnson[2], M. Yang[1], A.O. Emmanuel[1], B. Zheng[1], J.G. Barone[2], L. Serrano[1], J.A. Tischfield[1].* 1) Dept Gen, Rutgers Univ, Piscataway, NJ; 2) Dept Surgery, UMDNJ-RWJMS, New Brunswick, NJ.

Background: There are numerous etiologies of bladder obstruction in humans, which mainly affects males. SLC3A1 encodes a subunit of the transporter system for cystine and dibasic amino acids. Bladders from Slc3a1 knockout male mice age >3 months have cystine stones, hypertrophy, and outlet obstruction, but only a small fraction of cystinuria females age >20 months form stones. These observations suggest that cystinuria male mice may be a good model for bladder obstruction. How obstruction leads to changes in the ultrastructure and physiology of bladder epithelia remains to be determined. We hypothesize that obstruction-induced stretch of the bladder may lead to alterations in the cytoskeleton. Keratins (KRTs) are a large group of intermediate filaments in the cytoplasm of epithelial cells, and several KRTs are epithelial cell lineage markers. Thus, analysis of KRT expression may allow identification of the specific epithelial cell types affected by or involved in bladder obstruction. **Methods:** We examined mRNA expression changes for several KRTs in bladders from 4-5 months old cystinuria and control mice by quantitative real time PCR and for KRTs 7, 14, and 19 as part of an epithelial-to-mesenchyme (EMT) specific PCR array. Frozen bladder sections were analyzed by immunofluorescence to identify the cell tyles expressing KRTs 14 and 17. **Results:** KRTs 5, 7, 8, 18, 19, and 20 were expressed at similar levels in cystinuria and control male mice. The expression of KRTs 14 and 17 was over 30 times higher in bladders from cystinuria male mice compared with cystinuria females or control mice, and over-expression of KRT 14 was confirmed in the EMT PCR array. KRT 14 expression was localized to the basal layer in bladder sections from cystinuria female mice, whereas in cystinuria male mice there was extensive proliferation of the epithelial layer and KRT expression was observed in the apical layer as well as in the submucosal layers. KRT 17 expression was localized to the apical region in cystinuria female mice, whereas expression in cystinuria male mice extended from the apical layer towards the basal layer. **Conclusions:** The dramatic increase in KRT 14 expression in cystinuria males suggests that cells of the basal layer may be involved in the EMT process and this may account for the hypertrophy and increased fibrosis seen in these mice. Changes in KRT 17 expression suggest a change in phenotype from differentiated apical cells to a less mature phenotype.

PCSK9: FROM GENE AND VARIANTS TO PROTEIN AND PLASMA LEVELS. *M. Abifadel[1,2], J.P. Rabès[1,3], M. Varret[1], ME. Samson- Bouma[1], E. Bruckert[1], M. Devillers[1], V. Carreau[4], L. Tosolini[1], M. Marduel[1], A. Marques[1], P. Couvert[4], D. Bonnefont-Rousselot[5], M. Guérin[4], A. Carrié[4], A. Prat[6], N. Seidah[6], C. Boileau[1,3].* 1) INSERM U781, Hospital Necker, APHP, Université Paris Descartes, Paris, France; 2) Faculté de Pharmacie, Université Saint-Joseph, Beirut, Lebanon; 3) Laboratoire de Biochimie et de Génétique moléculaire, hôpital Ambroise-Paré, APHP ; Université Versailles-Saint-Quentin-en-Yvelines, UFR médicale Paris-Ile-de-France-Ouest, Boulogne; 4) INSERM UMR S939, hôpital Pitié-Salpêtrière; 5) UF de biochimie des maladies métaboliques, hôpital Pitié-Salpêtrière, APHP, Paris, France; 6) Laboratory of Biochemical Neuroendocrinology, Clinical Research Institute of Montreal, Montreal, QC, Canada.

Hypercholesterolemia is one of the major causes of coronary heart disease (CHD). The genes encoding the low density lipoprotein receptor (LDLR) and its ligand apolipoprotein B (APOB) have been the two genes classically implicated in autosomal dominant hypercholesterolemia (ADH). Our discovery of the implication of PCSK9 in hypercholesterolemia by linkage analysis studies in ADH families with no mutation in the LDLR or in the APOB genes brought to light an unknown actor in cholesterol metabolism that has been extensively investigated since. Several PCSK9 variants have been identified, some of them are gain of function mutations causing hypercholesterolemia by a reduction of LDL receptor levels, while others are loss of function variants associated with a reduction of LDL-C levels and a decrease in the risk of CHD. PCSK9 is a secreted protein that represents now a major therapeutic target for the treatment of hypercholesterolemia and prevention of CHD. By studying further patients with hypercholesterolemia unrelated to the LDLR or the APOB genes, we have recently identified new variants of PCSK9 and studied the effect of these variants on the maturation of the enzyme. Furthermore, we measured PCSK9 concentration, by an ELISA method, in the plasma of patients with familial hypercholesterolemia carrying different mutations of PCSK9 especially the p.S127R, p.F216L, p.R218S mutations that we have already reported. These data further contribute to the characterization of PCSK9 variants and mutations and their impact in cholesterol diseases.

2109/T

Mitochondrial DNA mutations in mexican patients with diabetes mellitus type 2 and their relation with corporal composition and dietary habits. *C. Torres-Pedraza[1,3], J. Becerra-Contreras[1], H.R. Martinez-Ramirez[1], A. Sarralde-Delgado[1], M. Escalante-Pulido[1], K.P.T. Reddy[2], L. Sandoval-Ramirez[1,2].* 1) IMSS, Guadalajara, Mexico; 2) CUCS, Universidad de Guadalajara, Guadalajara, Mexico; 3) Universidad del Valle de Atemajac (UNIVA),Guadalajara, Mexico.

OBJETIVE: To compare the corporal composition and intake habits of diabetic mellitus type 2 patients with and without mutations in the mitochondrial DNA. METHODS: The sequence of 3108-3717 bp region of mtDNA was analyzed by capillary electrophoresis. Mitochondrial DNA was obtained from blood samples of twenty T2DM patients (eight female and twelve men). We applied a 24-hour recall, food frequency and made an anthropometric assessment; the anthropometric measures was performed according to the protocol of the International Society for the Advancement Kinanthropometry (ISAK), which was used a Harpenden calipers (British Indicators Ltd., LondonR) with a sensitivity of 0.1 mm and a constant pressure of 10 mm2, for the seven skinfold evaluation (triccipital, biccipital, subscapular, abdominal, supraspinal, abdominal, iliac crest of). The fat percentage was calculated using the equation of Durning and Womesley and weight by using a scale tanita BC50 model, the diameters were measured with anthropometer. Anthropometric evaluation was done with the help of a specialized software called BORIS. The patient was given food and drink diary which had to do for three days, and returned later. The reminder information 24 hours and the food diary were analyzed at the software nutripac. RESULTS: A new mutation C3393T was detected in one patient (5%) and seven patients presented polymorphisms (4/20 had T3552A, 1/20 had T3394C, 1/20 had C3448A and 1/20 had the T3335C and T3396C polymorphisms). Four patients had a healthy BMI, sixteen (16/20) had overweight and obesity, according to the parameters established by the American Dietetic Association. CONCLUSIONS: All patients had a high percentage of body fat. The calories intake by patients was above their total caloric requirements. All they consumed more than 7% saturated fat, exceeding this rate to three times. Only five individuals were within the recommendations of 50 to 60% of intake carbohydrates, the rest of patients exceeded this percentage, especially who those showing polymorphisms.

2110/T

RRM2B mtDNA Depletion Syndrome presenting with Pyruvate Dehydrogenase Deficiency. *L.A. Wolfe[1,2], J.J McGrath[2], L.J Wong[3], G.D Vladutui[4].* 1) Undiagnosed Diseases Program, NHGRI, Bethesda, MD; 2) Department of Genetics, Yale School of Medicine, New Haven, CT; 3) Baylor College of Medicine, Houston, TX; 4) Robert Guthrie Biochemical & Molecular Genetics Laboratory, Kaleida Health Laboratories & the University, Buffalo, NY.

Purpose: Describe clinical and biochemical features of a male infant presenting with failure to thrive and severe diarrhea in the neonatal period. Case review: A 2-week-old male born to consanguineous Hispanic parents after an uneventful pregnancy and delivery, presented at 2 weeks of age with failure to thrive and severe diarrhea was admitted to the hospital for further evaluation. Laboratory evaluation revealed normal acylcarnitine profile, urine organic acids, and CK. Plasma lactic acid (15 mmol/L, normal <2.2), and pyruvate (0.48 mmol/L, normal 0.03-0.10) were elevated with a mild increase of alanine (435.4 uM, normal 142-421). Due to a high L: P ratio (33), a mitochondrial electron transport chain (ETC) disorder was suspected. Common mtDNA point mutations and deletions were negative. Sequencing analysis of 5 genes (SUCLG1, DGUOK, POLG1, SUCLA2, TK2) responsible for mtDNA depletion, complex IV assembly genes (SURF1, SCO1, SCO2, COX 10), SDH subunits A-D, and complex I assembly genes (C6ORF66, NDUFA1) were all negative. Methods used: prospective evaluation and clinical biochemical testing. A novel hemizygous unclassified missense variant, c.677G>A (p. R226H) in the PDHA1 gene was detected. On muscle biopsy, abnormal mitochondria with proliferation were noted. Profound deficiencies in complexes IV and II-III were detected with reduced complexes I and I-III activities. Meanwhile, deficiency in pyruvate dehydrogenase complex (PDC) activity was detected in blood lymphocytes. The patient was started on carnitine and ubiquinol, which improved his diarrhea, and he was discharged home. Subsequently, the patient's clinical condition continued to decline and he became ventilator dependent. MtDNA depletion syndrome was suspected and sequence analysis of the RRM2B gene, encoding a newly discovered p53-inducible ribonucleoside reductase subunit was performed. A homozygous c.109_110delAA (p. K37EfsX14) mutation was revealed. Results: Although an ETC deficiency may be secondary to the PDC defect, it is not known if mtDNA depletion would cause PDC deficiency. Thus, the clinical significance of p. R226H in PDHA1 remains unclear. This case underscores the complications in diagnosing mitochondrial ETC disorders.

2111/T

Novel Mutation in the Human Sucrase-Isomaltase Gene. *Z. Wu, S. Uhrich, C.R. Scott.* Department of Pediatrics, University of Washington, Seattle, WA 98195-6320.

Sucrase-isomaltase (SI) enzyme complex is a heterodimeric membrane-bound glycoprotein that resides on the intestinal brush border. It is comprised of two homologous subunits, sucrase and isomaltase. This enzyme is implicated in the digestion of dietary starch and disaccharides. Congenital deficiency of the SI complex causes a disorder resulting in maldigestion and malabsorption. This disorder is called congenital sucrase-isomaltase deficiency (CSID). The clinical phenotype is genetically transmitted as autosomal recessive disorder. To assist in understanding the genetic basis of CSID and to correlate genotype to phenotypic expression, we have established a diagnostic procedure that involves nucleotide sequencing of the SI gene. The SI gene is located on chromosome 3 (3q25.2-q26.2), spans about 100 kb, contains 48 exons and encodes a protein containing 1827 amino acids. Amino acids from 1 to 1007 form the isomaltase domain, whereas from 1008 to 1827 form the sucrase domain. Mutations occurring in any regions of the SI gene may have effects on both enzyme activities. We have examined DNA samples from eight patients who were diagnosed with CSID by bowel biopsy or positive hydrogen breath test. 18 molecular variations within the SI gene were identified in these patients that are interpreted to be responsible for CSID. By comparing our results with the mutation database (http://www.hgmd.cf.ac.uk) and SNP database (http://genome.ucsc.edu), 8 new variations are identified: one deletion (c.545delT), one presumed splicing error (IVS10 -2a>g) and six missense mutations (1) Q307X (c.975C®T), (2) E613X (c.1893G®T), (3) L741P (c.2278T®C), (4) R1124X (c.3427C®T), (5) I1378S (c.4189T®G) and (6) Y1417X (c.4307T®G). It may now be cost effective to use sequencing of the SI gene, rather than anesthesia, intestinal biopsy and enzyme assays, for confirmation of the diagnosis of CSID.

2112/T

Genetic techniques for newborn screening for cystinosis. *T. Vilboux[1], M.R. Erdos[2], R. Kleta[3], J.Z. Balog[4], I. Bernardini[1], M. Huizing[1], W.A. Gahl[1,4].* 1) Medical Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 2) Genome Technology Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 3) Centre for Nephrology, University College London, London, UK; 4) Office of the Clinical Director, Medical Genetics Branch, NIH, Bethesda, MD.

Cystinosis is an autosomal recessive disease characterized by lysosomal accumulation of cystine due to a defective lysosomal cystine transporter, cystinosin. Cystine deposits in various organs lead to renal failure, hypothyroidism, insulin-dependent diabetes, muscle deterioration, swallowing difficulty, retinal blindness, and cerebral involvement. The prevalence of cystinosis approximates 1/160 000. The causative gene, *CTNS* (12 exons), located on 17p13, encodes cystinosin, a 367 amino acid lysosomal membrane transport protein. The most frequent mutation is a 57-kb deletion detected in 60% to 70% of patients originating from northern Europe. Over 60 other *CTNS* mutations have now been reported worldwide. Prenatal diagnosis can be obtained by genetic analysis in families with a previous affected child, or by measuring 35S-labeled cystine incorporation into fibroblasts cultured from amniotic fluid or trophoblastic cell samples. An effective treatment for cystinosis is oral cysteamine, which lowers lysosomal cystine concentrations, thereby slowing the progression to renal failure and preventing non-renal complications. For efficient treatment, cysteamine should be given as early in life as possible, so early diagnosis of the disease is invaluable. We explored possibilities to include a genetic test in newborn screening programs, evaluating molecular methods. Specifically, from a newborn blood spot, the technique should be able to discriminate all the known *CTNS* mutations involved in infantile cystinosis and be able to differentiate carriers from patients. In addition, the technique should be rapid and amenable to high throughput. Two approaches are considered: the Luminex beads-based method (XMAP) and MALDI-TOF mass spectrometry from Sequenom (Iplex). Pilot experiments have been designed to show effectiveness of these techniques. Our cystinosis patient cohort is comprised of about 250 different DNA samples. Each sample was genotyped for the 57kb deletion and every non-homozygous deleted sample was sequenced for other mutations. We are using this large group of patients' DNA as templates for these techniques. So far, newborn screening tests based on molecular grounds are not yet available or implemented. Therefore, cystinosis will serve as a prototype disease for proof of principle for newborn screening on molecular grounds, after which it is likely that screening for other genetic diseases will follow.

2113/T

Beyond Genotype-phenotype Correlations In Lesch-Nyhan Disease. *R. Fu, S. Radhika, H.A. Jinnah.* Department of Neurology, Emory University, Atlanta, GA.

Lesch-Nyhan disease (LND) is a neurogenetic disorder of purine metabolism, which results from deficiency of the purine salvage enzyme, hypoxanthine-guanine phosphoribosyltransferase (HGprt). Clinically the disorder is characterized by overproduction of uric acid, motor disability, intellectual impairment, and self-injurious behavior. This enzyme has two functions, recycling both hypoxanthine and guanine into purine nucleotide pools. A mutation database for HGprt shows that the locations and types of mutations associated with human diseases are heterogeneous, with only limited genotype-phenotype correlations. However, prior studies with relatively small number of patient samples have shown a correlation between residual enzyme activity and clinical severity, but which of the two functions of HGprt may be most directly relevant to different aspects of the clinical phenotype remains uncertain. It is possible that loss of only hypoxanthine recycling or guanine recycling is responsible for the entire clinical phenotype, or for specific elements of the clinical phenotype. To explore a relationship between substrate recycling and clinical severity, 15 clinically relevant HGprt mutants were constructed in vitro and biochemically compared with normal HGprt. The mutants were selected based on clinical severity, recurrence among unrelated patients, and location of the mutation at the active site. All enzymes were engineered by site-directed mutagenesis with an amino-terminal his-tag, expressed and purified from *Escherichia coli*, and characterized in vitro with varying substrate concentrations to define k_{cat}, K_m and k_{cat}/K_m values for all substrates. The results show that each of these parameters are affected independently by different mutations and provide a solid framework to understand the correlation of substrate specificity with different aspects of the clinical phonotype. The results also provide an essential next step to a better understanding of pathogenesis that goes beyond simple genotype-phenotype correlations.

2114/T

Dilated cardiomyopathy associated with HMG-CoA Lyase deficiency in an adolescent: Does Carnitine supplementation prevent cardiomyopathy? *A. Saronwala[1], B.P. Abraham[2], C. Steigman[3], S.G. Kahler[1], E.A. Frazier[2], U. Dyamenahalli[2].* 1) Genetics (Pediatrics), University of Arkansas for Medical Sciences, Little Rock, AR; 2) Cardiology (Pediatrics), University of Arkansas for Medical Sciences, Little Rock, AR; 3) Pathology, University of Arkansas for Medical Sciences, Little Rock, AR.

3-Hydroxy-3-Methylglutaryl-CoA (HMG-CoA) lyase deficiency is a rare autosomal recessive inborn error of metabolism characterized by impaired leucine catabolism and ketogenesis. HMG-CoA lyase deficiency typically presents in the neonatal period and occasionally in early infancy or childhood with metabolic acidosis and hypo-ketotic hypoglycemia triggered by fasting or excessive protein intake. Cardiomyopathy has been reported in two patients, an infant and a 23 year old male. We report a patient with HMG-CoA lyase deficiency who was diagnosed with dilated cardiomyopathy in the adolescent period. At age 14 he presented with a two week history of cough and shortness of breath. He had frequent premature ventricular ectopic beats, moderate cardiomegaly and pulmonary edema, left ventricular hypertrophy and non-specific T-wave abnormality, and severely dilated left ventricle with severe reduction of left ventricular systolic function. Review of chest X-rays revealed slowly progressive cardiomegaly during the prior two years. He was hospitalized for intensive treatment, and then maintained on oral medications for congestive heart failure. After seven months of poor but stable cardiac function, he died suddenly during a hospitalization for metabolic decompensation. He was diagnosed with HMG-CoA lyase deficiency as an infant and was on a low-protein diet and L-carnitine supplement. This was given consistently during his first several years. He may not have been compliant in taking carnitine regularly during the several months before the onset of heart failure. All recorded plasma carnitine levels were normal. Autopsy revealed a firm small liver with a nutmeg-like pattern, small kidneys and brain, and marked cardiomegaly. Further studies are pending. Carnitine supplementation in HMG - CoA lyase deficiency is intended to replace carnitine lost as conjugates of hydroxymethylglutaric acid and related compounds, and to maintain a favorable free carnitine/acylcarnitine ratio. Carnitine is standard therapy in other organic acidemias, like propionic acidemia (PA). Cardiomyopathy has occurred several PA patients, many of whom have been on carnitine supplementation, and whose heart failure was not accompanied by systemic metabolic decompensation. Currently, there are no standard cardiac surveillance protocols for organic acidemias. Careful monitoring and prospective studies will be needed to understand the mechanisms involved.

Mutation analysis of peroxisome biogenesis disorders (PBD) using targeted massively parallel sequencing. *S. Levesque[1], W. Yang Yik[2], P. Marquis[3], S. Steinberg[4], J. Hacia[2], K. Dewar[3], N. Braverman[1].* 1) Dept. of Human Genetics, Montreal Children's Hospital Research Institute, McGill University, Montreal, Quebec, Canada; 2) Keck School of Medicine, University of Southern California, California, USA; 3) Genome Quebec Innovation Center, McGill University, Montreal, Quebec, Canada; 4) Dept. of Neurogenetics and Neurology, Kennedy-Krieger Institute and the John Hopkins Medical Center, Baltimore, Maryland, USA.

Genetic heterogeneity in the PBD precludes the identification of mutations with reasonable cost using Sanger sequencing in diagnostic DNA labs. Currently, sequencing of selected exons of a subset of PEX genes (PEX gene screen) enables detection of both mutations in 54% of patients. Although complementation studies can identify the defective gene, they remain time-consuming and labor intensive. Massively parallel sequencing technologies can now provide accurate sequences at high throughput with low cost per base, and could permit rapid identification of mutations in PBD patients. **Methods:** In a pilot experiment, singleplex PCR was performed on one patient DNA sample with unknown mutations. 58 amplicons were designed to cover all exons and splice site junctions of 6 PEX genes implicated in >96% of PBD. PCR products were pooled in equimolar quantity, tailed with sequencing primers and a unique barcode by a PCR-based protocol, and finally sequenced using the Roche/454 GS FLX Titanium. To assess sensitivity and specificity for different types of mutations, 39 unique mutations were amplified from multiple patients, pooled and processed as above. NextGENe® software was used for SNP/indel discovery, using an allele frequency cut off of 15% and a minimum of 3 reads for positive calls. **Results:** 93.4% of the sequence reads mapped to the selected genes, and only 5% of amplicons failed to produce sequencing reads. A homozygous non-synonymous mutation was found in the single patient. Sequence analysis of the pooled sample (mean coverage of 343 reads/amplicon) yielded a total of 119 variations, of which 34 were the expected mutations. Sanger traces are currently being reviewed to assess the specificity. Sensitivity was dependent on the mutation type. The detection rate was: 16/17 (94%) for SNPs, 10/13 (77%) for indel of £3bp and 8/9 (89%) for indel >3bp. Large indels up to 91bp were successfully detected given the long GS FLX Titanium reads. **Conclusion:** Our preliminary results showed that mutations in PBD patients can be identified with good sensitivity, including large indels. Further optimisation of coverage is needed to increase sensitivity and an algorithm will be developed to prioritize mutation confirmation. The panel of genes is being increased to all PEX genes and peroxisome single enzymes defects with overlapping phenotypes. This will allow efficient molecular diagnosis of most PBD patients and enable mutations detection in PEX genes not yet implicated in PBD.

2116/T

Pilot Study of Newborn Screening for Adrenoleukodystrophy in Maryland. *G. Raymond[1], W. Hubbard[2], K. Gibbons[1], A. Gifford[1], R. Jones[1], A. Liu[1], A. Kline[3], C. Theda[1,4], P. Donohue[2], W. Golden[2], S. Panny[5], F. Gulamali-Majid[5], A. Moser[1].* 1) Dept Neurogenetics, Kennedy Krieger Inst, Baltimore, MD; 2) Johns Hopkins Hospital, Baltimore, MD; 3) Greater Baltimore Medical Center, Towson, MD; 4) Frederick Memorial Hospital, Frederick, MD; 5) Maryland Department of Health and Mental Hygiene, Baltimore, MD.

Peroxisomal disorders are a genetically diverse group of conditions characterized by biochemical disruption of organelle-specific metabolic pathways. One of the major peroxisomal pathways is beta oxidation of long chain fatty acids and the most common disease involving this pathway is X-linked adrenoleukodystrophy (ALD) resulting from mutations in the ABCD1 gene. ALD has an incidence of approximately 1:17,000 and is characterized by adrenal and neurologic manifestations. Over 90% of affected males will develop primary adrenal insufficiency and 35% of boys will develop inflammatory cerebral demyelination that will result in severe disability and death before the age of ten. Newborn screening through tandem mass spectroscopy allows the detection and intervention in many genetic disorders. We have recently developed a technique that allows diagnosis of peroxisomal disorders using LC-MS/MS from newborn blood spots on filter paper and have demonstrated that the detection of lysophosphatidyl choline (lysoPC) conjugated to very long chain fatty acids is highly accurate and sensitive. We proposed to study the specificity of the testing by evaluating 5000 samples from three hospitals in Maryland. Consent was obtained from the parents for additional testing of the sample. Newborn cards were collected and processed in the standard fashion and sent to the Maryland State laboratory where a punch was obtained and then run on tandem MS to detect the conjugated lysoPC fraction. A follow up protocol was developed for the confirmation of abnormalities found on testing. To date we have consented over 4000 individuals and analyzed 3200 samples without a false positive and to date no affected individuals. While it is presently not certain what effect newborn screening for ALD will have, it is expected that the accurate detection and monitoring of at risk individuals will improve their care and outcomes.

Pharmacokinetics and pharmacodynamics of migalastat, a pharmacological chaperone of α-galactosidase A, in healthy volunteers. *D. Greene, A. Bragat, M. Adera, P. Boudes.* Amicus Therapeutics, Clinical Research, Cranbury, NJ 08512.

Background: Fabry disease is a lysosomal storage disorder caused by α-galactosidase A (α-Gal A) enzyme deficiency. 1 Deoxygalactonojirinmycin (DGJ, Amigal, migalastat hydrochloride, AT1001) is currently being evaluated as an oral therapy to treat Fabry disease in patients with responsive mutations in the gene that encodes the lysosomal enzyme α-Gal A. DGJ acts as a pharmacological chaperone for α-Gal A and has been shown to increase α-Gal A activity in vitro, in mouse models of Fabry disease and in Fabry patients. **Objective:** Characterize the pharmacokinetics of DGJ and evaluate the relationship between dose and the effect of DGJ on α-Gal A activity in healthy volunteers. **Methods:** Healthy volunteers were administered single oral doses of DGJ ranging from 25 to 2000 mg in the fasted state; single 100 mg oral doses of DGJ in the fasting state and immediately after a meal; and doses of 50 mg and 150 mg DGJ given twice daily (BID) for 7 days. DGJ concentrations in plasma and urine were measured by liquid chromatography-mass spectrometry. α-Gal A activity in WBC lysates from subjects on the BID regimen was measured using a fluorimetric assay that quantifies catalysis of a surrogate substrate, 4-methylumbelliferone. **Results:** DGJ was generally safe and well tolerated. Bioavailability was high (≥50%). Co-administration of DGJ with food resulted in a 40% reduction in bioavailability. Peak plasma concentrations were measured 2-3 hours after dosing. DGJ plasma levels increased proportionally with dose up to 1250 mg. DGJ was eliminated primarily unchanged by the kidney with an initial plasma half-life of approximately 4 hours. No accumulation was observed after seven days of BID dosing. Seven days of 50 mg and 150 mg twice-daily DGJ resulted in a dose-related increase in WBC α-Gal A activity of up to 1.9-fold of baseline. **Conclusion:** DGJ exhibits favorable pharmacokinetic properties. Renal elimination of DGJ is expected to result in elevated drug concentrations in the kidney, an organ significantly affected by Fabry disease. The DGJ-associated increases of α-Gal A activity in healthy volunteers is consistent with findings in the Fabry mouse model and in Fabry patients with responsive α-Gal A mutations. DGJ should be administered in the fasting state to optimize absorption of the drug. The safety, pharmacokinetic and pharmacodynamic data support the evaluation of DGJ as a potential oral agent for treating Fabry disease in patients with responsive mutations.

2118/T

Association of Methylenetetrahydrofolate reductase genotypes with diabetes mellitus. *K. Nakatani, K. Noma, K. Yasuda, J. Nishioka, T. Nobori.* Molec & Lab Med, Mie Univ Grad Sch Med, Tsu, Japan.

[Objective] Homocysteine (Hcy) is a sulfur-containing amino acid formed during the metabolism of methionine. Elevated levels of Hcy are leading to impaired endothelial through induction of the oxidative stress. The oxidative stress has also been shown to impair insulin action and secretion. Methylenetetrahydrofolate reductase (MTHFR) is an enzyme of to convert Hcy to methionine and its activity is closely related with Hcy levels. Single nucleotide polymorphism (SNP) of MTHFR 677C>T, which is located within the enzyme catalytic domain, has association with MTHFR activity and levels of Hcy. In this study, we investigated association between Hcy, glucose metabolism and MTHFR genotypes. Moreover, whether MTHFR genotypes could be a marker of impaired glucose metabolism. [Subjects and Methods] 451 Japanese volunteers (245 males and 206 females) were recruited in the hospital for medical check. After obtaining the written informed consent of each subject, anthropometry, 75-g oral glucose tolerance test (OGTT), blood pressure determination and biochemical examination were performed early in the morning after fasting overnight. SNP677 of MTHFR gene was genotyped by the single primer extension method. Insulin resistance was assessed using the homeostasis model assessment for insulin resistance (HOMA-R). [Results] (1) Plasma Hcy levels showed significant gender difference (male, female: 10.7±3.9 μmol/L, 8.6±2.0 μmol/L) and further analysis was performed within each gender. (2) Plasma Hcy levels were significantly associated with MTHFR 677TT genotype in both male and female, but no association with adiponectin levels which were associated with insulin resistance. male. (3)Of male subjects with each MTHFR genotypes, no differences were observed in OGTT. However, female subjects with MTHFR 677TT genotype showed significantly elevated plasma glucose after glucose loading in comparison with other genotypes. [Discussion]Insulin resistance was slightly influenced by plasma Hcy concentration but not by MTHFR genotypes. However, MTHFR genotypes were significantly associated with plasma Hcy in both female and male. Moreover, MTHFR genotypes were significantly associated with impaired glucose tolerance in female. Taken together, Hcy could affect glucose metabolism through impaired insulin secretion in female. In conclusion, MTHFR genotype could be a predictive marker of impaired glucose tolerance in female.

2119/T

Urinary Exosomes: Biomarkers for Kidney Disease. *D. Maynard[1], W. Westbroek[1], W. Gahl[1], M. Gunay-Aygun[1,2].* 1) Section on Human Biochemical Genetics, Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Office of Rare Disease Research, Office of the Director, NIH, Bethesda, MD.

Oral-facial-digital-syndrome type 1 (OFD-1) is an X-linked, male lethal ciliopathy, characterized by malformations of the face, oral cavity and digits and polycystic kidney disease (PKD). Renal cysts in OFD-1 generally originate from the glomeruli; cysts in autosomal dominant polycystic kidney disease (ADPKD) develop from any part of the nephron. Polarity in kidney epithelial cells is essential to the integrity and function of the kidney, since insertion of specific transporters and other proteins into apical membranes lining the renal tubule lumen or basal domains adjacent to the interstitium is critical. Studies of ADPKD renal tubule epithilia demonstrate that defects in membrane polarity affect specific sets of proteins involved in sodium transport and in EGF signal transduction. OFD-1 renal cells have not been studied.

Exosomes are 50-90 nm vesicles containing discrete packets of cytosol and are released by many cell types. Exosome membranes have the same orientation as the plasma membrane. Study of urinary exosomes provides a noninvasive means for detection and analysis of protein-expression/trafficking changes in renal tubule cells. Exosomes from OFD-1 and other PKD patients may contain a different contingent of membrane and/or cytosolic proteins due to protein mis-targeting/polarity defects in renal epithelial cells. We isolated exosomes from the urines of OFD-1 and other ciliopathy patients with PKD and from controls. We removed Tamm-Horsfall protein from the exosome samples and demonstrated by electron microscopy that this technique does not alter their morphology. We used proteomics combined with mass spectrometry to analyze the protein content of the exosomes. Preliminary proteomic results from OFD-1 and control urine samples found known exosome marker proteins (CD63, CD81, and CD9) as well as VPS (TSG101, Alix, and VPS28) proteins involved in multivesicular body (MVB) targeting and biogenesis. Proteins associated with hypertension and PKD or other kidney diseases (aquaporin-2, polycystin-1, -2, podocin, and neprilysin) were also found. These findings establish urinary exosomes as a system that reflects the contingent of proteins present in OFD-1 cells, and that can be investigated in other kidney disorders.

2120/T

Novel therapies for glycogen storage disease type III. *B. Sun[1], K. Boyette[1], B.L. Thurberg[2], P.S. Kishnani[1].* 1) Pediatrics, Duke University, Durham, NC; 2) Genzyme Corporation, Framingham, MA.

Mutations in the glycogen debranching enzyme gene cause glycogen storage disease type III (GSD III), resulting in accumulation of abnormal cytoplasmic glycogen in liver and muscle. Currently, other than symptomatic management of hypoglycemia there is no effective treatment for this disease. In this study, we evaluated the feasibility of using two FDA-approved therapies for other diseases to treat GSD III. 1) Enzyme replacement therapy with recombinant human acid alpha-glucosidase (rhGAA) is an approved therapy for Pompe disease. Based on the role of lysosomal glycogen degradation in general glycogen metabolism, we hypothesize that enhanced GAA enzyme activity will lead to rapid lysosomal glycogen clearance, increase glycogen shuffling from cytoplasm into lysosomes, thus reduce overall cytoplasmic glycogen levels in GSD III. 2) Rapamycin is a specific inhibitor of the mammalian target of rapamycin (mTOR) with clinical applications. mTOR is a key regulator of cell growth, protein synthesis, and glucose and lipid metabolism by interacting with a number of signaling pathways. We hypothesize that inhibition of mTOR signaling by rapamycin will alleviate glycogen accumulation in GSD III by reducing glycogen synthesis and glucose uptake. Primary muscle cultures were used as a cellular model of GSD III to test our hypotheses. Myoblasts were isolated from two GSD IIIa patient muscle biopsies. Pathology of the muscle biopsies was examined by light and electronic microscopy to confirm abnormal glycogen accumulation. Differentiation of myoblasts into mature myotubes was induced in low-serum medium. Fully differentiated GSD III myotubes were treated for 48 hours with 100 μg of rhGAA or 30 nM rapamycin in the culture medium. GAA enzyme activity and glycogen content were analyzed biochemically in these cells. rhGAA reduced glycogen level by 48% and 17% respectively, in cells from the two patients. In contrast, rapamycin reduced glycogen content by 50% and 29% respectively, in the same two patient cells accompanied by increased GAA enzyme activity. We next profiled the expression of 84 key genes involved in glucose and glycogen metabolism pathways using RT-PCR array after rapamycin treatment. The differential expression of some genes was further confirmed by Western blot analysis. In summary, rhGAA and rapamycin significantly reduced glycogen accumulation in GSD III muscle cells. These approaches have great potential for immediate clinical application for GSD III.

Novel quantitative virtual microscopy-based method to evaluate GL-3 inclusions in renal peritubular capillaries in patients with Fabry disease. *L. Barisoni[1], R. Colvin[2], C. Jennette[3], R. Gordon[4], J. Castelli[5], S. Sitaraman[5], P. Boudes[5].* 1) Department of Pathology, New York University School of Medicine, New York, NY; 2) Harvard Medical School, Massachusetts General Hospital, Boston, MA; 3) Department of Pathology and Laboratory Medicine, University of North Carolina, Chapel Hill, NC; 4) Department of Pathology, Mount Sinai School of Medicine, New York, NY; 5) Amicus Therapeutics, Cranbury, NJ.

INTRODUCTION & OBJECTIVES: Renal failure is a major cause of morbidity and mortality in patients with Fabry disease (FD), an X-linked disorder characterized by accumulation of globotriaosylceramide (GL-3) in different tissues. Levels of GL-3 cytoplasmic inclusions in peritubular capillaries (PTCs) of renal biopsies are considered the most useful pathologic measure of therapeutic efficacy. Previous trials of enzyme replacement therapy used a semi-quantitative light microscopy (LM) approach to measure GL-3 inclusions in PTCs; however, limitations in quantifying low levels of GL-3 using this method were identified. Here we describe a novel virtual microscopy (VM) quantitative method to measure GL-3 inclusions in PTCs. METHODS: Renal biopsies were collected from 17 patients with variable FD severity enrolled in Phase 2 studies of AT1001, a pharmacological chaperone in clinical development for the treatment of FD. Biopsy samples were scanned at 100X magnification into whole slide digital images to enable virtual annotation of PTCs and scoring of GL-3 inclusions by three pathologists. For each digitally-imaged biopsy sample, a minimum of 50 PTCs were annotated by one pathologist. The number of GL-3 inclusions within the cytoplasm of each annotated PTC was recorded by the other two pathologists using identical duplicates of the annotated virtual images. The final score for each biopsy sample was calculated as the average number of GL-3 inclusions per PTC. Inter-reader variability was assessed using the method of Bland and Altman. RESULTS: Using the published, semi-quantitative LM method, two pathologists scored 4/17 and 7/17 pre-treatment samples as “0” (using a scale from 0 to 3+), making it difficult to assess the effect of therapeutic interventions. Using the new quantitative VM method, GL-3 inclusions were detected in all samples tested, and the average number of GL-3 inclusions per PTC was calculated. Matched-pairs analysis of scores showed no evidence of systematic bias and indicated low inter-reader variability. CONCLUSIONS: The VM-based quantitative scoring system improves sensitivity of measuring GL-3 inclusions in PTCs. Additional advantages include the ability to annotate images for review, allow multiple pathologists to score the same slides and inclusions from remote locations, and create an auditable archive of samples for clinical trials.

2122/W

Progressive hearing loss in a knock-in mouse model for γ-actin related deafness. *M.C. Drummond[1], M. Zhu[2], I.A. Belyantseva[3], K. Halsey[4], D.F. Dolan[4], S.A. Camper[5], K.H. Friderici[1,6].* 1) Microbiology and Molecular Genetics, Michigan State University, East Lansing, MI; 2) Department of Genetics, Harvard Medical School, Boston, MA; 3) Section on Human Genetics, NIDCD, NIH, Rockville, MD; 4) Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI; 5) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 6) Department of Pediatrics and Human Development, Michigan State University, East Lansing, MI.

Ten dominant missense mutations in γ-actin (*ACTG1*) have been reported as the cause of hearing loss in DFNA20 families. Although the mutations are located in different functional domains of γ-actin, the end result is a progressive form of non-syndromic sensorineural hearing loss beginning in the high frequencies with an onset in the second to third decade of life. This shared phenotype is indicative of a common functional deficit in mutant γ-actin protein function (Zhu *et al* 2003). To address questions regarding the effects of these mutations on the structure and function of the inner ear and whether these mutations cause hearing loss via a loss of function versus a dominant negative mode of action, we generated a knock-in mouse model for the p.P264L mutation. Mice harboring the p.P264L substitution of ACTG1 in both the heterozygous and homozygous state are born at the expected Mendelian ratio, are viable, and do not have noticeable vestibular deficits. Mice homozygous for the p.P264L allele (normal level of expression) exhibit a high frequency loss by 4-5 weeks and nearly complete hearing loss by 6-7 weeks of age. In the organ of Corti, the hearing loss manifests by a loss of inner and outer hair cells with a base to apical progression. Morphologically, the outer hair cell loss is preceded by degeneration of the two shorter rows of stereocilia. Mice homozygous for a p.P264L allele that expresses only ~20% of the mutant protein exhibit a moderate threshold shift at 6 weeks of age and a similar but less severe phenotype of stereocilia degeneration. Compared to the previously characterized Actg1-null mice which have adult-onset progressive deafness, reduced viability and muscular myopathy (Belyantseva *et al* 2009), the p.P264L mutation produces fewer pleiotropic effects and a profound deafness by 6-7 weeks of age. Taken together, our data suggest a dosage-dependent dominant negative mode of action for p.P264L.

2123/W

Comparison of hearing and vestibular deficits in the *Coch*$^{G88E/G88E}$ and the *Coch*$^{-/-}$ mouse models and correlation with DFNA9 hearing and balance disorder. *N.G. Robertson[1], S.M. Jones[2], S. Given[3], A.B.S. Giersch[1], C.C. Morton[1].* 1) Dept Ob/Gyn & Pathology, BWH & Harvard Medical School, Boston, MA; 2) Dept of Communication Sciences and Disorders, East Carolina University, Greenville, NC; 3) Brody School of Medicine, East Carolina University, Greenville, NC.

Two mouse models have been developed to study the late-onset, progressive, sensorineural hearing loss and vestibular dysfunction known as DFNA9. This disorder results from missense and in-frame deletion mutations in *COCH* (coagulation factor C homology), encoding cochlin, the most abundantly detected protein in the inner ear. We have performed hearing and vestibular analyses by auditory brainstem response (ABR) and vestibular-evoked potential (VsEP) testing of *Coch*$^{G88E/G88E}$ (knock-in) and *Coch*$^{-/-}$ (knock-out) mouse models. In both, at 21 months of age, ABR thresholds were substantially elevated, with all frequencies affected in the *Coch*$^{G88E/G88E}$, but only at the highest frequency in the *Coch*$^{-/-}$ mouse model. Four of 8 *Coch*$^{G88E/G88E}$ mice, and 9 of 11 *Coch*$^{-/-}$ mice had absent ABRs. Interestingly, homozygous *Coch*$^{-/-}$ mice, but not the heterozygotes showed elevation of ABR thresholds, revealing that haploinsufficiency of *Coch* does not appear to affect hearing. In contrast, the heterozygotes of the knock-in mouse model *(Coch*$^{G88E/+}$*)* show ABR threshold elevations similar to that of the homozygotes (*Coch*$^{G88E/G88E}$), an observation in agreement with the autosomal dominant mode of inheritance for DFNA9. Vestibular testing showed elevated VsEP thresholds in *Coch*$^{-/-}$ mice at 13 and 21 months, the two ages tested. For the *Coch*$^{G88E/G88E}$ mice, VsEP thresholds were increased as early as 7 months of age but not at 5 months. These results indicate that in both mouse models, vestibular function is compromised before cochlear function. Analysis and comparison of hearing and vestibular function in these two DFNA9 mouse models, where deficits occur at such an advanced age, provide insight into the pathology of DFNA9 and age-related hearing loss and vestibular dysfunction as well as an opportunity to investigate potential interventional therapies.

2124/W

Sox10 BAC transgenic mouse modeling a complex neurocristopathy, PCWH. *K. Inoue[1], N. Aoyagi-Inoue[1], Y. Itoh[1], Y. Inoue[2], Y. Matsuda[3], M. Inagaki[3], T. Inoue[2], Y. Goto[1], S. Kohsaka[5], C. Akazawa[4].* 1) Dept MR & BD Res, Natl Inst Neurosci, NCNP, Kodaira, Japan; 2) Dept Biochem & Cell Biol, Natl Inst Neurosci, NCNP, Kodaira, Japan; 3) Dept Developmental Disorders,Natl Inst Mental Health, NCNP, Kodaira, Japan; 4) Tokyo Med & Dent Univ, Tokyo, Japan; 5) Natl Inst Neurosci, NCNP, Kodaira, Japan.

SOX10 is a transcription factor that is essential for the neural crest development and the myelin formation both in the central and peripheral nerve systems (CNS and PNS). SOX10 mutations are associated with two distinct neurocristopathies in human, i.e., Waardenburg-Hirschsprung disease (WS4) and peripheral demyelinating neuropathy, central dysmyelinating leukodystrophy, Waardenburg syndrome and Hirschsprung disease (PCWH). PCWH shows more complex and severe neurological phenotype. Clinical and molecular findings suggested that WS4 is caused by haploinsufficiency of SOX10, while PCWH is predicted to result from SOX10 acting as either dominant-negative or gain-of-function allele. Although model animals are available for WS4, no animal models for PCWH are currently present. To determine the molecular mechanisms for PCWH in vivo, we generated BAC-transgenic mice (Tg) carrying a PCWH-causing mutant Sox10. In addition to the circling behavior, hypopigmented coat color, neurosensory deafness, and abnormal enlargement of colon, all of which are characteristics of WS4, the Tg mice also showed abnormal motor coordination, suggestive of neurological abnormalities. Microscopic examinations in the CNS and PNS showed relatively normal migration and differentiation of oligodendrocytes and Schwann cells, but apparently delayed myelination in Tg mice. These findings suggested that the mutant Sox10 Tg mice mimic phenotypes observed in human patients with PCWH and thus serve as a model for PCWH.

2125/W

Alterations in cognition, affect, and neuromotor function implicate roles for *GTF2I* and *GTF2IRD1* in the cognitive and behavioural profile of Williams-Beuren syndrome. *E. Lam[1], E.J. Young[1], L.R. Osborne[1,2].* 1) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 2) Departments of Medicine and Molecular Genetics, University of Toronto, Toronto, Ontario, Canada.

Williams-Beuren syndrome (WBS) is a neurodevelopmental disorder that is associated with mild to moderate intellectual disability (average IQ 55 to 60) and relatively preserved language capabilities but extremely poor visuospatial and math skills. People with WBS are described as over-friendly with a lack of many normal social boundaries, but they also have increased levels of anxiety and specific phobias. WBS is caused by the deletion of approximately 1.55 million nucleotides on a single copy of human chromosome 7q11.23, resulting in the loss of over 25 genes, however, the specific genes that cause the neurological symptoms have yet to be identified. Studies of individuals with atypical deletions of the WBS region suggest that GTF2IRD1 and GTF2I may be involved in many neurological features of the disorder. We previously generated *Gtf2ird1*$^{-/-}$ mice and showed that they have behavioural features similar to the lack of inhibition seen in people with WBS. We have now generated a *Gtf2i*$^{+/-}$ mouse model and a combined-*Gtf2ird1/Gtf2i*-deletion (*Gtf*$^{+/del}$) mouse model where the genomic sequence of both genes has been deleted, to examine the phenotypic effects of hemizygosity for these two genes, either alone or in combination. In a test of spatial learning and memory using the Morris water maze, no significant differences between wildtype and mutant mice were found. The novel object recognition task, a measure of entorhinal cortical function, revealed that *Gtf2i*$^{+/-}$ and *Gtf*$^{+/del}$ mice have impairments in long-term recognition memory. Thus, deficiency of GTF2I protein alters cortically-encoded object memory but not hippocampal spatial memory. Female *Gtf*$^{+/del}$ mice also showed deficits in associative fear conditioned learning and memory, implicating a dysfunction of the amygdala that is consistent with the reduced amygdala activation observed in WBS patients. In rotarod performance, which provides an index of cerebellar-dependent neuromotor function, both *Gtf2i*$^{+/-}$ and *Gtf*$^{+/del}$ animals exhibited a decreased latency to fall as well as deficits in motor learning acquisition. Collectively, these results suggest that hemizygosity for both *Gtf2i* and *Gtf2ird1* affect aspects of cognition and behaviour. It is likely that these genes both contribute to the cognitive, affective, and motor impairments observed in WBS individuals. Additional analyses will help to determine how these proteins effect their influence on cognition and behaviour in rodents.

2126/W

A second-generation mouse model to study cerebral cavernous malformations lesion development. *D.A. McDonald[1], R. Shenkar[2], C. Shi[2], A.L. Akers[1], R.A. Stockton[3], M. Kucherlapati[4], R. Kucherlapati[4], M.H. Ginsberg[3], I.A. Awad[2], D.A. Marchuk[1].* 1) Molecular Genetics & Microbiology, Duke University Medical Center, Durham, NC; 2) Department of Neurosurgery, University of Chicago Hospitals, Chicago, IL; 3) Department of Medicine, University of California, San Diego, La Jolla, CA; 4) Department of Genetics, Harvard Medical School, Boston, MA.

Cerebral cavernous malformations (CCMs) are vascular lesions affecting the central nervous system. Late-stage lesions in humans appear as dilated, multicavernous, blood-filled capillaries lacking structural support. Patients with the disease suffer from recurrent headaches, seizures and hemorrhagic stroke. CCM occurs either sporadically or in a familial, autosomal dominant manner. Inherited forms of CCM are due to heterozygous germline mutations in one of three genes: *CCM1/KRIT1*, *CCM2/MGC4607*, and *CCM3/PDCD10*. Previous studies in late-stage, surgically-resected human CCM lesions found genetic and molecular evidence for a two-hit (germline plus somatic) mutation mechanism underlying CCM pathogenesis. No clinical samples of early-stage human CCM lesions are available, so the mechanisms of lesion genesis and development remain unknown. In order to study CCM pathobiology, we have created a knockout allele of the murine *Ccm1* gene. Mice heterozygous for *Ccm1* do not develop CCM lesions. Based on the two-hit mechanism of pathogenesis, we hypothesized that increasing the somatic mutation rate in these heterozygous mice would increase the chance of somatic mutation of the remaining wild-type allele, and increase the penetrance of the model. The mismatch repair complex gene *Msh2* is required for repair of point mutations and small insertions/deletions, consistent with the types of somatic mutations identified in human CCM lesions. Thus, we crossed *Ccm1* heterozygotes into the mutant background lacking *Msh2*. The sensitized $Ccm1^{+/-}Msh2^{-/-}$ mice show CCM lesions with high penetrance both by MRI and histology. These lesions are not observed in littermates possessing the various control genotypes. Significantly, the CCM lesions identified in these mice range in size from early-stage, single caverns to large, late-stage, multicavernous lesions. This *in vivo* model of CCM will enable us to study the molecular and genetic events that occur in the earliest stages of CCM lesion formation. Future work will use this mouse model to investigate the specific mechanisms that cause lesion genesis and growth as well as possible therapeutic strategies.

2127/W

A zebrafish model of human fetal motoneuron disease. *H.O. Nousiainen[1,2], R.J. White[2], D.L. Stemple[2].* 1) Pub Hlth Genomics, Nat Inst Hlth & Welfare, Helsinki, Finland; 2) Wellcome Trust Sanger Institute, Hinxton, UK.

Motoneurons are affected in several neurological disorders with variable severity and age of onset. The most early-onset forms of motoneuron disease, LCCS (MIM 253310) and LAAHD (MIM 611890), manifest already in utero and are characterized by severe atrophy of spinal cord motoneurons and fetal immobility. Both syndromes are caused by mutations in *GLE1*, which encodes for a protein that is involved in mRNA export, translation initiation, and translation termination. Gle1 knockout (Gle1-/-) zebrafish present with necrosis in the central nervous system at 2 days post fertilization. Acridine orange staining shows significantly more dying cells in the brain and spinal cord of Gle1-/- zebrafish, than in age-matched wild type siblings. The distribution of mRNA within the cells of Gle1-/- zebrafish also differs from controls. Thus Gle1-/- zebrafish provide an excellent model for studying the molecular mechanisms underlying neurodegeneration, and can also provide valuable insights into the pathogenesis of human motoneuron disease.

2128/W

A Novel Systems Biology Pathway Approach Identifying Pathways with Both Genetic and Biological Support in the Etiology of Parkinson's Disease. *Y. Edwards[1], S. Khuri[2], G. Beecham[1], G. Bademci[2], D. Tekin[2], E.R. Martin[1], W.K. Scott[2], Z. Jiang[3], D. Mash[4], J. Ffrench-Mullen[5], M.A. Pericak-Vance[1], N. Tsinoremas[3], J.M. Vance[2].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Dr. John T. Parkinson Disease (PD) is a complex neurodegenerative disease for which 6 genome-wide association studies (GWAS) and several gene expression studies have been performed. Despite these efforts, only variants in the microtubule-associated protein tau and α-synuclein genes have been consistently replicated. To improve the utility of these approaches, we applied a unique pathway analysis approach that utilized existing GWAS and gene expression data for PD. The top 5000 SNPs ($p<0.01$) from the GWAS described in Edwards et al (2010) were localized and the genes within a 20Kbp upstream and downstream window for each SNP were identified. Genes were only counted once, so linkage disequilibrium would not be a factor. The gene expression data from Papapetropoulos et al (2006) was sorted and for each of 7 patients and 4 controls one brain region was chosen to represent each of the 5 PD Braak stages. Rather than the traditional gene expression comparison of pooling one anatomical region between patients and controls, we identified genes that were significantly differentially expressed between each adjacent Braak region in each single individual. This adjusts for environmental variation and that all patients are not at the same stage of their disease. The average control expression profile per brain region was then subtracted from the corresponding brain region expression profile of each patient. GOstats was used to examine the pathways in KEGG. Over-represented pathways for the identified genes were calculated using a classical hyper-geometric statistical comparison of a query gene list against a reference gene list. A meta-analysis of the pathway results from GOstats was performed (based on the expression and GWAS results) using the Fisher's combined probability test. Melanogenesis (containing dopamine precursors) was the top overrepresented pathway in the GWAS analysis ($p=7.8E-5$) and axon guidance was the top pathway in the gene expression analysis ($p=7.0E-7$). 13 of the 205 KEGG pathways tested were overrepresented by both the GWAS and expression data; 4 of the top 10 pathways from each approach were identical. The top three pathways in meta-analysis were: axonal guidance ($p=1.4E-9$), focal adhesion ($p=4.2E-8$) and calcium signaling ($p=1.2E-7$). These pathways have both statistical and biological support to be important in PD and provide strong candidates for further evaluation of rare variants and potential therapeutic intervention for PD.

Spatiotemporal expression of the NSCLP gene, Crispld2, in neural crest cells and pharyngeal arches during mouse development. *Q. Yuan, E. Swindell, J.T. Hecht.* Pediatrics, Univ Texas Med Sch, Houston, Houston, TX.

Cysteine-rich secretory protein LCCL domain containing 2 (CRISPLD2 in human; Crispld2/Lgl1 in mice) was first identified in mice as a factor that plays a role in early branching morphogenesis of the developing lung and kidney. This gene in human maps to 16q22-24, a chromosomal region identified by genome scan studies as potentially containing a causal gene for nonsyndromic cleft lip with/without palate (NSCLP). Interrogation of candidate genes within this region found an association between CRISPLD2 and NSCLP in our nonHispanic white and Hispanic families. Expression of Crispld2 was detected in the mandible, nasal and palatal regions of E13.5 - E17.5 mouse embryos, which spans critical stages of lip/palatal formation. Our results suggest that Crispld2 is involved in craniofacial development and may be a causal gene for NSCLP. To further examine the role of Crispld2 in craniofacial development, we performed whole mount in situ hybridization to investigate the expression of Crispld2 at early embryonic stages. Expression of Crispld2 was detected in neural crest cells of E9.0 mouse embryos at the midbrain/hindbrain junction, from which the first pharyngeal arch originates. In addition, expression of Crispld2 in the budding first and second pharyngeal arches was observed in E10.0 mouse embryos. These results provide evidence that Crispld2 is involved in the formation of the two arches that are destined to form the oral and nasal structures. This expression data demonstrates that Crispld2 plays an important role in orofacial development.

The Human GATA4 G296S Mutation Disrupts Mouse Cardiac Morphogenesis. *C. Misra[1], N. Sachan[3], S. Koenig[1], C. McNally[3], D. Srivastava[4], V. Garg[1,2].* 1) Center for Cardiovascular and Pulmonary Research, Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) Department of Pediatrics, Ohio State University; 3) Department of Pediatrics, University of Texas Southwestern Medical Center, Dallas, Texas; 4) Gladstone Institute of Cardiovascular Disease and Department of Pediatrics, University of California, San Francisco, San Francisco, California.

Cardiac septal defects (CSD) are the most frequent form of congenital heart disease in children, accounting for almost 50% of all cases. We previously reported a heterozygous G296S missense mutation of the transcription factor, GATA4, in a large family with CSD (Garg et al.,2003). In vitro studies demonstrated the mutant GATA4 protein has reduced DNA binding activity and does not interact with the cardiac transcription factor, TBX5. To investigate the molecular and in vivo deficits of this point mutation, we generated a mouse harbouring the same mutation, Gata4 G295S. Homozygous Gata4-null mice have previously been reported to have cardiac bifida and exhibit defects in ventral morphogenesis. These defects are proposed to be due to abnormal Gata4 function in the endoderm. However, mice homozygous for Gata4 G295S have normal ventral body patterning and develop until approximately embryonic day 9.5, after which normal Mendalian ratios are not observed. Homozygous Gata4 G295S embryos dispay a looped heart tube, a single ventricular chamber but have thin ventricular myocardium. Gata4 protein levels are unchanged in the homozygous Gata4 G295S mutant embryos when compared to wildtype littermates. The cardiac abnormalities and the absence of ventral body patterning defects suggest the Gata4 G295S mutant protein can sufficiently activate downstream targets of Gata4 in the endoderm but not mesoderm. Consistent with this, decreased expression of Gata4 target genes in the developing heart was found by RT-qPCR. Decreased cardiomyocyte proliferation was found in the homozygous mutant embryos consistent with the thin myocardium. The Gata4 G295S heterozygous embryos and adult mice are being analyzed for cell proliferation and structural cardiac defects and the data will be presented. In summary, the Gata4 G295S mutant allele functions as a hypomorph in the mesoderm, and disrupts proper cardiac morphogenesis. The phenotype may be due to inability of the Gata4 G295S protein to interact with TBX5 in the heart which has an effect on cardiomyocyte proliferation.

Elucidation of Sensors and Effectors in Matrix Equilibrium Derives Novel Therapeutic Strategies for Scleroderma. *E. Gerber[1], D. Huso[2], B. Loeys[3], E. Davis[4], F. Wigley[5], H. Dietz[1, 6].* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Molecular and Comparative Pathobiology, Johns Hopkins University, Baltimore, MD; 3) Center for Medical Genetics, Ghent University Hospital, Ghent 9000, Belgium; 4) Department of Anatomy and Cell Biology, McGill University, Montreal, Quebec, Canada H3A 2B2; 5) Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 6) Howard Hughes Medical Institute, Chevy Chase, MD.

In the most common and severe presentation of scleroderma, systemic sclerosis (SSc), previously healthy individuals show acquired fibrosis of the skin and viscera associated with the production of autoantibodies. To gain a foothold in the pathogenesis of SSc, we studied a rare inherited form of scleroderma called stiff skin syndrome (SSS) that shows childhood onset of diffuse skin fibrosis. We showed that all patients with SSS have heterozygous missense mutations in the 4th latent transforming growth factor-β (TGFβ) binding protein-like domain of the extracellular matrix protein fibrillin-1. This domain harbors the only Arg-Gly-Asp (RGD) sequence in fibrillin-1 that mediates matrix-cell attachments via integrin bridging. Skin in SSS shows disorganized macroaggregates of fibrillin-1 that fail to contact neighboring cells at the dermal-epidermal junction. Concordant findings were observed in SSc patient skin. These data led to our hypothesis that cells sample the matrix using integrins, that fibrillin-1 is a critical informant regarding the status of the matrix, and that loss of integrin binding to fibrillin-1 results in a failure of communication, context-inappropriate matrix production, and fibrosis. In support of this concept, we now show that mice heterozygous for a SSS-associated mutation (W1570C) or one that substitutes RGE for RGD (leading to an obligate loss of integrin binding) both show rapidly progressive scleroderma, with dramatic thickening of the dermis and complete replacement of subcutaneous fat by collagen by 3 months of age. MicroRNA29 (miR29) emerged as a candidate modulator of matrix synthesis in scleroderma since it suppresses expression of multiple matrix proteins (e.g. types I and III collagens) and has been implicated in cardiac fibrosis. SSc fibroblasts show markedly reduced expression of miR29 and increased expression of miR29 target transcripts; both abnormalities are corrected upon treatment of cells with an integrin β1 activating antibody in a dose-dependent manner. Furthermore, animal models of SSS also show reduced miR29 expression in skin. These data are consistent with a model in which integrins act as sensor and miR29 as effector in the regulation of matrix equilibrium. Perturbation of this axis, as in SSS or SSc, would be sufficient to initiate profibrotic programs. Therapeutic strategies that activate integrins, including antibodies, soluble peptides and nutritional manipulations, are now being tested in SSS mice.

Dissecting the role of PORCN in focal dermal hypoplasia or Goltz syndrome. *W. Liu, I. Van den Veyver.* Dept OB/GYN, Baylor Col Med, Houston, TX.

Focal Dermal Hypoplasia (FDH) is an X-linked dominant developmental disorder with typical defects of skin, eyes and skeleton caused by mutations in PORCN. PORCN orthologs in mouse and Drosophila (Porcupine) lipid-modify Wnt proteins, which is essential for their secretion. We therefore hypothesize that PORCN is essential for skin, limb and skeletal development by mediating Wnt signaling and are using two approaches to address this hypothesis. One is to generate and characterize a mouse model with an inactivating mutation in Porcn. In a chimera generated with a Porcn gene-trapped ES cell line, we observed typical skin and distal limb defects, and congenital anomalies of kidneys and internal genital organs, with true hermaphroditism that precluded reproduction. Chimeric phenotypes can be expected for this X-linked dominant mutation and genotyping of affected tissues confirmed the Porcn mutation. This line did not result in germline transmission and we therefore set out to generate a conditional Porcn-mutant mouse; germline transmission has been obtained. Our second approach is to investigate how PORCN overexpression and knockdown affect WNT-signaling in cultured cells. To investigate if PORCN regulates WNT protein secretion, we co-overexpressed WNT3A, Wnt5a or Wnt1 with wild-type (WT) and mutant PORCN in HEK293T cells and assessed the amount of WNT protein in the cells and culture media by Western Blot. Compared to controls, we observed less WNT3A and Wnt5a in cell-extracts and more WNT3A and Wnt5a in the media with overexpressed wild-type PORCN, but not with overexpressed PORCN containing a nonsense mutation, indicating that as expected human PORCN up-regulates WNT3A and Wnt5a secretion. Interestingly, compared to controls, we observed less Wnt1 in cells and less in media with WT PORCN overexpression, while PORCN mutations did not affect Wnt1 secretion. These results indicate that, PORCN affects WNT protein secretion in humans, but the contribution or requirement of this pathway for secretion may vary for individual WNT proteins. We will further study other WNTs with this system and we are also investigating by immunolocalization whether human PORCN knockdown or mutations result in retention of WNTs in the endoplasmic reticulum (ER) and in reduced β-catenin activation. These studies will allow us to study PORCN function, its role in FDH.

2133/W

***C. elegans bbs* mutants display a variety of behavioural and developmental endophenotypes.** *C.A. Mok[1], T. Shekhar[1], M. Zhen[2], E. Héon[1].* 1) Prog Gen & Genome Biol, Sick Kids Hosp, Toronto, ON, Canada; 2) Sumuel Lunenfeld Research Institute, Mount Sinai Hosp, Toronto, ON, Canada.

Ciliopathies are a growing class of pleiotropic and genetically heterogenous disorders where the causative proteins localize to the primary cilia. Bardet-Biedl syndrome (BBS) proteins localize to the base of the cilia and undergo intraflagellar transport. The loss of their activity leads to ciliary dysfunction. The functional conservation of BBS genes in *C. elegans* has made this a useful tool to decipher the biological aspects of BBS. Previous studies revealed that *C. elegans* BBS proteins are present in ciliated neurons and their loss causes neurosensory deficits, manifested by defects in chemotaxis and thermotaxis. We further characterized the *C. elegans bbs* mutant endophenotypes for shared functional, behavioural, and developmental defects. Herein we identified previously unreported *bbs* endophenotypes that include changes to body/cell size, developmental timing, and exploratory behaviour. We observed defects to body size in *bbs* mutants, quantifiable as early as the L4 larval stage, and as late as 72-hours into adulthood. These defects applied to body length and width in *bbs* mutants, with no visible defects to cell count. In examining developmental timing, *bbs* mutant strains exhibited a developmental delay in transitioning between L1 and L4 larval stages. Behaviourally, *bbs* mutants exhibited previously described chemotaxis defects as well as defects to exploratory behaviour. Although *bbs* endophenotypes are likely linked to ciliary dysfunction, the underlying defects to protein localization and trafficking, or signalling pathways remain to be elucidated. These endophenotypes can now be used to further study biological questions relating to this pathology as well as the validation of possible variants linked to known or novel human ciliopathy genes. Furthermore an investigation of these endophenotypes may identify specific or shared interactors or forms of regulation yet to be defined.

Intrathecal TPP1 replacement in a canine model of LINCL. *B. Vuillemenot[1], M. Katz[2], J. Coates[2], S. Kanazono[2], P. Lobel[3], I. Sohar[3], S. Xu[3], P. Tiger[1], D. Kennedy[1], D. Musson[1], S. Keve[1], L. Tsuruda[1], C. O'Neill[1].* 1) BioMarin Pharmaceutical Inc., Novato, CA; 2) University of Missouri, Columbia, MO; 3) Robert Wood Johnson Medical School, University of Medicine and Dentistry of New Jersey, Piscataway, NJ.

Late infantile neuronal ceroid lipofuscinosis (LINCL) is a lysosomal storage disorder caused by mutations in the gene encoding tripeptidyl peptidase1 (TPP1). LINCL patients display accumulation of lysosomal storage materials in the brain and other organs accompanied by CNS degeneration and neurological decline. The LINCL dachshund model is a spontaneously occurring mutant that lacks expression of TPP1 and recapitulates many aspects of the human disease. The objective of this study was to determine if intrathecal (IT) TPP1 enzyme replacement attenuates the accumulation of storage materials and disease progression observed in TPP1-/- dachshunds. An additional goal was to determine the CNS distribution of TPP1 activity after IT administration. TPP1 was administered to one TPP1-/- and one homozygous wild type (WT) animal. An additional TPP1-/- and WT animal each received vehicle. Four IT administrations via the cisterna magna of 32mg TPP1 formulated in 2.3mL of artificial cerebrospinal fluid (CSF) or vehicle were administered monthly from four to seven months of age. Retinal electrophysiology, cognitive testing, and neurologic and ophthalmic examinations were performed throughout the study to measure functional changes. Animals were euthanized 48 hours after the fourth administration. Tissues from different areas of the CNS were analyzed for TPP1 activity and autofluorescent storage materials. TPP1 activity was distributed at greater than WT levels in many areas of the CNS of the TPP1-/- animal administered TPP1, with higher concentrations in areas proximal to CSF flow, especially those downstream from the injection site. There was a decrease in autofluorescence in CNS tissues correlating with TPP1 activity level. Systemic TPP1 exposure, peaking at one hour post dose, was also observed. No improvement was observed in neurologic, cognitive, or ophthalmic function in this animal compared to a vehicle treated TPP1-/- control. These results demonstrate the biochemical activity of IT administered TPP1 in an animal model of LINCL. Further studies with this model are in progress to optimize the delivery route and dosing regimen to attenuate neurological decline.

Conditional knockout mouse model for the *Fxr2* gene. *S.S. Pataskar[1], B.A. Oostra[2], D.L. Nelson[1].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.USA; 2) CBG Department Of Clinical Genetics, Erasmus University, Rotterdam, The Netherlands.

Fragile X Syndrome is a common form of intellectual disability caused by the absence of Fragile X Mental Retardation (FMR1) protein, FMRP. FXR1P and FXR2P (Fragile X Related Protein) are paralogs of FMRP. The three proteins share high sequence similarity, functional similarity and show overlapping tissue distribution. FXR2P is also highly expressed in brain and testis. FXR1P and FXR2P provide functional redundancy to FMR1P and may mask some phenotypic consequences of loss of function mutations in mice and humans. To unravel the biological mechanisms involved in the normal and abnormal functioning of Fragile X associated proteins, we are developing knockout mice lacking each of the genes and combinations including mutations that can be conditionally expressed via Cre/loxP system. A conditional knockout allele for the mouse *Fxr2* gene (cKO*Fxr2*) was created by engineering loxP sites flanking its exon 7. Heterozygous conditional cKO*Fxr2* mice were obtained by crossing cKO*Fxr2* mice with mice expressing neuron specific Cre recombinase (*Nse-cre*). Pups homozygous for the cKO*Fxr2* allele and also for *Nse-cre* transgene were analyzed for *Fxr2* expression. RT PCR analysis confirmed deletion of exon 7 in *Fxr2* transcript from brain tissues of these mice whereas no such ablation was observed in *Fxr2* transcript from testis. Immunohistochemical staining of brain tissue sections from these mice showed absence of FXR2P especially in hippocampus, thalamic and hypothalamic regions of the brain. A similar staining of tissue sections from testis showed presence of FXR2P in levels comparable to those in the testis of control cKO*Fxr2* mice without *Nse-cre*. We have also crossed cKO*Fxr2* mice with mice expressing *Hprt-Cre* recombinase which is expressed ubiquitously. RT PCR analysis confirmed deletion of exon 7 in *Fxr2* transcript from tissues like brain, liver, kidney and testis from mice homozygous for the cKO*Fxr2* allele and for *Hprt-Cre* transgene. We are in the process of crossing cKO*Fxr2* mice with those carrying cKO*Fxr1* and cKO*Fmr1* alleles. We expect to examine circadian rhythm activity patterns of these mice along with other behavioral phenotypes in animals where the *Fxr2* gene has been ablated in specific tissues individually and in combination with that of *Fxr1* and *Fmr1* genes.

2136/W

Identification of candidate regions for phenotype modifier gene in a new mouse model for Marfan syndrome. *G.R. Fernandes[1], B.L. Lima[1], S.M.G Massironi[2], L.V. Pereira[1].* 1) Departamento de Genética e Biologia Evolutiva, Instituto de Biociências ,USP; 2) Departamento de Imunlogia, Instituto de Ciências Biomédicas, USP .

Marfan Syndrome (MFS) is an autossomal dominant disorder associated with pleiotropic manifestations affecting the skeletal, ocular and cardiovascular systems. Despite presenting complete penetrance, MFS displays a wide clinical variability even within family members carrying the same mutation. Our group has developed a new mouse model, in which the Fbn-1 gene had the exons 19-24 replaced by a neomycin-resistance expression cassette flanked by LoxP sequences. Heterozygous mice developed some of the human phenotypes across the skeletal and cardiovascular systems, and lung manifestation (emphysema). Moreover, the onset of the phenotypes varies according to the isogenic background in which the mutation is present: in the 129/Sv strain manifestations are present as early as 3 months of age, while in the C57/BL6 animals will present the phenotypes only at 6 months of age. Therefore, this model is capable of reproduce the clinical aspects and variability observed in humans, and are an experimental system in which to identify modifiers genes of MFS. Here we report the initial results from the screening for modifier genes in both strains that control the MFS phenotypes. For this purpose, skeletal, lung and vascular phenotypes of 3-month-old heterozygous 129xC57 F2 mice were quantified, and the 10 most and less affected animals for each phenotype were genotyped along the genome with a 64 microssatelite set. Statistical analyses were made using the R/qtl package and the Minitab software. The analysis of the isogenic animals indicated that, independent of the onset and severity of disease, there is a significant phenotypic correlation, so a more severe skeletal phenotype is accompanied by a severe lung and cardiovascular phenotypes (0.70 £ρ£0.89). This correlation is not observed among the phenotypes of F2 mice (|ρ|£0.2), indicating that each system must be influenced by particular modifying factors. So far the screening has identified 4 suggestive (P<0.63) regions in chromosomes 3, 4, 6 and 14 controlling the skeletal phenotype; and one region on chromosome 18 that affects the aortic phenotype. Our results indicate the existence of at least 5 different modifiers genes controlling two distinct MFS phenotypes.

2137/W

A mutation in *Srebp2* leads to cataract formation in *lop13* mice. *K.M. Merath[1], R.R. Dubielzig[2], B. Chang[3], D.J. Sidjanin[1].* 1) Cell Biology, Medical College of Wisconsin, Wauwatosa , WI, 53226; 2) School of Veterinary Medicine, University of Wisconsin-Madison, Madison, WI , 53706; 3) The Jackson Laboratories, Bar Harbor, ME, 04609.

Cataracts are the leading cause of blindness worldwide and in order to develop novel therapies, the identification of the underlying molecular events participating in the development of cataracts is essential. The focus of this research is on the identification of the gene and associated molecular pathways that lead to autosomal recessive cataracts in the lens opacity 13 (*lop13*) mice. The *lop13* mutation arose spontaneously and the mice exhibit nuclear cataracts and fissures of the skin surrounding the eyes and the back of the neck. F2 mice were generated and genotyped and the linkage map established the *lop13* critical region as being between D15Mit118 and D15Mit33 on mouse chromosome 15. All 35 genes within the critical region were sequenced and the region was further narrowed to 520 Kb between *Csdc2* and Cyp2d9. A single C®T base pair substitution was identified in nucleotide 3112 of Sterol Regulatory Element Binding Protein 2 (*Srebp2*). This mutation results in the substitution of an evolutionarily conserved arginine to cysteine at amino acid 1038. To provide further genetic proof that the identified mutation was disease causing, mice were generated that carried a gene trapped *Srebp2* allele and these mice were then bred to the *lop13* mouse. The compound heterozygote mice exhibited cataracts and skin fissures, thus confirming that the disease causing mutation in the *lop13* mice is Srebp2^{Arg1038Cys}. Srebp2 plays an essential role in activating the transcription of several genes involved in the cholesterol biosynthesis pathway. Although *SREBP2* has been extensively studied, this gene has not been previously linked to cataract formation. Studies are currently in progress to evaluate the role of Srebp2^{Arg1038Cys} in maintaining the homeostasis of cholesterol within the lens.

2138/W

Lens opacity 11 (lop 11) is a loss of function mutation in Hsf4. *A. Ronchetti, B. Endres, D. Sidjanin.* Cell Biology, Neurobiology, and Anatomy, Medical College of Wisconsin, Milwaukee, WI.

Lens opacity locus 11 (*lop11*) is a spontaneous mouse mutant that exhibits autosomal recessive cataracts. In our previous study we identified an insertion of an early transposable element (ETn) in intron 9 of the *Hsf4* gene as responsible for the *lop11* mutation. The ETn insertion altered splicing of the *Hsf4* transcript following exon 9, resulting in a premature stop codon and a loss of exons 10-13. Although we were able to detect truncated $Hsf4^{lop11}$ protein in *lop11* lenses, the molecular consequences of the ETn insertion on the normal function of the Hsf4b protein and *lop11* cataract formation have not yet been investigated. We initially evaluated if *lop11* is a loss of function mutation due to the reduced protein stability of $Hsf4^{lop11}$. No difference between the stability of wt Hsf4 and $Hsf4^{lop11}$ proteins was identified. Western blot analysis showed presence of both the wt Hsf4 and $Hsf4^{lop11}$ in cytosolic and nuclear protein extracts. EMSA using nuclear extracts showed that $Hsf4^{lop11}$ abrogated binding to the heat shock element (HSE). Luciferase assay confirmed abolished ability of $Hsf4^{lop11}$ to bind to HSE. It has been previously shown that wt Hsf4 protein can bind to HSE only as a trimer. Native gel electrophoresis showed a lack of trimer formation for $Hsf4^{lop11}$. These findings suggest that in *lop11* a loss of the Hsf4 C-terminal end results in disrupted trimerization and abolished binding to HSE. A loss of Hsf4 function in the *lop11* lenses was further evaluated. Between P10-12 in *lop11* lenses the vacuole formation was noted between cortical fiber cells. Prior to P10 *lop11* lenses exhibited persistent nuclei in fiber cells. No differences were observed in the proliferation rate between wt and *lop11* lenses. These findings suggest that in lop11 a loss of Hsf4 function most likely results in a defect in fiber cell maturation and denucleation that ultimately leads to vacuole formation and cataracts.

2139/W

Animal modeling of TARP syndrome: Knocking down and knocking out *Rbm10*. *J.J. Johnston[1], K.S. Bishop[3], E.J. Spaulding[1], J.K. Teer[1, 2], P.F. Cherukuri[1, 2], N.F. Hansen[2], S.K. Loftus[1], K. Chong[4], J.C. Mullikin[2], L.G. Biesecker[1, 2].* 1) Genetic Disease Research Branch, NHGRI, Bethesda, MD; 2) NIH Intramural Sequencing Center, Bethesda, MD; 3) Zebrafish Core Facility, Genetics and Molecular Biology Branch, NHGRI, Bethesda, MD; 4) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, ON, Canada.

Micrognathia, glossoptosis, and cleft palate comprise a common malformation, Robin sequence. It is a component of the TARP syndrome, which comprises Talipes equinovarus, Atrial septal defect, Robin sequence, and Persistent left superior vena cava. This disorder is X-linked with apparently 100% pre- or postnatal lethality in affected males. We have previously characterized two families with TARP, performed massively parallel sequencing of X chromosome exons, filtered the results, used a unique algorithm to characterize variants, and showed that TARP is caused by truncating mutations in *RBM10*, which encodes RNA binding motif 10. These are the only known human mutations in this gene and there are no recognized animal models of this disorder. We hypothesize that *RBM10* dysregulates other developmental genes that cause other forms of Robin sequence or clefting. To better define the role of *RBM10* in development, we proposed to use zebrafish as a model organism. We designed a total of 3 splice morpholinos targeting zebrafish *rbm10*. Fish were collected at 6-8 dpf for alcian blue staining of cartilage to identify abnormal jaw development. The first morpholino yielded a phenotype of mandible underdevelopment, consistent with the human phenotype. The second and third morpholinos did not yield a recognizable phenotype. Only 1 of the 3 morpholinos blocked splicing as shown with RT-PCR analysis from 3 dpf fish. We hypothesized that maternal transcripts may rescue the embryos and worked toward a translation blocking morpholino. As the 5' end of the zebrafish transcript was incomplete, we used 5'-RACE to identify alternative splicing with 2 alternative translation start sites (equally represented in cloned products). Due to the complexity of the 5' end of the transcript and the negative result from the splice morpholinos we concluded that the fish is not a useful model for TARP syndrome. Concurrently, we have identified two mouse *Rbm10* knockout ES cell lines (*Rbm10*$^{tm1a(KOMP)Wtsi}$, *Rbm10*$^{GT(CSI176)Byg}$), which we obtained and are working towards creating transgenic lines.

2140/W

Modeling Mental Retardation in Cornelia de Lange Syndrome (CdLS) with *Drosophila melanogaster*. *I. Krantz[1], J. Li[2], D. Xu[3].* 1) Dept Pediatrics/Human Gen, Children's Hosp Philadelphia, Philadelphia, PA; 2) School of Arts and Sciences, University of Pennsylvania, Philadelphia, PA; 3) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Cornelia de Lange Syndrome (CdLS) is a dominant genetically heterogeneous diagnosis characterized by a striking constellation of cognitive impairment, growth delay and birth defects. Approximately 65% of CdLS probands have an identifiable mutation in cohesin structural (*SMC1A*, *SMC3*) or regulatory (*NIPBL*) genes. Cohesin has been well characterized for its role in sister chromosome cohesion during mitosis, however we, and others, have described a non-canonical role for cohesin as a critical regulator of gene expression, that is most likely the mechanism by which it manifests its phenotypic effect in CdLS. Homozygous mutation of cohesin factors in *Drosophila* (and other organisms) is embryologically lethal, while heterozygous loss has minimal known phenotypic effect. Targeted homozygous mutation of cohesin genes or disruption of cohesin structure has been shown to cause failure of γ-neuron pruning, a post-mitotic event, during *Drosophila* brain development. It remains unclear if loss of one copy of these cohesin genes, more closely representing the gene dosage in CdLS probands, also causes any structural or functional brain differences in *Drosophila*. We investigated brain development in *Drosophila* heterozygous mutants of cohesin structural and regulatory genes and observed γ-neuron pruning defects in mushroom bodies during the pupal stage. γ-neurons failed to be pruned at 20 hours after pupae formation in approximately 30% of the *SMC1*, *Rad21*, and *Nipped-B* heterozygous mutant pupae. This indicates that heterozygous cohesin mutations do exert an effect on normal brain development in the fly, although the effect is not fully penetrating. Parallel genome-wide expression analysis of the brain of these mutant flies will provide molecular insight into the effects of haploinsufficiency of cohesin genes. These experiments will be very important in understanding the alterations of the transcriptome in the *Drosophila* brain and how that relates to the cognitive status resulting from haploinsufficiency. These and ongoing learning/memory behavior studies will help to validate if the heterozygous cohesin mutant flies resemble CdLS probands with respect to the cognitive phenotype and can serve as a valuable model to study the neurocognitive aspects of CdLS.

2141/W

The first OPA1 mouse model of Dominant Optic Atrophy "plus phenotype" reveals the pathophysiological mechanism of this mitochondrial disease. *E. Sarzi[1], A. Benyagoub[1], C. Prouteau[2], N. Gueguen[2], V. Rigau[3], C. Delettre[1], P. Brabet[1], C. Hamel[1], P. Reynier[2], G. Lenaers[1].* 1) INSERM U583, Institute for Neurosciences, Montpellier, France; 2) Département de Biochimie et Génétique, CHU Angers - Inserm U694, 4 rue Larrey, 49933 Angers Cedex 9, France; 3) Service d'Anatomopathologie, Hôpital Saint-Eloi, 34090 Montpellier.

Dominant Optic Atrophy (DOA) is an inherited mitochondrial disease mainly caused by mutations in the OPA1 gene, encoding a dynamin-related GTPase involved in mitochondrial fusion, cristae organization and control of apoptosis. DOA is characterized by visual failure marked by a loss of Retinal Ganglion Cells (RGCs) which axons form the optic nerve. Recently, thorough characterization of DOA patients previously thought to be non-syndromic revealed neuromuscular involvements. We have generated a new Opa1 mouse model carrying the c.2708delTTAG mutation in Exon27, the most frequent mutation found in patients with DOA (30% of all cases). Firstly, using molecular, electrophysiological (Electroretinogram (ERG) and Visual Evoked Potentials (VEP)) and immuno-histological studies, we characterized the visual function of this mouse. Secondly, we evaluated the pathophysiological mechanism in the retina and optic nerve by dosage of the respiratory chain complex activities and by observation of the mitochondrial network structures with fluorescent and electron microscopy. Lastly, we studied peripheral organs such as skeletal muscles looking for potential neuromuscular defects. We show that from 6 months, heterozygous Opa1 animals present altered visual function, with significant delay in the VEP latencies, indicative of impaired optic nerve activity. We also demonstrated a loss of the RGCs, hallmark of DOA. In addition, prior to the appearance of the visual defect, we detected an isolated complex IV deficiency of the mitochondrial respiratory chain specifically in retina, while this parameter remains normal in the optic nerve and brain. Mitochondrial distribution and structure are also affected early in RGC soma and around the lamina cribosa, where axons get myelinated. Moreover, we also found a complex IV deficiency in muscle confirmed by the presence of COX negative fibres characteristic of mitochondrial myopathies. For the first time, we have generated a mouse model of Dominant Optic Atrophy with a DOA "plus phenotype" showing a specific deficiency of the mitochondrial respiration in the retina and skeletal muscle. In addition to being a more appropriate model for studying the pathophysiology of DOA, this mouse model represents a precious tool for better understanding mitochondrial diseases.

Pleiotropic Quantitative Trait Loci (QTL) Influence Phenotypes in the ATP8B1-Deficient Mouse. *L. Bull[1], U. Sanford[1], S. Shah[1], J. Robinson[1], C. Paulusma[2], J. Grenert[1,3], A. Knisely[4], R. Oude Elferink[2], S. Sen[1,5].* 1) Liver Center, University of California San Francisco, San Francisco, CA; 2) Tytgat Institute for Liver and Intestinal Research, Academic Medical Center, Amsterdam, The Netherlands; 3) Dept of Pathology, University of California San Francisco, San Francisco, CA; 4) Institute of Liver Studies, King's College Hospital, London, United Kingdom; 5) Department of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA.

Background: ATP8B1-deficient (*Atp8b1*$^{-/-}$) mice serve as a model of FIC1/ATP8B1 deficiency in humans. Phenotypes in the *Atp8b1*$^{-/-}$ mouse are influenced by strain background. To map QTL modifying phenotypes in *Atp8b1*$^{-/-}$ mice, we performed genetic mapping studies using mice of C57Bl/6J (B6) and 129S4 backgrounds, and both backcross and intercross strategies. Methods: *Atp8b1*$^{-/-}$ mice (121 backcross, 245 intercross) were phenotyped: At age ≥3 months, mice were fed a diet supplemented with 0.5% cholate (a bile acid) for 6 days. Mice were then fasted for ≥4 hours, and serum, gallbladder bile, and liver and intestinal tissue collected at sacrifice. DNA samples were genotyped for 242 informative markers; serum collected before and after diet administration was assayed for cholesterol, alkaline phosphatase (ALP), aspartate aminotransferase (AST), alanine aminotransferase (ALT), and bilirubin; and concentrations of cholesterol, phospholipid and bile salts in bile were measured. We have performed QTL analysis for 14 traits to date, using J/qtl. Pleiotropic QTL were defined as regions linked to ≥4 traits, including at least 1 trait that reached genomewide significance (established using 10,000 permutations), with remaining traits attaining pointwise significance. Results: Four genomic regions contain pleiotropic QTL. The phenotypes influenced vary between QTL, but in total encompass: initial and final serum cholesterol, ALP, AST, and ALT; final total serum bilirubin; rate of weight loss on cholate diet; liver: body weight ratio; and biliary phospholipid concentration. For 3 of the 4 pleiotropic QTL, serum cholesterol (initial or final) yielded the most significant evidence of linkage. B6 alleles were usually associated with greater phenotypic abnormalities than were 129 alleles. Conclusion: We have genetically mapped 4 pleiotropic modifier QTL of ATP8B1 deficiency in the mouse. The sequence variants underlying these loci likely influence processes central to manifestation of ATP81 deficiency. Their identification will enhance our understanding of the role of ATP8B1, and the human orthologs of genes at these loci may be modifier genes in human ATP8B1 deficiency.

2143/W

A53T-alpha-synuclein overexpression impairs dopamine signaling and striatal synaptic plasticity in old mice. *S. Gispert Sanchez[1], A. Kurz[1], K.L. Double[2], I. Lastres-Becker[1,10], A. Tozzi[3,9], M. Tantucci[3], V. Bockhart[4], M. Bonin[5], M. Garcia-Arencibia[6], J. Fernandez-Ruiz[6], M. Gerlach[7], U. Wüllner[8], H. Lüddens[4], P. Calabresi[3,9], G. Auburger[1].* 1) Dept Neurology, Frankfurt Univ, Frankfurt, Frankfurt, Germany; 2) Prince of Wales Medical Research Institute and the University of New South Wales, Randwick, Sydney, Australia; 3) Clinica Neurologica, Università di Perugia, Ospedale S. Alpha-synuclein was implicated in Parkinson's disease when missense mutations in the alpha-synuclein gene were found in autosomal dominant Parkinson's disease and alpha-synuclein was shown to be a major constituent of protein aggregates in sporadic Parkinson's disease and other synucleinopathies. We have generated two mouse lines with overexpression of A53T-SNCA in nigrostriatal neurons which show a progressive reduction of spontaneous movement in absence of neurodegeneration. Now we studied striatal dysfunction to understand early disease mechanisms. Analysis of the neurotransmitter content demonstrated that dopamine (DA) levels correlated directly with the level of expression of SNCA, an observation also made in SNCA-deficient (knockout, KO) mice. However, the elevated DA levels in the striatum of old A53T-SNCA overexpressing mice are not transmitted appropriately since the DA degradation enzyme COMT showed reduced expression and DA receptors detected by immunoblots and autoradiography were upregulated. Extensive transcriptome studies via microarrays and quantitative real-time RT-PCR (qPCR) of altered transcript levels of the DA-inducible genes Atf2, Cb1, Homer1 and Pde7b indicated a progressive and genotype-dependent reduction in the postsynaptic DA response. As a functional consequence, long term depression (LTD) was absent in corticostriatal slices from old transgenic mice. In conclusion, we observe a dysfunction of dopaminergic neurotransmission and impaired synaptic plasticity in the A53T-SNCA overexpressing mice, reflecting early changes within the basal ganglia prior to frank neurodegeneration.

2144/W

A new mouse model for Marfan Syndrome present phenotypic variability associated to the genetic background, and to the overall levels of Fbn1 expression. *BL. Lima[1], E. Santos[1], G. Ribeiro[1], C. Merkel[1], M. Soukoyan[1], A. Kerkis[1], S. Massironi[2], J. Visintin[3], LV. Pereira[1].* 1) Departamento de Genética, Instituto de Biociências - USP, São Paulo, Brazil; 2) Departamento de Imunologia, Instituto de Ciências Biomédicas - USP, São Paulo, Brazil; 3) Departamento de Reprodução Animal, Faculdade de Veterinária e Zootecnia - USP, São Paulo, Brazil.

Marfan syndrome is an autosomal dominant disease of connective tissue caused by mutations in the fibrillin-1 encoding gene FBN1. Patients present cardiovascular, ocular and skeletal manifestations, and although being fully penetrant, MFS is characterized by a wide clinical variability both within and between families. Here we describe a new mouse model of MFS that recapitulates the clinical heterogeneity of the syndrome in humans. Heterozygotes for the mutant allele mgΔloxPneo, the same internal deletion of exons 19-24 of mgΔ mouse model, present defective microfibrillar deposition, emphysema, deterioration of aortic wall and kyphosis. However, the onset of the phenotypes is earlier in the 129/Sv than in C57BL/6 background, indicating the existence of genetic modifiers of MFS between these two mouse strains. In addition, we characterized a wide clinical variability within the 129/Sv congenic heterozygotes, indicating the influence of epigenetic factors in disease severity. Finally, we show a strong correlation between the overall Fbn1 expression and the severity of the phenotypes, i.e., mice with lower expression of Fbn1 gene tend to have more severe phenotypes in the three affected systems, supporting the hypothesis of the protective role of normal fibrillin-1 in MFS pathogenesis.

2145/W

Access to Mouse Models of Human Disease. *S. Rockwood, M. Sasner, C. Lutz, S. Murray, C. Heffner, L. Donahue.* Genetic Research Science, Jackson Lab, Bar Harbor, ME.

Access to model organisms is of paramount importance to advancing the research objectives of the bio-medical research community. To facilitate this access, the Mouse Repository at The Jackson Laboratory has served as a centralized resource that distributes and preserves high health status mouse models of human disease for over a half century. Hundreds of new strains are added each year to one of the largest collections of characterized mouse strains available. Advances in recent years have lead to increasing numbers of models in several notable categories. **Micro RNA mutants.** Mouse mutants involving microRNAs represent a rapidly growing subset of the Repository. The bic/miR-155 knockout mice can be used to assess the role of miR-155 and its target genes (including cytokines, chemokines, and transcription factors) in homeostasis and regulation of the immune system. miR-17~92 cluster overexpression is associated with human lymphomas and other cancers, autoimmune defects, and altered expression of tumor suppressor and pro-apoptotic genes. **Alzheimer & Parkinson's Models.** Specific sub-repositories have been formed for both disease areas, with some aged models available. **Cre-expressing models.** Equally important are the Cre recombinase-expressing strains that are used in conjunction with floxed mutants. Because most existing Cre strains have not been fully characterized and 'ectopic' expression of Cre recombinase can confound analysis, we have undertaken a project to characterize Cre recombinase activity in embryonic and adult mouse tissues. Results are displayes in a database including images and expression patterns annotated with terms from the Mouse Anatomical Dictionary. **Tool Strains.** These strains allow the detection of recombinase activity, permit tissue specific expression of fluorescent proteins, make possible tissue specific ablation and make accessible recent advances in iPS technology. Although each mouse model may differ in its scientific application, each shares similar operational aspects in that each is part of the Repository's quality assurance program. The Repository maintains a searchable online resource (www.jaxmice.jax.org/query). Researchers wishing to have strains considered for inclusion in the Repository may submit their strains to: (www.jax.org/grc/index.html). This project has been supported by NCRR (RR09781, RR11083, RR16049), NIA, HHMI, The Ellison Medical Foundation and from several private charitable foundations.

2146/W

A VCP R155H Knock-In Mouse Model exhibits progressive muscle, bone and brain pathology typical of human IBMPFD Syndrome. *M. Badadani[1], A. Nalbandian[1], J. Vesa[1], G. Watts[2], D. Eric[1], V. Caiozzo[3], D. Wallace[1], V. Kimonis[1].* 1) Pediatrics, Univ California at Irvine, Irvine, CA; 2) School of Medicine, Health Policy and Practice, University of East Anglia, Norwich, Norfolk, UK; 3) Department of Orthopedic Surgery, University of California, Irvine, CA, USA.

Dominant mutations in the valosin containing protein (VCP) gene cause inclusion body myopathy associated with Paget's disease of bone and frontotemporal dementia (IBMPFD) is characterized by progressive muscle weakness, dysfunction in bone remodeling, and frontotemporal dementia. VCP plays an essential role in the endoplasmic reticulum associated degradation of proteins by binding to ubiquitinated substrates and transferring them to the 26S proteasomes of the ubiquitin proteasome system. To elucidate the pathological mechanisms underlying the disease progression of IBMPFD, we generated a knock-in mouse model with the R155H mutation and analyzed the progression of disease up to 15 months of age. Muscle strength measurements demonstrated progressive muscle weakness in mutant mice starting before the age of 6 months and reaching the 17.9% decrease by 15 months of age. Motor performance, analyzed by the rotarod analysis showed progressive decline beginning at 3 months of age and reaching 22% decline by the age of 15 months. Histological analyses of mutant muscle performed by hematoxylin and eosin staining, and electron microscopy showed vacuolization of myofibrils, centrally located nuclei, and disorganized muscle fibers. Immunohistochemical analyses of the quadriceps muscle tissues from mutant mice showed accumulation of TDP-43- and ubiquitin-positive inclusion bodies in 4% of quadriceps myofibrils. LC3 staining of muscle sections showed increased number of autophagosomes, and increased apoptosis was demonstrated by elevated Caspase-3 activity (2.8-fold increase) and increased number of TUNEL-positive nuclei in mutant quadriceps. X-ray microtomography (uCT) images show radiolucency of distal femurs and proximal tibiae in knock-in mice and uCT morphometrics shows decreased trabecular pattern and increased cortical wall thickness. Bone histology and bone marrow derived macrophage cultures in these mice revealed increased osteoclastogenesis observed by TRAP staining suggestive of Paget bone disease. Moreover homozygous mice die by 21 days and show increased number of vacuoles and central nuclei within quadriceps, and dysregulation of cardiac myofibers and hepatocytes. In conclusion, the R155H knock-in generated mouse model replicates human disease, and therefore, can be used to clarify the mechanisms causing IBMPFD and develop novel therapies for this important disease.

Mutations in *RP1* cause dominant retinitis pigmentosa via a dominant-negative mechanism. *E.A. Pierce[1], A. Saveliev[1], R.W.J. Collin[2], I. van den Born[3], Q. Liu[1].* 1) FM Kriby Center for Ophthalmology, Univ Pennsylvania School of Medicine, Philadelphia, PA; 2) Department of Human Genetics and Nijmegen Centre for Molecular Life Sciences, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands; 3) The Rotterdam Eye Hospital, Rotterdam, The Netherlands.

The inherited retinal degeneration retinitis pigmentosa (RP) is a common cause of vision loss. Mutations in the retinitis pigmentosa 1 (*RP1*) gene are a common cause of autosomal dominant RP (adRP), and have also been found to cause recessive RP. The RP1 protein is a photoreceptor-specific microtuble-associated protein (MAP) that is required for normal organization membrane discs in the light-sensitive photoreceptor sensory cilia (PSCs; also called outer segments) of rod and cone cells. It is not currently understood how mutations in *RP1* lead to photoreceptor degeneration. **Methods and Results:** To ask if haploinsufficiency of *RP1* can cause adRP, we evaluated the retinal function of the parents of an RP patient who is homozygous for a c.686delC (p.Pro229GlnfsX35) mutation in exon 3 of *RP1*, which is predicted to be a null allele. Both parents, who are heterozygous for the mutation, were found to have normal retinal function, excluding haploinsufficiency as a cause of RP1 disease. To distinguish between dominant-negative and gain-of-function mechanisms of dominant RP1 disease, we generated and characterized gene targeted *Rp1*-Q662X point mutation knockin mice that mimic the common p.R677X mutation in human RP1, as well as the other pathologic truncating *RP1* alleles identified to date. The *Rp1*-Q662X mice express a truncated version of the Rp1 protein, and experience photoreceptor degeneration. We next characterized lines of *Rp1*-Q662X mice supplemented with tagged Rp1 wild-type transgenes, and found that normal levels of transgenic wild-type Rp1 protein delayed or prevented degeneration in homozygous *Rp1*-Q662X mice, excluding gain-of function as the causative mechanism. **Conclusions:** These results indicate that truncating mutations in *RP1* cause adRP via a dominant-negative mechanism, while null *RP1* alleles cause recessive disease. Furthermore, our data suggest that gene augmentation therapy could be beneficial for dominant RP1 disease, and demonstrate the importance of investigating the mechanisms underlying other forms of adRP.

2148/W

Blind-sterile 2* is a hypomorphic mouse mutation in *Alkylglycerone phosphate synthase (Agps). *R. Liegel[1], B. Chang[2], D.J. Sidjanin[1].* 1) Cell Biol, Med College Wisconsin, Milwaukee, WI; 2) The Jackson Laboratories, Bar Harbor, ME.

Blind sterile locus 2 (bs2) is a novel autosomal recessive spontaneous mouse mutation resulting in a phenotype of congenital cataracts as well as male-specific sterility. Clinically, *bs2* homozygote mice exhibit bilateral nuclear cataracts and microphthalmia. Histological evaluation of eye sections reveals that *bs2* mice have severely disrupted lens epithelial and fibroblast cells resulting in mature cataracts. Histological evaluation of testes show that *bs2* testes are smaller than WT controls, do not contain mature sperm, and contain large multinucleate cells in the seminiforous tubules. Initial linkage analysis mapped *bs2* to mouse chromosome 2, approximately 45cM from the centromere. Fine mapping narrowed the region containing the locus to a 3.1Mb region containing 19 genes. Sequencing of *alkylglycerone-phosphate synthase (Agps*), a gene within this region, revealed a G to A substitution at the +5 position of intron 14. This mutation, located within the splice-donor site, results in aberrant splicing of Agps mRNA and formation of two alternatively-spliced transcripts in the *bs2* mouse. Agps encodes a ubiquitously expressed peroxisomal protein which catalyzes an early step in the synthesis of ether lipids. We present evidence that *bs2* mice have significantly decreased levels of ether lipids. Human mutations in Agps result in rhizomelic chondrodysplasia punctata type 3 (RCDP3), a disease for which *bs2* is the only animal model. The hypomorphic *bs2* mouse represents a useful model for investigation of the tissue specificity of ether lipid requirements which will be particularly valuable for elucidating the mechanism of cataract formation resulting from ether lipid depletion.

2149/W

Podocyte-specific expression of wildtype or mutant Trpc6 in mice is sufficient to cause glomerular disease. *C.P. Canales[1,2], P. Krall[2,3], P. Kairath[2,3], P. Carmona-Mora[1,2], J.D. Carpio[4,5], S.A. Mezzano[5], J. Li[6], C. Wei[6], J. Reiser[6], J.I. Young[1,2], K. Walz[1,2].* 1) John P. Hussman Institute for Human Genomics, Miami, FL; 2) Centro de Estudios Científicos, CECS, Valdivia, Chile; 3) Universidad Austral de Chile, Valdivia, Chile; 4) Institute of Anatomy, Histology and Pathology , Valdivia, Chile; 5) Nephrology Laboratory, School of Medicine, Universidad Austral, Valdivia, Chile; 6) Division of Nephrology and Hypertension, Leonard Miller School of Medicine, University of Miami.

Focal and Segmental Glomerulosclereosis (FSGS) is a major cause of end stage renal disease and is increasing in frequency. TRPC6 (Transient receptor potential channel 6) is a six transmembrane domains protein which function is related with the calcium transport towards the cytoplasm through a pore located between the transmembrane domains 5 and 6. Mutations in the TRPC6 gene have been associated with familiar forms of FSGS affecting children and adults. In addition, acquired glomerular diseases are associated with an increase in TRPC6 expression levels. However, the exact role of TRPC6 in the pathogenesis of FSGS remains to be elucidated. In this work we have generated and characterizated three different transgenic mouse lines with podocyte-specific overexpression of the wild type and two previously described mutant forms of Trpc6 (P111Q and E896K) that were related to FSGS. Consistent with the human phenotype a significantly increased but non-nephrotic range of albuminuria was detectable in some transgenics. The histological analysis of the transgenic lines demonstrated that they developed a kidney disease similar to human FSGS with significant increase of the mesangial matrix, perihilar hyalinosis and glomerular collapse. Moreover, differences in the presence of glomerular lesions were found between the wild type mice and mice expressing the wild type Trpc6 as well as the mutant forms of the channel. Finally, electron microscopy analysis of glomerulus of transgenic mice showed extensive podocytes foot process effacement. Taken together, our results indicates that overexpression of Trpc6 (wild type or mutated) in podocytes is sufficient to cause a kidney disease consistent with FSGS. This data contribute to reinforce the central role of podocytes in the etiology of FSGS and these mice constitute an important new model to study future therapies and outcomes of this complex disease.

2150/W

Function of the Williams Syndrome Transcription Factor Baz1b. *G. Didelot, A. Reymond.* Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland.

One example of recurrent chromosomal rearrangements is the heterozygous ~1.5 Mb microdeletion associated with the Williams-Beuren syndrome (WBS). WBS is a neurodevelopmental disorder characterized by mental retardation with unique cognitive and personality profile, distinctive facial features, supravalvular aortic stenosis, short stature, connective tissue anomalies, hypertension, infantile hypercalcemia, dental and kidney abnormalities, premature aging of the skin, impaired glucose tolerance and silent diabetes. This syndrome results from hemizygosity of 25 genes, five of which encode transcription factors. We focused on one of these regulatory molecules, the Williams Syndrome Transcription Factor BAZ1B, because we hypothesized that even modest perturbations in his dosage might substantially alter the expression of target genes, thus profoundly affecting the phenotype of patients. BAZ1B was biochemically identified as a major component of two distinct chromatin-remodeling complex: WINAC, a SWI/SNF-type complex, and WICH, a ISWI-type complex. To address the physiological and molecular role of BAZ1B in vivo, we ablated the expression of its ortholog, Baz1b, in mice using a transposable element insertion in its 5'UTR region. All Baz1b-/- pups die just before birth from a cardiac defect. Fetuses with this genotype appear, however, healthy and alive at E18.5 suggesting a defect in the last steps of their development. No residual expression of Baz1b transcripts is found in the Baz1b-/- fetuses, while it is considerably reduced in the hemizygous Baz1b+/- models. We will present a detailed description of the cardiac anomalies of these animals. To identify the target genes of the Williams Syndrome Transcription Factor BAZ1B and thus possibly pinpoint the genes, which when dysregulated are potentially playing a role in the WBS phenotype and/or the Baz1b-/- cardiac defect, we performed ChIP-sequencing using two different anti-BAZ1B antibodies in lymphoblastoid cell lines from control individuals and WBS patients.

2151/W

Medaka Model for Fibrodysplasia Ossificans Progressiva. *A. Shimizu[1,2], N. Shimizu[2].* 1) Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan; 2) Advanced Research Center for Genome Super Power, Keio University, Tsukuba, Japan.

Fibrodysplasia ossificans progressiva (FOP) is a very rare genetic disease (1 in 2 millions) with a symptom of ectopic ossification (bone formation) in the skeletal muscle, tendon, ligament and articulation, and inherited in an autosomal dominant manner. Mutations in the ACVR1 (activin A receptor, type I) /ALK2 gene on the chromosome 2q24.1 was considered responsible for this disease. The ACVR1 is a member of ALK gene family (ALK1-ALK7), producing a 57-kDa transmembrane receptor kinase for a ligand BMP4, of which certain missense mutation results in uncontrolled signaling for bone formation. Previous report demonstrated that intramuscular injection of a viral vector carrying dominant mutant of Alk2 caused local bone dysplasia in the muscle of rats, but it was insufficient to use as FOP model for detailed analysis of pathogenesis. Here, we report a novel FOP model using small fish "medaka". In this study, we first confirmed the presence of all members of ALK family in the medaka genome and performed detailed analysis of medaka Alk2 gene in terms of the genome structure, tissue and developmental expression, cDNA cloning and in vitro mutagenesis. We produced a transgenic medaka that over-expressed a mutant Alk2 gene in the skeletal muscles and exhibited significantly reduced skeletal muscle formation. However, the ossification was not observed. Therefore, we changed a strategy to produce more intricate transgenic medaka by employing the Cre-loxP system, Desmin gene promoter for specific expression in muscle progenitor cells and hsp70 gene promoter for stringent expression of Cre upon heat shock induction. Moreover, ligand BMP4 was used in place of receptor Alk2. We produced two types of transgenic medaka that carry the construct DES::loxP-GFP-loxP-BMP4 and hsp::Cre-Cherry, respectively. By crossing these two types of transgenic medaka, we were able to produce a novel transgenic medaka, in which expression of relevant genes can be under the control of time and space during development or local heat shock induction. We will present the interesting phenotypes as a medaka model of FOP.

2152/W

Genetic Association Study between *ABCG5*, *ABCG8* genes and Cholelithiasis. *H. Yang[1], S. Shih[2,4], K. Hu[2,4], H. Chan[1], T. Chang[1], C. Hung[2], H. Wang[2], M. Lin[1], Y. Lee[1,3,5].* 1) Medical Research Dept, Mackay Memorial Hospital, Taipei, Taiwan; 2) Internal Medicine Dept, Mackay Memorial Hospital, Taipei, Taiwan; 3) Pediatrics Dept, Mackay Memorial Hospital, Taipei, Taiwan; 4) Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 5) Pediatrics Dept, Taipei Medical University, Taipei, Taiwan.

Cholelithiasis prevalence was increased in Taiwan in decades. It is thought to be a complex process caused by genetic and environmental factors. Composition of biliary bile and genes involved in biliary bile regulation are highly associated with cholelithiasis. Adenosine tripohsphate-Binding Cassette (ABC) transporters are known to involved in biliary bile excretion and transport. The ABCG5 and ABCG8 belong to G subfamily of ABC transporter. Both of them have been demonstrated in association with cholelithiasis in Caucasian via genome-wide association scan. The aim of this study is to find if *ABCG5* and *ABCG8* genes polymorphisms associate with cholelithiasis in Taiwanese population. We enrolled 375 patients with cholelithiasis and 379 gallstone-free controls in our study. Polymorphisms of *ABCG5 E604Q* (rs6720173), *ABCG8 D19H* (rs11887534), *C54Y* (rs4148211) and *T400K* (rs4148217) were performed by TaqMan SNP genotyping assays. The frequencies of genotype, allele, carrier and haplotype were calculated directly and analyzed by Haploview 4.1 program. Our data showed no significant associations between cholelithiasis and specific *ABCG5/8* SNPs. This suggests that *ABCG5/8* genes do not confer increased susceptibility to cholelithiasis.

2153/W

In-vitro treatment with pravastatin and dexamethasone normalizes abnormal deposition of elastic fibers in dermal fibroblasts derived from patients with Restrictive Dermopathy - Possible therapeutic implications. *A. Hinek[1], B.H.Y. Chung[2,3], R. Teitelbaum[3], P. Shannon[4], D. Chitayat[2,3].* 1) Heart Centre, Hosp Sick Children, Toronto, Canada; 2) Division of Clinical and Metabolic Genetics, Hosp Sick Children, Toronto, Canada; 3) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Canada; 4) Department of Pathology and Laboratory Medicine, UoT, Toronto, Ontario, Canada.

Restrictive dermopathy (RD) is a lethal genodermatosis caused by mutations in lamin A or ZMPSTE24. We hypothesize that potential treatments used in another laminopathy, Hutchinson-Gilford progeria (HGPS), may also produce therapeutic effects in RD. We report the effect of statin and bisphosphonate on the fibroblasts and the surrounding extracellular matrix (ECM) obtained from a fetus with RD. CASE REPORT: The couple was 1st cousins of Pakistani origin with unremarkable family history. They had 2 pregnancies resulting in intra-uterine death at 27-28 weeks, both preceded by decreased fetal movement and oligohydramnios. In the 2nd pregnancy, autopsy revealed classical features of RD and their 1st pregnancy was retrospectively diagnosed with the same condition. IN-VITRO STUDIES: Sequencing of ZMPSTE24 gene showed homozygous p.Glu237Stop mutations in the 2nd fetus. Cultured skin fibroblasts showed abnormal lamin accumulation in the rim of the nuclei. Immuno-histochemistry showed abnormal assembly of elastin fibers due to defective deposition of fibrillin-1. While the RT-PCR showed normal expression of fibrillin-1 mRNA, Western blotting demonstrated peculiar accumulation of pro-fibrillin-1 and proportional deficiency in mature fibrillin-1. This indicates a defective processing of profibrillin-1 to fibrillin-1 which may prevent its assembly into normal microfibrils. Importantly, we found that pravastatin (100μM), but not pamidronate (100μM), ameliorated defective cleavage of pro-fibrillin-1 and improved deposition of microfibrils. Combination of pravastatin and dexamethasone (20μM) lead to further normalization of faulty elastic fibers deposition in the RD fibroblasts. CONCLUSION: Defective nuclear envelope architecture is associated with various phenotypes in laminopathies. There are in-vitro and in-vivo evidence that suggests inhibitors of fernesylation and geranylgeranylation are promising treatment for HGPS. However, for atypical progeria and mandibuloacral dysplasia, data available are so far not supportive. Our finding suggests that ZMPSTE24 deficiency may (indirectly) lead to defective profibrillin-1 processing and prevent the normal assembly of elastic fibers. This may explain the abnormal skin phenotype seen in RD. Our findings also highlight the potential of pravastatin and dexamethasone in alleviating RD phenotype. Further research is required to uncover the mechanism resulting in the correction of the abnormal elastogenesis in RD.

2154/W

Homozygosity Mapping and Linkage Studies in Saudi Arabian Patients with Hereditary Deafness. *F. Imtiaz[1], M. Al-Owain[2], K. Ramzan[1], G. Bin-Khamis[3], R. Allam[1], A. Al-Mostafa[1], S. Al-Hazza[4], K. Taibah[5].* 1) Genetics, KFSH & RC, Riyadh, Saudi Arabia; 2) Medical Genetics, KFSH & RC, Saudi Arabia; 3) Otolaryngology, KFSH & RC, Saudi Arabia; 4) Opthalmology, KFSH & RC, Riyadh, Saudi Arabia; 5) ENTMedical Centre, Riyadh, Saudi Arabia.

Deafness is the most common sensory deficit in human populations (1:1000 child births) with both genetic (50%) and environmental (50%) etiologies. Hearing impairment is clinically and genetically heterogeneous. It can be non-syndromic or can be associated with other symptoms (e.g. Usher or Pendred syndrome). It has been estimated that at least 300 human protein-coding genes are involved in the hearing process. Recessively inherited diseases are more prevalent in populations where consanguineous marriages are common, like Saudi Arabia. We are currently conducting a study to define the genetics of deafness in this population. Families with profound congenital deafness and an autosomal recessive mode of inheritance are a powerful resource for genetic linkage studies of recessively inherited deafness. Over 120 such families have been enrolled from different cities of Saudi Arabia. Affected individuals are initially screened for mutations in *GJB2* (*DFNB1*) by direct sequencing. According to our results, unlike various other populations, *DFNB1* is not a prevalent cause of deafness in the Saudi population. After performing homozygosity mapping and/or linkage analysis to identify candidate loci/genes in families where *DFNB1* has been excluded, mutations in numerous deafness-causing genes (*ATP6V1B1*, *LHFPL5*, *MARVELD2*, *MYO6*, *MYO7A*, *MYO15A*, *OTOF*, *SLC26A4*, *TMC1*, *TMPRSS3*, *USH1G*, and *WHRN*) have been identified. To conclude, a different set of genes are more common in Saudi Arabia as compared to other populations thereby complicating the identification of deafness loci/genes in this population. The benefit of this study will provide knowledge and awareness through carrier screening and genetic counseling; overall having a major impact upon early intervention and prevention of hereditary deafness.

Identification of a novel locus on Chromosome 11 in a large family with IMAGe Syndrome. *V.A. Arboleda[1], H. Lee[1], D. Braslavsky[2], S.F. Nelson[1], I. Bergada[2], E. Vilain[1].* 1) Department of Human Genetics, University of California, Los Angeles; 2) Division of Endocrinology, Hospital de Niños, Buenos Aires, Argentina.

IMAGe Syndrome (Intrauterine growth restriction(IUGR), Metaphyseal dysplasia, Adrenal hypoplasia congenita, and Genital anomalies) is a multisystem developmental disorder with life-threatening consequences. The severity of each of the symptoms is variable, with some cases diagnosed in the neonatal period due to adrenal crisis while others only come to attention in early childhood with developmental delay, and discovery of the skeletal phenotype and/or endocrine anomalies, The genital anomalies -cryptorchidism and hypospadias- are only present in 46, XY neonates. Although initially described in isolated cases, the IMAGe syndrome was recently identified in a large five-generation family from Argentina. Within this pedigree, there were seven affected individuals who were studied here, while ten members of the family died in the neonatal period, presumably affected by the same condition. Saliva was collected from seven affected and one unaffected and genomic DNAs from these samples were analyzed on the Affymetrix 250K SNP arrays. Familial relationships were confirmed by examining the extent of sharing between every possible pair of samples, and no large blocks of homozygosity were detected in any of the samples, indicating that consanguinity was not likely to have contributed to the disorder. The samples were analyzed using a custom script that detects Identical-by-descent (IBD) regions (B. Merriman, in preparation). One region on chromosome 11 was identified as IBD among all seven affected individuals and not with the one unaffected. The region is 17.1Mb in size, containing 590 UCSC known genes. The equivalent LOD score for this linkage signal is 5.4. This region on chromosome 11 is the first locus identified in association with the IMAGe syndrome. We cross analyzed this small region using the UCLA Gene Expression Tool (UGET) to identify potential candidates that are co-expressed with known genes important in cartilage and adrenal development for sequence analysis. Identifying the genetic loci responsible for this severe and often fatal condition of the newborn will allow clinicians to better understand, diagnose and, ultimately, treat patients with IMAGe syndrome.

2156/W

An interactor of SPG11 and SPG15 also accounts for hereditary spastic paraplegia (SPG48). *M. Slabicki[1], E. Mundwiller[2], M. Theis[1], D.B. Krastev[1], S. Samsonov[3], M. Junqueira[1], M. Paszkowski-Rogacz[1], J. Teyra[3], A.K. Heninger[1], I. Poser[1], F. Prieur[4], J. Truchetto[2], C. Confavreux[5], C. Marelli[2], A. Durr[2], J.P. Camdessanche[4], A. Brice[2], A. Shevchenko[1], M.T. Pisabarro[3], F. Buchholz[1], G. Stevanin[2].* 1) Max Planck Institute for Molecular Cell Biology and Genetics, Dresden, Germany; 2) CR-icm, INSERM / UPMC UMR_S975 - NEB, Paris, France; 3) Structural Bioinformatics, BIOTEC TU Dresden, Germany; 4) Hôpital Nord, Saint Etienne, France; 5) Hôpital Neurologique, Lyon, France.

Hereditary spastic paraplegias (HSP) are rare neurodegenerative disorders caused by the degeneration of the cortico-spinal tracts leading to lower-limb spasticity. HSP is a highly heterogeneous condition with at least 46 loci identified so far. A potential interaction of two of the responsible genes, SPG11 and SPG15, has been suggested on the basis of similar neurological symptoms and common expression profiles in adult rat brain. Using proteomic studies, we have identified a protein partner of spatacsin and spastizin, the protein products of the SPG11 and SPG15 genes. We investigated if any unexplained HSP cases could be linked to mutations in this SPG11/15 partner. Direct sequencing of this gene in 166 unrelated HSP patients, including 38 and 64 cases with a recessive or dominant inheritance pattern and 64 sporadic cases identified 7 known and 15 new variants, respectively. Most of these variants were not considered causative, because they did not affect protein sequence, were not predicted to alter correct splicing or were also found frequently in controls. More interestingly, we found a homozygous mutation in two French siblings (FSP-083), which was not detected in 156 Caucasian and 242 North-African control chromosomes. In these patients, a complex indel generated a frameshift and a premature stop codon. Both affected patients presented with progressive spastic paraplegia associated with urinary incontinence since age 50 and 49, respectively. Cerebral MRI was normal but spinal hyperintensities at C3-C4 and C7 were observed in one. Both parents died at the age of 72 and 77, respectively, of non neurological causes. They originated from two neighboring villages but there was no known consanguinity. However, the analysis of three close microsatellite markers and the loss of heterozygosity (LOH) search using CYTO_12 (Illumina) microarrays confirmed that the region is homozygous in both affected patients. In conclusion, we identified mutations in 2 HSP patients in a novel and rare HSP-associated gene, SPG48.

2157/W

Determining the impact of *GALNT12* germline mutations on hereditary colorectal cancer. *E. Clarke, R. Green, J. Green, P. Parfrey, M. Simms, K. Mahoney, B. Younghusband, M. Woods.* Discipline of Genetics, Memorial University, St. John's, Newfoundland, Canada.

Approximately 35% of all colorectal cancer can be attributed to familial risk. The Canadian province of Newfoundland and Labrador (NL) has the second highest incidence rate of colorectal cancer (CRC) in North America. Previous mutation analysis investigating the NL CRC population has revealed that the high frequency of hereditary CRC in NL is likely attributed to novel susceptibility genes. Recently, Guda et al. identified somatic and germline disease causing variants in *GALNT12* among CRC patients. These results suggest that *GALNT12* may be a novel gene associated with CRC susceptibility. *GALNT12* encodes an enzyme that is involved in glycosylation and is highly expressed in the human colon. The purpose of this study was to investigate the impact of *GALNT12* germline mutations in NL CRC families referred to the genetics clinic. We sequenced *GALNT12* in 130 CRC patients to investigate if variants within this gene segregate with the disease. Probands included in the study have a high family incidence of CRC and were referred to the Provincial Medical Genetics Program. Twenty percent (20%) of our cohort fulfills the high risk Amsterdam I criteria while an additional 65% of the families fulfill the Revised Bethesda criteria. Approximately 8% of the cohort harbours a mutation in one of the known genes associated with CRC. We identified three different variants in the *GALNT12* gene - c.907G>A (3 probands), c.781G>A (2 probands) and c.1187A>G. Functional testing by Guda et al. has shown that the c.907G>A variant reduces the enzymatic activity of the protein to 37% of wild-type (WT). These tests also revealed that c.781G>A decreases the enzymatic activity to 85% of WT and therefore this variant is considered neutral. The third variant identified, c.1187A>G, has not been previously reported and the effect this variant has on enzymatic activity is currently unknown; however, PolyPhen, SIFT and Panther predict this variant to be pathogenic. Two families showed segregation of c.907G>A with the disease. Both of these families fulfill the Revised Bethesda criteria. In total, we identified three CRC probands that harbour a *GALNT12* mutation and another proband with a possible causal variant. None of the probands identified with a *GALNT12* variant harboured any other mutations that occur within the known genes associated with CRC, namely *APC,MUTYH, MLH1, MSH2, MSH6* and *PMS2*. This study further supports the association between *GALNT12* and the development of hereditary CRC.

2158/W

The rs854560 variant of the PON1 predisposes individuals to harbouring low high density lipoprotein levels. *B. Baz[1], M. Vigilla[1], O. Alboudary[1], P. Muiya[1], E. Andres[1], M. Alshahid[2], S. Majid[1], N. Dzimiri[1].* 1) Department of Genetics, Reseach Centre, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia; 2) King Faisal Heart Institute. King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia.

The involvement of paraoxonase 1 (PON1) gene polymorphism in dyslipidaemic disorders and early onset of coronary artery disease (CAD) remains poorly studied. In a preliminary genome-wide linkage study on early onset CAD involving two families (22 individuals) with predominant heterozygous familial hypercholesterolaemia, we identified several loci, among others, on chromosome 7 which harbours the PON1 gene, using the Affymetrix Gene Chip 250 sty1 mapping array. The present study pursued a population-based association analysis for 5 selected PON1 variants rs854560, rs662, rs854552, rs3917577 and rs3735590 in 1013 cases harbouring low high density lipoprotein (lHDL) levels versus 2035 normolipidaemic controls using the Applied Biosystems real-time PCR procedure. Among these variants, rs854560 [Odds ratio(95% Confidence Interval = 1.13(1.02-1.23); p=0.015] was associated with lHDL levels. Thereby, the autosomal recessive mode of inheritance [1.28(1.10-1.51); p=0.002] appeared to be responsible to this causative association. None of the variants was related with CAD per se. However, the recessive mode for rs3917577 showed a causative relationship [1.23(1.03-1.47); p=0.023] with the disease, but no confounding effect of gender, age, myocardial infarction, type 2 diabetes mellitus, or obesity was observed. The results indicate that PON1 is a susceptibility gene for harbouring lHDL, and the presence of the rs3917577 variant increases the risk of acquiring CAD among dyslipidaemic individuals.

2159/W

Prader-Willi syndrome with normal intellect: A forme fruste phenotype caused by deletion of the HBII-85 small nucleolar RNA cluster. *S. Demczuk[1,2], G.E. Graham[2], N. Carson[2].* 1) Dept of Laboratory Medicine, Saskatoon Health Region, Saskatoon, SK; 2) Dept of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON.

Prader-Willi syndrome (PWS) is caused by paternal deficiency of genes in the 15q11.2 chromosomal region either through deletion, imprinting defect or maternal uniparental disomy. Our patient is a 36year-old woman who came to our attention after her first-born child with Down syndrome was referred to "rule out Prader-Willi syndrome". The patient provided the intriguing history that she had been diagnosed with Prader-Willi syndrome in the mid-1980s and that she had a paternal cousin with typical PWS. She recalled being told that her future children would be at risk of having PWS. We were able to obtain copies of consultations from three clinical geneticists dating back to this period. One clinician had made the diagnosis of PWS; the other two did not feel that the patient had enough features to make this diagnosis. At the time a 550 band karyotype was normal; FISH or methylation investigations of the 15q11.2 region were not performed. The patient had a measured IQ of 87 in childhood and was treated for hypogonadotrophic hypogonadism in adolescence. Her current findings include normal stature, moderate obesity without dietary restriction, the characteristic facial features and straight ulnar borders of the hands. She meets at least 5 of the seven major diagnostic criteria for PWS. Molecular testing for PWS by methylation sensitive multiplex ligation-dependant probe amplification (MRC Holland) showed a deletion of maximum 363.8 kb involving the HBII-85 C/D box small nucleolar (sno)RNA cluster. Most C/D box snoRNAs are involved in 2'-O-ribose methylation of ribosomal RNAs. There are two clusters of C/D box snoRNAs in 15q11.2: HBII-52 and HBII-85. They are paternally imprinted, highly expressed in brain and contained within introns of the SNRPN gene. Their targets and functions are unknown. Two reported families with a paternally inherited microdeletion of the entire HBII-52 cluster did not manifest features of PWS, so a crucial role of the HBII-85 C/D box snoRNA cluster in the pathogenesis of PWS is suggested by the report of a patient with a microdeletion encompassing the HBII-85 cluster, the HBII-438A and a portion of the HBII-52 cluster of snoRNAs. However, unlike our patient, this individual has a classical cognitive phenotype with mild intellectual disability. Our data further supports a critical role for the HBII-85 snoRNA cluster in the causation of PWS and demonstrates that deletion of this cluster is compatible with a normal intellect.

SNP Genotyping Supporting CTT Deletion in NFIC Gene Associated with RDD. *J. Dong[1], A.C. Acevedo[2], M.G. Martinez[3], H. Riveria[3], L. ÖZER[4], YX. Wu[1], M. MacDougall[1].* 1) Orthodontics, University of Alabama at Birmingham, Birmingham, AL; 2) 2Dental Anomalies Clinic, University Hospital of Brasilia, Department of Dentistry, Faculty of Health Science, University of Brasilia, Brasilia, Brazil; 3) Central University of Venezuela, Ciudad Universitaria, Caracas, Venezuela; 4) Ankara University Faculty of Dentistry Department of Pedodontics 06500 Besevler Ankara Turkey.

Radicular dentin dysplasia (RDD) is a rare disease with an estimated prevalence of 1/100,000 in general population. RDD patients present with short roots that lead to premature loss of both primary and permanent dentitions. The genetic cause of the condition is unknown. Previously, our laboratory have identified a c*+8-10delCTT in the 3' terminal untranslated region of human NFIC gene in a RDD family. The deletion was found in both alleles of the proband but only a single deleted allele in his unaffected sister and parents who are first cousins. To confirm if the deletion is a disease causing mutation in RDD, four additional RDD families from 4 different countries (Untied States, Brazil, Venezuela and Turkey) were added to this panel. NFIC gene mutational analysis was performed by PCR and sequencing using NFIC gene specific primers and SNPs genotyping was carried out by sequencing and TaqMan assay. SNPs distributed around 130kb segment of the NFIC gene on chromosome 19 were genotyped in the five RDD families as well as in unrelated controls. Our results showed that the homozygous deletion was seen in the probands from three out of the five RDD families, the heterozygous carriers for the deletion allele are cosegregated in their unaffected parents and siblings. The frequency of the c*+8-10delCTT allele was 1.13% (4/354) in Caucasians, and 0% in Hispanics (0/72) and African American (0/80) unrelated control chromosomes. Furthermore, we constructed the haplotypes based on the genotyping data and pedigree information. Haplotype analysis showed that the patients carrying the homozygous deletion have two identical haplotypes, where both of their biological parents and their siblings who are heterozygous healthy carriers for the mutation do share one affected haplotype, but the patients from other two RDD families who do not carry the CTT deletion present different haplotypes. Our studies indicated that the NFIC c*+8-10delCTT allele is likely associated with the autosomal recessive RDD and suggested that the RDD is a genetically heterogeneous disorder. This study will allow us to understanding tooth root formation and mechanisms underlying abnormal root development. The study is supported by IOHR/ UAB-SOD.

Mutations in MYBPC2 cause Distal Arthrogryposis type 2B (DA2B). *H. Gildersleeve, M. McMillin, A.E. Beck, M.J. Bamshad.* Dept Pediatrics, Univ Washington, Seattle, WA.

The Distal Arthrogryposis (DA) syndromes are a group of autosomal dominant disorders characterized by multiple congenital contractures of the digits, wrists, and ankles. We have defined at least 10 different DA types (DA1-DA10) based on clinical criteria, and over the past decade we and others have discovered mutations in TNNI2, TPM2, TNNT3, MYH3, MYH8, MYH2, MYH13, and, most recently, MYBPC1 that explain about half of all DA cases. The proteins encoded by these genes are perhaps both qualitatively and quantitatively the most important molecules in skeletal muscle, as they bring about the production of force. As part of an ongoing effort to screen candidate genes that encode components of the contractile complex for mutations that cause DA, we sequenced MYBPC2 in 70 families with DA2B or Sheldon-Hall syndrome (OMIM#601680). MYBPC2 is an ortholog of MYBPC1 that encodes a myosin regulatory protein expressed in fast-twitch myofibers. In 2 of 70 families, we found frameshift mutations that segregate with affected individuals in each family and that were not found in 200 control chromosomes matched by ancestry. Both mutations are single base pair deletions, c.1995delT in exon 18 and c.2808delC in exon 24, which are predicted to lead to premature protein truncation. This finding suggests that haploinsufficiency of myosin binding protein C2 results in congenital contractures. These results bring to nine the total number of genes that are known to underlie DA syndromes. While mutations in MYBPC2 appear to be an infrequent cause of DA2B, understanding the mechanism by which contractile force production is perturbed by MYBPC2 mutations could provide important insights about general mechanisms that underlie heritable congenital contractures.

2162/W

Loss of PAK3 kinase activity underlies a novel form of X-linked neuroichthyosis. *P. Magini[1], T. Pippucci[1], S. Coppola[2], E. Stellacci[2], R. Zuntini[1], S. Miccoli[1], E. Pompilii[1], C. Graziano[1], G. Cenacchi[3], I. Neri[4], C. Garone[5], D.M. Cordelli[5], V. Marchiani[5], R. Bergamaschi[6], G. Neri[7], O. Zuffardi[8], L. Mazzanti[9], A. Patrizi[4], E. Franzoni[5], G. Romeo[1], M. Tartaglia[2], M. Seri[1].* 1) Genetica Medica, Università di Bologna, Bologna, Italy; 2) Dipartimento di Biologia Cellulare e Neuroscienze, Istituto Superiore di Sanità, Roma, Italy; 3) Anatomia e Istologia Patologica, Università di Bologna, Bologna, Italy; 4) Dermatologia, Università di Bologna, Bologna, Italy; 5) Neuropsichiatria Infantile e Disturbi Comportamento Alimentare, Univerità di Bologna, Bologna, Italy; 6) Pronto Soccorso Pediatrico e Pediatria d'Urgenza, Università di Bologna, Bologna, Italy; 7) Istituto di Genetica Medica, Università Cattolica del Sacro Cuore, Roma, Italy; 8) Genetica Medica, Università di Pavia, Pavia, Italy; 9) Ambulatorio di Auxologia, Sindromologia e Malattie Rare, Università di Bologna, Bologna, Italy.

The term 'neuroichthyosis' defines a clinically and genetically heterogeneous group of syndromes in which ichthyosis can be found in association with various neurological disorders, including spasticity, epilepsy, polyneuritis and pyramidal tract signs. Here we report the identification of a gene potentially responsible for a novel X-linked form of syndromic neuroichthyosis characterized by ichthyosis, agenesia or hypoplasia of corpus callosum, microcephalia, seizures, mental retardation and spastic tetraparesis. Linkage analysis performed on a three-generation family transmitting the trait revealed a critical region of nearly 25 Mb in Xq21.33q24 including about 250 genes. Based on the clinical overlap with cardio-facio-cutaneous syndrome, the scanning of the entire coding sequence of PAK3, which encodes a serine/threonine kinase with an important role in the cytoskeleton organization and linked to RAS signaling, allowed the identification of a G-to-T missense change at position c.1167 (K389N) co-segregating with the trait in the family. The mutation affected a highly conserved residue within the kinase domain of the protein, and was not observed in more than 450 control chromosomes X, strongly arguing against the possibility that the variant was a disease-unrelated polymorphism. PAK3 had been previously reported to be mutated in isolated mental retardation. Functional characterization of the PAK3 K389N mutant documented impaired kinase activity in vitro, similarly to what observed for some of the mutants associated with non-syndromic mental retardation. Confocal laser scanning microscopy analysis indicated a cytoplasmatic localization, as observed for the wild type protein. These data suggest a causative role of the PAK3 K389N mutation in the pathogenesis of this novel form of X-linked neuroichthyosis. While the possibility that another gene within the critical region might contribute to the trait, worsening the clinical picture caused by loss of PAK3 catalytic activity, can not ruled out, the relevant expression of PAK3 in keratynocytes at both mRNA and protein levels would suggest an implication of this gene also in the ichthyosis occurrence, possibly resulting from kinase activity-independent function of the protein.

2163/W

Molecular Analysis of *SEC23IP* as a Potential Candidate Waardenburg Syndrome Gene. *T.A. Maher[1], G. Zhou[1], J.M. Milunsky[1,2,3].* 1) Center for Human Genetics; 2) Department of Pediatrics; 3) Genetics and Genomics, Boston University School of Medicine, Boston, MA.

Waardenburg syndrome (WS) is a genetically heterogeneous congenital neurocristopathy. It is an auditory-pigmentary syndrome characterized by pigmentary abnormalities of the hair, including a white forelock, premature graying, pigmentary changes of the iris, such as heterochromia irides, and congenital sensorineural hearing loss. There is quite marked expressivity of the syndrome both within and between families. Waardenburg syndrome has been classified into 4 main phenotypes. WS type 1 is distinguished by the presence of dystopia canthorum. WS type 2 is distinguished from type 1 by the absence of dystopia canthorum and is further divided into 5 subtypes. WS type 3 has dystopia canthorum and upper limb abnormalities. WS type 4, also known as Waardenburg-Shah syndrome, has the additional feature of Hirschsprung disease and is also divided into 3 subtypes. WS1 and WS3 are caused by mutations in the *PAX3* gene, WS2A by mutations in *MITF*, WS2D by mutations in *SNAI2*, WS2E by mutations in *SOX10*. WS2B and 2C have been mapped to 1p21-p13.3 and 8p23 respectively. WS4A is caused by mutations in the *EDNRB* gene, WS4B by mutations in *EDN3* and WS4C by mutations in *SOX10*. The detection rate for mutations in the 4 main phenotypes is quite variable and very limited in some phenotypes thus indicating one or more undiscovered genes are involved in WS. Over the past 20 years there have also been at least 8 other genes associated with WS. Our clinical molecular diagnostics laboratory currently sequences *PAX3*, *MITF*, *SOX10*, *EDNRB* and *EDN3* and also performs deletion/duplication (MLPA) analysis for the above genes. Recently, a publication by McGary et al, performing an analysis of orthologous genes to look at alternative models for human disorders, indicated *SEC23IP* may be involved in causing WS. They observed a plant-human phenolog relating negative gravitropism in Arabidopsis to WS in humans. This finding was confirmed by *SEC23IP* expression in the neural crest cells of Xenopus embryos. We sought to determine if the *SEC23IP* gene was responsible for the majority of WS2 and/or a minority of WS1 in patients who previously had negative clinical molecular testing. We performed *SEC23IP* sequencing of the 18 coding exons on a small cohort of 9 WS2 and 6 WS1 patients. No mutations were identified in this cohort. Further molecular studies of a larger cohort are necessary to evaluate if mutations in this gene are causative of a minority of WS.

2164/W

Autosomal recessive spastic paraplegia with thin corpus callosum among Arabs, clinical and genetic findings. *S. Majid[1], H. Murad[2], B. Baz[1], R. Al Amr[1], S. Al Yamani[2], S. Al-Wadaee[1], B. Meyer[1], S. Bohlega[2].* 1) Functional Genomics, Dept. of Genetics, King Faisal Specialist Hosp, Riyadh, Saudi Arabia; 2) Department of Neurosciences, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia.

Spastic paraplegia represents a group of heterogeneous neurodegenerative disorders. One of the most common and clinically distinct forms of familial spastic paraplegia is autosomal recessive hereditary spastic paraplegia with thin corpus callosum (ARHSP-TCC). Mutations in spatacsin gene (KIAA 1840) have been recently identified as a frequent cause of ARHSP-TCC. All the mutations described in the spatacsin. This far results in loss of function. Three unrelated Saudi Arabian families were studied with ARHSP-TCC. Ten affected individuals were studied. Clinical presentations include early gait disturbance at early age (2-14 years), rapid progression of spastic paraplegia with mild to moderate cognitive impairment and evidence of peripheral neuropathy in two families. Brain MRI showed thin corpus callosum accompanied by perventricular white matter changes and cortical atrophy. Linkage analysis localized the gene to SPG11 (chr. 15). Sequencing revealed three mutations. The first is an insertion of 23 bp (L1268L fsX), the second is a 1 bp deletion (S1923R fsX), and the third is a substitution leading to a stop codon (R651X). All three mutations lead to premature truncations within the coding region of the SPG11 gene encoding spatacsin. The identification of these mutations confirms further a causative link between spatacsin gene and ARHSP-TCC in these families.

2165/W

Homozygous duplication at 10p11.21 in a boy with clinical manifestations of Lin-Gettig syndrome. *J.F. Mazzeu[1,2], F. Zhang[3,4], C.M. Carvalho[3], A.C. Krepischi[1,5], S. Yatsenko[3], E. Pardono[1], P.A. Otto[1], C. Rosenberg[1], J. Lupski[3,6,7], A.M. Vianna-Morgante[1].* 1) Departmento de Genética e Biologia Evolutiva, Universidade de São Paulo, São Paulo, Brazil; 2) Departmento de Genética e Morfologia, Universidade de Brasília, Brasilia, Brazil; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 4) State Key Laboratory of Genetic Engineering and MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, China; 5) Hospital AC Camargo, São Paulo, Brazil; 6) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 7) Texas Children's Hospital, Houston, TX, USA.

Lin-Gettig syndrome is an extremely rare disorder previously reported in only three patients presenting with craniosynostosis, agenesis of the corpus callosum, severe mental retardation, peculiar facies, camptodactyly and hypogonadism. Here we report a boy with clinical manifestations of Lin-Gettig syndrome, born to consanguineous parents. He presented with severe developmental delay, bilateral deafness, hoarse cry, short stature, craniostenosis of sagittal suture, plagiocephaly, microcephaly, dolicocephaly, bitemporal depression, facial asymmetry, apparent hypertelorism, downslanting palpebral fissures, ptosis, strabismus, blue sclerae, long philtrum, micrognathia, highly arched palate, submucosal cleft, low-set ears, hyperfolded ear-helix, short neck, pterygium coli, mamilar hypertelorism, shawl scrotum, cryptorchidism, café-au-lait spots, congenital hip-dislocation, bilateral single palmar crease, camptodactyly, and posterior protrusion of calcaneus. Magnetic resonance imaging documented agenesis of the corpus callosum with enlarged lateral ventricles. He had an atrial sept defect. Since the etiology of Lin-Gettig syndrome is unknown, we tested the patient for microimbalances by array-CGH using an Agilent 244K platform. Two homozygous duplications 300 kb apart at 10p11.21 were detected: a 250 kb duplication including the 5'end of *PARD3* gene, and a 160 kb duplication encompassing *CREM* and the 3'end of *CCNY*. Both parents were found to be heterozygous for each of the two duplications. Although present in four copies in the patient, the *CREM* gene is less likely to contribute to his clinical phenotype since its main role is in spermiogenesis, and both parents carry three copies of this gene. On the other hand, disruption of *PARD3* and/or *CCNY* might be causative of the phenotype, acting as recessive mutations. *CCNY* is involved in the control of cell division, in the regulation of cyclin-dependent kinases. *PARD3* is involved in asymmetrical cell division and polarized growth, and knock-out mice for *Pard3* present with embryonic lethality, abnormal heart development, growth retardation, prominent telencephalic vesicles, short tail and edema. The complexity of these malformations is comparable to that of our patient's clinical signs, supporting homozygous *PARD3* disruption as potentially contributing to the phenotype.

Association of LOC339766 with High Myopia in Caucasian Family Cohorts. *R. Metlapally[1,2], K. Tran-Viet[2], D. Abbott[2], F. Hawthorne[2], F. Malecaze[3], P. Calvas[3], D. Mackey[4], T. Rosenberg[5], S. Paget[3], J. Guggenheim[6], Y. Liu[2], R. Allingham[1], M. Hauser[2], Y. Li[2,7], T. Young[1,2].* 1) Duke Eye Center, Durham, NC, USA; 2) Duke Center for Human Genetics, Durham, NC, USA; 3) Toulouse University Hospital, Toulouse, France; 4) Lions Eye Institute, Centre for Ophthalmology and Visual Science, University of Western Australia, Perth, Australia; 5) Gordon Norrie Centre, National Eye Clinic, Hellerup, Denmark; 6) School of Optometry and Vision Sciences, Cardiff University, Cardiff Wales, United Kingdom; 7) Department of Biostatistics and Bioinformatics, Duke University Medical Center. Durham, NC, USA.

Introduction: We previously reported a high-grade myopia locus on chromosome 2q37 which has been independently replicated in other studies. To identify the causative variant/s, we employed a multi-pronged approach comprised of intra-locus densely spaced SNP family-based association analyses to refine the interval, contracted interval candidate gene identification, SNP variant discovery by case/control cohort candidate gene sequencing, and subsequent genotyping and association analysis in a full high-grade myopia family dataset for assessing myopia susceptibility. **Methods:** Illumina GoldenGate genotyping was performed on the original 4.56 Mb interval using 145 SNPs with an average spacing of 31.5 kb in a cohort of 146 multiplex high-grade myopia families. Family-based pedigree disequilibrium test (PDT) and the association in the presence of linkage (APL) test were used for determining association of markers with myopia phenotype stratified by severity. The region incorporating the LOC339766 gene showed significant association. To identify potential risk-associated sequence variants, sequencing was performed on coding exons in this gene in an independent select case (< -6.00 diopters (D) spherical equivalent (SE)) and control (> +0.50 D SE) dataset. Genotyping and association analyses were performed on variants identified and tagging SNPs using Taqman™ allelic discrimination assays in Caucasian Duke and International cohorts. Expression profiling studies were performed using an RNA panel of systemic tissues and retinal tissue. **Results:** PDT analyses from the GoldenGate assay data revealed significant association of several SNPs with high-grade myopia status involving the LOC339766 gene (p<0.01). Genotyping results (with variants identified and tagging SNPs) revealed significant association of the LOC339766 gene polymorphisms with myopia. The Duke cohort showed association with SNPs rs10203853 and rs17868346 (p <0.01, min p=0.004) and the International cohort showed association with SNPs rs17863814 and rs28900694 (p <0.01, min p=1x10-4). The results were consistent after correcting for multiple testing. LOC339766 was expressed in several systemic tissues and the retina. **Conclusions:** LOC339766 gene variants are associated with myopia in Caucasians. The 2q37 locus may play an important role in autosomal dominant juvenile-onset myopia development. Studies to further characterize this hypothetical gene are underway.

Missense mutations in *TCF8* cause late-onset Fuchs Corneal Dystrophy and interact with *FCD4* on chromosome 9p. *S.A. Riazuddin[1,2], N. Zaghloul[1], A. Al-Saif[1], L. Davey[1], B. Diplas[1], D. Meadows[2], A. Eghrari[2], M. Minear[3], Y. Li[3], G. Klintworth[4], N. Afshari[4], S. Gregory[3], J. Gottsch[2], N. Katsanis[1,5].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore,MD 21205, USA; 2) Center for Corneal Genetics, Cornea and External Disease Service,Wilmer Eye Institute, Johns Hopkins Hospital, Baltimore,MD 21205, USA; 3) Center for Human Genetics, Duke University Medical Center, Durham, NC 27710, USA; 4) Department of Ophthalmology, Duke University Medical Center, Durham, NC 27710, USA; 5) Center for Human Disease Modeling, Department of Cell Biology, Duke University, Durham, NC 27710, USA.

Fuchs corneal dystrophy (FCD) is a degenerative genetic disorder of the corneal endothelium that represents one of the most common causes of corneal transplantation in the United States. Despite its high prevalence (4% over the age of 40), the underlying genetic basis of FCD is largely unknown. Here we report missense mutations in *TCF8*, a transcription factor whose haploinsufficiency causes posterior polymorphous corneal dystrophy (PPCD), in a cohort of late-onset FCD patients. In contrast to PPCD-causing mutations, all of which are null, FCD-associated mutations encode rare missense changes suggested to cause loss of function by an *in vi*vo complementation assay. Importantly, segregation of a recurring p.Q840P mutation in a large, multigenerational FCD pedigree showed this allele to be sufficient but not necessary for pathogenesis. Execution of a genome-wide scan conditioned for the presence of the Q840P allele identified an additional late-onset FCD locus on chromosome 9p, whereas haplotype analysis indicated that the presence of the TCF8 allele and the disease haplotype on 9p leads to a severe FCD manifestation with poor prognosis. Our data suggest that PPCD and FCD are allelic variants of the same disease continuum and that genetic interaction between genes that cause corneal dystrophies can modulate the expressivity of the phenotype.

Altered mTOR-dependent Signaling and Differential mGluRs expression patterns in Fragile X Syndrome. *F. Tassone[1,2], C. Hoeffer[3,4], E. Klann[3], H. Wong[3], E.I. Sanchez[1], M. Careaga[2,5], P. Ashwood[2,5], R.J Hagerman[2,6].* 1) Department of Biochemistry and Molecular Medicine, University of California, School of Medicine, Davis, CA, USA; 2) M.I.N.D. Institute, University of California Davis Medical Center, Sacramento, CA, USA; 3) Center of Neural Science, New York University, NY , USA; 4) Smilow Neuroscience Institute, New York School of Medicine, NY, USA; 5) Medical Microbiology and Immunology, University of California at Davis, CA, USA; 6) Department of Pediatrics, University of California, School of Medicine, Davis, CA, USA.

Multiple studies have revealed the important role played by the mTOR (mammalian target of rapamycin) signaling pathway in learning and memory. All components of the mTOR pathway, which is involved in protein synthesis-dependent phase of synaptic strengthening, are present in dendrites suggesting a role for mTOR in the regulation of local translation through phosphorylation of its downstream targets. Thus, we have investigated whether altered mTOR signaling is present in subjects with fragile X syndrome (FXS), as the fragile X mental retardation protein, FMRP, absent in FXS subjects, plays an important role in translational repression. Our preliminary findings indicate that translation control mediated by the mTOR pathway is compromised in FXS. mTOR signaling cascade controls initiation of cap-dependent translation and is under control of metabotrobic Glutamate Receptors (mGluR). Group I mGluRs have been implicated in the pathogenesis of FXS. It is believed that the Fragile X Mental Retardation Protein (FMRP), which is absent in FXS, normally serves as a brake to the signaling pathway involving these receptors. Looking at the many mGluRs are functionally important in the periphery and are widely expressed on peripheral blood mononuclear cells. Our preliminary results show an altered cellular expression and signaling of mGluRs on PBMCs resulting in a differentially altered immune response following immune activation in the presence of mGluR agonists. The observed increases in translational signaling suggest excessive basal translation in FMRP-deficient cells, and this activity may contribute to the cognitive and behavioral deficits observed in subjects with FXS. The dysregulation of this system leads to down regulation of neurotransmitter receptors and possibly to abnormal neurodevelopment. Finally, the differentiation of mGluRs expression patterns and their role in the immune response in children with FXS will help differentiate therapeutic targets for future research.

2169/W

Genetic Mapping of Hereditary Vitreoretinopathy in a Three-Generation Family. *K. Tran-Viet[1], D. Abbott[1], E. Burner[1,3], C. Johnson[2], M. Johnson[2], W. Call[1], B. Zhao[1], R. Metlapally[1,3], Y. Li[1], T. Young[1,3].* 1) Duke Ctr Human Gen, Duke Med Ctr, Durham, NC; 2) Retina Consultants, Ltd, Fargo, ND; 3) Duke University Eye Center, Durham, NC.

Introduction: Wagner syndrome (WS) (OMIM 143200) is an autosomal dominant (AD) vitreoretinopathy characterized by vitreous fibrillary condensations, chorioretinal dystrophy, lattice degeneration, and high myopia, with a predisposition of developing cataracts and retinal detachment. WS maps to chromosome 5q13-14 with reported mutations in the CSPG2 gene. We studied a large three-generation Caucasian family with presumed WS, with either an AD inheritance model with reduced penetrance or an autosomal recessive (AR) model. No CSPG2 sequence variations were identified. A whole genome linkage study was performed to identify a novel locus. **Methods:** Genomic DNA samples derived from venous blood or saliva were collected from 38 family members (9 affected). Linkage mapping of genomic DNA was performed using the Illumina Infinium HumanLinkage-24 Panel (5913 SNPs). Genotype data were checked for Mendelian inconsistencies. Affected-only AD and AR linkage models were run using FASTLINK/HOMOG and MERLIN for two-point and multipoint analyses, respectively. Multipoint linkage was analyzed by MERLIN using two sub-pedigrees. Full pedigree multipoint analysis for suggestive linkage regions (LOD >1.5) was performed using SIMWALK. **Results:** AD model parametric multipoint analysis demonstrated HLOD scores > 2.00 at chromosome 12q12-12q14.1, with a peak HLOD score of 2.27 (rs1107654). Multipoint analysis with SIMWALK replicated a peak in this region (peak LOD = 1.975). FASTLINK two-point analysis demonstrated several clustered chromosome 12q SNPs with HLOD > 1.0, with a peak HLOD score of 1.23 on rs10875671. Parametric multipoint AR model analysis demonstrated HLOD scores of > 1.80 at chromosomal regions 7q21.3-7q31.1 (rs714438), 8p12-8p11.21 (rs1522845), 8q12.1-8q13.3 (rs884839), 9q21.31-9q22.2 (rs1359168), and 14q31.3-14q32.32 (rs942190). SIMWALK analysis of MERLIN multipoint results replicated all regions. Two-point linkage analysis only confirmed the 9q and 14q regions. **Conclusion:** We report a linkage peak at chromosome 12q12-12q14.1 [13.23 cM] associated with vitreoretinopathy in an AD model. Novel loci at chromosomes 9q [17.88 cM] and 14q [36.61 cM] were determined using a recessive model. Chromosome 12q12-12q14.1 is a known locus of the COL2A1 gene associated with Stickler syndrome. Interval refinement and candidate gene screening studies are underway.

2170/W

Novel FRMD7 gene mutation in a large multigenerational Indian family with X-linked congenital Nystagmus. *R. Uppala[1,5], R. Singh[2], S.K. Nath[3], M. Naveed[4], U. Ratnamala[1].* 1) Cancer Centre, Creighton Univ, Omaha, NE, USA; 2) Dr. P.L. Desai Eye Center, Navrangpura, Ahmedabad-380009, India; 3) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK USA; 4) Center for Arab Genomic studies (CAGS), Dubai, United Arab Emirates; 5) Green Cross Blood Bank, Ahmedabad, India.

Congenital nystagmus (NYS) is characterized by bilateral, and uncontrollable, involuntary movement of the eyes; its frequency is ~1:1500 live births. It is one of the most common neuro ophthamalological disorders among live births, and also reduces visual acuity. Nystagmus is transmitted in X-linked dominant, X-linked recessive and autosomal dominant forms with high penetrance and variable expressivity. Four NYS genomic locations (NYS1, NYS2, NYS3 and NYS4), mapped to Xq26.2, 6p12, 7p11.2 and 13q31-q22 respectively using family-based linkage analysis have been documented. Very recently, ~30 mutations of the FRMD7 gene, which maps to Xq26.2 region, have been found in NYS patients, suggesting that this gene plays an important role in the NYS development. We report a novel mutation of the FRMD7 in a large eleven-generation Indian pedigree with an isolated non-syndromic NYS in which 62 members affected by NYS with different phenotypic expression including asymmetric pendular eye movements with unidirectional jerky NYS and head nodding. The missense mutation, c.A917G, predicts a substitution of Arg for Gln at codon 305 (Q305R) within exon 10 of FRMD7. This mutation was found to be at a highly conserved residue within the FERM adjacent (FA) domain, hypothesized to have a regulatory function, based on similarity to other protein kinase substrates. A detailed data of the present family and mutation spectrum of FRMD7 gene will be presented.

2171/W

X-chromosome-specific array-CGH analysis indicates new genes, other than the *L1CAM* gene, involved in L1 syndrome. *Y.J Vos, K.K van Dijk-Bos, C.S. van der Werf, H. Alkema, R.M.W. Hofstra, K. Kok.* Department of Genetics, University Medical Centre Groningen, the Netherlands.

The L1 syndrome is an X-linked recessive disorder with a prevalence of one in every 30,000 newborn males. It comprises four neurological syndromes, all associated with mutations in the *L1CAM* gene. These syndromes are: HSAS (X-linked Hydrocephalus with Stenosis of the Aqueduct of Sylvius), MASA (Mental retardation, Aphasia, Spastic paraplegia and Adducted thumbs), SPG1 (X-linked complicated hereditary spastic paraplegia type 1) and X-linked ACC (Agenesis of Corpus Callosum).

Because only 20% of the patients clinically suspected of having L1 syndrome carry a mutation in the *L1CAM* gene, other genes might be involved. An X-chromosome specific 48K-oligonucleotide array was used to detect deletions that could include genes potentially involved in L1 syndrome. We have focused on the X-chromosome, since 95% of all L1 syndrome patients are males and family cases mostly show an X-linked recessive inheritance. By screening 60 selected patients (without a mutation in the *L1CAM* gene), 10 candidate deletions were identified containing 11 candidate genes, *DGAT2L6*, *POU3F4*, *GDI1*, *ASMTL*, *ATP6AP1*, *MID1*, *FRMPD4*, *MAP3K15*, *TGIF2LX*, *DDX53* and *TMEM27*. Based on additional criteria five genes were selected as being the best candidates, e.g. *POU3F4*, *DGAT2L6*, *GDI1*, *DDX53* and *TGIF2LX*. Sequence analyses of these five genes in 95 L1 syndrome patients showed in only one gene (the *GDI1* gene), in addition to the deletion, one probably pathogenic mutation, c.153-3C>T. From the low deletion and mutation frequency found, we conclude that at least the five selected genes do not appear to be major players in L1 syndrome.

Not finding a frequently involved second L1 syndrome gene might be caused by the selection of the candidate genes (maybe, one or more of the remaining six genes do harbor more mutations) or by the initial screening method searching for micro deletions (>2kb). By using this method, genes that only have point mutations or small deletions could have been missed. To overcome both we plan X chromosome-specific exome resequencing for this cohort.

2172/W

Heterozygous Germline Mutations in the CBL Tumor-Suppressor Gene Cause a Noonan Syndrome-like Phenotype. *S. Martinelli[1], A. De Luca[2], E. Stellacci[1], C. Rossi[3], S. Checquolo[4], F. RAS signaling plays a key role in controlling appropriate cell responses to extracellular stimuli, and participates in early and late developmental processes. While enhanced flow through this pathway had been established as a major contributor to oncogenesis, recent discoveries have revealed that aberrant RAS activation causes a group of clinically related developmental disorders characterized by facial dysmorphism, a wide spectrum of cardiac disease, reduced growth, variable cognitive deficits, ectodermal and musculoskeletal anomalies, and increased risk for certain malignancies. Here, we report that heterozygous germline mutations in CBL, a tumor-suppressor gene encoding for a multivalent adaptor protein with E3 ubiquitin ligase activity mutated in myeloid malignancies, can underlie a phenotype with clinical features fitting or partially overlapping Noonan syndrome (NS), the most common condition of this disease family. Independent CBL mutations were identified in two sporadic cases and two families from among 365 unrelated subjects with NS or suggestive features and negative for mutations in previously identified disease genes. Phenotypic heterogeneity and variable expressivity were documented. Mutations were missense changes altering evolutionary conserved residues located in the RING finger domain or the linker connecting this domain to the N-terminal tyrosine kinase binding domain, a known mutational hot-spot in myeloid malignancies. Mutations were shown to affect CBL-mediated receptor ubiquitylation and dysregulate signal flow through RAS. These findings document that germline mutations in CBL alter development to cause a clinically variable condition that resembles NS and that possibly predisposes to malignancies.

TRIM50 Williams Beuren Syndrome gene, a novel component of aggresomes, interacts with p62. *C. Fusco[1], M. Egorov[2], M. Monti[3], L. Micale[1], B. Augello[1], E.V. D'Addetta[1], F. Cozzolino[3], M.G. Turturo[1], A. Calcagni[1], M.N. Loviglio[1], P. Pucci[3], R.S. Polishchuk[2], G. Merla[1].* 1) Laboratory of Medical Genetics, IRCCS Casa Sollievo Della Sofferenza Hospital, San Giovanni Rotondo, Italy; 2) Telethon Institute of Genetics and Medicine, Via P. Castellino 111, 80131 Naples, Italy; 3) CEINGE Advanced Biotechnology and Department of Organic Chemistry and Biochemistry, Federico II University, Napoli, Italy.

We recently showed that TRIM50 encodes a cytoplasmic E3-ubiquitin ligase. TRIM50 is hemizygous in the Williams Beuren syndrome, a developmental genomic disorder, caused by a 1.5 Mb deletion at 7q11.23 including about 28 genes. We have further characterized TRIM50 by performing fluorescence and electronic microscopy and proteomic approaches. Our results show that TRIM50 forms cytoplasmic bodies highly mobile, labile and dynamic. TRIM50 bodies, in response to MG132 proteasomal inhibition, by a microtubule dependent transport move towards to and colocalize to aggresomes by strengthen its interaction with HDAC6, a well-characterized aggresomes component. Further we provide experimental evidences that TRIM50 interacts and colocalize with p62/SQSTM1, a multifunctional adaptor protein involved in various cellular processes including autophagic clearance of aggregation-prone polyubiquitinated proteins. Together the data presented show that TRIM50 protein forms a multimeric protein complex with both HDAC6 and p62. The proposed model suggests that TRIM50 might mediate the ubiquitination of yet unknown substrates for the Proteasome-dependent degradation under basal cellular conditions. Under proteasome inhibition, TRIM50 through HDAC6-microtubules association participates to and likely directs the storage of polyubiquitinated misfolded protein to aggresomes. Then, in concert with p62, TRIM50 delivers them to autophagy for ultimate degradation. Finally this work point out that the haploinsufficiency of TRIM50 might play a role in the determination of Williams Beuren syndrome phenotypes through the accumulation of its yet unknown substrates.

2174/W

BBS Mutational Analysis in a Multi-Ethnic Cohort: A Strategic Approach. *G. Billingsley[1], C. Deveault[1], E. Héon[1,2].* 1) Programme of Genetics & Genome Biology; 2) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, Ontario, Canada.

Bardet-Biedl syndrome (BBS, OMIM 209900) is a rare autosomal recessive, genetically heterogeneous disorder for which 14 BBS genes have been identified. This genetic heterogeneity, with the size of the genes involved, challenged the cost effectiveness of mutational analysis of BBS, which influenced the various approaches used to find mutations. We present our approach to mutational analysis of our multi-ethnic cohort of 83 BBS families (104 cases) for BBS1 -12. Our results suggest that strategies for efficient and cost-effective screening are possible and should take in consideration the type of population studied. We have identified two BBS disease alleles in 75% of our families. In our study the most commonly mutated genes were BBS10 (30%), BBS1 (23%), BBS2 (17.5%) and BBS12 (16%). Together these 4 genes account for 61% (51/83families) of the total mutational load. No mutations were found for BBS3 or BBS11. 68% of the identified principle mutation alleles were novel (46/68) and were found only in one family. The presence of these "private" alleles creates a challenge for rapid screening. Recurrent mutations (BBS1-M390R, BBS10 - C91LfsX5, BBS2-Y24X) were mostly of European ancestry except for one (BBS10: K243IfsX15 - found in South African Black). 33 of our patients had homozygous BBS mutations. 39% of these (13/33) reported consanguinity and another 22% (7/33) were from geographic isolates. Initial screening for recurrent mutations in BBS1 (M390R - 13% of our cohort) and BBS2 (Y24X - 2.5%) by PCR-restriction enzyme, followed by sequencing of BBS10 and BBS12 (1-2 exons) can potentially detect 45-50% of the BBS patient mutations. Subsequent sequencing of BBS1 would bring this to at least 60% detection. The use of dedicated microarrays for assaying previously reported BBS mutations (e.g. Asper Ophthalmics) would have identified only 37% of our cohort, mostly in BBS1 and BBS10. Analysis of consanguineous or large isolated families using homozygosity mapping (STRP/SNP) and sequencing of the related BBS genes was successful in identifying mutations in BBS5 and BBS8, genes that are minor contributors to BBS. For a mixed population, preliminary screening of recurrent mutations, sequencing of BBS10 and BBS12 and homozygosity mapping of consanguineous families can greatly facilitate the detection of disease causing BBS mutations. For a predominantly Caucasian population, the sequencing of BBS1 could be included earlier.

2175/W

Genetic screening of LCA in Belgium: predominance of *CEP290* and identification of potential modifier alleles in *AHI1* of *CEP290*-related phenotypes. *F. Coppieters[1], I. Casteels[2], F. Meire[3], S. De Jaegere[1], S. Hooghe[1], N. Van Regemorter[4], H. Van Esch[5], H. Kroes[6], J. Vandewalle[7], T. de Ravel[5], B.P. Leroy[1, 8], E. De Baere[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Department of Ophthalmology, Leuven University Hospitals, Leuven, Belgium; 3) Hôpital Des Enfants Reine Fabiola, Brussels, Belgium; 4) Centre de Génétique de Bruxelles, Free University of Brussels, Brussels, Belgium; 5) Center for Human Genetics, Leuven University Hospitals, Leuven, Belgium; 6) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 7) Department of Pediatrics, Ghent University Hospital, Ghent, Belgium; 8) Department of Ophthalmology, Ghent University Hospital, Ghent, Belgium.

Leber Congenital Amaurosis (LCA), the earliest form of all inherited retinal dystrophies, is genetically heterogeneous, with 14 genes accounting for 70% of patients. Here, 91 LCA probands underwent LCA chip analysis and subsequent sequencing of 6 genes (*CEP290*, *CRB1*, *RPE65*, *GUCY2D*, *AIPL1*, and *CRX*), revealing mutations in 69% of the cohort, with major involvement of *CEP290* (30%). In addition, 11 patients with early-onset retinal dystrophy (EORD) and 13 patients with Senior-Loken syndrome (SLS), LCA-Joubert syndrome (LCA-JS) or cerebello-oculo-renal syndrome (CORS) were included. Exhaustive re-inspection of the overall phenotypes in our LCA cohort revealed novel insights mainly regarding the *CEP290*-related phenotype. The *AHI1* gene was screened as a candidate modifier gene in three patients with the same *CEP290* genotype but different neurological involvement. Interestingly, a heterozygous novel *AHI1* mutation, p.Asn811Lys, was found in the most severely affected patient. Moreover, *AHI1* screening in five other patients with *CEP290*-related disease and neurological involvement revealed a second novel missense variant, p.His758Pro, in one LCA patient with mild mental retardation and autism. These two *AHI1* mutations might thus represent neurological modifiers of *CEP290*-related disease.

2176/W

Homozygosity mapping for Bardet-Biedl Syndrome genes reveals *SDCCAG8* as a novel BBS gene and expands the phenotypic ciliopathy spectrum. *H. Dollfus[1,3], X. Bei[2], E. Schaefer[3], A. Zaloszyc[3], Y. Perdomo[3], K. Aliferis[4], A. Toutain[5], M. Gerard[6], L. Perrin[6], M. Fischbach[7], JL. Mandel[8], V. Marion[3], N. Katsanis[9], C. Stoetzel[3].* 1) Service de Genetique Medicale, Hopitaux Universitaires de Strasbourg, Strasbourg, France; 2) Developmental and Stem Cell Biology Center for Human Disease Modeling 456 Nanaline Duke Building Duke University Medical Center Durham, NC 27710; 3) Laboratoire de Génétique Médicale, Equipe Avenir-Inserm, Faculté de Médecine de Strasbourg, Université de Strasbourg, Strasbourg, France; 4) Centre de Référence pour les Affections Rares en Génétique Ophtalmologique (CARGO) et Service de Génétique Médicale, Hôpitaux Universitaires de Strasbourg, Strasbourg, France; 5) Service de génétique, Pôle Biologie, CHRU de Tours - Hôpital Bretonneau, Tours, France; 6) Unité fonctionnelle de génétique clinique, Département de Génétique, CHU de Paris - Hôpital Robert Debré, Paris, France; 7) Service de pédiatrie 1, CHU Hôpital de Hautepierre, Strasbourg, France; 8) Institut de Génétique et de Biologie Moléculaire et Cellulaire (IGBMC), CNRS, INSERM, Université de Strasbourg, Illkirch, and College de France, France; 9) Center for Human Disease Modeling Duke University 466A Nanaline Duke Building Box 3709 Duke University Medical Center Durham, NC 27710.

Whereas more then 75% of families presenting with Bardet-Biedl syndrome (BBS), an emblematic ciliopathy, are known to carry mutations in the known BBS genes, identifying novel genes remains a challenge as large consanguineous informative families are rare. Homozygosity mapping (6.0 Affymetrix SNP chip) was performed on 22 consanguineous BBS families. One large consanguineous gipsy family showed a unique segment of homozygosity on chromosome 1 (240-242.38 Mb) spanning 5 candidate genes (PLD5, CEP170, SDCCAG8, AKT3, ZNF238) that showed an unremarkable DNA sequence of their coding exons. RNA isolated from fibroblast cell lines, derived from 4 affected members, revealed a deep intronic mutation (c.740+356C>T) predicted to cause the loss of an ESE site showed by in silico, Western Blot and Q-PCR analysis. Further exploration revealed two additional BBS families that both showed a very small homozygosity region (less then 2Mb) matching the chromosomal region of interest which carried mutations in SDCCAG8 (p.K227X/K227X for the first family and p.R374X/R374X for the second). Analysis of another major BBS cohort revealed two other families with SDCCAG8 compound heterozygote mutations respectively: Y232X/R247fsX250 and T482fsX493/D543fsX566. Herein, we show that SDCCAG8 is a novel BBS gene as all the patients showed constantly 4 among the following major diagnostic features for BBS: obesity, retinal degeneration, kidney failure, hypogonadism and mild mental retardation. Strikingly, the patients did not show polydactyly (a very frequent but not obligatory BBS feature) as compared to our phenotype-genotype data on more than 300 BBS families. This is the first genotype-phenotype correlation that could be an indicator for priority screening of SDCCAG8 after classical screening of the common BBS mutations. Meanwhile, independently another group identified SDCCAG8 (NPHP10) as a major Senior-Loken gene using a powerful exon capture strategy (Otto et al, submitted). Therefore, the spectrum of SDCCAG8 mutation includes at least two ciliopathy phenotypes: SLS and BBS. Overall, SDCCAG8 mutations account for a small mutational load in BBS families (about 1%) but discloses interesting phenotypic characteristics important for genetic counselling and for deciphering the biological involvement of the BBS genes in their multiple clinical manifestations.

2177/W

Somatic/gonadal mosaicism explains reduced penetrance in a syndromic form of ectrodactyly, including eye abnormalities, suspected through array-based comparative genomic hybridization. *S. Raskin[1,2], A. Bonalumi[1], J. Souza[1], F. Faucz[1], V. Sotomaior[1], S. Alliman[3], B. Dupont[4], F. Bartel[4], R. Rodriguez[4], C. Schwartz[4], C. Skinner[4].* 1) Pontificia Universidade Catolica do Paraná, Curitiba, Parana, Brazil; 2) Centro De aconselhamento e Laboratorio Genetika, Curitiba, Parana, Brazil; 3) Signature Genomics, Spokane, Washington, U.S.A; 4) Greenwood Genetic Center, Greenwood, South Carolina, U.S.A.

Background:Split-hand/foot malformation (SHFM), or ectrodactyly, is characterized by underdeveloped or absent central digital rays, clefts of the hands and feet, and variable syndactyly of the remaining digits. SHFM occurs as both an isolated finding and a component of many syndromes. SHFM is a heterogeneous condition caused by abnormalities at one of multiple loci. These include SHFM1 (SHFM1 at 7q21-q22), SHFM2 (Xq26), SHFM3 (FBXW4/ DACTYLIN at 10q24), SHFM4 (TP63 at 3q27), and SHFM5 (DLX1 and DLX 2 at 2q31). Where most SHFM conditions are caused by deletions or sequence mutations, SHFM3 is unique in that it is caused by submicroscopic tandem chromosome duplications of FBXW4/ DACTYLIN. Methods and Results: In order to show that array-based comparative genomic hybridization (array CGH) should be considered an essential aspect of the genetic analysis of patients with SHFM, we report on a family with two brothers who have ectrodactyly. Interestingly, both also have ocular abnormalities. Their sister and both parents are healthy with no signs of ectrodactyly. DNA of all five family members were analyzed using a commercial oligonucleotide-based DNA microarray. The two affected brothers were found to have a small duplication of approximately 539 kb at 10q24.32. This duplication includes LBX1, BTRC, POLL, and FBXW4/ DACTYLIN genes. Using qPCR we confirmed that the patients' sister and father do not have the microduplication, but we found the mother to be a carrier of a mosaic duplication, estimated at 20%. Conclusions: In this family, two children were affected with ectrodactyly and were found to have a duplication over the SHFM3 locus. The mother carries a mosaic duplication as a constitutional change. Therefore, we demonstrate that somatic/gonadal mosaicism is a mechanism that gives rise to SHFM. We also suggest that ocular abnormalities may be part of the clinical description of SHFM3.

Autozygosity mapping to uncover new genes causing spondylocostal dysostosis. *D.B. Sparrow[1,2], D. Sillence[3], M.A. Wouters[4,5], S.L. Dunwoodie[1,2].* 1) Developmental Biology, Victor Chang Cardiac Research Institute, Sydney, NSW, Australia; 2) St Vincents Clinical School, Faculty of Medicine, University of New South Wales, Sydney, NSW, Australia; 3) Discipline of Genetic Medicine, The Children's Hospital at Westmead, Clinical School, University of Sydney, Sydney, NSW, Australia; 4) Structural and Computational Biology Division, Victor Chang Cardiac Research Institute, Sydney, NSW, Australia; 5) School of Medical Sciences, Faculty of Medicine, University of New South Wales, Sydney, NSW, Australia.

Abnormal vertebral segmentation (AVS) occurs with an incidence of 2 in 1000 live births. 90% of cases involve one or two vertebrae, causing a non-progressive spinal curvature termed congenital scoliosis (CS). 10% of cases are more severe, with malformation of multiple blocks of vertebrae, such as in the disorder spondylocostal dysostosis (SCD). AVS arises during embryonic development by a disruption of somitogenesis (the process of formation of the somites, the precursors to all skeletal muscle of the body and the axial skeleton). The Notch signalling pathway is a key regulator of somitogenesis, and it is therefore not surprising that the developmental defects in SCD can be caused by disruptions to components of the Notch signalling pathway. We have identified causative mutations in four genes associated with this pathway: DLL3, MESP2, LFNG and HES7. However, the genetic lesion has been identified in only 30% of SCD cases, suggesting that additional genes are associated with SCD. To uncover these genes, we are using autozygosity screening in consanguineous SCD-affected families, allowing rapid identification of chromosomal regions that are identical-by-descent in affected individuals. Chromosomal regions identified in this way are being screened for genes involved in somitogenesis and/or Notch signalling, and candidate genes screened for sequence variation. Since not all variation is necessarily causative of the congenital abnormalities, missense mutations present in affected individuals are being screened by a variety of functional assays to determine their effects on protein function.

Non-syndromic bilateral and unilateral optic nerve aplasia associated with microdeletion of 10q23.33q23.33: first familial case and potential role of CYP26A1 and CYP26C1 genes in optic nerve development. *E. De Baere.* Ctr Med Gen Ghent, Ghent Univ Hosp, Ghent, Belgium.

Optic nerve aplasia (ONA, MIM #165550) is a very rare unilateral or bilateral condition that leads to blindness in the affected eye, and is usually associated with other ocular abnormalities. Although bilateral ONA often occurs in association with severe congenital anomalies of the brain, non-syndromic sporadic cases with bilateral ONA have been described. So far no autosomal dominant non-syndromic ONA has been reported. The genetic basis of this condition remains largely unknown, as no other developmental genes than PAX6 are known to be implicated in sporadic bilateral ONA. Here we report an autosomal dominant form of non-syndromic ONA in a Belgian pedigree, with non-penetrance in the first generation (I:1), unilateral microphthalmia and ONA in the second generation (II:1) and bilateral ONA in two sibs of the third generation (III:1; III:2). The affected individuals underwent an extensive ophthalmological, endocrinological and neurological evaluation, including neuro-imaging of the visual pathways. The latter uncovered unilateral ONA in the microphthalmic eye of II:1. Genomewide copy number screening revealed a 249-363 kb microdeletion of chromosome 10q23.33q23.33 in all affected individuals (II:1, III:1; III:2) and in unaffected I:1, containing three genes EXOC6, CYP26A1 and CYP26C1. The latter two encode retinoic acid degrading enzymes. This is the first study reporting an autosomal dominant form of non-syndromic ONA. The diagnostic value of neuro-imaging in uncovering ONA in microphthalmic patients is demonstrated. Our findings implicate the CYP26A1 and CYP26C1 genes as potential novel candidate genes for non-syndromic ONA.

2180/W

Genome-wide SNP Genotyping Identifies the *Stereocilin* (STRC) Gene as a Major Contributor to Pediatric Bilateral Sensorineural Hearing Loss. *L. Francey[1], Y. Sun[1], H. Kadesch[1], D. Clark[1], H. Hakonarson[1,2], N. Spinner[3], L. Conlin[3], I. Krantz[1].* 1) The Division of Human Genetics; 2) The Center for Applied Genomics; 3) and The Department of Pathology, The Children's Hospital of Philadelphia, Philadelphia, PA.

Hearing loss is the most prevalent sensory perception deficit in humans, affecting 1/500 newborns. Hearing loss can be syndromic or nonsyndromic and is genetically heterogeneous. Nearly 80% of inherited nonsyndromic bilateral sensorineural hearing loss (NBSNHL) is autosomal recessive. Although many causal genes have been identified, most do not significantly contribute etiologically, excepting *GJB2*, that accounts for nearly 50% of all recessive SNHL. More than 60% of all children with a NBSNHL do not have an identifiable genetic cause. To identify genetic contributors, we genotyped 560 *GJB2* negative pediatric probands with NBSNHL. Assaying for copy number variants (CNVs) we identified 4,136 deletion CNV's which were filtered by a CNV ranking program, PECONPI, that generated a ranked list of 184 CNVs including over 285 unique candidate genes. 3/560 probands and 1 affected sibling were found to have a homozygous deletion of Chr15q15.3 that includes the *Stereocilin* (*STRC*) gene, an additional 3 probands and 1 affected sibling were found to have a heterozygous deletion. In a control population, 9/1,193 were found to have a heterozygous deletion. Mutations in *STRC* have been rarely reported as a cause of recessive SNHL. 'Deafness Infertility Syndrome (DIS)' was described in 3 unrelated consanguineous families cosegregating SNHL, male infertility and a homozygous, contiguous gene deletion of Chr15q15.3, encompassing *STRC* and *CATSPER2*. After identifying the Chr15q15.3 deletion CNV, sequencing of the *STRC* gene was undertaken in probands with the CNV as well as a CNV negative cohort of 48 probands and 3 siblings with mild-moderate NBSNHL and 40 probands with severe-profound NBSNHL who were all *GJB2* negative. Interpretation of sequencing results has been complicated due to a tandem duplication of Chr15q15.3 and the existence of a *STRC* pseudogene that is 99.6% homologous to the *STRC* coding region. We identified 15 mild-moderate BSNHL probands with homozygous or compound heterozygous alterations of the *STRC* gene. The heterozygous deletion CNV probands were subsequently found to have a deleterious variant on the trans allele of *STRC*. In our subcohort of 48 mild-moderate probands without the CNV, 9 were found to have biallelic alterations in *STRC*, representing a minimal prevalence of 18% among mild-moderate NBSNHL probands. The severe-profound NBSNHL cohort was not found to have homozygous or compound heterozygous mutations.

A review of novel NKX2.1/TITF1 mutations in a Molecular Diagnostics Laboratory. *S.M. Kirwin, K.M.B. Vinette, I.L. Gonzalez, V.L. Funanage.* Biomedical Research/Molecular Diagnostics Lab, Nemours/duPont Hospital for Children, Wilmington, DE.

Background/Objective: The transcription factor NKX2.1/TITF1 (thyroid transcription factor 1) belongs to the homeodomain containing transcription factor family and is located on chromosome 14q13. Haploinsufficiency of the gene product has been linked to both benign hereditary chorea (BHC) as well as the more recently described brain-thyroid-lung disease. The objectives of the present work: 1) detection of NKX2.1 mutations in patients suspected to have BHC, congenital hypothyroidism, interstitial lung disease or a combination of these symptoms; 2) analysis of mutations in related family members, and 3) report of unpublished mutations found in our laboratory. Methods: Sequencing of the NKX2.1 gene in samples submitted for molecular confirmation in suspected cases of BHC, choreoathetosis, thyroid dysfunction, or respiratory distress was performed. When sequencing analysis proved negative for mutations, an assay developed in our lab for copy number/dosage analysis allowed us to determine whether a deletion of one or more exons had occurred. Results: We have sequenced 112 probands and 14 related family members. We have detected 24 cases (21% of probands), which were positive for 22 different mutations. Three patients were deleted for one copy of NKX2.1; 10 exhibited frameshift changes resulting in an alteration of the stop codon; 4 carried a missense mutation; 6 were found to have a nonsense mutation, and 1 family was found to carry a splice site change. Thus far no mutations associated with known phenotypes have been detected in exon 1 of NKX2.1. We believe that a mutational hot-spot exists in the homeodomain within exon 3, as a large number of mutations occur in this region. Amongst family members tested, 78% of family members were found to carry the proband's mutation. As not all parents have been available or considered for genetic testing, we were able to confirm a de novo origin for the proband's mutation in only one case. One particular patient and a similarly affected parent were found to carry a synonymous change (S291S) of unknown pathogenicity, although this serine codon is highly conserved in 4 classes of vertebrates. Conclusion: Our findings reveal the critical role of DNA sequencing and copy number analysis of the NKX2.1 gene in patients exhibiting respiratory distress, elevated TSH and/or movement disorders.

Identification of a novel duplication of chromosome 12q14 and the *TBK1* gene in normal tension glaucoma patients. *J.H. Fingert[1], J.L. Stone[2], A.L. Robin[3], B. Roos[1], L.K. Davis[4], T.E. Scheetz[1], W.L.M. Alward[1], Y.H. Kwon[4], T.H. Wassink[4], V.C. Sheffield[5,6], E.M Stone[1,6].* 1) Ophthalmology and Visual Science, University of Iowa, Iowa City, IA; 2) Glaucoma Specialists, Baltimore, MD; 3) Ophthalmology and International Health, Johns Hopkins University, Baltimore, MD; 4) Psychiatry, University of Iowa, Iowa City, IA; 5) Pediatrics, University of Iowa, Iowa City, IA; 6) Howard Hughes Medical Institute, Iowa City, IA.

Purpose: Normal tension glaucoma (NTG) is a significant cause of vision loss in the United States. We studied a large pedigree to identify the gene that causes NTG in its members and to better characterize this gene. **Methods:** An African American NTG pedigree was studied with linkage and copy number variation (CNV) analysis using microarrays of SNPs. We tested a cohort of 400 glaucoma patients (74 of which had NTG) and 500 control subjects for a CNV that was found in the NTG pedigree. We tested expression of genes encompassed by this CNV in human retina using RT-PCR. The effect of the CNV on expression of encompassed genes was tested using RNA collected from pedigree member skin cells using expression microarrays. **Results:** Ten members of the pedigree had an autosomal dominant form of NTG. Linkage analysis mapped the gene that causes glaucoma in the pedigree to a 17 Mbp region of chromosome 12 (Max NPL score = 19.83). Further examination of SNP markers within the linked region identified a duplication that spanned 700 Kbp. This duplication was not detected in a cohort of 500 control subjects nor was it previously reported in publicly available databases. Furthermore, two unique overlapping duplications were detected in two (2.7%) of 74 normal tension glaucoma subjects. The duplication spanned four genes (*XPOT*, *TBK1*, *RASSF3*, and *GNS*). RT-PCR experiments showed that all four genes are expressed in human retina. Microarray studies showed that expression of *TBK1* in fibroblasts was increased by 1.55-fold in family members with the duplication when compared to family members without the duplication. Expression levels of other genes in the duplication were not altered to the same degree. **Conclusions:** Linkage and CNV analysis of a large pedigree identified an NTG locus with a 700 Kbp duplication on chromosome 12. Duplication of one of the encompassed genes (*TBK1*) is the likely cause of NTG in our pedigree. The expression of *TBK1* is increased by the duplication and *TBK1* is already known to interact with another NTG gene (optineurin). Prior studies of TBK1 find that it is a kinase that regulates the expression of genes in the NFkB pathway, some of which are involved in apoptosis. The duplication of *TBK1* may lead to NTG via dysregulation of such pathways. These data suggest that duplication of *TBK1* is the cause of NTG in our pedigree and perhaps up to 2.7% of NTG cases. However, functional studies and animal model studies will be necessary for definitive proof.

Genetics of isolated microspherophakia: identification of a novel locus. *A. Kumar[1], M.R. Duvvari[1], J. Shetty[2], G. Murthy[3], S.H. Blanton[4].* 1) MRDG, Indian Institute of Science, Bangalore, Karnataka, India; 2) Bangalore West Lions Superspeciality Eye Hospital and Cornea Grafting Center, Bangalore, Karnataka, India; 3) Prabha Eye Clinic and Research Centre, Bangalore, Karnataka, India; 4) Miami Institute of Human Genomics, University of Miami Miller School of Medicine, Miami, USA.

Microspherophakia (OMIM 251750) is a rare autosomal recessive (AR) congenital disorder characterized by small spherical lens. It may present as an isolated finding or occur together with a variety of features in one of several syndromic disorders such as autosomal dominant (AD) Marfan syndrome, AD (OMIM# 608328) and AR (OMIM# 277600) forms of Weill-Marchesani syndrome (WMS), AD glaucoma-lens ectopia-microspherophakia-stiffness-shortness syndrome (GEMSS, OMIM 137765), AD microspherophakia with hernia (OMIM 157150), and AD microspherophakia-metaphyseal dysplasia (OMIM 157151). Marfan syndrome (MFS) and AD WMS are both caused by mutations in the FBN1 (fibrillin-1) gene. Mutations in the ADAMTS10 gene cause AR WMS. The gene for isolated microspherophakia (MSP) has not been identified so far. The purpose of this study was to map and identify the gene for MSP in five consanguineous Indian families. We have performed a whole-genome linkage scan in one of the five families and identified a locus for the MSP on chromosome 14q24.1-q32.12 between markers D14S588 and D14S1050. The remaining four families did not map to this locus, suggesting genetic heterogeneity. We are currently evaluating candidate genes in the region. The detailed results of our linkage scan and candidate gene analysis will be presented and discussed.

2184/W

Linkage of Fuchs endothelial corneal dystrophy (FECD) to a novel locus on chromosome 17q21.2-22. *M.A. Minear[1], N.A. Afshari[2], J. Rimmler[1], B. Zhao[1], E. Balajonda[2], G.K. Klintworth[2], S.G. Gregory[1], Y.-J. Li[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Ophthalmology, Duke University Medical Center, Durham, NC.

Fuchs endothelial corneal dystrophy (FECD) is a late-onset disorder and a leading indication for corneal transplants in the USA. To identify novel genetic loci that contribute to FECD, we ascertained a large multiplex Caucasian family in which FECD appears to segregate as an autosomal dominant trait. 38 family members were recruited: 17 were affected with FECD (grade 2 guttae or above, as defined by the Krachmer scale), 9 were unaffected, 7 had an unknown FECD status (due to young age or insufficient exam data), and 5 were spouses. Genome-wide SNP genotyping was performed using the Illumina GoldenGate Linkage Panel IV (5858 SNPs) or the Infinium HumanLinkage-12 platform (6090 SNPs). Within the most significant linkage peaks, SNPs that did not overlap between the two linkage chips were genotyped using Taqman allelic discrimination assays (Applied Biosystems, Inc.). Family relationships were confirmed with RELPAIR. Quality control measures excluded SNPs that deviated from Hardy-Weinberg equilibrium or had genotype call rates <95%, and excluded samples with call rates <95%. Two-point parametric (dominant and recessive models) and non-parametric linkage analyses were performed using FASTLINK and MERLIN, respectively. Multipoint parametric and nonparametric linkage analyses were performed using MERLIN on three sub-pedigrees to meet the bit size criteria of the program. Regions of interest were followed up with SIMWALK using the full pedigree. Markers in high linkage disequilibrium ($r^2 \geq 0.16$) were excluded to reduce type I error inflation due to missing parental genotype data. Two-point LOD scores > 1.0 were noted for 19 SNPs on 11 chromosomes with FASTLINK, and for 21 SNPs on 11 chromosomes with MERLIN. Only chromosome 17q21.2-q22 (13 cM) showed overlapping evidence of linkage between multiple statistical approaches. The highest LOD score under the MERLIN dominant multipoint model was 2.36 at rs962272, and 14 flanking SNPs had LOD scores above 2.0; with the Merlin nonparametric multipoint model, rs962272 had a LOD score of 1.21 and the same 14 flanking SNPs had LOD scores above 1.0. The SIMWALK multipoint model showed supporting evidence within the same region (peak LOD = 1.39 at rs736604, slightly proximal to rs962272). Further work in this locus is underway to identify a minimal haplotype sharing region to narrow the width of the linkage peak. Our findings suggest that a novel locus for Mendelian FECD exists on chromosome 17.

2185/W

Identification of a chromosomal locus associated with recessive dysfunction of sodium homeostasis in a Bedouin family. *R. Parvari[1,2], E. Muhammad[1], N. Leventhal[3], V. Chalifa-Caspi[2], J.C. Beck[4], V.C. Sheffield[4], E. Hershkovitz[3].* 1) Dept Gen & Virology, Ben Gurion Univ, Beer Sheva, Israel; 2) National Institute of Biotechnology in the Negev, Ben Gurion University of the Negev, Beer Sheva, Israel; 3) Pediatric Endocrinology & Metabolism unit, Soroka Medical Center, Beer Sheva 84101 and Faculty of Health Sciences, Ben Gurion University of the Negev, Beer Sheva , Israel; 4) Department of Pediatrics - Division of Medical Genetics, Howard Hughes Medical Institute, University of Iowa, Iowa City, IA USA.

Genetic diseases resulting in excessive salt loss from sweat glands include aldosterone insensitivity syndrome of multi-system pseudohypoaldosteronism type I (PHA) and cystic fibrosis that result from mutations in genes encoding epithelial Na+ channel (ENaC) subunits and transmembrane conductance regulator (CFTR) respectively. In three nuclear consanguineous families we identified a novel autosomal recessive dysfunction of sodium homeostasis, characterized by salt wasting in sweat glands in infancy that is responsive to supplementary sodium. After linkage to the ENaC and CFTR genes were excluded, genome wide linkage analysis using the Affymetrix GeneChip mapping 250K array was performed. One homozygous region larger than 16 cM and 11.9 Mb was identified on chromosome 15q21.3-q23 and corroborated after testing all family members for microsatellite markers in the regions. The lod scores for linkage to this region were 2.81 and 3.65 for two point and multiple points, respectively. This finding establish the contribution of a novel gene in the regulation of NaCl uptake in sweat secretions.

2186/W

Homozygosity Mapping and Mutation Profile of the *MYO7A* Gene in Saudi patients with Usher Syndrome. *K. Ramzan[1], F. Imtiaz[1], M. Al-Owain[2], G. Bin-Khamis[3], R. Allam[1], A. Al-Mostafa[1], S. Al-Hazza[4], K. Taibah[5].* 1) Genetics, KFSHRC, Riyadh, Saudi Arabia; 2) Medical Genetics, KFSHRC, Riyadh, Saudi Arabia; 3) Otolarynology, KFSHRC, Riyadh, Saudi Arabia; 4) Opthalmology, KFSHRC, Riyadh, Saudi Arabia; 5) ENT Medical Centre, KFSHRC, Riyadh, Saudi Arabia.

Usher syndrome deafness-blindness disorder, is a clinically and genetically heterogeneous disorder. Three clinical subtypes of Usher syndrome have been identified, with mutations in different set of genes. Usher syndrome type 1 (USH1) is the most severe form of Usher syndrome. The *MYO7A* gene is responsible for *USH1B*, the most common subtype. Homozygosity mapping is a robust approach that is highly suited for genetically heterogeneous autosomal recessive disorders in populations where consanguinity is prevalent. For genotyping, DNA samples were processed on Gene Chip Human Mapping 250K Arrays (Affymetrix, Santa Clara, CA) following the instructions provided by the manufacturer. Homozygosity mapping was carried out using CNAG software that uses SNP genotypes generated by a DM algorithm for the detection of copy number changes and blocks of homozygosity. For affected individuals where the homozygosity blocks were identified on chromosome 11q13.5 harboring MYO7A, direct sequencing was performed for the entire coding and flanking intronic regions. Because of the high frequency of consanguinity in our patients this approach allowed us to quickly identify eleven *MYO7A* mutations in fourteen families with Usher Syndrome. Though many different mutations in this gene have been identified worldwide, the purpose of this study was to document the *MYO7A* variants present in the Saudi population.

2187/W

A new locus for otosclerosis, OTSC10, maps to chromosome 1q41-44. *I. Schrauwen[1], N. Weegerink[2], E. Fransen[1], C. Claes[1], K. Vanderstraeten[1], M. Ealy[3], R. Pennings[2], C.W.R.J. Cremers[2], P. Huyghen[2], R.J.H. Smith[3], H.P.M. Kunst[2], G. Van Camp[1].* 1) Department of Medical Genetics, University of Antwerp, Belgium; 2) Department of Otorhinolaryngology, Donder's Centrum for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, The Netherlands; 3) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, USA.

Otosclerosis is a common form of hearing loss characterized by a disordered bone remodeling in the otic capsule. The abnormal bone remodeling can result in conductive hearing loss due to fixation of the stapes footplate, but sensorineural hearing loss can also be present. Although its etiology remains unknown, otosclerosis can be considered a complex disease with rare monogenic forms. Linkage analysis in large families segregating autosomal dominant otosclerosis has led to the identification of 7 loci (OTSC1-5, 7-8). However, none of the corresponding genes has been cloned. In the OTSC2 region however, indications have been found that TCRB is the causative gene in the region. In this study a new large Dutch otosclerosis family with autosomal dominant inheritance is investigated. After exclusion of the known loci, a genome scan was performed using the HumanCytoSNP-12 BeadChips (Illumina Inc, San Diego, USA). Linkage analysis using Simwalk version 2.91 localized the gene on chr1q41-44 with a maximum LOD score of 3.3. This locus, named OTSC10, measures 26.1Mb and contains 306 genes/gene predictions. This new gene localization confirms the strong genetic heterogeneity of otosclerosis, as almost every new large family still maps to a different locus. As no mutation for monogenic otosclerosis has been identified yet, this represents another opportunity to identify the first one.

2188/W

An exome strategy to identify the genetic basis of nonsyndromic mental retardation in large consanguineous Arab families. *S. Kantarci[1,2], L. Al-Gazali[3], P. Tonellato[1,2], M. Boguski[1,2], N. Bissar-Tadmouri[4].* 1) Department of Pathology, Beth Israel Deaconess Medical Center, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Department of Pediatrics, Faculty of Medicine and Health Sciences, UAEU, Al-Ain, United Arab Emirates; 4) Department of Basic Medical Sciences, University Of Sharjah, College of Medicine, Sharjah, United Arab Emirates.

Mental retardation (MR; intellectual disability) affects approximately 1-3% of the general population. Genetic causes are found in approximately two-thirds of cases. Non-syndromic mental retardation (NSMR) is isolated MR without major physical abnormalities, dysmorphism, or neurological abnormalities. An autosomal recessive mode of inheritance may responsible for about one-fourth of all cases with NSMR. Identification of loci/genes responsible for NSMR is difficult due to broad genetic heterogeneity, small family sizes in Western populations, and the absence of clinical criteria for grouping the families for linkage analysis. To our knowledge, 13 autosomal recessive NSMR loci (MRT1-MRT13) have been mapped. While numerous X-linked genes responsible for NSMR have been identified, only six autosomal genes (PRSS12, CRBN, CC2D1A, GRIK2, TUSC3, and TRAPPC9) are known to cause NSMR. A traditionally successful approach for the identification of novel autosomal recessive NSMR genes is through studying populations with high rates of consanguineous marriage or by studying isolated populations with a strong founder effect. In the world, the highest rates of consanguineous marriages are present among Arab countries ranging around 20-50% of all marriages, and specifically first cousin marriages which may reach 25-30% of all marriages. Therefore, rates of rare autosomal recessive diseases are higher in these populations compared to Western populations. We have recruited three consanguineous Arab families with at least three affected siblings who have prior normal standard karyotype and Fragile-X molecular testing. Clinical history, three-generation pedigree, dysmorphologic and neurologic examinations were obtained from each family. We use SOLID whole exome resequencing approach to identify novel genes associated with autosomal recessive NSMR. We are in the process of analyzing data of ~40Mb genome size (exomes). Knowledge about the underlying genetic basis of NSMR can result in more accurate genetic counseling (particularly prenatal genetic counseling), improved understanding of fundamental mechanisms, and hope of specific therapeutic interventions that address the specific genomic pathology involved. Furthermore, the knowledge that is likely to be gained from this study will improve clinical delineation of NSMR.

2189/W

Identification of mutations in Meckel Syndrome using Exome Sequencing. *J. Tallila[1], A. Daly[1], M. Kestilä[2], R. Salonen[3], I. Barroso[1], A. Palotie[1], L. Peltonen[1,4].* 1) Department of Human Genetics, Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) National Institute of Health and Welfare, Public Health Genomics Unit, Helsinki, Finland; 3) Department of Medical Genetics, Vaestoliitto, Helsinki, Finland; 4) Institute for Molecular Medicine, Finland (FIMM), Helsinki, Finland.

Meckel syndrome (MKS, [MIM 249000]) is an autosomal recessive, early lethal disorder characterized by a combination of severe malformations. Minimum diagnostic criteria are cystic dysplasia of the kidneys with fibrotic changes in the liver and occipital encephalocele or some other central nervous system malformation. Identification of the underlying disease causing genes has shown that MKS is an allelic disorder with several other syndromes with overlapping phenotypes, e.g. Joubert syndrome. In the Finnish population 90% of the MKS cases are caused by homozygous mutations in either *MKS1* or *CC2D2A* (MKS6) genes: a 29 bp intronic deletion in the *MKS1* gene (c.1483-7_35del) and a C>T substitution in the coding region of *CC2D2A* (c.1762C>T), respectively. Both of these mutations result in abnormal splicing. In addition, systematic sequence analysis of all known MKS genes showed that two Finnish MKS cases were compound heterozygotes: one for mutations in *MKS1*; and one for mutations in *CEP290* (MKS4). In six typical unrelated Finnish MKS cases the underlying mutation still remains unknown. To solve the molecular background of MKS in these families we used exome sequencing, which has proven to be a powerful, efficient strategy for identifying genes underlying rare Mendelian disorders. We sequenced the "GENCODE exome" consisting of a 47.9Mb target in one sibling pair and four unrelated affected fetuses. After Agilent solution-based hybrid capture the enriched targets were sequenced using an Illumina GAII sequencer. An average of 5Gb of sequence was generated per affected individual as paired-end, either 54 or 76-bp reads, with a mean depth of »100-fold. The sequence was aligned using the MACH program and variants were called using SAMtools. The sequencing data was filtered against variants found in 1000 Genomes and dbSNP data. As MKS is a recessive disease, we monitored for genes with two novel potential pathogenic variants (non-synonymous and splice site), which also should be shared by the siblings. All the cases were found to share at least two or more potentially pathogenic variants in 10 transcripts. We are currently conducting follow-up studies and validating the detected variants.

2190/W

Association Study of Primary Open Angle Glaucoma (POAG) with SNP Markers on 2p16 Region. *R. Sharafieh[1,2], J. Aragon-Martin[1,2], A.H. Child[2], M. Sarfarazi[1].* 1) Molecular Ophthalmic Genetics Laboratory, University of Connecticut Health Center, Farmington, CT. USA; 2) Dept. of Cardiac and Vascular Sciences, St. George's, University of London, London, England UK.

Purpose: A combination of linkage mapping and gene association studies have been used to establish an association between SNP markers and a group of Afro-Caribbean POAG subjects from Barbados. The two highly associated SNPs of rs12994401 and rs1533428 are located within the *AK127244* gene and map to the upper boundary of the POAG locus of *GLC1H* on 2p16. We aimed to reproduce this study in an unrelated group of British Caucasian POAG subjects, and further screen our previously linked POAG families for possible mutations in the *AK127244* gene. **Methods**: A total of 692 Caucasian subjects (277 POAG, 71 LTG and 344 normal controls) were genotyped for 3 SNP markers on 2p16.3 region. An additional group of 34 African subjects were also genotyped for the same SNPs. Genotypic and allelic association studies were carried out by standard Chi-squared tests. Seven familial probands were also sequenced for the *AK127244* gene using an ABI-3100 Gene Analyzer instrument. **Results**: No genetic association was identified for POAG, LTG or their combined group with 3 SNP markers of rs1533428 (Allelic p-values of 0.368, 0.715 and 0.378), rs11686436 (0.334, 0.511 and 0.298) or rs12994401 (0.447, 0.715 and 0.620), respectively. Likewise, haplotype association tests between each two set of SNP markers for the pooled group of glaucoma cases (POAG and LTG) was not statistically significant. Only the T&T haplotype permutation for the rs1533428/rs11686436 combination was marginally significant (p=0.013). However, this test proved to be insignificant after correction for multiple testing. Comparison of allelic frequencies in 34 African cases with the published data did not show any significance for the 3 SNP markers that we tested. Since these 3 SNP markers are located within the *AK127244* gene, we further sequenced this gene in 7 familial probands from the *GLC1H* locus. Of the 41 SNP markers observed, 18 were non-coding and the remaining showed no mutations in the affected subjects. **Conclusions**: The reported genetic association of rs1533428 and rs12994401 in the Barbados cohort of Afro-Caribbean POAG cases could not be replicated in our group of 348 British Caucasian POAG and LTG subjects. Moreover, the *AK127244* gene, which harbors these SNP markers, showed no mutations in our *GLC1H*-linked POAG families. In conclusion, the reported genetic association may either have a minute role in the non-African POAG populations or be limited to the Afro-Caribbean population of Barbados.

2191/W

Mutations in TTC37 cause tricohepatoenteric syndrome (phenotypic diarrhoea of infancy). *D. Chitayat[1], J.L. Hartley[2,3], N.C. Zachos[4], B. Dawood[5], M. Donowitz[4], J. Forman[6], R.J. Trichohepatoenteric syndrome (THES) is characterised by life-threatening diarrhoea, immunodeficiency, liver disease, trichorrhexis nodosa, facial dysmorphism, hypopigmentation and cardiac defects. We further characterised the phenotype and elucidated the molecular basis of THES. Methods: Twelve patients with classical THES from 11 families had detailed phenotyping. Autozygosity mapping was undertaken in consanguineous families using 250k single nucleotide polymorphism (SNP) arrays and linked regions were evaluated using microsatellite markers which confirmed one region from which candidate genes were analysed. The effect of mutations on protein production and/or localisation in affected patient liver and intestinal epithelial cells was characterised by immunohistochemistry. Results: Previously unrecognised platelet alpha granule abnormalities were identified. The THES locus was mapped to 5q14.3 - 5q21.2. Sequencing of candidate genes demonstrated mutations in TTC37, encoding the uncharacterised tetratricopeptide repeat protein- thespin, which bioinformatic analysis suggests may be involved in protein-protein interactions or act as a chaperone. Preliminary studies of enterocyte brush-border ion transporter proteins showed reduced expression or mislocalisation in all THES patients. Conclusion: THES is caused by mutations in TTC37. TTC37 mutations have a multisystem effect which may be due to abnormal stability and / or intracellular localisation of TTC37 target proteins.

Combined genome-wide SNP genotyping and exome sequencing for disease-gene mapping in a single family. *L. Potocki[1,2], O.A. Shchelochkov[7], M.N. Bainbridge[4], S.A. Yatsenko[1], D.M. Muzny[4], D.A. Scott[1], S. Ben-Shachar[1], R.A. Lewis[1,2,3,5,6], R.A. Gibbs[1,4], J.W. Belmont[1,6], L.M. Franco[1,3].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Texas Children's Hospital, Houston, TX; 3) Department of Medicine, Baylor College of Medicine, Houston, TX; 4) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 5) Department of Ophthalmology, Baylor College of Medicine, Houston, TX; 6) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 7) Division of Genetics, Department of Pediatrics, University of Iowa Hospitals and Clinics, Iowa City, IA.

We describe the cases of two siblings with a similar phenotype of severe developmental delay, microphthalmia, blepharophimosis, optic nerve hypoplasia with absent retinal vessels, and progressive bone marrow failure. Chromosome analysis revealed a 46,XY complement in one sibling and a 46,XX complement in the other. Sex reversal, with female external genitalia and gonadal dysgenesis, was observed in the child with the 46,XY chromosome complement. Copy number analysis performed with an Agilent 244,000-oligonucleotide microarray revealed no abnormalities. SNP genotyping on both siblings and their parents, performed with Illumina 610-Quad BeadChips, revealed extended regions of homozygosity in each affected individual. Under the assumption of an autosomal recessive disorder, we searched the genotyping data for regions that were homozygous in both affected offspring and heterozygous in each parent. These regions comprised approximately 30 megabases. We then sequenced the entire exome of one affected sibling with NimbleGen capture and SOLiD sequencing. The regions of interest compiled from the SNP genotyping data were used as a filter to reduce the number of candidate mutations identified by exome sequencing. Our results illustrate the potential and the limitations of this combined approach to identify disease genes when only a small number of affected individuals from the same family are available for analysis.

2193/W

Genomic Deletion of a Single Isoform of MBD5 at 2q23.1 is Associated with Microcephaly, Intellectual disability, and Autistic Behaviors. *L. Zhang[1,3], S. Debrosse[3], R. Pyatt[4,5], D. Thrush[4,5], A. Parikh[2,3].* 1) Dept Medicine, Case Western Univ SOM, Cleveland, OH; 2) Dept Pediatrics, Case Western Univ SOM, Cleveland, OH; 3) Dept Human Genetics, Case Western Univ SOM, Cleveland, OH; 4) Nationwide Children's Hospital, Columbus, OH; 5) Dept Pathology, Ohio State Univ, Columbus, OH.

The 2q23.1 microdeletion syndrome has been described in 17 patients to date and the size of underlying genomic deletions vary considerably. Clinical features of this syndrome include severe mental retardation (MR), short stature, microcphaly, epilepsy and coarse facies. Genomic deletion of *methyl CpG-binding domain protein 5 (MBD5)* gene including all of its six isoforms has been implicated to be responsible for the core features of this syndrome. Here we describe a patient with a clinical phenotype including microcephaly, hypotonia, psychomotor retardation, intellectual disability, autistic behavior, chronic constipation, polydipsia, hyperphagia and subtle dysmorphism but no seizures to date. Oligonucleotide microarray study revealed a single microdeletion of ~210 kb at 2q23.1 in this patient. Neither of the biological parents were found to have this deletion. Interestingly, this *de novo* deletion involves the 5'-UTR of only one of the six predicted isoforms of *MBD5* gene and does not overlap with previously identified minimal critical region encompassing the coding region that is shared among all *MBD5* isoforms. MBD5 is a member of the methyl CpG-binding domain protein family including MECP2 which is deficient in Rett syndrome. MBD5 contains a PWWP domain, which has been shown to bind methylated lysines of histones. Previous studies have shown that *MBD5* is expressed in the mammalian brain and in particular the deleted isoform was cloned by 5'-RACE from a human brain cDNA library. This isoform has multiple non-coding 5' exons, and a proximal promoter region 450kb upstream from the proximal promoter region of all the other isoforms. Although the final protein product is predicted to be the same as another major isoform, this isoform allows the protein to be expressed under regulations that are different from the others, which may be crucial in the developing brain. Although the precise function of MBD5 has not been characterized, it is a promising candidate to advance our understanding of cognition and autistic behaviors.

2194/W

Identification of a novel gene associated with recessive high myopia. *O.S. Birk[1], S. Mordechai[1], A. Pasanen[3], R. Ofir[1], K. El Amour[2], J. Levy[4], N. Belfair[4], T. Lifshitz[4], G. Narkis[1,2], K. Elbedour[2], J. Myllyharju[3], L. Gradstein[4].* 1) The Morris Kahn Laboratory of Human Genetics at the National Institute for Biotechnology in the Negev, Beer-Sheva, Israel; 2) Institute of Genetics at Soroka Medical Center,Ben-Gurion University, Beer-Sheva, Israel; 3) University of Oulu, Finland; 4) Department of ophthalmology at Soroka Medical Center,Ben-Gurion University, Beer-Sheva, Israel.

Autosomal recessive high myopia was diagnosed in Bedouin Israeli consanguineous kindred. Some affected individuals had also variable expressivity of early onset cataract, peripheral vitreo-retinal degeneration, and secondary loss of sight due to severe retinal detachments. Through genome-wide linkage analysis, the disease-associated gene was mapped to ~1.7 Mb on chromosome 3q28 (maximum LOD score 11.5). Sequencing of the entire coding regions and intron-exon boundaries of the 6 genes within the defined locus, identified a single mutation in one of the genes within the locus. In vitro studies of the mutated vs. native protein have been done to demonstrate the functional effect of the mutation. This is the first identification of a gene whose mutation is associated with autosomal recessive pathological myopia.

2195/W

Pelizaeus-Merzbacher-Like disease caused by a homozygous mutation in AIMP1/P43. *M. Feinstein[1], B. Marcus[1], I. Noyman[2], H. Flusser[2], Z. Shorer[2], I. Shelef[4], I. Cohen[1], S. Khateeb[1], S. Sivan[1], O.S. Birk[1,3].* 1) The Morris Kahn Laboratory of Human Genetics at the National Institute of Biotechnology in the Negev, Ben-Gurion University of the Negev, Beer Sheva, Israel; 2) Division of Pediatrics at Soroka Medical Center, Beer Sheva, Israel; 3) Genetics Institute at Soroka Medical Center, Beer Sheva, Israel; 4) Department of Radiology at Soroka Medical Center, Beer Sheva, Israel.

Pelizaeus-Merzbacher-Like disease (PMLD) is a hypomyelinating leukodystrophy, a disorder involving aberrant myelin formation presenting with rotatory nystagmus, progressive spastic paraplegia, severe motor impairment and neurological deterioration within the first months of life. The known forms of the disease are caused by homozygous mutations in GJA12 and HSPD1. Two remotely related Bedouin kindred in southern Israel presented with an autosomal recessive phenotype of PMLD. Homozygosity at the two known loci was ruled out in affected individuals. DNA samples of 5 affected individuals and 7 non-affected obligatory carrier first-degree relatives were analyzed using 250k SNP Affymetrix arrays, and fine mapping was done using microsatellite markers. The phenotype-associated locus was mapped to a 8.94 Mb region on chromosome 4q24 (maximum multipoint LOD score of 4.25). Sequence analysis of 14 candidate genes of the 39 genes in the region unraveled a two-nucleotide (CA) deletion mutation in AIMP1/P43 encoding ARS-Interacting Multifunctional Protein 1. AIMP1 functions as a non-catalytic component of the multi-synthetase complex, catalyzing the ligation of amino acids to their cognate tRNAs. The deletion causes a frameshift mutation resulting in a premature stop codon amputating the 312aa protein after 127 aa, abrogating AIMP1/P43's main catalytic domain .The mutation was not found in 190 control chromosomes.

2196/W

GENETIC ANALYSIS OF FAMILIAL AUTOSOMAL RECESSIVE HYPERCHLORHIDROSIS. *M. Feldshtein[1], S. El-Krinawi[2], B. Yerushalmi[2], D. Landau[2], H. Romi[1], B. Marcus[1], D. Vullo[3], R. Ofir[1], s. Sivan[1], C.T. Supuran[3], O.S Birk[1,4].* 1) The Morris Kahn Laboratory of Human Genetics at the National Institute of Biotechnology in the Negev, Ben Gurion University, Beer Sheva, Israel; 2) Division of Pediatrics,Soroka Medical Center,Beer Sheva, Israel; 3) Universita degli Studi di Firenze, Laboratorio di Chimica Bioinorganica, Rm. 188, Via della Lastruccia 3, I-50019 Sesto Fiorentino (Firenze), Italy; 4) Division of Genetics,Soroka Medical Center,Beer Sheva, Israel.

Cystic fibrosis (CF) is caused by mutations within the cystic fibrosis transmembrane conductance regulator (CFTR). Elevated levels of sweat electrolytes as measured in the "sweat test" are the classical routine diagnostic criterion for this disease. A Bedouin kindred in southern Israel presented with an autosomal recessive phenotype of elevated sweat electrolytes with no clinical evidence of CF. Homozygosity at the CFTR locus was ruled out in affected individuals. We studied 26 individuals (including 7 affected) of 3 related families. DNA samples of 7 affected individuals and 4 non-affected obligatory carrier parents were analyzed using 250k SNP Affymetrix arrays. Homozygosity loci unique to the affected individuals were further analyzed using microsatellite markers. The phenotype-associated locus was mapped to a 5.6 Mb region on chromosome 15q22 with a maximum two-point LOD score [Zmax] = 6.65, recombination fraction [q] = 0.0 at D15S153. Sequence analysis of 5 candidate genes of the 60 genes in the region, unraveled a single missense mutation in CA12, encoding carbonic anhydrase, a ubiquitous enzyme that catalyzes the reversible hydration/dehydration reactions of carbon dioxide. The mutation is within the preserved catalytic domain of the enzyme. Of 300 Bedouin controls, the mutation was found in only one individual in a heterozygous state. The mutant protein showed 71% activity of the wildtype enzyme. Unlike the wildtype enzyme which was not inhibited by chloride, bromide or iodide, the mutant protein was inhibited in the submicromolar range by these anions.

2197/W

Identification of the molecular defect underlying a novel neurological autosomal recessive phenotype. *D. Fine[1], H. Flusser[2], B. Marcus[1], S. Khateeb[1], Z. Shorer[2], S. Sivan[1], O. Birk[1,3].* 1) The Morris Kahn Laboratory of Human Genetics at the National Institute of Biotechnology in the Negev; 2) Division of Pediatric at Soroka Medical Center, Ben-Gurion University of the Negev, Beer Sheva, Israel; 3) Genetics Institute at Soroka Medical Center, Ben-Gurion University of the Negev, Beer Sheva, Israel.

A consanguineous inbred Israeli Bedouin kindred presented with an autosomal recessive phenotype of microcephaly, mental retardation and dysmorphism reminiscent of Cornelia de Lange syndrome, with a long philtrum, hypertelorism, thin lips, synophris, low anterior hairline and narrow forehead. Brain MRI and CT demonstrated agenesis of corpus callosum and/or partial hypoplasia of vermis - not characteristic to Cornelia de Lange syndrome. Homozygosity of affected individuals in loci of 3 genes associated with Cornelia de Lange was ruled out using STS markers. Genome-wide scan of 6 individuals using the GeneChip Human Mapping 250K SNP microarrays was done following fine-mapping using STSs, and candidate genes within this locus are being sequenced in search for the disease-associated gene. A 7Mb region of homozygosity on chromosome 10p harboring 48 genes was identified (maximum MultiPoint LOD score 4.99). Sequencing of 30 of the 48 genes identified a single duplication mutation of 13 nucleotides within the coding region of a novel gene, truncating the encoded 1,039 aa protein to 739 aa. The mutation was not found in 400 Bedouin control chromosomes.

2198/W

Identification of the molecular defect causing non-CF meconium ileus: a likely modifier of cystic fibrosis. *H. Romi[1], I. Cohen[1], S. El-Krinawi[2], D. Landau[2], B. Yerishalmi[2], R. Ofir[1], S. Sivan[1], O.S. Birk[1,3].* 1) The Morris Kahn Laboratory of Human Genetics at the National Institute for Biotechnology in the Negev, Beer-Sheva, Israel; 2) Division of Pediatricsat Soroka Medical Center,Ben-Gurion University, Beer-Sheva, Israel; 3) Genetics Institute at Soroka Medical Center, Ben-Gurion University, Beer-Sheva, Israel.

Meconium ileus (MI) is a form of neonatal intra-luminal intestinal obstruction that occurs in the terminal ileum due to accumulation of thick, viscoid meconium. MI occurs in ~15-20% of CF patients. Eighty to ninety percent of infants presenting with MI will develop CF later in life. A unique autosomal recessive form of non-CF meconium ileus was shown to be prevalent in a large inbred Israeli-Bedouin kindred. Some of the patients required surgical treatment while others managed with conservative treatment. Homozygosity of affected individuals at the locus of CFTR and at the CF modifier 1 locus was rued out. Genome wide homozygosity screening followed by fine mapping demonstrated linkage to a ~ 4 Mb region on chromosome 12p13. Two-point linkage analysis using SUPERLINK software demonstrated maximum LOD score of [Zmax] = 4.16 at recombination fraction [q] = 0.0. A missense mutation was found in one of the 60 genes within the locus, a gene encoding a protein that is expressed specifically in the intestine and that is known to interact with the CFTR protein. In-vitro assays demonstrated that the mutation dramatically decreased the enzymatic activity of the encoded protein. A second homozygous mutation in the same gene, fully abrogating the functional domain of the enzyme, was found in another case of non-CF MI in another inbred Bedouin kindred. Of 240 unrelated Israeli-Bedouin control individuals, only three were heterozygous to the affected allele and none were homozygous for the mutation. We suggest that the gene identified in this study is a likely candidate as a modifier of meconium ileus in CF.

2199/W

Pre and post-axial polydactyly caused by a novel dominant GLI3 mutation in a large kindred. *M. Volodarsky[1], Y. Langer[1], S. Sivan[1], O.S. Birk[2].* 1) The Morris Kahn Laboratory of Human Genetics at the National Institute of Biotechnology in the Negev; 2) Genetics Institute at Soroka Medical Center, Ben-Gurion University of the Negev, Beer Sheva, Israel.

A large Jewish Moroccan kindred presented with 12 cases of isolated polydactyly. Affected individuals had either pre-axial, post-axial or combined polydactyly. Most had also syndactyly. Using polymorphic markers adjacent to candidate genes, linkage to SHH, GJA1, HOXD13, LMBR1, FBLN1 was ruled out. Analysis using markers D7S691 and D7S1526 near GLI3 followed by sequencing of the coding sequence of the gene, demonstrated that the phenotype in this family was due to a novel c.A1802G (p.H601A) mutation in exon 12 of GLI3 abrogating one of the C2H2 type zinc fingers of the encoded protein. The study demonstrates the significant phenotypic variability of GLI3 mutations, with the same mutation leading to pre or post-axial polydactyly.

2200/W

Characterization of the genetic defect underlying an autosomal recessive leukodystrophy. *J. Zolotushko[1], H. Flusser[3], B. Markus[1], M. Heverin[2], I. Björkhem[2], S. Sivan[1], O. Birk[1,3].* 1) The Morris Kahn Laboratory of Human Genetics, National Institute of Biotechnology in the Negev, Ben-Gurion University, Beer-Sheva, Israel; 2) Division of Clinical Chemistry, Karolinska University Hospital, Huddinge, Sweden; 3) Genetics Institute, Soroka Medical Center, Beer-Sheva, Israel.

An Israeli-Bedouin kindred presented with an autosomal recessive phenotype of convulsions near birth, mental retardation and cerebral palsy. Brain MRI demonstrated significant reduction in white matter and agenesis of corpus callosum. Linkage analysis ruled out association with twelve genes known to be associated with inherited defects of white matter or agenesis of corpus callosum. Using 250K SNP microarrays, a region of homozygosity on chromosome 1p33-1p32.3 was identified and further narrowed down to 6.75cM (7.25 Mb) between D1S2824 and D1S200, with a maximum multipoint LOD score of 6. Six candidates of the 62 genes in the linkage interval were sequenced, identifying a novel missense mutation, C307T, in DHCR24, resulting in substitution of arginine to cysteine at amino acid 103 (conserved exposed residue) within the flavin adenine dinucleotide (FAD) binding domain. DHCR24 (24-dehydrocholesterol reductase) encodes an FAD-dependent oxidoreductase expressed in the endoplasmic reticulum membrane, which catalyzes the reduction of the delta-24 double bond of sterol intermediates during cholesterol biosynthesis. Missense mutations in this gene have been associated with desmosterolosis. Plasma sterol quantification in two affected individuals demonstrated a normal cholesterol level, but ~300-fold increased levels of desmosterol proving deficient activity of 24-dehydrocholesterol reductase. The novel DHCR24 mutation we describe leads to excessive desmosterol accumulation much beyond that previously described, and a unique severe novel clinical phenotype.

2201/W

Mutation of THOC6, a member of the THO/TREX complex, causes autosomal recessive mental retardation. *C. Beaulieu[1], L. Huang[2], D. Bulman[3], E. Puffenberger[4], D.R. McLeod[1], A.M. Innes[1], K.M. Boycott[2], J.S. Parboosingh[1].* 1) Department of Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada;; 3) Ottawa Hospital Health Research Institute, Ottawa, ON, Canada; 4) Clinic for Special Children, Strasburg, PA, USA.

Mental retardation (MR; also known as intellectual disability) is the most frequent handicap affecting 2-3% of children. Autosomal recessive inheritance accounts for at least 25% of unexplained MR and is an emerging field of study with a number of genes now identified. We recently described a novel autosomal recessive neurodevelopmental disorder in four patients from two related Hutterite families. The patients have mild to moderate intellectual disability, head circumference at the 2nd centile, distinctive facial features, and minor malformations of the heart and genitourinary system. The Hutterites are a genetically isolated Anabaptist group living on the North American prairies; their population numbers over 40,000, the majority of whom are descendants of 89 founders. Identity-by-descent mapping identified a 5.1 Mb locus on 16p13.3 containing 173 genes. Genes within the region were prioritized using data mining and expression microarrays. Ninety-seven genes were sequenced. A homozygous variant, p.G46R, in THOC6 was identified in a conserved amino acid; this variant was not present in 150 general population or 500 Hutterite controls. THOC6 is part of the THO/TREX complex involved in the nuclear export of transcripts; knockdown of members of this complex has the greatest effect on the export of inducible heat shock protein mRNA. Expression changes observed on patient microarrays support a detrimental effect of THOC6 function on nuclear export of this group of mRNAs. Additional studies on mRNA export using patient cell lines and zebrafish functional studies are underway. This is the first example of a human disorder associated with the THO/TREX complex and may provide a link between the export of stress inducible transcripts and neurodevelopment.

2202/W

Exome Sequencing in Obligate Carrier Parents of an Autosomal Recessive Nonsyndromic Mental Retardation (NSMR) Sibship Reveals a Novel Mutation in the *TECR* Gene on Chromosome 19p13. *M. Caliskan[1], J.X. Chong[1], L. Uricchio[1], R. Anderson[1], P. Chen[1], C. Sougnez[2], K. Garimella[2], M. DePristo[2], S. Gabriel[2], S. Das[1], D. Waggoner[1,3], D.L. Nicolae[1,4,5], C. Ober[1,6].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) The Broad Institute of MIT and Harvard, Boston, MA; 3) Pediatrics, University of Chicago, Chicago, IL; 4) Medicine, University of Chicago, Chicago, IL; 5) Statistics, University of Chicago, Chicago, IL; 6) Obstetrics and Gynecology, University of Chicago, Chicago, IL.

Mental retardation (MR) is one of the most common disabilities among children, affecting 1-3% of the population. The majority of MR cases occur without other associated abnormalities, a condition that is referred to as NSMR. We previously mapped a novel locus for autosomal recessive NSMR to chromosome 19p13 in a consanguineous family with 5 affected and 9 unaffected children (Nolan et al. 2008; Am J Med Genet 146A:1414). Subsequent genotyping of members of this family with the Affymetrix 500k array defined a 2 Mb critical region, which contained 82 genes. To identify the causal mutation in this family, we included the obligate carrier parents in a larger exome sequencing study. Of the 70 variant sites (33 missense, 37 synonymous) in the critical region, 18 were heterozygous in both parents and considered candidate NSMR mutations. We were able to eliminate 16 of the 18 as causal mutations because they had reported allele frequencies of >0.10 in dbSNP. The remaining 2 candidate mutations segregated with NSMR in the family but only one was predicted by both SIFT and PolyPhen to be a damaging mutation that very likely alters protein function and, therefore, downstream phenotypes. This putatively pathogenic mutation resulted from the substitution of a leucine for a highly conserved proline at amino acid 182 (Pro182Leu) in the TECR protein. TECR is a synaptic glycoprotein that is involved in the synthesis of very long chain fatty acids (VLCFAs). Although the precise mechanism through which the Pro182Leu mutation in TECR leads to mental retardation is not known, genetic diseases involving perturbations to normal synthesis and degradation of VLCFA have significant neurological consequences and mutations in other genes in the VLCFA pathway result in NSMR. The role of TECR in fatty acid synthesis and the phenotypes of affected individuals suggest that the NSMR observed in this family is an inborn error of metabolism in which fatty acids are not properly metabolized, highlighting the importance of normal lipid homeostasis for proper nervous system development.

2203/W

Combination of linkage mapping and microarray-expression analysis identify NF-κB signalling defect as a novel cause for non syndromic autosomal recessive mental retardation. *O. PHILIPPE[1], M. RIO[1], A. CARIOUX[2], JM. PLAZA[3], P. GUIGUE[1], F. MOLINARI[1], N. BODDAERT[1], C. BOLE-FEYSOT[3], P. NITSCHKE[3], A. SMAHI[1], A. MUNNICH[1], L. COLLEAUX[1].* 1) Hôpital Necker-Enfants malades, FRANCE, Paris, France; 2) Plateforme de Génomique de la Fondation Imagine Paris, France; 3) Plateforme de Bioinformatique de l'Université Paris Descartes, Paris, France.

Autosomal-recessive (AR) inheritance accounts for nearly 25 percent of non syndromic mental retardation (MR), but the extreme heterogeneity of such conditions markedly hampers gene identification. In the course of a project aiming to identify ARMR, we ascertained a consanguineous Tunisian family of three MR children with mild microcephaly and usual white-matter abnormalities with discordance between T2 and FLAIR sequences. The combination of autozygosity mapping and RNA expression profiling identified the *TRAPPC9* gene, which encodes a NF-kappaB-inducing kinase (NIK) and IkappaB kinase complex beta (IKK-beta) binding protein, as a likely candidate. Sequencing analysis revealed a nonsense variant (c.1708C>T [p.R570X]) within exon 9 of this gene that is responsible for an undetectable level of TRAPPC9 protein in patient skin fibroblasts. Moreover, TNF-alpha stimulation assays showed a defect in IkBalpha degradation, suggesting impaired NF-kappaB signalling in patient cells. A series of patients have been recruited on the basis of the association of MR, mild microcephaly and T2/FLAIR dissociation. Interestingly recent results of *TRAPPC9* molecular screening in these patients suggest that *TRAPPC9* mutations may define a clinically recognizable phenotype. In conclusion, this study provides the first demonstration of NF-kappaB signalling defect as a cause of autosomal recessive MR. Moreover, our study may shed light on the role of NF-kappa B in the myelination process in the central nervous system.

2204/W

Mutation screening and cellular complementation aid gene identification in mitochondrial complex I deficiency. *T.B.L. Haack[1], F. Madignier[2], K. Danhauser[2], J. Hoser[3], H. Mayr[9], I. Wittig[4], S. Biskup[5], P. Freisinger[10], B. Rolinski[8], E. Lamantea[7], G. Uziel[6], R. Horvath[11], M. Tesarova[12], V. Tiranti[7], W. Sperl[9], M. Zeviani[7], T. Meitinger[1,2], H. Complex I deficiency is a frequent biochemical condition, accounting for about one third of respiratory chain disorders. Impairment of complex I activity compromises the transfer of electrons derived from carbohydrate and, partly, from fatty acid oxidative catabolism to the downstream protein complexes of the respiratory chain. The broad phenotypic spectrum and seemingly loose association with causative gene defects pose a major hurdle in clinical diagnosis; hence, there is an urgent need for new strategies enabling us to fill the gap between biochemical definition and molecular correlate in complex I disorders. In 150 complex I-deficient index patients, we screened all 45 subunits and 6 assembly factors of complex I by high resolution melting curve analysis and Sanger sequencing and identified causative mutations in 30 cases. We identified for the first time mutations in genes encoding two complex I subunits and one assembly factor. Taking advantage of the defined biochemical defect present in patient-derived fibroblast cell lines, we performed a lentiviral complementation experiment to substantiate the pathogenic role of the mutations. Stable transduction of mutant cell lines with wild-type cDNA demonstrated a significant restoration of complex I activity. As many cases remained unresolved, we initiated a whole exome sequencing approach. With a focus on mitochondrial proteins and the complementation approach, we are able to reduce the number of candidate genes and to descriminate pathogenic from non-pathogenic variants.

Identification of a missense mutation for Infantile Hypertrophic Pyloric Stenosis in the transcription factor *FOXF1*. *K.V. Everett, C. Shaw-Smith, R.M. Gardiner, E.M.K. Chung.* Institute of Child Health, University College London, London, United Kingdom.

Purpose: Infantile Hypertrophic Pyloric Stenosis (IHPS) is the most common cause of gastrointestinal obstruction in the first months of life with an incidence of 1-8 per 1000 live births in Caucasians. It affects infants 2-6 weeks after birth with symptoms of projectile vomiting, weight loss and dehydration. Disease pathology is restricted to the pylorus at the base of the stomach associated with smooth muscle hypertrophy. Treatment is by surgery. A genetic predisposition to IHPS is well established. It is commonly inherited as a 'complex' multifactorial trait but monogenic families are well described. We previously mapped the IHPS5 locus to chromosome 16q24 in a family with 8 affected individuals in which IHPS is inherited as a dominant trait with reduced penetrance. The aim of this study was to identify the disease gene, and disease-causing mutation, in this family. **Methods**: *In silico* interrogation of the chromosome 16q24 locus identified the transcription factor *FOXF1* as a candidate gene. *FOXF1* was re-sequenced in an affected individual from this family. Verification and familial segregation of a plausible causal variant was performed using a restriction digest. 570 control chromosomes taken from UK blood donors were genotyped for this same variant to determine population frequency. **Results**: Re-sequencing identified a single missense mutation, R139Q, in the transcription factor gene *FOXF1*. Restriction digest analyses demonstrated that it segregated in the heterozygote state with affected individuals and obligate carriers. This mutation was not detected in 570 control chromosomes. The R139Q mutation alters a conserved residue in the W2 domain of FOXF1, the region of the protein responsible for binding to the minor groove of DNA. **Conclusion**: We hypothesize that the R139Q change which we have identified in FOXF1 will affect DNA-binding and/or trans-activation ability. We predict that this causes IHPS either by altering the efficacy of FOXF1 to trigger the expression of a downstream target gene or by enabling FOXF1 to bind to non-specific targets; both may be part of a pathway involved in controlling smooth muscle development or function in the gut or pylorus. *In vitro* experiments to characterise the effect of the R139Q mutation are being performed. This should shed light on the pathophysiology of IHPS, reveal disease pathways and candidate genes for the condition, and improve the understanding of the role of FOXF1 in the development of the foregut.

Initial analysis of whole exome and whole genome sequencing in the NIH Undiagnosed Disease Program. *T.C. Markello[1], D.A. Adams[1], K. Fuentes Fajardo[1], M. Sincan[1], H. Carlson-Donohoe[1], C.J. Tifft[1], T.M. Pierson[1,4], C. Toro[1], J.K. Teer[3], P.F. Cherukuri[3], N.F. Hansen[3], S.S. Ajay[3], H. Ozel Abaan[3], E.H. Margulies[3], P. Cruz[3], J.C. Mullikin[2], W.A. Gahl[1], NISC Comparative Sequencing Program.* 1) Undiagnosed Diseases Program, NIH/NHGRI, Bethesda, MD; 2) NIH Intramural Sequencing Center, NIH, Bethesda, MD; 3) Genome Technology Branch, NHGRI, NIH, Bethesda, MD; 4) Neurogenetics Branch, NINDS, NIH, Bethesda, MD.

The NIH Undiagnosed Diseases Program began analyzing single families with whole exome and whole genome sequencing in October 2009. We have completed sequencing 28 whole exomes and 1 whole genome. The current plan is to complete 60 exomes and 7 genomes by September 2010. The first 8 families chosen for sequencing included 3- four member families with two affected siblings and both parents, 3- three member families with a single affected along with both parents, and one four member family with one affected and one unaffected sibling with both parents. The final family had 4 individuals, with an autosomal dominant parent -child inheritance. One family had both parents and one affected child analyzed by whole exome, and the other affected child by whole genome sequencing. One family involved a consanguineous first cousin mating. 4 families had skeletal phenotypes and 7 of the 8 had significant neuro-developmental phenotypes. Exome capture and sequencing produced a total of 674Mb high quality sequence and an average coverage of 78.4% of the UCSC " known genes" sequence. The single whole genome data was truncated to the rest of the family's exome data. To analyze the sequences, high-density SNP array data previously obtained on these same individuals were used to construct linkage regions for recessive, dominant, and conjoint new mutations; this excluded up to 80% of the genome for recessive cases with two affected children. dbSNP130 data were used as an optional filter. For each variation from the reference sequence every family trio or quartet was examined for loci that followed homozygous, compound heterozygous recessive, or autosomal dominant (germ line mosaic) new mutation inheritance patterns. The final selection criterion used conservation information by the CDPred algorithm to prioritize candidates by the potential deleteriousness of each variation. For the single case of consanguinity, there were 113 variants that met criteria, 27 that were not in dbSNP130, and only 2 that had significant CDPred scores. One variation was identified and verified to be a homozygous mutation in AFG3L2, the first recessive diagnosis involving this gene. For the other families we have between 68 and 201 viable candidates that pass all exclusion constraints. These candidates are being evaluated using additional bioinformatics and laboratory assays. Analysis of these data and the remaining whole exome and whole genome evaluations are ongoing.

2207/W

A repeat mediated homozygous deletion in *ADAMTSL4* leads to isolated ectopia lentis. *A. Rump[1], J. Artelt[1], T.F. Neuhann[2], S. Tinschert[1], T.M. Neuhann[1].* 1) University of Technology Dresden, Institute of Clinical Genetics, Dresden, Germany; 2) Praxis Prof. Neuhann & Kolleagues, Munich, Germany.

To date, only two different homozygous mutations in *ADAMTSL4* have been reported in patients with isolated ectopia lentis, each mutation in one consanguineous family. We report eight individuals from seven non-consanguineous and non-related families with isolated ectopia lentis. All of them have an identical homozygous *ADAMTSL4* mutation not reported so far: a deletion of 20 bp within exon 6 (NM_019032.4:c.759_778del20). In a screen of 360 ethnically matched unaffected individuals, we found two further heterozygous mutation carriers. This deletion is flanked by a perfectly matching 8 bp direct repeat as well as two perfect DNA polymerase α frameshift hotspots, suggesting a repeat mediated recurrent mutation event. However, the deletion always comes along with the same SNP-haplotype in all individuals (affected as well as carriers), suggesting a single founder. These findings might best be explained by a "mixture" of both scenarios: a repeat mediated mutation due to the local DNA sequence environment occurred in a small number of individuals, i.e. there is a small group of different founders for the very same mutation. Our results further support the association of *ADAMTSL4* null-mutations to isolated ectopia lentis. Screening of *ADAMTSL4* should be considered in all patients with isolated ectopia lentis, with or without family history. In patients from non-consanguineous families, we propose a two-step diagnostic approach starting with an examination of exon 6 before sequencing the entire coding region of *ADAMTSL4*.

2208/W

Molecular studies of the PANK2 gene in patients with PKAN. *F. Annesi[1], M. Doco-Fenzy[2], G. Lesca[3], P. Tarantino[1], E.V. De Marco[1], D. Civitelli[1], F.E. Rocca[1], G. Provenzano[1], V. Greco[1], V. Scornaienchi[1], A. Gambardella[1,4], A. Quattrone[1,4], G. Annesi[1].* 1) Inst Neurological Sci, National Research Council, Mangone, Cosenza, Italy; 2) Service de Génétique, Hopital-Maison Blanche, CHU-Reims, 45 rue Cognacq Jay, 51092 REIMS cedex, FRANCE; 3) Service de Génétique moléculaire et clinique, CHRU de Lyon - Hôpital Edouard Herriot, 5 Place d'Arsonval, 69437 LYON CEDEX 03, FRANCE; 4) Institute of Neurology, University Magna Graecia, Catanzaro, ITALY.

Pantothenate kinase-associated neurodegeneration (PKAN) is an autosomal recessive disorder characterized by progressive dystonia, rigidity, choreoathetosis, spasticity, retinitis pigmentosa, optic atrophy, parkinsonism and iron accumulation in the brain. Clinical data suggest two forms of PKAN: a classic form characterized by early onset and rapid progression and an atypical form with later onset and a more slowly progressive course. Many patients with classical and atypical PKAN have mutations in the gene encoding pantothenate kinase 2 (PANK2) and a specific magnetic resonance imaging (MRI) pattern called eye-of-the-tiger. In this study we performed a mutational analysis of the PANK2 gene in 10 PKAN patients from Italy and France. Brain MRI examinations were not available for all the patients. The entire coding region (seven exons) was investigated for point mutations by sequencing analysis; furthermore, we used PCR real time to identify any possible exonic rearrangements. In 9 patients no PANK2 mutations were identified; only one patient showed an already described point mutation, but in the heterozygous state. Our results excluded PANK2 point mutations and exonic rearrangements in our patients, both in atypical and classic forms. This confirms the genetic heterogeneity in PKAN and therefore the importance of investigating the role of other responsible genes.

Statement of Purpose: The purpose of this study was the identification of the Autosomal Dominant Striatal Degeneration (ADSD) causing mutation and the analysis of its functional consequences. ADSD is characterized by bradykinesia, dysarthria and muscle rigidity resembling idiopathic Parkinson's disease. Methods: 17 members of a German ADSD family underwent neurologic examination and received MRI examinations. DNA was isolated from white blood cells. All individuals, seven of whom are affected, were included in the initial genome wide scan and the fine mapping. Coding exons and intronic flanking regions of all 21 protein coding genes in the candidate region were analyzed for sequence variations by direct DNA-sequencing and RFLP-analysis. Phosphodiesterase 8B (PDE8B) activity of mutated and wildtype PDE8B was determined using the cAMP-Glo™ Assay. Protein expression was determined qualitatively by western blot analysis. PDE8B expression in different human tissues was measured by quantitative real time PCR and qualitative RT-PCR. Subcellular localization was determined using confocal microscopy. Summary of results: We mapped ADSD to a 3.25 Mb candidate region on chromosome 5q13.3-14.1. A maximum LOD score of 4.1 (Θ=0) was obtained at marker D5S1962. We found one sequence variation resulting in a frameshift (c.94G>C+c.95delT) in the PDE8B gene. The mutation alters the amino acid sequence of the PDE8B-protein C-terminal of amino acid 31 and introduces a premature stop after 63 amino acids. The sequence variation segregates with ADSD and was neither found in 500 controls nor in the database dbSNP. No other potentially ADSD causing mutation was detected. The mutation results in a loss of cAMP-degrading activity. PDE8B expression is higher in putamen than in pallidum, total brain, and peripheral tissues. We did not observe any difference in the localization of wild type versus mutant protein. Conclusion: Our results strongly argue that ADSD is caused by the PDE8B mutation. However, these data would be strengthened further if a second family with ADSD had been available for the study. PDE8B degrades cAMP, a second messenger implied in dopamine signaling. Dopamine is one of the main neurotransmitters involved in movement control and is deficient in Parkinson's disease. We believe that the functional analysis of PDE8B will help to further elucidate the pathomechanism of ADSD as well as contribute to a better understanding of movement disorders.

Differential expression of miRNA-411 in FSHD myoblasts. *N. Harafuji[1], S. Rongye[1], P. Schneiderat[2], M. Walter[2], YW. Chen[1,3].* 1) Center for Genetic Medicine Research, Children's National Medical Center, Washington DC; 2) Friedrich-Baur-Institute, Department of Neurology, Ludwig-Maximilians-University of Munich, Germany; 3) Department of Integrative Systems Biology and Department of Pediatrics, George Washington University, Washington DC.

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant muscular dystrophy, which is linked to the contraction of the D4Z4 array at chromosome 4q35. Previous studies suggest that this shortening of the D4Z4 array causes an abnormal expression of genes, and defects in cell cycle regulation and differentiation of myotubes. In this study, we hypothesized that misregulation of microRNAs (miRNAs) in FSHD is involved in the disease progression. To identify miRNAs misregulated in FSHD myoblasts, we performed miRNA expression profiling using TaqMan Human MicroRNA Array v1.0 (Applied Biosystems). The profiles of eight primary human myoblasts (four FSHD and four controls) at two time points, 0 hour and 48 hours post differentiation (PD) were analyzed, respectively. We identified 26 and 11 miRNAs significantly changed in expression in FSHD myoblasts at 0 and 48 hours PD, respectively. The expression change of miR-411 at the 0 time point was further validated using TaqMan MicroRNA Assays (Applied Biosystems). To localize the miR-411 in myoblasts, we performed in situ hybridization with Locked Nucleic Acid (LNA)-Digoxigenin (DIG) labeled probes (Exiqon). The miR-411 was localized in the cytoplasm with stronger expression in the FSHD myoblasts. We further examined miR-411 expression in a mouse model of FSHD which overexpressing Pitx1 in skeletal muscles (Pandy and Chen, ASHG abstract) and localized the miR-411 expression in the atrophic fibers. Our results showed that miR-411 was upregulated in FSHD primary myoblasts and may be involved in the muscle atrophy process in FSHD.

2211/W

Candidate Mutation Discovery In Autosomal Dominant Diseases. *M. Bainbridge[1,2], D. Baldridge[3], I. Newsham[1], Y. Wu[1], M. Wang[1], D. Muzny[1], J.L. Jefferies[4], B.H. Lee[3], R.A. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College Med, Houston, TX; 2) Structural and Computational Biology and Molecular Biophysics, Baylor College Med, Houston, TX; 3) Molecular and Human Genetics, Baylor College Med, Houston, TX; 4) Pediatric Cardiology, Baylor College of Med, Houston, TX.

Rare coding variants in the human genome have been implicated in the development of a multitude of Mendelian diseases. Recent studies of large scale whole genome and targeted sequencing have shown that rare variants are significantly more common than originally thought. Our ability to distinguish disease causing mutations from benign mutations in targeted sequencing studies is thus hampered by the prevalence of rare non-synonymous SNPs, especially for dominantly inherited diseases. To alleviate this problem, we have developed a collection of human variants from multiple requencing projects conducted at the HGSC. Currently this collection contains over 120,000 singleton, coding non-synonymous variants which have not been described in either the Thousand Genomes project or in dbSNP. Using this resource, we were able to eliminate 50-75% of the candidate mutations in two separate whole exome sequencing projects to yield a short candidate list of causative mutations for autosomal diseases Osteogenesis Imperfect type V (OIV), and Left Ventricular Non-Compaction (LVNC). Our work outlines strategies for discovery of candidate mutations for autosomal dominant diseases and highlights the importance targeted sequencing across large, phenotypically-normal, populations.

2212/W

Linkage of a large Chinese family with nevoid basal cell carcinoma syndrome to a novel locus at chromosome 22q13. *T. Zhang[1], W. Chen[1], Q. Xing[2], W. Guo[1], Y. Lu[1].* 1) Dept. of Oral and Maxillofacial Surgery, Ninth People's Hospital,Shanghai Jiao Tong University School of Medicine, Shanghai, China; 2) Institutes of Biomedical Sciences Fudan University, Shanghai, China.

BACKGROUND Nevoid basal cell carcinoma syndrome (NBCCS,OMIM109400)is an autosomal dominant disorder characterized by a wide range of developmental abnormalities and a predisposition to neoplasms including multiple basal cell carcinomas (BCCs), keratocystic odontogenic tumor (KCOT), palmer and plantar pits and skeletal deformities. Recent evidences have indicated that patched gene, PTCH, is a NBCCS susceptibility gene. Our previous study has excluded PTCH as the causative gene in a large Chinese family with NBCCS, but the gene responsible is still unknown. OBJECTIVE To localize the pathogenic gene of the NBCCS family. METHODS Clinical data and blood samples were obtained from the extended pedigree with five generations including 10 affected members. A total genome scan was performed with a 500K SNP Affymetric DNA microarray for 21 individuals. After initial generation of a genome-wide, two-point LOD score, linkage was confirmed and the critical interval was established by genotyping of short tandem repeat (STR) microsatellite markers (D22S1177, D22S272, D22S423, D22S276,D22S1157, D22S1171, D22S282, D22S1140, D22S1168, D22S928, D22S1160). RESULTS A genome-wide linkage scan localized the disease interval to the long arm of chromosome 22, with a maximum two-point parametric LOD score of 4.72. Haplotype analyses refined the critical interval to 22q13.1-13.31, spanning a 6-MB region. CONCLUSION We have thus identified a new pathogenic gene locus for NBCCS on chromosome 22q13.1-13.31. The identification of the disease-causing gene will provide further insights into the pathogenesis of NBCCS.

The SPATAX (Spastic PAraplegia and cerebellar ATAXia) network. *A. Brice[1,2], A. Mantonnier[1], M. Koenig[3], C. Depienne[1,2], S. Forlani[1], C. Tallaksen[4], G. Stevanin[1,2,5], A. Durr[1,2], all members of the SPATAX network.* 1) CR-icm, INSERM / UPMC UMR_S975, NEB, Paris, France; 2) APHP, Pitie-Salpetriere Hospital, Dpt of Genetics and Cytogenetics, Paris, France; 3) IGBMC, Illkirch, France; 4) Dep. of Neurology, Oslo University Hospital, Ulleval, Oslo, Norway; 5) EPHE, Paris, France.

Cerebellar ataxias and spastic paraplegias are two closely related groups of rare neurodegenerative diseases resulting from dysfunctions of the spinal cord andor the cerebellum or its afferent or efferent structures. These clinical signs are often associated in complex forms of these diseases. They are thus diagnosed in the same clinical centers and are studied according to similar protocols. This is why in 2001, Drs Alexandra Durr (Paris) and Chantal Tallaksen (Oslo), created the SPATAX network (Spastic PAraplegia and cerebellar ATAXia) to centralize biological material and coordinate research within the first international network on these rare diseases. The SPATAX network counts 36 teams of clinicians and scientists distributed in 17 countries, mainly from Europe, North Africa, Middle-East and South-America. Thanks to a very active collaboration, SPATAX members have collected a large number families and sporadic cases presenting these pathologies (more than 4500 sampled patients centralized in Paris), together with a very precise description of the symptoms according to a common clinical diagnosis chart validated within the network. This allowed important progresses in the knowledge of these very complex pathologies by the establishment of phenotype-genotype correlations in large series of patients. Since 2003, SPATAX reported 4 new loci for autosomal recessive spastic paraplegias (SPG28, SPG30, SPG32, SPG46), one new locus of dominant spastic paraplegias (SPG37), two loci in dominant ataxias (SCA25, SCA31) and 4 new loci among recessive ataxias (SAX2, ataxia with epilepsy, MSS, JBTS3). An effective collaborative work within the network allowed to identify simultaneously three new genes of spastic paraplegias, SPG11, SPG15 and SPG48. Similarly, in recessive ataxias, after the identification of the AOA2 gene, responsible as AOA1, of cases associating ataxia and oculomotor apraxia, we identified the ADCK3 gene. So, the continuous efforts of the network makes possible the establishment of the genetic diagnosis for more and more patients together with the design of rational diagnosis strategies.

Mondino, Pavia, 27100 PV, Italy; 9) Caenorhabditis elegans laboratory, Department of Experimental Medicine and Biochemical Sciences, University of Rome “Tor Vergata”.

Nonprogressive congenital ataxias are rare and heterogeneous neurological syndromes. We report the case of a girl with cerebellar hypoplasia, and a non progressive form of congenital ataxia and mental retardation (MR). Karyotype showed a *de novo* translocation involving chromosomes Xq25 and 8q24. We defined the boundaries of the translocation using FISH analysis, and determined the breakpoints with long range PCR. Array-CGH (244K) excluded further deletion/duplication. On chromosome 8, the translocation interrupts intron 2 in the 5’ UTR of the Protein Tyrosine Kinase 2 gene (*PTK2*), which encodes for a tyrosine kinase involved in cellular migration and in central nervous system development and myelination. A half dose *PTK2* mRNA expression was shown by real time RT-PCR in patient’s fibroblasts. On the X chromosome, the translocation juxtaposes, in the same orientation, the promoter and exons 1-2 of *PTK2* to the THO Complex 2 gene (*THOC2*). THOC2 protein is involved in spliced m-RNA export from the nucleus to the cytoplasm. Using RT-PCR and a combination of a forward primer in *PTK2* exon 1, and a reverse primer in exons 2 or 6 of *THOC2*, we demonstrated that a fusion transcript is produced from the X-derivative: it contains exon 1 of *PTK2*, and continues in THOC2, skipping its exon 1. Because THOC2 exon 1 contains the first ATG (Met) codon, the fusion transcript is not predicted to give a protein. A wild-type *THOC2* mRNA is however produced, because the translocation leaves intact the wild-type promoter. Using real-time RT-PCR, we showed that in patient’s lymphoblasts *THOC2* mRNA was apparently up regulated (2.5 times), but this increase is mostly due to the fusion product (2.0) than to the wild type transcript (0.5). *THOC2* is highly expressed in Purkinje cells (BrainAtlas), compared to a widespread expression of *PTK2*. Using DHPLC screening, no mutation was found in *PTK2* (9 males, 9 females) and *THOC2* (9 males) genes in unrelated patients with a neuroradiologic/clinical profile similar to our patient. C.elegans *ptk-2* mutant does not have phenotype. Preliminary data for thoc-2 mutant show that animals that reach adulthood are sterile, with vulva defects, and barely move. The lin-12/Notch pathway independently specifies vulva development and neuronal functions regulating locomotion. In conclusion, we hypothesize that in our patient the fusion *PTK2-THOC2* transcript, driven by *PTK2* promoter, is causing a tissue specific downregulation of the wild type *THOC2* gene.

2215/F

Clinical features of Spinocerebellar ataxia type 31 (SCA31) in Japanese population. *Y. Ichikawa[1], K. Araki[2], F. Katada[2], T. Fukutake[2], S. Tsuji[1], J. Goto[1].* 1) Dept Neurology, Univ Tokyo, Tokyo, Japan; 2) Dept Neurology, Kameda Medical Center, Chiba, Japan.

Background: Autosomal dominant cerebellar ataxias (ADCAs) are heterogeneous neurodegenerative diseases characterized by progressive cerebellar ataxia occasionally accompanied with other findings. Spinocerebellar ataxia type 31 (SCA31) were mapped on 16q22.1 and caused by the insertion mutation. The C/T substitution in the 5'UTR of *PLEKHG4* was specifically linked to SCA31 patients. **Objectives:** To reveal frequency of SCA31 among Japanese ADCAs and clinical features of SCA31. **Patients and Methods:** The 366 Japanese ADCA families were analyzed on the referral basis. The gene loci of SCA1, 2, 6, 7, 8, 12, 17, Machado-Joseph disease (MJD) / SCA3, and dentarorubral-pallidoluysian atrophy (DRPLA) were examined by the fragment analyses. The insertion mutation of SCA31 was analyzed using the published primers (Sato *et al*., *AJHG*, 2009). Detection of the C/T substitution in *PLEKHG4* was accomplished by DHPLC analysis and direct sequencing method. **Results:** Among 366 Japanese ADCA families, MJD was the most common ADCA (105families: 28.7%), followed by SCA6 (73families: 19.9%) and DRPLA (56families: 15.3%). SCA31 ranked as the fourth frequent ADCA (50families: 13.7%). We examined 53 patients from 49 SCA31 families whose clinical information was available. The average age at onset of SCA31 was 57.7±6.8 years old (40-73 years). Significant correlation between the size of insertion and the age of onset was not revealed among our patients. All patients showed ataxic gait or dysarthria as their initial symptoms (ataxic gait: 83%, dysarthria: 17%). Although it has been reported that the characteristic clinical feature of SCA was slowly progressive pure cerebellar ataxia, pyramidal signs including hyperactive deep tendon reflexes or Babinski's positive signs were shown in 42% of the SCA31 patients. The C/T substitution in *PLEKHG4* was presented in 52 patients from 48 SCA31 families. Two patients from two independent families did not have C/T substitution but C/C genotype in *PLEKHG4*. They are suggested as recombinant cases. One of the two C/C type patients, 60 year-old female, showed depression, frontal signs, hyperactive tendon reflexes and rigidity besides cerebellar ataxia. **Conclusion:** SCA31 accounted for 14% of Japanese ADCA families. Pyramidal signs were shown in around 42% of the SCA31 patients. Among 50 SCA31 families, two families (4%) did not carry C/T substitution in *PLEKHG4*.

2216/F

Siblings of pathologically proven multiple system atrophy: an application of whole genome analysis toward finding strong genetic factors for sporadic diseases. *H. Ishiura[1], B. Ahsan[1], J. Mitsui[1], Y. Takahashi[1], Y. Fukuda[1], Y. Ichikawa[1], Y. Nakahara[1], K. Hara[2], H. Takahashi[2], A. Kakita[2], O. Onodera[2], M. Nishizawa[2], J. Goto[1], S. Tsuji[1].* 1) Department of Neurology, The University of Tokyo, Tokyo, Japan; 2) University of Niigata, Niigata, Japan.

Background Multiple system atrophy (MSA) is a sporadic neurodegenerative disorder characterized by various combinations of autonomic dysfunction, cerebellar symptoms, parkinsonism and pyramidal signs. MSA has been classified into two subtypes, MSA-C (characterized by predominant cerebellar ataxia) and MSA-P (characterized by predominant parkinsonism). Although MSA is a sporadic disorder, previous studies suggest that MSA-P is more prevalent in Europe or North America than in Japan, raising the possibility of involvement of some genetic factors. We have recently identified rare familial aggregations in MSA. Identification of the causative gene for MSA in these multiplex families would help to elucidate the molecular mechanisms of familial MSA, and, furthermore, bring insights into the disease mechanisms of sporadic MSA. **Method** A family with 2 siblings with pathologically confirmed MSA was examined. Their parents were first cousins, raising the possibility of autosomal recessive mode of inheritance. Linkage analysis was performed using SNP-HiTLink after genotyping with Affymetrix' SNP6.0 arrays. Whole genome resequencing of the proband was performed using an Illumina GAIIx system. **Result** With assumption of autosomal recessive mode of inheritance, linkage analysis showed the candidate region of ~70Mb on 4 chromosomes. A total of 187.5 Gb of paired end reads was obtained. 92.5% was mapped properly, and 89.9% was mapped uniquely. Average coverage was 58X. A total of 3.49M SNPs was called. In comparison with the SNP array calls, 99.8% called by the sequence analysis was concordant. Among the 3.49M SNPs, 3.15M SNPs (90.2%) were registered in dbSNP and exonic SNPs were 19,432, which were comparable with those of previous reports. Of the 3.49M SNPs, 67.3K SNPs were found in the candidate region, 248 were located in exons or splice sites, 134 were nonsynonymous or at splice sites, and only 4 were novel. **Conclusion** We conducted whole genome resequencing of a patient with familial MSA. The 4 novel nonsynonymous variants are considered as candidates for pathogenic mutation for MSA, which are being investigated.

2217/F

New mutation in the *PRKCG* gene in three Portuguese patients with autosomal dominant spinocerebellar ataxia. *C. Martins[1,2], J. Pinto-Basto[1,2,3], J. Sequeiros[1,2,3], I. Alonso[1,2].* 1) UnIGENe, IBMC, Univ. do Porto, Porto, Portugal; 2) CGPP, IBMC, Univ. do Porto, Porto, Portugal; 3) ICBAS, Univ. do Porto, Porto, Portugal.

Spinocerebellar Ataxia type 14 (SCA14) is an autosomal dominant neurodegenerative disorder characterized by progressive gait and limb ataxia, dysarthria and nystagmus, although other neurological symptoms may also be present. SCA14 is caused by mutations in the *PRKCG* gene which encodes PKCγ, a member of a family of serine/threonine kinases, which role is to regulate several cellular processes such as signal transduction, cell proliferation and differentiation and synaptic transmission. PKCγ has an N-terminal regulatory region composed by a C1 domain (with 2 Cys-rich sub-domains, C1A and C1B) responsible for diacylglycerol binding and a C2 domain, which mediates Ca^{2+} and phospholipids binding, and a C-terminal catalytic region composed by C3/C4 domains. We have studied the coding and the intronic flanking sequences of the 18 exons that compose *PRKCG* gene in a series of 54 index cases of Portuguese families with autosomal dominant spinocerebellar ataxia (ADCA), with or without other associated symptoms and negative for the presence of an expansion at the SCAs 1, 2, 3 (MJD), 6, 7, 17 and DRPLA *loci*. PCR and sequencing analysis were performed. Three patients presented new missense mutations at the regulatory region, one in exon 3 (at PKCγ C1A sub-domain) and two in exon 4 (at C1B). One of the mutations identified in exon 4 was confirmed in an additional patient from this family. Though the analysis of co-segregation of the mutation and the disease in the families is not concluded, several bioinformatic softwares indicated a pathogenic effect for the mutations detected. Clinically, all the cases presented progressive pure cerebellar ataxia and late age-at-onset of the disease (above the age of 53). These results confirm exon 4 as a mutational hot-spot where, until now, have been described 15 of the 26 *PRKCG* mutations found in SCA14 patients. Additionally, patients with ADCA, already tested for the most common SCA types, should be screened for mutations at *PRKCG* exon 3 (corresponding to PKCγ C1A sub-domain) and exons 4 and 5 (C1B sub-domain).

2218/F

Screening of 38 Nonsyndromic Autosomal Recessive Deafness Genes Identifies Mutations in 63% of Families in Turkey. *M. Tekin[1], A. Sirmaci[1], D. Duman[2], F.B. Cengiz[2], H. Ozdag[3].* 1) Dept Human Genetics, Univ Miami, Miami, FL; 2) Div Pediatric Genetics, Ankara Univ, Ankara, Turkey; 3) Biotechnology Institute, Ankara Univ, Ankara, Turkey.

More than 60% of prelingual deafness is genetic in origin, and of these up to 93% are monogenic autosomal recessive traits. Causal mutations have been identified in one of 38 different genes in a subset of patients with nonsyndromic autosomal recessive deafness (NSARD). In this study we screened 50 unrelated Turkish families with at least three affected children with NSARD born to consanguineous parents. Probands from all families were negative for mutations in the GJB2 gene, two large deletions in the GJB6 gene and the m.1555A>G substitution in the MTRNR1 gene. Each family was subsequently screened via autozygosity mapping with Affymetrix 10K SNP arrays. If the phenotype cosegregated with a haplotype flanking one of the 38 genes, mutation analysis of the gene was performed. We identified 23 different autozygous mutations in 11 genes, other than GJB2, in 27 of 50 families, which along with GJB2, explains deafness in 63% of families with NSARD. Relative frequencies of genes following GJB2 (18.9% from previous data) were MYO15A (9.7%), TMC1 (6.4%), TMIE (6.4%), OTOF (4.8%), MYO7A (4.8%), CDH23 (3.2%), SLC26A4 (1.6%), PCDH15 (1.6%), LRTOMT (1.6%), SERPINB6 (1.6%), and TMPRSS3 (1.6%). 18 of 23 mutations were reported for the first time in this study. All identified mutations cosegregated with deafness in families and were negative in at least 100 Turkish hearing controls. Novel deafness genes are yet to be discovered in the remaining 23 families (37%). This study was supported by Tubitak 105S464 and 108S045 grants and funds from UM to M.T.

Re-sequencing analysis of candidate region for a neurodegenerative disorder by massively parallel sequencing. *T. Kaname[1,2], A. Tsujino[3], K. Yanagi[1], K. Hayashi[4], M. Tsukahara[2,5], K. Fujimori[2,6], I. Kikuzato[2,7], M. Teruya[2,8], Y. Imada[2,5], M. Nezuo[2,5], S. Yano[2,5], Y. Sato[2,7], Y. Miwa[2,5], T. Niikawa[9], K. Yoshiura[4], K. Naritomi[1].* 1) Dept Med Genet, Univ Ryukyus, Nishihara, Japan; 2) Okinawa Cutting-Edge Genome Project; 3) Dept Clinical Neuroscience and Neurology, Nagasaki Univ Graduate Sch Biomed Sci, Nagasaki, Japan; 4) Dept Hum Genet, Nagasaki Univ Graduate Sch Biomed Sci, Nagasaki, Japan; 5) TTC, Okinawa, Japan; 6) AIST, Tsukuba, Japan; 7) OSTC, Okinawa, Japan; 8) OITC, Okinawa, Japan; 9) Res Inst Personal Health Sci, Health Sciences University of Hokkaido, Hokkaido, Japan.

The genes underlying mendelian disorders have been identified through positional cloning, a process of meiotic mapping, physical mapping, and candidate-gene sequencing. Before the process of candidate-gene sequencing during positional cloning, it is important to narrow the candidate region for the disease, which requires survey of the genome in large number of families or patients. Due to the performance of the conventional sequencer, it is difficult to identify causative mutations for uncharacterized mendelian disorders, such as a disease consists of small number of familial cases. Next-Generation Sequencing technologies have brought new approaches of genetic analyses for personal genome or human diseases. The technologies can accurate giga-base order of sequence within a single run, allowing for complete resequencing of whole candidate region of a genetic disease in patients, whose responsible gene is not identified. Amyotrophic lateral sclerosis is a neurodegenerative disorder characterized by the death of motor neurons in the brain, brainstem, and spinal cord, resulting in fatal paralysis. It is well known that the ALS has genetic heterogeneity. Approximately 10% of ALS cases are familial. Many types of ALS, which have not been identified causative mutations, are still remaining. We analyzed candidate region in a familial ASL patient by massively parallel sequencing using next-generation sequencer. The candidate fragments were enriched by array-capture method. Then, a fragment library was constructed and sequenced to a depth >200-fold using the SOLiD 3 plus system. SNP calling program extracted 190 SNPs in the candidate region. Comparison of the calling SNPs and the dbSNP database allowed us to find novel four variations in the patient. In addition to the novel SNPs, 18 of non-synonymous were detected.

2220/F

HPRT deficiency causes broad transcriptional aberrations in cellular and signaling pathways. *T. Kang, T. Friedmann.* Department of Pediatrics, UCSD School of Medicine, La Jolla, CA.

HPRT deficiency in humans leads to the severe neurological and metabolic disorder of Lesch Nyhan Disease (LND). We have virtually no understanding of the mechanisms by which the underlying purine defects in LND produce the neurological phenotype. We have carried out extensive microarray-based analysis of global transcriptional patterns in human fibroblasts made HPRT deficient by expression of an shRNA targeted to HPRT. Gene ontology (GO) and gene set enrichment analysis (GSEA) have identified aberrant gene expression in a variety of cellular developmental and signaling pathways, including those related to the Alzheimer's-presenilin pathways. We have also used ChIP-Seq methods to examine the effects of HPRT deficiency on epigenetic gene regulation, and have identified a number of genes whose activation or inactivation by promoter interaction with methylated histones H3K4me3 and H3K27me3 is affected by HPRT deficiency. We conclude from these studies that HPRT plays a crucial role in regulation of gene expression in many cellular processes, apparently to some extent by epigenetic mechanisms. These new insights clarify some of the complex systems defects and mechanisms responsible for neuropathology in human HPRT deficiency.

2221/F

A novel homozygous intronic DARS2 mutation in a family with congenital leukoencephalopathy. *S. Miyatake[1], N. Miyake[1], S. Yamashita[2], K. Kurosawa[3], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Department of Neurology, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan.

Leukoencephalopathy is an inclusive condition presenting the impairment of the white matter of the brain, and has several different forms and causes. We analyzed a one Japanese-Chinese consanguineous family with severe congenital encephalopathy. Three of four children are affected in this family and two of the affected deceased at 8 years and 2 years old, respectively. Their common clinical phenotypes include psychomotor retardation, cerebellar ataxia and peripheral neuropathy. There were no abnormal biochemical findings. The level of lactate and pyruvate were within normal range in both blood and cerebrospinal fluid. Based on their consanguinity suggesting that this disease inherits in autosomal recessive fashion, we performed homozygosity mapping using three affected children, one unaffected child and unaffected parents by GeneChip Human Mapping 10K XbaI (Affymetrix). Then, we identified only an informative homozygous region on chromosome 1 spanning 8 Mb. Among this region, DARS2 (aspartyl-tRNA synthetase 2) gene is included, which is the causative gene for leukoencephalopathy with brainstem and spinal cord involvement and lactate elevation (LBSL, MIM #611105). Although our cases did not show the elevation of lactate and pyruvate levels, their lesions and clinical features were very similar to LBLS. Thus we performed the direct sequence for DARS2 gene as a primary candidate gene, and identified a novel homozygous intronic mutation. This change was not observed in normal 184 control samples. We extracted mRNA from fibroblast derived from one patient and the father (mutation carrier) and confirmed the exon skipping by RT-PCR and sequencing. Furthermore, we showed complete loss and the decrease to half level of DARS2 protein in affected and carrier (parent) compared with the normal control fibroblast by immunoblotting, respectively. We concluded that the novel homozygous intronic DARS2 mutation is a real culprit for LBLS in a Japanese-Chinese consanguineous family.

2222/F

Parkin mutations and Juvenile Parkinson disease in Portuguese patients. *S. Morais[1], J. Pinto-Basto[1,2], J. Sequeiros[1,2], I. Alonso[1].* 1) CGPP and UnIGENe - IBMC, Univ. Porto, Porto, Portugal; 2) ICBAS, Univ.Porto, Porto, Portugal.

Parkinson disease (PD) is one of the most common movement disorders, the aetiology of which remains mostly unknown. The majority of PD cases are sporadic, although the discovery of genes linked to rare familial forms has provided valuable insights into disease mechanisms. Autosomal recessive juvenile Parkinson disease (AR-JP) is genetically heterogeneous and, apart from age at onset, clinically indistinguishable from idiopathic PD. AR-JP presents with rigidity, bradykinesia and resting tremor, usually before age 50 years. Abnormal behavior or psychiatric symptoms may also occur. Among the recessive forms, mutations in *PARK2*, mapping to chromosome 6q25.2-27, are found in approximately 50%; of the cases. PARK2 is composed by 12 exons and encodes parkin, an E3 ubiquitin ligase. We received samples from 155 Portuguese patients showing PD features with variable age at onset, and performed *PARK2* mutation analysis for diagnostic testing. Mutation screening was performed by PCR amplification of all coding regions, followed by bidirectional direct sequencing. In patients in whom no mutation was found, we also perform MLPA (multiplex ligation-dependent probe amplification) to detect possible large deletions/duplications. We confirmed the clinical diagnosis in 22.6% (35/155) of the patients. Age at onset of these cases ranged from 3 to 42 years-old. Sixteen different mutations were found, including missense mutations, small deletions or insertions, and large deletions. Homozygous mutations were found in 65.7%. Large deletions were present in 48.6% of the patients; the most frequent mutation - c.155delA - was present in 41.4% of the cases. Age at onset is an important clinical feature when considering the molecular genetic diagnosis of juvenile PD, but its variation is still considerable. Our results show that the c.155delA mutation is highly recurrent in the Portuguese population. Large deletions are responsible for juvenile PD in about half of these patients, making MLPA an essential approach in this molecular diagnosis, in addition to direct sequencing.

2223/F

Neurofibromatosis caused by neurofibromin mutations in a large cohort of Portuguese patients. *R. Bastos-Ferreira[1, 2], J. Pinto-Basto[1, 2], M. Barbosa[3], M. Reis-Lima[4], I. Alonso[1], J. Sequeiros[1, 2].* 1) CGPP and UnIGENe, IBMC, Porto, Portugal; 2) ICBAS, University of Porto, Porto, Portugal; 3) Centro de Genética Médica Jacinto Magalhães, INSA, Porto, Portugal; 4) HPP Boavista, Porto, Portugal.

Neurofibromatosis type 1 (NF1) is a common autosomal dominant disease with complete penetrance, but highly variable clinical expression. This condition is characterized by café-au-lait spots, axillary and inguinal freckling, neurofibromata, Lisch nodules, optic gliomas, distinct bone lesions and, in a subset of patients, learning disability/development delay. NF1 is caused by mutations in the *NF1* gene, one of the largest in the human genome. Mutations are scattered throughout the gene and include point mutations and small and large rearrangements, including whole gene deletions. In 50% of the patients mutations are *de novo*. *NF1* is located on chromosome 17q11.2, spanning over 250Kb, and is composed by 57 exons. Its product, neurofibromin, is a tumor suppressor protein, with 8,457 aminoacids. Our aim was to collect a large sample of NF1 patients, with detailed clinical data, and perform mutation analysis of the *NF1* gene, in order to establish genotype-phenotype correlations. We have ascertained 72 Portuguese patients with a clinical diagnosis of NF1 and performed neurofibromin mutation analysis, for diagnostic testing. Mutation screening was performed by PCR amplification of all coding and flanking regions, followed by bidirectional direct sequencing. In the Human genome there are several *NF1* pseudogenes which can lead to an incorrect diagnosis. In order to overcome this, we have introduced additional techniques such as RT-PCR and *NF1* isolation. Until now, we have performed mutational analysis in 27 clinically diagnosed NF1 patients and have found four nonsense mutations and one large gene rearrangement confirming the clinical diagnosis in five patients. All mutations result in truncated proteins, much smaller than the normal neurofibromin. In the remaining patients no mutations were found so far. Our sample of patients shows that neurofibromin truncated mutations may be frequent in Portuguese patients and that large gene rearrangements can also be present in a significant percentage of patients. NF1 has a large phenotypic heterogeneity and mutation screening in this gene can be invaluable to confirm and establish an early diagnosis, and to allow proper genetic counselling, including the offer of prenatal diagnosis.

2224/F

Autossomal Dominant Spastic Paraplegia: mutational characterization of a large sample of Portuguese patients. *A.F Brandão[1,2], A. Lopes[1], J.L. Loureiro[2,3], J. Pinto-Basto[1,2,4], P. Coutinho[2,3], J. Sequeiros[1,2,4], I. Alonso[1,2].* 1) CGPP, IBMC, Porto, Portugal; 2) UnIGENe, IBMC, Porto; 3) Serviço de Neurologia, Hospital de São Sebastião, Feira; 4) ICBAS, Universidade do Porto, Porto.

Hereditary spastic paraplegias (HSPs) are a group of rare neurodegenerative disorders with clinical and genetic heterogeneity. Clinically, can be divided into: pure, characterized mainly by slowly progressive weakness and spasticity in the lower limbs, and complex, with additional features. Genetically, three modes of inheritance have been described: autosomal dominant (AD), autosomal recessive (AR) and X-linked (XL). Among AD-HSP, mutations in *SPG4* and *SPG3A* are described to account for about 50% of cases. SPG4 encodes spastin, an ATPase belonging to the AAA protein family and SPG3A encodes atlastin-1, a Golgi transmembrane GTPase. Recently, mutations in the receptor expression enhancing protein 1 (*REEP1*) have been found to cause the third most frequent form of AD-HSP: SPG31. We have clinically ascertained 145 Portuguese patients corresponding to 74 families showing HSP with dominant inheritance and 71 patients without known family history of HSP and performed mutation analysis in the 3 genes, taking into account clinical information. Mutation screening was performed by PCR amplification of all coding and flanking regions, followed by bidirectional direct sequencing. In patients in whom no mutation was found, we have also performed MLPA to detect large deletions or duplications. By molecular analysis we identified 12 mutations in *SPG4*, 2 in *SPG3A* and 1 in *REEP1* (SPG31). In *SPG4*, we found 8 missense mutations, 5 of which are novel, a 3 bp duplication, 1 frameshift mutation and 1 intronic deletion. By MLPA, a large genomic non-contiguous deletion in *SPG4* was identified in a family with a complex phenotype and early disease onset. This large rearrangement was confirmed in two additional patients from this family. In *SPG3A*, both mutations identified are missense and affect atlastin-1 highly conserved residues, in patients with early disease onset. We have also found the first SPG31 Portuguese family, showing a *REEP1* nonsense mutation, in a patient with a pure phenotype. This novel mutation leads to a truncated protein. In conclusion, this work enlarges the number of patients and mutations identified in AD-HSPs and allow the estimation of SPG4, SPG3A and SPG31 mutation frequency. Until now, in Portugal, SPG4 represents 15% of the cases, SPG3A 5% and SPG31 1%, frequencies significantly different from the described in other populations.

2225/F

31 novel mutations in SPG11/spatacsin identified using both direct sequencing and MLPA. *G. Stevanin[1,2,3], E. Denis[2], E. Mundwiller[1], E. Ferdiko[2], C. Cazeneuve[2], E. Leguern[1,2], A. Durr[1,2], A. Brice[1,2], C. Depienne[1,2].* 1) CR-icm, INSERM / UPMC UMR_S975, NEB, Paris, France; 2) APHP, Département de Génétique et Cytogenetique, Groupe Hospitalier Pitie-Salpetriere, 75013 Paris, France; 3) EPHE, Paris, France.

Background: mutations in SPG11/spatacsin are the major cause of autosomal recessive spastic paraplegia with thin corpus callosum. Recently genomic rearrangements were also involved. Methods: We used 60 unrelated patients with spastic paraplegia and thin corpus callosum +/- mental retardation or cognitive delay, all referred to the Department of Genetics of the Pitie-Salpetriere Hospital for SPG11 diagnosis. The SPG11 gene was investigated using direct sequencing of all exons and MLPA (multiplex ligation-dependent probe amplification). Results: 40 different truncating SPG11 mutations, 31 of which were novel, were identified in 26 index patients (43.3%). 35 mutations were point mutations or small indel and 5 were genomic rearrangements that introduced premature termination codons in the protein sequence and were compatible with a degradation of the corresponding mRNA by the nonsense-mediated mRNA decay. In addition, 2 heterozygous missense variants which altered highly conserved amino-acid residues of the protein were found associated with a truncating mutation. Analysis of the affected relatives and parents, when possible, showed that the mutations segregated with the disease and that heterozygous compound mutations were inherited each from a healthy parent. Finally, we identified new missense polymorphisms that did not segregated with the disease. Conclusions: These findings expand the SPG11 mutation spectrum and highlight the importance of screening the whole coding region with both direct sequencing and a quantitative method. Rearrangements accounted for 12,5% of the mutated cases and can now be easily detected using MLPA. Rare missense polymorphisms are frequent in SPG11, complicating interpretation of diagnosis.

2226/F

Mottled hypopigmentation on the trunk in a Japanese case of PCWH with p.Q377X nonsense mutation in SOX10 gene. *K. Fukai[1], T. Oshimo[1], Y. Abe[2], Y. Hozumi[2], A. Tanaka[3], K. Yamanishi[4], M. Ishii[1], T. Suzuki[2].* 1) Dermatology, Osaka City Univ, Osaka, Japan; 2) Dermatology, Yamagata Univ. Yamagata, Japan; 3) Pediatrics, Osaka City Univ, Osaka, Japan; 4) Dermatology, Hyogo College of Medicine.

We reported a case of PCWH with SOX10 nonsense mutation on exon 5. The patient had a mottled hypopigmented macules on the truck, which was not described before. We also reviewed the cutaneous changes of PCWH and WS4 associated with SOX10 mutations. A Japanese boy was born after a 39-weeks pregnancy. He was the second child of healthy nonconsanguineous parents, with a healthy elder brother. There was no family history of dyschromatosis or neurological diseases. He had blue irises, nystagmus, and growth deficiency from birth. When he was a 3-month-old baby, his hair was light brown color, which was significantly lighter than most of the Japanese infants. Mottled hypopigmentation of the skin was apparent on his abdomen, inguinal and the thigh. At the age of 2 years, Hirschsprung disease was noted and the 15cm of the colon was surgically removed. Meanwhile, the otolaryngological examination revealed an anomaly of internal ear, the malfunction of the three semicircular canals, and severe deafness. At the age of three, he can manage to pull himself up by holding on to something but cannot walk, indicating severe delay of motor development. Heterochromia of the ireses has been pointed out by Ophthalmologists. We identified a single nucleotide substitution (1129C®T) in the last exon5 of SOX10 gene. This substitution changes codon 377 from CGA (Arginine) to the stop codon TGA (p.Q377X). So far, 22 cases with PCWH or WS4 associated with SOX10 mutations have been described. The so-called white forelock was noted in 5 cases with severe phenotype of PCWH. Therefore, the presence of white forelock may be indicative for PCWH with severe neurological changes. In this case, the hypopigmented macules were present not only on the abdomen, but also on the back, and the margin of the leukoderma is obscure. This is clearly different from the white macules of piebaldism, which is associated with KIT mutation. The presence of white macules on the back may suggest the significance of the SOX10/MITF system for the post-natal survival of melanocytes within epidermis. Dermatologists, especially pediatric dermatologists, should be aware that mottled hypopigmentation on the trunk is possibly a suggestive cutaneous sign for WS4 or PCWH.

2227/F

Jaffe-Campanacci syndrome and neurofibromatosis type 1, revisited: case report and review of the literature from the geneticist's perspective. *S.L. Ruppert, D.R. Stewart.* National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Jaffe-Campanacci syndrome (JCS) is a disorder characterized by multiple non-ossifying fibromas (NOFs) of the long bones in association with café-au-lait macules (CALMs). NOFs are sharply demarcated osteolytic lesions located eccentrically in the metaphysial area. With completion of skeletal growth they stop enlarging and tend to heal spontaneously. If the repair is incomplete, however, pathologic fracture may occur. The CALMs seen in JCS patients typically have smooth ("Coast of California") borders. Axillary freckling has been reported in some JCS patients, but other signs of neurofibromatosis type 1 (NF1), including neurofibromas and Lisch nodules are reportedly absent. Mental retardation is a variable feature of the disorder. JCS was first described in 1958 and later named in 1982. The incidence and genetic etiology of JCS are not known. All reported cases to date are sporadic and without recurrence. No formal diagnostic criteria have been proposed. The literature includes several case reports of patients with both NF1 and multifocal NOFs, including a small number of families with more than one affected individual. Many of these patients have Lisch nodules and/or pathologically proven neurofibromas as well as CALMs and axillary freckling. There is only one report in the literature of a child with NF1 and multifocal NOFs who had genetic testing; this patient was found to have an intragenic NF1 gene deletion. We present a case report of a 26-year-old Caucasian male who received a clinical diagnosis of NF1 at age 6 years due to multiple CALMs and faint axillary freckling. There is no family history of NF1. At age 13 years he sustained bilateral femoral fractures that were retrospectively attributed to NOFs. No Lisch nodules or neurofibromas were noted at that time and it was therefore suggested that the findings were more supportive of a diagnosis of JCS. On examination at age 25 years the patient was found to have approximately 10 skin lesions consistent with cutaneous neurofibromas and Lisch nodules in both eyes. Genetic testing showed a nonsense mutation in the NF1 gene. The overlap between JCS and NF1 is striking. It would be valuable to patients, healthcare providers and researchers alike to understand whether the disorders are, in fact, allelic. This would improve genetic counseling and management of affected patients and would also raise awareness of multifocal NOFs as an established feature of NF1.

2228/F

Copy Number Variation and Loss of Heterozygosity In Saudi Patients With ASD. *N. Al Tassan[1], J. Shinwari[1], L. Al Sharif[1], D. Khalil[1], A. Almuslamani[2], H. Khalak[1], M. Ghannam[1], B. Meyer[1], M. Nester[2], M. Aldosari[2].* 1) Department of Genetics, KFSH & RC, Riyadh, Saudi Arabia. MBC-03-06 P.O Box 3354, Riyadh 11211 Saudi Arabia; 2) Department of Neurosciences , King Faisal Specialist Hospital. P.O Box 3354, Riyadh 11211 Saudi Arabia.

Autistic Spectrum Disorders (ASD) represents a genetically heterogeneous complex developmental disorder. Although there is no defined single genetic cause, in <10% of reported cases ASD has been found to be associated with a recognized cause, such as fragile X syndrome [FXS] (Xq27.3), tuberous sclerosis [TSC] (9q or 16p) and Angelman (AS)/Prader-Willi (PW) syndrome (15q11-q13 chromosome abnormality). Several approaches have been used to find candidate genes linked to/ or associated with ASD. These include genome wide scans, linkage studies of multiplex families, cytogenetic studies and copy number variation [CNV]. These different approaches have yielded a number of associated and susceptible genes and high risk loci in several chromosomes which include; 1p, 2q32, 5q, 6q21, 7q22,11p12-p13,13q, 16p13, 17q,19p and X=ACq13-q21. Single base pair substitutions in NLGN3, NLGN4, SHANK3 and PTEN genes were identified in rare cases of ASD with different degrees of severity. Here we report on the results of CNV and LOH in families with 2 or 3 affected individuals with ASD from the Saudi Arabia, where there is a high rate of consanguinity and endogamy. Clinical assessment of these patients classified them on the extreme end of the Autism spectrum. Analysis of 250K and/or 6.0 microarray data revealed a number of candidate loci in these families in which some may represent novel loci. Our data confirms the genetic heterogeneity and complexity of the disorder.

2229/F

A novel analysis of genomic rearrangements in multifactorial Hirschsprung disease. *Q. Jiang, Y-Y. Ho, A. Chakravarti.* Institute of Genetic Medicine, Baltimore, MD.

Hirschsprung disease (HSCR, OMIM 142623) is a developmental neurocristopathy characterized by the absence of intramural ganglion cells along variable lengths of the gastrointestinal tract. HSCR is a typical multifactorial disorder with an incidence of 1/5,000 live births, male predominance (sex-ratio of 4:1), sibling recurrence rate of 4%, variable expression and non-mendelian inheritance. To date, 12 genes (RET, GDNF, NRTN, SOX10, EDNRB, EDN3, ECE1, ZFHX1B, PHOX2B, TCF4, KIAA1279, SEMA3D (described at this meeting)) with segregating mutations and variants have been identified in syndromic, familial and sporadic cases. However, many other additional genes, identified through studies of mouse models of HSCR, are likely to exist. We have identified a total of 67 such proven and candidate HSCR genes. Approximately 12% of HSCR cases are likely to harbor a visible chromosomal change: the incidence of smaller chromosomal mutations and polymorphisms (CNVs) are unknown. In this study, we custom designed an array for comprehensive CGH analysis of dosage alterations in all of these 67 HSCR genes. We used the Agilent technology to assess genomic dosage using 45K probes across ~6 mb of the 67 genes and examined 11 isolated and 7 syndromic HSCR patients (16 males, 2 females). Of these, 8 cases were short-segment HSCR, 3 long-segment HSCR, 4 cases were total colonic aganglionosis and 3 cases were unclassified. To test the consistency of the technology and possible batch effect, we performed technical replication experiments in different batches. Under stringent criteria for calling CNVs, we identified 63 changes in the 18 patients (3.5 CNVs/patient). The most common loss, 8 out of 18 patients (44.4%), was a 2 kb deletion of the 5'UTR and translation start site of ZFHX1B (ZEB2), a gene mutant in Mowat-Wilson syndrome. The most common gain, 15 out of 18 patients (83.3%), was a 2 kb duplication containing SEMA3A and including a conserved sequence covering exon3 that encodes part of the sema domain. These changes do not exist in extant databases. Further validation of these results and a screening of a larger number of patients is currently underway.

Large *SPG11* gene rearrangements cause Hereditary Spastic Paraplegia type 11 in Portuguese patients. *M.C. Pereira[1,2], J. Loureiro[2,3], J. Pinto-Basto[1,2,4], P. Coutinho[2,3], J. Sequeiros[1,2,4], I. Alonso[1,2].* 1) CGPP, IBMC, Porto, Portugal; 2) UnIGENe, IBMC, Porto, Portugal; 3) Serv. Neurologia, Hosp. São Sebastião, Feira, Portugal; 4) ICBAS, Universidade do Porto, Portugal.

Hereditary spastic paraplegias (HSPs) compose a group of heterogeneous genetic disorders both clinical and genetically. Among the autosomal recessive forms of these neurodegenerative diseases, SPG11 is the most common one, and is mainly characterized by early onset rapidly progressive spasticity of the lower limbs, the presence of a thin corpus callosum and cognitive impairment. In order to better understand SPG11 distribution among the Portuguese population we genetically characterized a group of 43 patients with spastic paraplegia. Mutation screening was performed by direct sequencing of the PCR amplified coding regions and flanking intron boundaries of the *SPG11* gene, to detect point mutations, followed by MLPA analysis for detection of large gene rearrangements (deletions or duplications). We were able to identify 8 different mutations (5 frameshift and 3 large deletions), confirming SPG11 in 9 patients. Amongst these, we found through direct sequencing a novel 4 base pair small deletion and though MLPA analysis three new large gene rearrangements, comprising two different single exon deletions and an interesting case of a heterozygous complex entire gene rearrangement. All result in a truncated spatacsin leading to disease through a loss of function mechanism. Our results, together with other previously reported SPG11 Portuguese families, show that point mutations, like c.529_533delATATT and c.733_734delAT, seem to be very prevalent in our population. Nevertheless, gene dosage analysis proved to be an important resource in SPG11 molecular diagnosis revealing that a considerable amount of SPG11 cases can arise from large gene rearrangements.

2231/F

Copy number variation as a marker of genomic instability and disease severity in neurofibromatosis type 1 (NF1). *J.D. Schiffman[1,2], B. Demarest[1], L. Cannon-Albright[3], D. Viskochil[2], D.A. Stevenson[2].* 1) Department of Oncological Sciences, University of Utah, Salt Lake City, UT; 2) Department of Pediatrics, University of Utah, Salt Lake City, UT; 3) Department of Internal Medicine, University of Utah, Salt Lake City, UT.

Background: Neurofibromatosis Type 1 (NF1) affects 1 in 3000 children and is caused by mutations in the *NF1* gene. NF1 individuals have a wide spectrum of clinical manifestations including bone dysplasias, cafe-au-lait macules, neurocognitive defects, and cancer. The severity of phenotype differs within and between NF1 families. Unlinked genomic modifiers of phentoype have been suggested, but not yet identified. Copy number variations (CNVs) recently have been described to affect risk in other complex diseases. Objective: To perform genome-wide CNV analysis in NF1 individuals as markers of increased genomic instability and modifiers of disease severity. Methods: DNA was extracted from NF1 cases (n=45) and run on Affymetrix SNP 6.0 microarray chips. SNP 6.0 CEL files were obtained from normal controls (n=101) from a previous, unrelated GWAS investigation (Shi et al. 2009). CNVs were identified using Nexus Copy Number software (BioDiscovery, Inc.). Total number CNVs/genome, total number CNVs within cancer genes/genome, and total structural variation (size)/genome were compared between NF1 cases and controls using Wilcoxon Rank Sum test. We also divided NF1 cases into mild (n=15) vs. severe (n=21) phenotypes in cases with enough clinical data and analyzed CNV differences between both categories. Results: NF1 cases had 118 ± 44 mean total CNVs vs. 54 ± 12 CNVs in controls ($p<2.2x10e-16$), 20 ± 13 mean CNVs within cancer genes vs. 8 ± 3 in controls ($p<2.5x10e-15$), and 32.5 ± 24 MB mean total structural variation/genome vs. 7.3 MB ± 5 in controls ($p<2.2x10e-16$). The slope of acquired cancer gene CNVs in NF1 cases was steeper than controls, corresponding to 26% increase in CNVs within cancer genes for every additional CNV ($p=4.23x10e-5$). We found 16 distinct CNV loci that differed between NF1 cases with mild vs. severe phenotypes with $p<0.05$, and 3 distinct loci with $p<0.01$. Conclusions: CNVs differ in total number, size, and location between NF1 individuals and healthy controls. In addition, this NF1 cohort had an increased number of cancer gene CNVs for every increase in over-all number of CNVs/genome. Furthermore, genome-wide CNVs differed between NF1 individuals with mild vs. severe phenotypes. These differences in genomic structural variation may reflect underlying genomic instability and explain the increased cancer risk in the NF1 population. We are currently in the process of validating the results in a larger cohort with additional controls.

Molecular Diagnosis of Amyotrophic Lateral Sclerosis (ALS): Evaluation of Four Autosomal Dominant Genes. *M. Chen, S.D. Batish, C. Stanley, E. Couchon, C. Braastad, J. Jones, M. Ito.* Athena Diagnostics, Inc. Worcester, MA.

Amyotrophic lateral sclerosis (ALS) is an adult-onset, progressive neurodegenerative disorder characterized by the death of motor neurons in the brain, brainstem, and spinal cord, with eventual fatal paralysis. ALS prevalence in the United States is 4 to 8 per 100,000 individuals. There are more than twelve types of ALS with significant clinical overlap, and while the majority of cases are sporadic, approximately 5-10% of cases are familial. Heritable forms of the disorder show multiple modes of inheritance, with autosomal dominant being most prevalent. In May 2009, Athena Diagnostics, Inc., began offering DNA testing for ALS; the test menu includes four genes responsible for autosomal dominant forms of ALS, including *Superoxide Dismutase 1* (*SOD1*), *Fused in Sarcoma/Translated in Liposarcoma* (*FUS*), *Angiogenin* (*ANG*), and *TAR DNA-Binding Protein* (*TARDBP*). Herein, we report DNA test results for approximately 500 unrelated families in which the diagnosis of ALS was suspected based on clinical findings. In the *SOD1* gene, we identified 10 different previously published mutations in 24 patients; furthermore, two different missense mutations of unknown clinical significance were found in three additional cases. Molecular testing of *FUS* was positive in 11 individuals, with identification of three different previously published mutations in six individuals and five different frame-shift mutations predicted to be disease-associated. Interestingly, all five novel frame-shift mutations were located in one particular exon (exon 14). In addition, *FUS* sequencing identified five novel missense mutations of unknown clinical significance. Two different *ANG* mutations were identified in three patients, and one *ANG* variant of unknown clinical significance was found in two unrelated individuals. Finally, *TARDBP* sequencing identified four different previously published mutations in five individuals. In conclusion, *SOD1* mutations were found in 55% of test-positive individuals, *FUS* mutations accounted for 25% of positive test results, and *ANG* and *TARDBP* mutations were responsible for approximately 7% and 12% of genetically-linked ALS cases, respectively. When compared to *SOD1* testing alone, the addition of three new genes to Athena's ALS testing menu has almost doubled test sensitivity. The clinical sensitivity is approximately 8%, which is similar to other published reports.

2233/F

A new locus (SPG46) maps to chromosome 9 in a Tunisian family with a complicated autosomal recessive hereditary spastic paraplegia with mental impairment and thin corpus callosum. *A. Boukhris[1,2,3], I. Feki[2], N. Elleuch[2], M.I. Miladi[2], A. Boland-Augé[4], J. Truchetto[1], E. Mundwiller[1], D. Zelenika[4], A. Brice[1,3], C. Mhiri[2], G. Stevanin[1,3].* 1) CR-icm, INSERM / UPMC UMR_S975, NEB, Paris, France; 2) Department of Neurology, Habib Bourguiba University Hospital, Sfax, Tunisia; 3) AP-HP, Pitié-Salpêtrière Hospital, Department of Genetics and Cytogenetics, Paris, France; 4) Centre National de Génotypage, Evry, France.

Hereditary spastic paraplegia (HSP) with thin corpus callosum (TCC) and mental impairment is a frequent subtype of complicated HSP, often inherited as an autosomal recessive (AR) trait. It is clear from molecular genetic analyses that there are several underlying causes of this syndrome, with at least 6 genetic loci identified to date. However, SPG11 and SPG15 are the 2 major genes for this entity. Our objective was to map the responsible gene in a large consanguineous AR-HSP-TCC family of Tunisian origin excluded for linkage to the SPG7, SPG11, SPG15, SPG18, SPG21 and SPG32 loci. A genome-wide scan was undertaken using 6000 SNP markers covering all chromosomes. The genome-wide search identified a single candidate region on chromosome 9, exceeding the LOD score threshold of +3. Fine mapping using additional markers narrowed the candidate region to a 45.1-Mb interval (15.4 cM). Mutations in 3 candidate genes were excluded. Phenotypic presentation in 5 patients was suggestive of a complex HSP that associated an early onset spastic paraplegia with mild handicap, mental deterioration, congenital cataract, cerebellar signs and TCC. The mapping of a novel AR-HSP-TCC locus further demonstrates the extensive genetic heterogeneity of this condition. We propose that testing for this locus should be performed, after exclusion of mutations in SPG11 and SPG15 genes, in AR-HSP-TCC families, especially when cerebellar ataxia and cataract are present.

2234/F

Genetic heterogeneity in congenital mirror movements. *S. Gulsuner[1], H. Uysal[2], R. Bilgen[2], K. Bilguvar[3], M. Gunel[3], T. Ozcelik[1].* 1) Department of Molecular Biology and Genetics, Bilkent University Faculty of Science, Ankara, Turkey; 2) Department of Neurology, Akdeniz University Faculty of Medicine, Antalya, Turkey; 3) Department of Neurosurgery, Yale University School of Medicine, New Haven, CT, United States.

Mirror movements (MM) in humans are rare and they generally accompany conditions such as Klippel-Feil or Kallmann syndromes, Friedreich ataxia, phenylketonuria, Parkinsonism, schizophrenia, central nervous system invasions and epilepsies. They are characterized by involuntary contralateral movements of upper extremities during voluntary movements. Here, we describe a three-generation consanguineous family with multiple members displaying variable degrees of MM with or without juvenile myoclonic epilepsy. Pedigree analysis suggests autosomal dominant inheritance. High-resolution microarray genotyping of 16 individuals from the family and analysis of the data according to autosomal recessive model revealed stretches of 9 homozygous regions ranging from 1.04 Mb to 1.7 Mb on chromosomes 1, 3, 4, 7, 8, 16 and 17. Linkage analysis with a dominant model and full or 90 percent penetrance parameters independently resulted in positive LOD scores for three chromosomal regions: chromosome 3 (1.28), chromosome 15 (1.71) and chromosome 22 (3.62). Minimal critical regions for each locus were determined by haplotype analysis. Three chromosome 22 genes, SYN3, TIMP3 and LARGE, were sequenced in two affected individuals but no mutation detected. Recently, mutations in DCC were shown to cause congenital mirror movements in two chromosome 18 linked families (Science 328:592, 2010). However, chromosome 18 is not implicated under any inheritance model in our family. These findings suggest that there is genetic heterogeneity in MM. At present we are performing next-generation exome sequencing to identify the genetic basis of this condition in our family.

Identification of mutations in the *NAGLU* gene in a mild form of Mucopolysaccharidosis IIIB through targeted high-throughput sequencing.

K.K. Selmer[1], G.D. Gilfillan[1], P. Strømme[2], K. Brandal[1], H.S. Hjorthaug[1], D. Misceo[1,3], S. Nakken[4], T. Hughes[1,3], S.K. Braekken[5], R. Lyle[1], D.E. Undlien[1,3]. 1) Department of Medical Genetics, Oslo University Hospital, Oslo; 2) Department of Pediatrics, Oslo University Hospital, Oslo; 3) Institute of Medical Genetics, University of Oslo, Oslo; 4) Department of Tumor Biology, Institute of Cancer Research, University of Oslo, Oslo; 5) Department of Neurology, Oslo University Hospital, Oslo, Norway.

Ultra high-throughput sequencing techniques (HTS) have proven useful in the identification of genetic causes of Mendelian disease by targeted resequencing and exome sequencing. When available linkage information exists, linked regions can be captured directly and the familial occurrence reduces the possibility of genetic heterogeneity and the uncertainty of mode of inheritance. We identified a Norwegian family consisting of healthy parents and eight children, of whom four were similarly affected, with static developmental delay from the age of two. From their mid-twenties peripheral and night vision was reduced and their cognitive abilities started to slowly regress. At present the patients are between 47 and 61 years old. They are severely demented with loss of expressive verbal language and ambulation is very restricted. As no etiological diagnosis had been set, linkage analysis was performed. Autosomal recessive inheritance was assumed and power analyses showed an expected maximum LOD score of 2.3. Linkage analysis was performed using Affymetrix 10K SNP arrays and subsequent calculations done in Merlin showed two linkage peaks reaching a LOD score of 2.3 on chromosomes 9 and 17. The linked regions were 31 Mb and contained more than 180 genes. Eighteen candidate genes were sequenced, but no mutations were detected. Using custom NimbleGen Sequence Capture Arrays we captured the linked coding regions and performed HTS on chromosome 9 with Roche 454 and on chromosome 17 with Illumina Genome Analyzer II. We identified 124 new single nucleotide variants (SNVs) located in coding regions. When considering potential compound heterozygous SNVs, two mutations identified in NAGLU had previously been observed in patients affected by Mucopolysaccharidosis IIIB (MPS IIIB, also called Sanfilippo syndrome B). MPS IIIB is an autosomal recessive disorder caused by an enzyme deficiency of α-N-acetyl-glucosaminidase due to mutations in NAGLU. This diagnosis was confirmed in the Norwegian family by the finding of elevated heparan sulfate in the urine and low levels of α-N-acetyl-glucosaminidase activity in cultured fibroblasts. The phenotype in this Norwegian family is much milder than what is usually described in MPS IIIB, as such patients rarely reach the age of 30. Our findings show how targeted HTS might accelerate the identification of disease causing mutations in Mendelian disease, and also add examples to the rarely described attenuated form of MPS IIIB.

2236/F

Evidence of association of SNPs in *MSH6* with café-au-lait macule burden in neurofibromatosis type 1.

A. Pemov[1], H. Sung[2], J.L. Sloan[3], S. Ruppert[1], J. Mullikin[4], P. Cruz[4], A.F. Wilson[2], D.R. Stewart[1]. 1) Genetic Disease Research Branch, NHGRI, NIH, Bethesda, MD; 2) Inherited Disease Research Branch, NHGRI, NIH, Baltimore, MD; 3) Genetics and Molecular Biology Branch, NHGRI, NIH, Bethesda, MD; 4) Genome Technology Branch, NHGRI, NIH, Rockville, MD.

Background. The cause of the variation in phenotypic severity in neurofibromatosis type 1 (NF1) is unknown and may be due to genetic modifiers. We hypothesized that variation in *germline* gene expression of certain genes correlates with variation in the severity of quantifiable phenotypic features of NF1. **Methods.** We performed whole-genome transcriptional profiling (Illumina HumanRef-8 arrays) in lymphoblastoid cell lines from 79 individuals affected with NF1 and 23 controls. A single observer quantified severity in multiple NF1 sub-phenotypes, including café-au-lait macules (CALM) number. We examined the correlation of the 6 NF1 sub-phenotypes with the level of each of the 22,177 transcripts. To control for multiple testing, we calculated a False Discovery Rate (FDR), in addition to a nominal *P*-value of the significance of the regression. We filtered for FDR (< 0.3), expression range (~2X) and expression level (mean log2 > 6.0). We validated 22 QTTs by quantitative PCR on low-density microfluidic arrays (ABI). By qPCR, 9 QTTs remained statistically significant (nominal *P*-value < 0.05). Exons, 5'-UTR, 3'-UTR and limited intronic regions of three genes (*MSH6, MED21, DPH2*), whose expression significantly correlated with CALM burden were subject to Sanger sequencing in 99 patients (79 from original set and 20 new). Two additional genes (*MSH2, MLH1*) which products are known to form functional complexes with MSH6 were also subject to sequencing analysis. The genotypes of the sequenced SNP variants were regressed against CALM burden. **Results.** We found evidence of association for two non-coding *MSH6* SNPs (rs3136316, MAF ~0.20 and rs1800934, MAF ~0.20) with CALM burden (nominal *P* <0.05). We also identified four rare (MAF < 0.05) SNPs in the 3'-end of *MSH6*, which when collapsed in a single group, correlated significantly with CALM burden (*P* = 0.047). **Conclusions.** We identified six SNPs in *MSH6* that are associated with the number of café-au-lait macules in NF1. Functional tests and genotyping of rs3136316 and rs1800934 in a second independent cohort of phenotyped patients is underway. *MSH6* is involved in mismatch repair. Our findings are of interest since CALMs arise secondary to bi-allelic inactivation of *NF1*, the same pathogenic mechanism as NF1-associated tumors. If validated, *MSH6* would be the first identified modifier gene of NF1.

2237/F

Continued UBE-1 Mutation Screening in X-linked Lethal Infantile SMA (XL-SMA) and Investigations of Functional Defects in Ubiquitination.

M.E. Ahearn[1], L. Baumbach[1], J. Ramser[2], K.O. Yariz[1], T. Prior[3], S. Srinivasan[1], Z. Nawaz[1], H. Kierstead[4], A. Meindl[2]. 1) Univ Miami Medical School, Miami, FL; 2) Gynaekologische Tumorgenetik Ismaningerstr, Munich, Germany; 3) Ohio State University, Columbus, OH; 4) University of California at Irvine, Irvine, CA.

X-linked infantile SMA (MIM 301830) is a lethal form of SMA with early onset/congenital contractures and/or fractures. We have previously described three novel UBE1 (Ubiquitin-Activating Enzyme E1) Exon 15 variants, found in five unrelated X-linked SMA families: two missense mutations (c.1617 G>T, p.Met539Ile; c.1639 A>G, p.Ser547Gly) present each in one family, and one synonymous C>T substitution (c.1731 C>T, p.Asn577Asn) identified in three additional unrelated families. Both missense mutations occur in conserved amino acids within a conserved protein domain, while the 1731 C>T SNP alters methlyation in a hyper-methylated region of the gene. Over the last two years, we have identified at least fifteen new potential cases of XL-SMA, many of which represent sporadic cases. We continue to screen for UBE1 mutations in this cohort, as well as in a set of males under age 2 who have SMA clinically, but fail to have detectable SMN-1 gene deletions. We will present our latest information regarding genotype-phenotype correlations. Importantly, UBE1 is responsible for the activation of ubiquitin, the first step of the ubiquitin-proteasome pathway (UPP). "Activated" ubiquitin is transferred from UBE1 to a family member of the ubiquitin carrier protein enzymes (E2s) by a thioester linkage (E2-S-Ub). We have begun a series of in vitro and in vivo experiments to evaluate possible functional effects of UBE1 mutations on the UPP. To examine in vitro possible functional effects on ubiquitin activation, we are generating HA-Tagged UBE1 cDNAs (wild-type and mutant, containing each of the three novel variants detected in XL-SMA patients) for transformation and expression in E. coli. Purified UBE1 proteins are quantified for use in ubiquitin-activation and E2 charging assays. Two types of in vivo experiments are also being performed: one using a mammalian cell line harboring a temperature-sensitive (ts) UBE1 mutation which will be transfected with plasmids expressing wild-type or mutant UBE1 protein(s), and secondly, human motor neuron cultures which will be transfected with known UBE1 mutations to assay effects of mutations on ubiquitination and neuronal development. In addition, we are evaluating overall ubiquitination activity in several XL-SMA patient cell lines (as compared to controls), as another measure of in vivo effects. These important experiments should shed important new insights into pathogenesis of human UBE1 mutations.

2238/F

Variant in SPG4 linked to early onset hereditary spastic paraplegia. *C. DiVincenzo, C.D. Braastad, C.D. Elzinga, I.D. Karbassi, J.G. Jones, S.D. Batish.* Athena Diagnostics/ThermoFisher Scientific, Worcester, MA.

Variants found in the SPG4 (spastin) gene are associated with autosomal dominant hereditary spastic paraplegia (HSP). Typically symptoms of HSP present in young adulthood, though a varied age of onset has been seen ranging from infants to the elderly. No mechanism has been identified as the cause of this widely varying age of onset[Durr 1996],[Yip 2003]. The ability to link a specific variant with a predictive age of onset could prove useful in diagnostic testing to better assess a clinical diagnosis as well as family member risk and potential treatment. If more variants are able to be linked with a particular range of onset, it may help to determine a mechanism for such a varied age of onset. Through the course of diagnostic testing for hereditary spastic paraplegia (HSP) at Athena Diagnostics, we have identified 14 individuals carrying the variant R499H. Of these patients, two are related (mother and daughter) and the remaining twelve are seemingly unrelated. This variant is inherited maternally in one family tested at Athena, but appears to have arisen de novo in other patients (paternity not confirmed). Individuals with de novo occurrences of this variant have an average age of onset of 6 years old (SD = 3.8 years), consistent with early-onset HSP. Interestingly, in the family where R499H is inherited, both mother and daughter experienced onset of symptoms within the first two years of life. There are also three independent patients whose cases were previously published by others, 1 familial case, 2 sporadic cases, but no definitive familial studies were described[Park 2005],[Depienne 2006],[Crippa 2006]. The R499H variant is found in Exon 13 of SPG4. It lies within the AAA cassette domain of the protein. This region is highly conserved and is thought to be involved with intracellular processes, specifically microtubule interactions[Errico 2002]. The change of arginine to histidine at position 499 was predicted as damaging to the SPG4 protein by both SIFT and PolyPhen.

A Genetic Mechanism for Facioscapulohumeral muscular dystrophy. *R.J.L.F. Lemmers[1], P.J. van der Vliet[1], R. Klooster[1], S. Sacconi[2], P. Camano[3], J.G. Dauwerse[1], L. Snider[4], K. Straasheijm[1], G.J. van Ommen[1], G.W. Padberg[5], D. Miller[6], S.J. Tapscott[4], R. Tawil[7], R.R. Frants[1], S.M. van der Maarel[1].* 1) Department of Human Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Centre de reference pour les maladies Neuromusculaires and CNRS UMR6543, Nice University, Nice, France; 3) BioDonostia Health Research Institute, Hospital Donostia, San Sebastián, Spain; 4) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA; 5) Department of Neurology, Radboud University Medical Center Nijmegen, Nijmegen, Netherlands; 6) Department of Pediatrics, University of Washington, Seattle, WA; 7) Department of Neurology, University of Rochester Medical Center, NY.

Facioscapulohumeral muscular dystrophy (FSHD) affects 1:20,000 people and is clinically characterized by progressive and often asymmetric weakness and wasting of facial, shoulder girdle and upper arm muscles. FSHD is most often caused by contraction of the D4Z4 macrosatellite repeat array, but only when this array resides in a specific genetic background of chromosome 4q. Repeat contractions on other, non-permissive 4q backgrounds and contractions of its homologue on chromosome 10q are non-pathogenic. D4Z4 repeat contractions cause a local chromatin relaxation, resulting in the transcriptional deregulation of genes within or close to D4Z4. The candidate gene DUX4 has been identified within each D4Z4 unit and encodes for a double homeobox protein. Different from DUX4 transcripts originating from internal units, the DUX4 transcript from the last D4Z4 unit is spliced to a unique last exon in the region immediately flanking D4Z4. This exon contains a poly(A) signal which presumably stabilizes the distal transcript. Distal DUX4 transcripts can be observed in FSHD myotubes. We discovered sequence polymorphisms in the FSHD locus that separate FSHD-permissive chromosome 4 backgrounds from non-permissive genetic backgrounds of chromosomes 4 and 10. These polymorphisms are restricted to specific sites in the FSHD locus. We show evidence that these polymorphisms functionally affect the regulation of the FSHD locus thereby for the first time not only providing an explanation for the striking haplotype-specificity of FSHD, but also uncovering a genetic mechanism that unifies all patients with FSHD.

Preliminary whole genome sequencing analysis of monozygotic twins with a concordant unique neurological phenotype. *K.V. Fuentes Fajardo[1], S.S. Ajay[3], T.C. Markello[1], D.A. Adams[1], C. Toro[1], M. Sincan[1], H. Carlson-Donohoe[1], P.F. Cherukuri[3], N.F. Hansen[3], H. Ozel Abaan[3], J.C. Mullikin[2], W.A. Gahl[1], E.H. Margulies[3], NISC Comparative Sequencing Program.* 1) Undiagnosed Diseases Program, NHGRI/NIH, Bethesda, MD; 2) NIH Intramural Sequencing Center, NIH, Bethesda MD; 3) Genome Technology Branch, NHGRI, NIH Bethesda MD.

Advances in Next Generation Sequencing technology have made whole genome sequencing a practical reality for clinical research applications. Other investigators have reported on whole genome sequencing of monozygotic twins discordant for multiple sclerosis. No discordant variant was identified as the cause of MS in the affected twin. We have an opportunity to sequence concordant twins. Two of the NIH Undiagnosed Diseases Program's initial choices for whole genome sequencing were a 24 year-old monozygotic twin pair concordant for the unique phenotype that includes early childhood neuro-cognitive deficits, rare seizures, and slowly progressive movement disorder characterized by myoclonus with ataxia. A detailed neurologic evaluation, including metabolic screening, candidate gene sequencing and mitochondrial DNA studies was not diagnostic. We will present the interim analysis of genomic variations we have found in one or both twins and contrast and compare them to the reference human genome sequence; an a priori unknown variant, that could be anywhere in the human genome, must be in both twins. The search will be one of the most rigorous tests of whether whole genome sequencing can be successfully used to identify a disease-causing variant, or whether the intrinsic background false positive rate will overwhelm our current analytic tools.

2241/F

Identification of genomic deletions spanning the *PCHD19* gene in two unrelated girls with Intellectual Disability and Seizures. *J.B. Vincent[1], A. Noor[1], A. Janson[2], M. Ayub[3], C.F. Morel[2].* 1) Neurogenetics Sect, R30, Ctr Add/Mental Hlth,Clarke Div, Toronto, ON, Canada; 2) The Fred A. Litwin Family Centre in Genetic Medicine, University Health Network, Toronto, Ontario, Canada; 3) St. Luke Hospital, Durham, UK.

Recently, missense and truncating mutations in the gene *PCDH19* have been reported to cause Female-Restricted Epilepsy with Mental Retardation (EFMR). EFMR (MIM#300088) is an X-linked disorder characterized by early onset seizures and Intellectual Disability (ID). Interestingly, unlike typical X-linked mode of inheritance, the phenotype is restricted to females, and males are unaffected carriers. Previously, using sequence analysis, several mutations in PCHD19 have being shown to cause EFMR. Here, we report two unrelated female patients with deletions spanning PCHD19 genes. These deletions were identified by genome-wide Copy Number Variation (CNV) analysis using high density microarrays and were validated by qPCR. In first case, we have identified a denovo 603 Kb heterozygous deletion in a female patient with fits (since one year of age), ID and additional clinical features including hyperactivity and aggressive behavior. The deletion spans entire *PCDH19* gene and four other Refseq annotated genes (*TNMD*, *SRPX2*, *TSPAN6* and *SYTL4*). In another unrelated female patient, we have identified a 3 Mb interstitial deletion at Xq21.33-q22.1 which spans entire *PCHD19* gene and two other annotated genes (*LOC442459* & *TNMD*). This patient had first episode of seizures at the age of 8 months, second seizure occurred at 13 months, with subsequent bouts of seizures occurring approximately every 25 days. Other clinical features include developmental delay, ID and aggressive behavior. The *PCDH19* is highly expressed in brain and protein encoded by this gene belongs to the cadherin superfamily. Cadherins play a crucial role in the neuronal cell adhesion and several members of this family have been previously implicated in ID and autism (*CDH15*, *PCDH9* and *PCDH10*). In conclusion, we have demonstrated that CNVs at the *PCDH19* locus can also cause EFMR. Moreover, our findings provide further support for the involvement of *PCHD19* in EFMR.

2242/F

The role of the JAK-Stat3 pathway in inherited photoreceptor (PR) degenerations (IPDs). *C.K. Jiang[1], M.J. Szego[1], A.N. Bramall[1], L.R. Pacione[1], W.W. Hauswirth[2], R.R. McInnes[1,3].* 1) Program in Stem Cell and Developmental Biology, Hospital for Sick Children Research Institute, Toronto, M5G1L7; 2) Department of Ophthalmology, University of Florida, Gainesville, Florida 32610-0284, USA; 3) The Lady Davis Institute, Jewish General Hospital, McGill University, Montreal H3T1E2.

The critical biochemical changes that occur in the retina, in response to an IPD mutation, are largely unknown. To identify the molecules that confer or resist the risk of death, we examined the retinal mRNA population in the *Rds*$^{+/-}$ mouse IPD model by microarray and qPCR analysis, at an early stage of degeneration (7 weeks old) when 85-90% of the mutant PRs were still alive. We identified 9 up-regulated mRNAs encoding proteins that constitute a putative JAK-Stat3 cytokine signaling pathway, of which the nexus is the transcription factor *Stat3* (2.3-fold increased, n=3, p<0.05). By qPCR, *Stat3* mRNA was also found increased in two other IPD models: *TgRHO(P347S)* (2.4-fold, n=3, p<0.05) and *Rd1*$^{-/-}$ (3.0-fold, n=3, p<0.05). By immunoblotting, we found comparable increases of both the STAT3 protein and its active form, pSTAT3: 2.8-fold (n=3, p<0.01) and 6.3-fold (n=3, p<0.01) in 7 weeks old *Rds*$^{+/-}$ retinas; 4.0-fold (n=3, p<0.01) and 3.6-fold (n=3, p<0.01) in 3 weeks old *TgRHO(P347S)* retinas; and 1.9-fold (n=3, p<0.05) and 2.6-fold (n=3, p<0.01) in 12 days old *Rd1*$^{-/-}$ retinas, respectively. By immunostaining of *Rds*$^{+/-}$ retinas, we determined that the increased STAT3 and pSTAT3 proteins were localized predominantly to Müller glia cells, less to mutant PRs. We confirmed the increase in *Stat3* expression in mutant PRs using laser capture microdissection vs. age matched wild type retinas: by qPCR, *Stat3* mRNA was found increased 2.4 fold (n=3, p<0.05) in 7 weeks old *Rds*$^{+/-}$ PRs and 5.4 fold (n=3, p<0.05) in 12 days old *Rd1*$^{-/-}$ retinas. Since Stat3 signaling can mediate apoptotic responses in other contexts, we asked whether the increased *Stat3* expression in mutant PRs was pathogenetic. We used subretinal injections of an AAV2-CBA-Cre virus, whose expression is PR-specific, to delete *Stat3* from *Stat3*$^{flox/flox}$*; Rd1*$^{-/-}$ mutant PRs. The effect of PR *Stat3* deletion was variable; but overall, PR survival increased: 14/18 AAV2-CBA-Cre injected retinas had significantly increased PR survival vs. controls, with an average increase of 16.7%±8.7% (n=14; p<0.05), ranging from 6.9% to 41.1%. We conclude that these results suggest that the increased expression of *Stat3* in mutant PRs is pathogenetic in the *Rd1*$^{-/-}$ retina. Whether this proapoptotic role of *Stat3* is a general response to PR mutation will be evaluated through specific deletion of the PR-*Stat3* gene in different IPD models (eg. *TgRHO(P347S)* and *Rd1*$^{-/-}$ model), using PR-specific *Opsin-Cre* mice crossed to *Stat3*$^{flox/flox}$ mice.

Aberrant microRNA expression in HPRT-deficient human neuroblastoma cells: A regulatory role for a housekeeping gene? *G. Guibinga, G. Hrustanovic, T. Friedmann.* Department of Pediatrics, UCSD School of Medicine, La Jolla, CA.

The mechanisms responsible for neuropathology in the HPRT-deficiency disorder Lesch Nyhan Disease (LND) are poorly understood. We have previously presented evidence that the underlying purine biosynthetic defect in HPRT-deficient human teratocarcinoma cells results in aberrant expression of transcription factors vital for neurogenesis in vitro, including down-regulation of LMX1a an En1, among others. The composite effect of these changes are reflected by disrupted neurogenesis. We have now examined the expression of microRNAs in wild type and HPRT-deficient human SH-Sy5y neuroblastoma cells at basal state and during retinoic acid-induced in vitro differentiation and have detected aberrant expression of a number of microRNAs. One such dysregulated microRNA is miR-181a which has LMX1a and En1 as potential regulatory targets. In HPRT-deficient SH-Sy5y cells, miR-181a is significantly up-regulated and LMX1a and En1 are both expressed at markedly reduced levels. Over-expression of miR-181a leads to significant repression of En1 and Lmx1a gene expression. Furthermore, treatment of cells with an inhibitor of miR-181a leads to significantly increased expression of both Lmx1a and En1. These and other data suggest that aberrant microRNA expression in HPRT deficiency may play a causal role in the development of the neurological defects in LND.

Myostatin expression in different mice models for neuromuscular disorders. *D. Zilbersztajn-Gotlieb, D. Ayub-Guerrieri, P.C.G. Onofre-Oliveira, P. Martins-Machado, A.F. Santos, A.B. Martins-Bach, M. Vainzof.* Universidade de Sao Paulo, Sao Paulo, Sao Paulo, Brazil.

Myostatin is a TGFβ superfamily member and is a negative regulator of skeletal muscle growth. Inhibition of myostatin has been considered as a potential therapeutic target against muscle degeneration in muscular dystrophies. The expression of myostatin in the dystrophic process is not clearly known, and the aim of the present study is to analyze the relative expression of myostatin in four strains of mice model for muscular dystrophies, as compared to normal controls. The relative expression of myostatin was analyzed using real time PCR, in the gasctrocnemius and dyaphragm muscles of adults (3 months old) mice from the following strains of dystrophic mice: *Dmd*^{mdx} (dystrophin deficient, mild phenotype, model for Duchenne muscular dystrophy), *Lama2*^{dy2J}*/J* (laminin-α2 deficient, severe phenotype, model for Congenital Muscular Dystrophy 1A), *SJL*, dysferlin deficient model for Limb Girdle Muscular Dystrophy 2B, *Large*^{myd} (defect in glycosylation of α-DG, severe phenotype in older animals, model for Congenital Muscular Dystrophy 1D), and controls *C57Bl*. In normal *C57Bl* controls, the expression of myostatin in the gastrocnemius was significantly different that the observed in diaphragm muscles. Comparing to normal controls and considering the two different muscles (gastrocnemius and diaphragm), higher or lower levels of expression was observed in the 4 mice models. The present study showed variation among relative expression in different muscular dystrophies and types of muscles, in mice models with different mutations in genes expressing muscle proteins. Our results suggest that each primary defect in the studied muscular dystrophies has its own pathway of muscle degeneration/regeneration. These data have significant importance and must be considered for future investigations using the modulation of the expression of myostatin aiming therapies. Genes and Disease: Molecular Genetic Approach to Identify Gene Mutations Causing Distal Hereditary Motor Neuropathy. *O.M. Albulym[1,2], A. Antonellis[3], M. Kennerson[1,2,4], S. Reddel[1,2,4], G. Nicholson[1,2,4].* 1) Northcott Neuroscience Lab., ANZAC Research Institute, Concord, NSW, Australia; 2) Sydney Medical School, University of Sydney, NSW 2008 Australia; 3) University of Michigan Medical School, Department of Human Genetics, Department of Neurology, Ann Arbor, MI; 4) Molecular Medicine Laboratory, Concord Hospital, NSW 2139, Australia.

Hereditary motor neuropathies (HMN), also known as distal spinal muscular atrophy (SMA) or spinal Charcot-Marie Tooth (spinal CMT), mainly affect motor neurons in the peripheral nervous system. They can be subdivided into proximal HMN and distal hereditary motor neuropathy (dHMN). Distal hereditary motor neuropathies are a group of clinically and genetically heterogeneous disorders characterized by weakness and wasting of distal muscles of the upper and lower limbs [1,2]. Mutations in several genes have been identified for dHMN. They include Berardinelli-Seip congenital lipodystrophy (BSCL2), small heat shock 27kDa protein 1 (HSPB1), small heat shock 22kDa protein 8 (HSPB8), glycyl-tRNA synthetase (GARS), senataxin (SETX), and dynactin 1 (DCTN1) [1]. Recently, a mutation causing HMN has been identified in the small heat shock 27kDa protein 3 gene (HSPB3) [3]. We aim to (i) investigate the frequency and distribution of known mutations and (ii) identify new pathogenic mutations in six genes in an Australian cohort of dHMN patients consisting of 119 familial and isolated cases. These genes are BSCL2, HSPB1, HSPB8, GARS, SETX and DCTN1. Exonic and exonic-intronic boundaries of BSCL2, HSPB1, SETX, DCTN1 and HSPB8 genes were amplified with 2.5X HRM Master Mix and scanned by a 96-well Light-Scanner (Idaho Technology). All exons of GARS gene were analyzed by direct sequencing. The genes SETX and DCTN1 are being scanned. We have detected one BSCL2 mutation (N88S) in three patients (2.5%), and two different mutations in GARS (H418R and S581L) in two patients (1.7%). No mutations were detected in DCTN1, HSP22, HSP27, and SETX. Our findings indicate that by screening these six genes we have accounted for mutations in 4.2% of our dHMN families. We concluded that the yield of mutations in DCTN1, HSP22, HSP27, and SETX is low in these patients. This study also provides further evidence for genetic heterogeneity of dHMN. [1] Irobi, J., P. De Jonghe, et al. (2004). “Molecular genetics of distal hereditary motor neuropathies.” Hum Mol Genet 13 Spec No 2: R195-202. [2] Irobi, J., I. Dierick, et al. 2246/F

A novel *ARX* gene mutation in a female individual with early onset epileptic encephalopathy. *W. Andreoli[1], G. Di Rosa[2], S. Rossato[1], S. Sartori[1], R. Polli[1], A. Murgia[1].* 1) Pediatrics, University of Padua, Padua, PD, Italy; 2) Child Neuropsychiatry Unit, University Hospital of Messina, Messina , Italy.

The *ARX* (Aristaless Related Homeobox) gene belongs to a large family of homeodomain transcription factors thought to play an essential role in neural development. This gene is located on the short arm of the X chromosome (Xp22.13) and consists of five exons that encode a protein of 562 amino acids. Mutations in the *ARX* gene are associated with a wide range of disorders from severe developmental abnormalities of the brain structure to syndromic and non-syndromic forms of X-linked mental retardation (XLMR) that can be associated with normal or abnormal brain morphology. Mental retardation and epilepsy often occur together. In the course of a mutational scanning, performed in a cohort of subjects with epileptic encephalopathy of the first year of life, we have detected a novel frame-shift mutation in exon 5 of the *ARX* gene, predicted to yield a protein with truncation of the 5 COOH-terminal amino acids (p.Thr487GlufsX5). The mutation has been detected in a 2 year-old female individual with a very severe neurodevelopmental delay and a clinical history of infantile spasms and focal seizures with onset at about three months of age. The brain magnetic resonance imaging (MRI) is normal and no dysmorphic features or genitalia alterations are reported. An X-inactivation analysis of the androgen receptor (AR) locus was performed which showed a ratio of 70:30 consistent with a skewed inactivation pattern. Analysis of the mutation segregation on the parents' DNA is currently underway. The novel truncating mutation we have detected is the most C-terminal alteration described in the *ARX* gene, nevertheless it truncates an extremely conserved region possibly relevant for protein-protein interactions and is therefore highly likely pathogenic. The majority of female carriers of *ARX* mutations so far reported in literature have normal brain MRI scan or partial to complete agenesis of the corpus callosum, with normal cognition or mild mental retardation. The patient we report is the first description an affected female, showing a severe phenotype with neurodevelopmental impairment and early epileptic encephalopathy, but absence of malformations or dysmorphic features.

Molecular characterization of a cohort of Stargardt and Stargardt-like affected individuals and families. *M.B. Gorin[1,2], A. Martinez[1], Y.-Q. Gao[1], M.C. Ortube[1], D.B. Farber[1].* 1) Dept Ophthalmology, Jules Stein Eye Inst - UCLA, Los Angeles, CA; 2) Dept Human Genetics, David Geffen Sch. of Med - UCLA, Los Angeles, CA.

We performed mutation analyses of the ABCA4, PRPH2, VMD2 and ELOVL4 genes, in a cohort with the diagnosis of Stargardt or Stargardt-like Disease. We sequenced the ABCA4 gene for 99 affected individuals and 24 family members from 92 families. A subset of individuals (41) was initially screened by SSCP of the ABCA4 exons prior to complete DNA sequencing of the exons and exon-intron junctions. We compared the detection of probable and definite disease-causing mutations identified by sequencing with the predicted detection that would be observed with the ABCR400 chip and the ability of the SSCP to detect sequencing-confirmed variants. For the 99 affected individuals, sequencing identified 123 variants that were represented in 1087 occurrences (average: 11 per person). Two or more mutations (including both cis and trans configurations) were found for 44 individuals. Thirty-two individuals had only a single ABCA4 mutation. Sixty-three different ABCA4 mutations were identified of which 43 are currently included in the ABCR400 chip. If we assume 100% sensitivity for the ABCR400 chip, we would have identified 30 affected persons with either 2 or more ABCA4 mutations and 40 affected people with a single ABCA4 mutation. The ABCR400 chip would have identified 92% of the affected people who were positive with at least one of the disease-causing variants detected by sequencing and 68% of those affected persons identified by sequencing with 2 or more mutations. In contrast, SSCP was a poor screening method for ABCA4, detecting only 31% of all of the variant occurrences and 48% of the mutations that were identified by direct sequencing. Seven individuals (5 families) had a mutation in PRPH2. One of these individuals was found to have two mutations (trans) in the ABCA4 gene and one mutation in the PRPH2 gene. No mutations were found in the sequencing of VMD2 and ELOVL4 for those individuals with either one or no ABCA4 mutations (definite and/or probable). Even with complete exon sequencing, a number of clinical Stargardt cases are not identified with mutations in known Stargardt-related genes. This is partly due to genetic heterogeneity, as evidenced by the identification of several individuals with PRHP2 mutations and the excess number of individuals (17) with no identifiable ABCA4 or PRPH2 mutations. In addition to the need to find more comprehensive methods for identifying ABCA4 mutations, the genetic heterogeneity for this group of disorders has yet to be defined.

Frequency of SMA in Western India. *A. Gupta, J. Sheth, F. Sheth.* Department of Molecular Geneti, FRIGE's Institute of Human Genetics, Ahmedabad, Gujarat, India.

Spinal muscular atrophy (SMA) is an autosomal recessive disorder with a frequency of 1:6,000 to 1:10,000 live births. It is characterized by degeneration of lower motor neurons and occasionally bulbar motor neurons leading to progressive limb and trunk paralysis as well as muscular atrophy. In 98%; cases it is due to allelic deletion of exon 7 and exon 8 of the SMN1 and SMN2 gene. Due to overlapping phenotype of SMA with other motor neuron disease; it remains undiagnosed and require high index of clinical suspicion followed by confirmative molecular diagnosis. Our study is aimed at to identify the frequency of SMN gene deletion in children and adults with motor neuron disease. Molecular analysis was performed on 33 patients in the age range of 2 months to 50 years having clinical phenotypes of lower motor neuron disease and bulbar dysfunction in adults; poor sucking ability, reduced swallowing and respiratory failure in children. Genomic DNA isolated from blood was used to detect the SMA1 and SMN2 gene deletion in exon 7 and exon 8 using restriction enzyme Dra1 and Dde1 respectively. Twenty two of 33 (67%) suspected as SMA type I (Werdnig Hoffmann) were in the age range of 0-6month, 4 (12%) suspected as type II were in the age of 7-18months, 1 (3%) suspected as type III (Kugelberg-Welander) were in the age of >18months, and 4 (12%) as type IV in the age range of 32-50 years. The analysis of both exon 7 and 8; homozygous deletion were observed in 82%; of SMA I [n=18], 50%; SMA II [n=2] and confirmed diagnosis was observed in one case clinically suspected with SMA III. One of the four suspected SMA IV patients showed homozygous deletion of exon 7 in SMN2 gene. In 9 cases no deletion were found in any of the exons. Our study suggest that; with the advent of molecular techniques, SMN gene deletion studies are the first line of investigations in those with impaired lower motor neuron function and are highly prevalent in children.

2249/F

A novel ASPA gene mutation in Canavan Disease. *H. Onay, A. Durmaz, A. Vahabi, H. Akin, F. Ozkinay.* Department of Medical Genetics, Ege University , Izmir, Turkey.

Human aspartoacylase (ASPA) gene which catalyzes the deacetylation of N-acetyl-L-aspartate is mutated in Canavan disease (CD), is a severe autosomal resesif leukodystrophy. CD is characterized by macrocephaly, ataxia, severe motor and mental retardation, dysmyelination and progressive spongial atrophy of the brain. To date more than 50 mutations have been described in patients having Canavan Disease. We present a novel mutation within the ASPA gene in a family with as CD. A couple applied for genetic counselling with a history of lost child having a clinical diagnosis of CD. No molecular analysis was performed on the child. The proband was a 1-year-old girl and died due to CD. She was hospitalized for motor mental retardation. Brain magnetic resonance imaging (MRI) revealed increased T2 signal intensity and MR spectroscopy showed elevated brain N-acetyl-aspartate confirming the diagnosis of CD. Sequencing analysis for ASPA gene was perfomed on the parents. Heterozygous Y88X mutation was detected in both parents. This mutation was not described before in CD and results in premature stop codon. Here we present a case of CD having a novel mutation in ASPA gene.

2250/F

Novel mutations of ZFHX1B responsible for the typical cases of Mowat-Wilson syndrome. *Y. Yamada[1], K. Yamada[1], S. Mizuno[2], N. Furuya[3], M. Matsuo[4], M. Urano[4], Y. Hiraki[5], K. Kurosawa[3], K. Saito[4], N. Wakamatsu[1].* 1) Dept Gen, Inst Dev Res, Aichi Human Service Ctr, Kasugai, Aichi, Japan; 2) Ctrl. Hosp., Aichi Human Service Ctr., Kasugai, Aichi, Japan; 3) Kanagawa Children's Med., Ctr., Yokohama, Kanagawa, Japan; 4) Inst. Med. Genet., Tokyo Women's Med Univ., Shinjuku, Tokyo, Japan; 5) 5Hiroshima City Children's Med. Ctr., Hiroshima, Japan.

The mutations of *ZFHX1B* cause an autosomal dominant disorder of Mowat-Wilson syndrome associated with profound mental retardation, delayed motor development and specific facial features such as hypertelorism, often with microcephaly, epilepsy, congenital heart disease, and Hirschsprung disease. We performed molecular analysis of *ZFHX1B* to confirm diagnosis of Mowat-Wilson syndrome. To screen for mutation, DNA fragments including each exon of *ZFHX1B* from patients and normal controls were amplified by PCR and subjected to direct sequencing analysis. In this study, performed after our last reports (Yamada et al. ASHG, 2005 and Ohstuka et al. J. Child Neurol., 2008), 11 novel mutations were found in the typical patients with Mowat-Wilson syndrome, 2 nonsense mutation (2400C>G, S800X; 2761C>T, R921X) and 9 frame-shift mutations including three mutations inserted one base (1338insC, 446fs455X; 1427insA, 476fs481X; 2351insT, 784fs794X), five mutations deleted one base (460delG, 154fs211X; 1169delT, 390fs395X; 1417delA, 473fs486X; 2282delC, 761fs486X; 2718delT, 906fs929X), and a mutation deleted four bases (1270delAGCC, 427fs438X). We have identified 43 mutations in *ZFHX1B* up to the present. In 41 typical cases with profound mental retardation and specific facial features, 18 nonsense mutations and 23 frame-shift mutations were detected. These mutations generated truncated protein without the zinc finger domain located in the C-terminal region.

2251/F

Identification of a novel locus for juvenile primary lateral sclerosis by homozygosity mapping. *A. Al-Saif[1], S. Bohlega[2].* 1) Department of Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, KSA; 2) Department of Neurosciences, King Faisal Specialist Hospital & Research Centre, Riyadh, KSA.

Primary lateral sclerosis is a rare progressive motor neuron degenerative disorder affecting the upper motor neurons. It leads to weakness and spasticity of limbs, trunk and bulbar muscles. The age of onset is between 35 and 66 years but a subtype of this disorder (juvenile primary lateral sclerosis, JPLS) begins in early childhood and inherited as an autosomal recessive disorder. Mutations in ALS2 gene were previously identified in some JPLS families. In a consanguineous family with four JPLS patients (age of onset between 2 and 3 years), we performed homozygosity mapping using SNP genotyping arrays and identified a novel locus on chromosome 8 (p11.21-p12). The four affected individuals shared homozygosity of this region but none of their seven normal siblings. Identification of the genetic defect in this region will help understanding the pathophysiology of primary lateral sclerosis and motor neuron degeneration.

2252/F

Mutant HTT mRNA toxicity in the pathogenesis of Huntington Disease. *M. Banez-Coronel[1,2], S. Porta[4], B. Kagerbauer[1,2], E. Mateu[1,2], I. Ferrer[3,4], X. Estivill[1,2], E. Martí[1,2].* 1) Centre for Genomic Regulation, Barcelona, Catalonia, Spain; 2) Centro de Investigación Biomédica en Red en Epidemiología y Salud Pública (CIBERESP), Barcelona, Catalonia, Spain; 3) Centro de Investigación Biomédica en Red sobre Enfermedades Neurodegenerativas (CIBERNED), Barcelona, Catalonia, Spain; 4) Institut Neuropatologia, Servei Anatomia Patològica, IDIBELL-Hospital Universitari de Bellvitge, Universitat de Barcelona, Barcelona, Catalonia, Spain.

Huntington's disease (HD) is a dominantly-inherited neurodegenerative disorder that results from expanded CAG repeats in the exon 1 of the huntingtin gene. It is widely accepted that the abnormally extended polyglutamine tract in the Huntingtin protein (HTT) produces toxic activities that lead to progressive striatal and cortical neurodegeneration; however many aspects of HD pathology still remain unexplained. A range of neurodevelopmental and neurodegenerative diseases associated with trinucleotide repeat expansion appears to be caused by RNA-mediated mechanisms including RNA toxicity or aberrant splicing (1-3). Here we have investigated the possible deleterious effect of the mutated HTT exon1 mRNA and the mechanisms related. Vectors expressing translated and untranslated (wild type and CAG expanded) forms of the exon 1 of the human HTT gene were transfected into differentiated neuroblastoma cells and cell viability was evaluated at different time-points after transfection. The results revealed that mutant HTT is able to exert a cytotoxic response at the RNA level. The expression of the expanded HTT mRNA led to the generation of small CAG-repeated RNAs (sCAG) in human cells. In consonance with previous in vitro studies (4), Dicer depletion prevented the production of sCAG in cells trasfected with mutant HTT. This was accompanied by a dramatic reduction in the subsequent cytotoxicity in vivo, suggesting an important role of sCAG in HTT-mediated pathogenesis. In consonance, an increased expression of sCAGs was also found in human brain samples from HD patients when compared to control individuals. Finally, the transfection of exogenous sCAGs (siCAG7) in differentiated neuroblastoma cells also resulted in strong toxicity. On the other hand, the administration of sCAG on different human cells had a mild effect on non-neuronal cell metabolism. This result support a link between the generation of sCAG and the cell loss specificity observed in HD. Our results suggest an additional mechanism that may take place in HD pathogenesis, where the abnormal expression of CAG-repeated small RNAs may initiate a cell-type specific, transcriptome-dependent detrimental response. 1. Pathogenic consequences of *ATP7A* mutations causing X-linked distal hereditary motor neuropathy. *S. Chu[1, 2], G.A. Nicholson[1, 2, 3], R. Chaudhry[1], R. Hyland[6], A. Shanu[2, 4], J.F.B. Mercer[5], R.M. Llanos[5], P.K. Witting[2, 4], S. Myers[6, 7], M.L. Kennerson[1, 2, 3].* 1) Northcott Neuroscience Laboratory, ANZAC Research Insitute, University of Sydney, Concord, Australia; 2) Department of Medicine, University of Sydney, Camperdown, Australia; 3) Molecular Medicine Laboratory, Concord Hospital, Concord, Australia; 4) Redox Biology Group, Department of Pathology, University of Sydney, Camperdown, Australia; 5) Centre for Cellular and Molecular Biology, School of Life and Environmental Sciences, Deakin University, Burwood, Australia; 6) Neuro Cell Biology Laboratory, Molecular Medicine Research Group, School of Biomedical and Health Sciences, University of Western Sydney, Campbelltown, Australia; 7) School of Medicine, University of Western Sydney, Campbelltown, Australia.

Distal hereditary motor neuropathies (distal HMN) are a clinically and genetically heterogeneous group of disorders affecting the peripheral motor nerves. We have identified two missense mutations (P1386S and T994I) in the copper transport gene *ATP7A* that cause X-linked distal hereditary motor neuropathy on chromosome Xq13-q21 (distal HMNX). Male patients with these mutations present with variable age onset distal muscle wasting of both upper and lower limbs but show no clinical or biochemical abnormalities of Menkes Disease (MD) or occipital horn syndrome (OHS), disorders typically associated with *ATP7A* gene mutations. The *ATP7A* gene encodes a P-type ATPase that plays an important role in copper homeostasis and the delivery of copper to cuproenzymes. The ATP7A protein resides in the *trans*-golgi network (TGN) in basal copper levels and trafficks to cytoplasmic vesicles and the plasma membrane when copper levels are elevated. Our studies show a trafficking defect in patient fibroblasts where the mutant ATP7A protein fails to traffic from the TGN in elevated copper conditions. While mechanisms underlying the MD and OHS phenotypes have been explored, the underlying cause of axonal degeneration of the motor neurons in distal HMNX is poorly understood. We hypothesise that mutant ATP7A disrupts the availability of ATP7A laden vesicles and that excess cytoplasmic copper over time activates pathways of axonal degeneration. We aim to develop a neuronal cell model by transfecting T994I and P1386S expression constructs into SH-SY5Y cells. Copper loading experiments will be performed to confirm the trafficking defect in a neuronal cell model. The mechanism of oxidative stress as a potential cause of axonal degeneration will be explored by examining the activity of the copper enzyme, cytoplasmic Cu/Zn superoxide dismutase (SOD1) and testing gene markers of oxidative stress under normal and elevated copper conditions in both the neuronal cells and patient fibroblasts expressing the mutant ATP7A protein.

2254/F

***Hsp70i* and the CMT peripheral neuropathic phenotype.** *J. Saliba[1], M. Khajavi[1], W. Wojciech[1], J.R. Lupski[1, 2, 3].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Pediatrics, Baylor College of Med, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Charcot Marie Tooth disease (CMT) is the most common hereditary peripheral neuropathy with a prevalence of 1 in 2,500. CMT is most often the result of a 1.4 Mb duplication of the 17p11.2-p12 region of chromosome 17 that includes the dosage sensitive peripheral myelin protein 22 gene (*PMP22*). In addition, a number of point mutations in over two dozen genes, including *PMP22*, have been discovered to be associated with CMT. Numerous point mutations within myelin genes can cause severe peripheral neuropathies through protein accumulation within the ER, which leads to cellular stress and ultimately apoptosis of the Schwann cells. Therapeutic methods attempting to regulate *PMP22* expression have shown promise, however these methods may not be effective in the alleviation of cellular stress. Previously, the oral administration of curcumin, a small molecule derived from the curry spice tumeric, has been shown to significantly decrease the percentage of apoptotic Schwann cells and partially alleviates the severe neuropathic phenotype of *Trembler-J* (*Tr-J*) mice in a dose dependent manner. Comparative expression profiling of the sciatic nerves of curcumin treated and untreated *Tr-J* mice revealed a significant increase in the expression of the heat shock protein, Hsp70i. Additionally, reduction of Hsp70i dosage in *Tr-J* mice results in a more severe peripheral neuropathy and upon curcumin treatment a rise in mortality. Based on these findings, we investigated the possible therapeutic role of Hsp70i further by producing F1 generation and an F2 generation *Tr-j* mice that over express *Hsp70i* on a mixed background. Within the F1 generation one copy of the *Hsp70i* transgene leads to a visibly healthier phenotype and improved neuromotor function. In addition, to further assess the role of *Hsp70i* expression in the alleviation of cellular stress and the peripheral neuropathic phenotype, other small molecular compounds known to induce *Hsp70i* expression are being screened for their potential benefits.

2255/F

Founder Effect in French Canadian Action Myoclonus-Renal Failure Syndrome (AMRF). *E. Andermann[1], D. Amrom[2], J. Mulley[3], M.A. Bayly[4], M. Jomphe[5], M. Talani[2], M. Pierre[6], S. Berkovic[7], F. Andermann[8], L. BACKGROUND: AMRF, an autosomal recessive form of progressive myoclonus epilepsy with renal failure, was initially described in three French Canadian families in 1986. Subsequently, additional families were reported in other continents. Disease onset is usually in the late teens or early twenties, and begins with tremor and proteinuria, progressing to action myoclonus, tonic-clonic seizures and renal failure. The gene for this disease was recently found to be SCARB2/LIMP2, a lysosomal protein. OBJECTIVES: To characterize the SCARB2 mutations in French-Canadian patients with AMRF, and their family members and to confirm founder effect in these families. METHODS: The original French Canadian families were contacted and family histories updated. Additional families were also ascertained. Blood was obtained on 85 family members, and exon 7 of the SCARB2/LIMP2 gene was sequenced for the c.862C>T (Q288X) mutation found in one of the original French Canadian families. Haplotyping and genealogical studies to find common ancestors employing the BALSAC database were also performed. RESULTS: All five original AMRF patients have died. Four new patients in two families were homozygous for the Q288X mutation, but the mother of one of the original patients was found to carry another SCARB2 mutation, suggesting allelic heterogeneity. In one of the new families, both parents are second degree cousins to one of the original probands and to one another. Twenty-eight unaffected individuals in four families who were not obligate carriers were found to be heterozygous for the Q288X mutation. This included one carrier couple, who were later found to have an affected son. Over 20 other married-in spouses of these mutation carriers had negative sequencing of the entire SCARB2 gene. Haplotype analysis resulted in a shared haplotype of over 7.2 Mb, strongly suggesting identity by descent. Genealogies of 4 families have been traced to the beginning of the17th century, and thirty-two ancestors common to all 4 families have been identified. CONCLUSIONS: The finding of the same SCARB2 mutation and common haplotype in at least four French Canadian families who were previously not known to be related strongly suggests a founder effect. Carrier screening for the founder mutation in this population can be carried out without sequencing the entire SCARB2 gene. This has important implications for prenatal diagnosis, genetic counseling and prevention of this severely debilitating disease.

Dentatorubral pallidoluysian atrophy: clinical and genetic analysis of a Sicilian pedigree. *G. Annesi[1], M. D'Amelio[2], P. Tarantino[1], V. Lo Re[2], P. Ragonese[2], G. Salemi[2], A. Quattrone[3], G. Savettieri[2], P. Aridon[2].* 1) Istituto di Scienze Neurologiche, Mangone (CS), CS, Italy; 2) Dept. di Biomedicina Sperimentale e Neuroscienze Cliniche, Università di Palermo, Palermo,Italy; 3) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Objectives: To describe clinical, radiological and genetic features of a three generation Sicilian family affected by Dentatorubral-Pallidoluysian atrophy (DRPLA). Material and Methods: We obtained clinical and genealogical information from twelve people of a three generation pedigree. Five out of seven affected living people were examined and blood samples were obtained. All family members signed an informed consent form. Neurological evaluations, neurophysiological and neuropsychological examinations, neuroimaging studies were performed. Genomic DNA was extracted from peripheral blood by standard methods. Triplet expansion in DRPLA was detected by PCR amplification with fluorescent primers. PCR products were separated onto a capillary sequencer (3130XL genetic analyzer-Applied Biosystems) and the length of specific DRPLA fragments was confirmed by direct sequence analysis. Results: The proband of the family, a 48-year-old man, at the age of 37, began to experience episodes of loss of consciousness with generalized seizures. Afterwards he developed an unsteady gait, involuntary movements of the head, face and limbs, in addition to cognitive and psychiatric symptoms. Neurological examination was characterize by choreiform movement, myoclonus and cognitive deterioration. His gate was ataxic and tandem walking was impossible. All laboratory tests were normal. Cranial MRI showed mild diffuse atrophy. An electroencephalogram revealed abnormalities in the right frontal and temporal lobes. Somatosensory, motor and brainstem auditory evoked potentials were altered. Two sisters of the proband reported similar symptoms with different degree of gait, speech disturbance and choreoathetosis. The first son of the proband, a nephew and two young first cousins, at the age of 15 started to complain of myoclonic epilepsy, and variable degree of cognitive disturbance. Molecular analysis of all affected people revealed a heterozygous CAG repeats expansion in ATN-1 gene, confirming the DRPLA diagnosis. All the heterozygous expanded alleles were fully sequenced. Conclusions and Discussion: We provided a detailed description of the main clinical, genetic and radiological features of the second Italian family with DRPLA. Our results further support ATN-1 gene as causative of DRPLA. As a whole, the phenotype mainly overlapped known DRPLA cases but our data show that the disease may have a great variability of age, type of onset and course of the disease.

Depletion of CTCF, even in the absence of expanded GAA triplet-repeats, is sufficient to reproduce the epigenetic silencing of the *FXN* gene seen in Friedreich ataxia. *S.I. Bidichandani, A.M. Castro, Y.K. Chutake.* Dept Biochemistry/Molec Biol, Oklahoma Univ Hlth Sci Ctr, Oklahoma City, OK.

Friedreich ataxia (FRDA) patients are homozygous for an expanded GAA triplet-repeat sequence in intron 1 of the *FXN* gene. The expanded GAA triplet-repeat results in deficiency of *FXN* gene transcription, which is reversed via administration of histone deacetylase inhibitors indicating that transcriptional silencing is due to an epigenetic abnormality. FRDA patients show depletion of the chromatin insulator protein CTCF (CCCTC-binding factor) in the 5'UTR of the *FXN* gene in FRDA, and coincident heterochromatin formation involving the +1 nucleosome via recruitment of heterochromatin protein 1. It has been suggested that epigenetic silencing of the *FXN* gene is likely due to spreading of heterochromatin from the expanded GAA triplet-repeat. Here we show that knockdown of CTCF in a human cell line (HEK293; ChIP assays confirmed depletion of CTCF at the *FXN* locus) that does not contain expanded GAA triplet-repeats at the *FXN* locus resulted in recruitment of heterochromatin protein 1 to nucleosome +1 and *FXN* transcriptional deficiency, as is seen in FRDA. We previously showed that FRDA patients have overexpression of *FAST-1*, an antisense transcript that overlaps with nucleosome +1. Indeed, CTCF knockdown in HEK293 cells also reproduced the *FAST-1* overexpression seen in FRDA. Together, these data indicate that depletion of CTCF is sufficient to explain the epigenetic silencing of the *FXN* gene seen in FRDA, and is a critical mediator of the molecular pathogenesis of FRDA.

Molecular analysis of EIF2B genes in patient with late onset CACH/VWM syndrome. *B-Z. Yang[1], S.E. Sparks[2], N. McNeill[1], C.K. Brasington[2], J-H. Ding[1].* 1) Inst Metabolic Disease, Baylor Res Inst, Dallas, TX; 2) Levine Children's Hospital at Carolinas Medical Center, Charlotte, NC.

Childhood ataxia with central nervous system hypomyelination or leukoencephalopathy with vanishing white matter syndrome (CACH/VWM) is an autosomal recessive disorder characterized by episodes of rapid deterioration during and/or after infection, leading to a progressive vanishing of the white matter replaced by cerebrospinal fluid. Clinical phenotypes include: 1. fatal infantile/congenital form; 2. early childhood form associated with extra-neurological symptoms and 3. juvenile and adult forms (ovarioleukodystrophy), all of which are mostly caused by eukaryotic initiation factor 2B (eIF2B) defect leading to the term of eIF2B-related leukoencephalopathies. In this study, we report a patient with adult form of CACH/VWM. Patient is a 25-year old male who initially presented with neurological deterioration following a traumatic head injury at 18 years of age. He subsequently had 4 more instances of head trauma leading to neurological deterioration and loss of ambulation at 22 years of age. A seizure disorder, controlled with antiepileptics began after the second head injury. A brain MRI demonstrated diffuse leukodystrophy. On exam he is wheelchair dependent, has slow, dysarthric speech, truncal and intentional ataxia, and signs of a peripheral neuropathy. Once available, the brain MRI was further reviewed and showed signs consistent with CACH/VWM. To investigate the molecular defect, genomic DNA was extracted from patient's blood, and all exons and flanking intronic regions of the five EIF2B genes were amplified. The PCR products were purified and sequenced. Sequence analysis revealed that the patient is a compound heterozygous for a c.728C>T (p.P243L) mutation and a novel mutation c.715G>C in exon 8, which results in an Aspartic acid to Histidine substitution at codon 239 (p.D239H) in the EIF2B4 gene. The novel mutation c.715G>C was verified by a PCR/restriction test, but was not detected in the normal control subjects. In addition, this patient also carries a variation c.1759A>G (p.I587V) in the EIF2B5 gene, for which both parents are heterozygous. Sequence analysis confirmed that this patient's father carries c.1759A>G and mutation c.728C>T; mother with c.1759A>G and novel mutation c.715G>C. Further studies will improve our understanding of genetic causes in late onset CACH/VWM patients.

Protein-RNA interactive network of X-linked Mental Retardation (XLMR) genes. *N. Zhong[1, 2], XG. Tao[2].* 1) Dept Human Gen, New York State Inst Basic Res, Staten Island, NY; 2) Peking University Center of Medical Genetics.

To better understand the biological mechanism associates with X-linked Mental Retardation (XLMR), a protein-RNA network was constructed with a yeast tri-hybrid (Y3H) system, followed by in vitro gel mobility assays. 2115 pairs of protein-RNA interaction were performed by constructing RNA sequence of 3' UTR fragment derived from 47 XLMR genes and 45 genes encoding neuron synapses or neuronal development with Y3H. 275 positive interactions were identified. Our results showed that proteins SERPINI1, OFD and ZNF41 have the most connections with 3'UTR of RNAs, suggesting that these proteins may locate in the centre of the network and play important roles in regulation. Potentially they might be a candidate for some XLMR diseases whose underlying gene is yet unidentified. HOPA 3'UTR and PQBP1 3'UTR were interacted by common synaptic or neuron developmental proteins. A cluster, composed of 3'UTR of OTC, PAK3, KIAA1202 and proteins of GPC3, MID1, FTSJ1, HADH2, showed the associations between synaptic or neuron developmental genes and XLMR. Analysis with systems biology approach, eight clusters of protein-RNA interaction, including one cluster of 14 nodes with 19 edges, one of 7 nodes with 9 edges, one of 6 nodes with 13 edges, three of 4 nodes with 4 edges, one of 5 nodes with 6 edges, and one of 6 nodes with 6 edges, were identified. In addition, three clusters of RNA-RNA association, two of which are 4 nodes with 6 edges and one of 4 nodes with 4 edges, and two clusters of protein-protein association, one is 4 nodes with 6 edges and the other, 5 nodes with 10 edges, were identified. In summary, our study may have open a new avenue to investigate the XLMR pathogenic mechanism.

Convergent transcription of an ataxin-7 antisense RNA represses sense promoter activity through Dicer-1 dependent processing of double-stranded RNA. *P. Ladd[1], B.L. Sopher[2], V.V. Pineda[2], G.N. Filippova[3], A.R. La Spada[1,4,5,6].* 1) Pediatrics, UCSD, La Jolla, CA; 2) Laboratory Medicine, Univ of Washington, Seattle, WA; 3) Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Cellular & Molecular Medicine, UCSD, La Jolla, CA; 5) Institute for Genomic Medicine, UCSD, La Jolla, CA; 6) Rady Children's Hospital, San Diego, CA.

Spinocerebellar ataxia type 7 (SCA7) is a polyQ disease characterized by retinal and cerebellar degeneration. SCA7 is caused by expansion of a CAG repeat in the ataxin-7 gene. Both the ataxin-7 CAG repeat tract and start site of translation are located in exon 3. We identified an alternative promoter (P2A) located ~1 kb 5' to exon 3. Promoter activity and boundary were confirmed by luciferase reporter assays. We also identified an antisense (AS) non-coding RNA, SCANT1 (for SpinoCerebellar Ataxia Noncoding Transcript 1) that is convergently transcribed across exon 4, exon 3, and P2A. RNase A/T1 dsRNA duplex assays on fibroblast RNAs revealed dsRNAs in the region of bidirectional transcription. Northern blot analysis of human tissues detected small RNAs (20-60 nt), suggesting that small processed RNA fragments are being produced in this region. To understand the regulation of promoter P2A, we tested if expression of SCANT1 in trans could reduce the luciferase activity of the promoter fragment, and noted no effect. To test if SCANT1 transcription regulates P2A in cis, we performed gene trap assays with ataxin-7 P2A - exon 3(CAG10) - exon 4 genomic fragment constructs with a 3' IRES-luciferase (luc) in sense orientation, and a Renilla luciferase (Rluc) in AS orientation. The AS promoter was replaced with a tet-regulatable element (TRE) to yield the TRE-only ataxin-7 construct, and a second version created by cloning a polyA transcription termination signal ("polyA trap") in AS orientation into exon 3. We confirmed the integrity of the polyA trap by comparing TRE-only and TRE-polyA-trap ataxin-7 vectors, and observed marked reduction of Rluc/luc for the TRE-polyA-trap. After doxycycline treatment, we also measured ataxin-7 expression by qPCR, and observed significant de-repression of ataxin-7 sense expression in TRE-polyA-trap transfected cells. To determine if RNA processing machinery is involved in SCANT1 regulation of P2A, we performed Dicer-1 knockdown on cerebellar astroctyes with an integrated ataxin-7 genomic fragment, and detected a significant increase in ataxin-7 sense expression. No evidence for Drosha or argonaute protein involvement in SCANT1 regulation of ataxin-7 expression was seen. Our findings indicate that AS-mediated repression of the ataxin-7 sense promoter operates by convergent transcription, yielding dsRNAs that are processed by Dicer-1, providing evidence for Dicer-1-dependent co-transcriptional silencing in higher organisms.

Transgenic expression of the ALS4 senataxin R2136H mutation yields a neurological phenotype in mice. *C.L. Bennett[1], Y. Chen[2], B.L. Sopher[6], G.A. Garden[6], A.R. La Spada[1,3,4,5].* 1) Pediatrics, Univ of California, San Diego, La Jolla, CA; 2) Department of Lab Medicine, University of Washington, WA; 3) Cellular & Molecular Medicine, Univ of California, San Diego, La Jolla, CA; 4) Institute for Genomic Medicine, San Diego, La Jolla, CA; 5) Rady Children's Hospital, San Diego, CA; 6) Department of Neurology, University of Washington, Seattle, WA.

Amyotrophic lateral sclerosis (ALS) is an adult-onset neurodegenerative disorder characterized by upper and lower motor neuron degeneration, leading to fatal paralysis. The majority of ALS cases are sporadic (SALS); however, various familial forms of ALS (FALS) represent up to 10% of all cases. Despite years of study, the mechanistic basis of motor neuron loss in ALS remains ill-defined. Very recently, a pair of discoveries has demonstrated that ALS can be caused by mutation in either of two DNA/RNA binding proteins (TDP-43 and FUS/TLS). This has led to a paradigm shift positing that altered RNA transcript production and processing are responsible for ALS motor neuron disease pathology. Thus far, however, accurate recapitulation of ALS-like neuromuscular phenotypes in mouse models expressing mutations in these two genes has not been achieved. ALS4 is a juvenile-onset, autosomal dominant form of FALS, characterized by limb weakness, muscle wasting, pyramidal signs, and relentless disease progression. We discovered that gain-of-function mutations in the senataxin (SETX) gene are responsible for ALS4. Interestingly, recessive loss-of-function mutations in SETX also produce a neurological phenotype - in this case, an inherited ataxia, known as ataxia with oculomotor apraxia type 2 (AOA2). The senataxin protein contains a conserved superfamily 1, DNA/RNA helicase domain in the C-terminus, indicating a key role in RNA processing. Furthermore, senataxin appears to regulate RNA polymerase II transcription termination of short transcripts, and may play a role in transcription-coupled DNA repair. To determine how SETX mutations produce a toxic gain-of-function, we derived transgenic mice using the murine prion protein (MoPrP) vector, as MoPrP drives expression throughout neurons and all other cell types in the CNS, including the different cell types that comprise the neuromuscular system. We generated both wild-type transgenic mice (PrP-SETX-wt) and transgenic mice expressing a known ALS4 mutation (PrP-SETX-R2136H). PrP-SETX-R2136H transgenic mice display a slowly progressive neurological phenotype, based upon significantly impaired rotarod performance in comparison to PrP-SETX-wt mice, beginning at six months of age. PrP-SETX-R2136H transgenic mice also exhibit reduced stride length and hind limb drag on ledge test, suggesting that they suffer neuromuscular disease. Our findings thus indicate that ALS4 can be accurately recapitulated in transgenic mice.

A novel splicing alteration in *UBA1* results in significant reduction of *UBA1* expression in X-linked infantile SMA. *J. Ramser[1], C. Lenski[1], A. Meindl[1], M. von Rhein[2], B. Wirth[3], M.E. Ahearn[4], L. Baumbach[4].* 1) OB/GYN, Klinikum r.d. Isar, Technische Universitaet Muenchen, Munich, Germany; 2) Department of Neuropediatrics, University Children's Hospital Mainz, Mainz, Germany; 3) Institute of Human Genetics, Center for Molecular Medicine Cologne, University of Cologne, Cologne, Germany; 4) Dr. John T. Macdonald Department of Human Genetics, University of Miami Miller School of Medicine, Miami, USA.

X-linked infantile spinal-muscular atrophy (XL-SMA; MIM #301830) is an X-linked disorder presenting with the clinical features hypotonia, areflexia and multiple congenital contractures (arthrogryposis) associated with loss of anterior horn cells and infantile death. Recently we have identified *UBA1* (also named *UBE1*) which plays a key role in the Ubiquitin-Proteasome System as the underlying disease gene for XL-SMA (Ramser *et al.*, AJHG, 2008). In addition to two missense mutations in *UBA1* exon 15 in two XL-SMA families, we have identified a synonymous C to T substitution (c.1731 C>T, p.Asn577Asn) in the same exon in another three unrelated families. Here we report our further investigations which demonstrate that this synonymous substitution leads to a significant reduction of *UBA1* expression. Applying quantitative PCR in white blood cells of an affected male we demonstrate a reduction to one fifth normal steady-state levels of *UBA1* mRNA as compared to six healthy male controls. Additionally, analysis of a total of eight female carriers from three independent XL-SMA families displayed a reduction of *UBA1* mRNA to one half, compared to eight female healthy controls. Furthermore, *in silico* analyses revealed the c.1731 C>T substitution targets a specific exonic splice enhancer (ESE) motif that can bind SC35, a protein involved in splicing, and could lead in close proximity to the generation of a second putative ESE which functions as a SRp55 binding site. This indicates a possible modification of the splicing process as the underlying cause for the detected reduced expression. Indeed, current quantitative PCR analyses of a weakly expressed *UBA1* transcript lacking exon 15 (delta-exon 15 variant) revealed a 16-fold increase of expression of this variant in white blood cells of an affected individual as compared to four male healthy controls. Female carriers displayed a three fold expression increase as compared to female healthy controls. Since the absolute expression level of the delta-exon 15 variant is even in disease state still rather low as compared to the wild type transcript (estimated two percent) we do not expect to detect the increase of the variant to be pathogenic. We propose that the synonymous c.1731 C>T mutation causes the generation of aberrantly spliced RNA products (at the expense of the wild type transcript) which are likely a target of nonsense-mediated RNA decay (NMD). This possibility is being further investigated.

IQCB1 (NPHP5) mutations in Leber congenital amaurosis with very late nephronophthisis. *I. Perrault[1], R. Salomon[2], V. Morinière[2], K. Tory[3], N. Delphin[1], E. Silva[4], H. Dollfus[5], C. Hamel[6], C. Antignac[2], A. Munnich[1], JM. Rozet[1], S. Saunier[2], J. Kaplan[1].* 1) Dept Gen - Hopital Necker, INSERM U781, Paris, Cedex 15, France; 2) Dept Gen - Hopital Necker, INSERM U574, Paris, Cedex 15, France; 3) 1st Department of Pediatrics, Semmelweis University, Budapest, HONGRIE; 4) Center for Hereditary Eye Diseases Department of Ophthalmology, University Hospital of Coimbra Av Bissaya Barreto 3000-075 Coimbra Portugal; 5) Clinique Ophtalmologique, Hôpitaux Universitaires de Strasbourg, Strasbourg, France; 6) Inserm U583 Physiopathologie et thérapie des déficits sensoriels et moteurs. Hôpital St Eloi - Montpellier , France.

Purpose: Leber congenital amaurosis (LCA) is the earliest and most severe retinal degeneration with onset in the first months of life. Hitherto, mutations in 13 genes were reported to account for 2/3 of LCA. Mutations in one of them, CEP290 (NPHP6), result in a variety of phenotypes ranging from isolated retinal degeneration to pleiotropic disorders including nephronophthisis (Senior-Løken syndrome; SNLS) and cerebellar vermis aplasia (Joubert syndromes; JBTS). Recently, genetic and physical interactions were reported between CEP290 and IQCB1 (NPHP5) which mutations have been reported to account for SNLS. This finding prompted us to look for IQCB1 mutations in LCA patients. Patients and Methods: We considered 240 LCA patients with no cerebellar or renal alterations when ascertained. Direct sequencing of LCA genes found no mutation. Probands' DNAs were screened for mutations by direct sequencing using primers designed from the intronic sequences flanking the 13 IQCB1 coding exons. Clinical data were updated for renal function. Results: 22 IQCB1 disease alleles were identified in 11 families (13 patients; 8 different mutations, 5/8 novel). Consistent but highly variable hyperopia (+3 to +10) was noted. Patients of 7 families were affected with LCA type II (rod-cone dystrophy). Three unrelated cases presented with type I (cone-rod dystrophy), 2/3 of whom were mentally retarded with normal brain MRI. Fundus showed multiple white-dots and/or snail track aspect in the mid-peripheral retina (n=5). Update of renal history revealed nephronophtisis symptoms with early to very late onset in 6/11 families (9 patients; 4 y<end-STAGE disease renal>55 y) while 5/11 families are under investigations (n=7 patients). Discussion: Owing to its onset at birth, LCA is the presenting symptom in several multisystemic disorders which diagnosis is usually made when extraocular symptoms are overt i.e. in the first two decades of life. However, here we report that in SNLS the age at onset of renal failure may vary widely from patient to patient even within families, ranging from early childhood to very late adulthood(>55y). The observation of non exceptional late-onset renal failure requires a close follow-up of patients with IQCB1 mutations whatever their age and more generally of patients whose genotype is unknown. Conversely, the identification of mutations in all LCA genes but CEP290, warrants the absence of risk to develop syndromic LCA making extra-ocular investigations useless.

2264/F

Molecular Analysis of PKD2 Splicing Induced by a Novel Missense Mutation in Autosomal Dominant Polycystic Kidney Disease. *Y. Tan[1], J. Blumenfeld[2, 3], A. Michaeel[1], S. Donahue[2, 3], M. Balina-Marin[3], T. Parker[3], D. Levine[3], H. Rennert[1].* 1) Dept Pathology/Laboratory Med, Weill Cornell Medical Col, New York, NY; 2) Departments of Medicine, Weill Cornell Medical College, , New York, NY; 3) The Rogosin Institute, New York, NY.

Autosomal dominant polycystic kidney disease (ADPKD) is a common, clinically heterogeneous heterogeneous multi-systemic disorder characterized the development of renal cysts,chronic kidney disease, and various extra-renal manifestations. The disease is caused by mutation in either one of two principal genes, PKD1 and PKD2. Here we report the identification of a private missense change in the PKD2 gene (p.Arg440Ser), using SURVEYOR Nuclease-WAVE-sequencing mutation analysis, in a patient presenting with kidney cysts and a family history of ADPKD. This mutation in the first position of exon 6 resulted in premature termination and destruction of a conserved acceptor splice site. Quantitative reverse-transcription (qRT)-PCR analysis demonstrated that the aberrantly spliced PKD2 transcript was present at substantial higher amounts in the patient's peripheral blood leukocytes, and, in varying degrees, in other patients with ADPKD as well as in normal control individuals. Our study presents is the first case of a missense change that also affects RNA splicing in ADPKD. We hypothesize that differential expression of aberrantly spliced variants contributes to the clinical variability observed in ADPKD.

2265/F

Genes in the Ureter Budding Pathway: Exploratory Association Study in a Dutch cohort of Vesico-Ureteral Reflux Patients. *A.M. van Eerde[1], K. Duran[1], E. van Riel[1], C.G.F. de Kovel[1], B.P.C. Koeleman[1], N.V.A.M. Knoers[2], K.Y. Renkema[2], H.J.R. van der Horst[3], A. Bökenkamp[4], J.M. van Hagen[5], L.H. vd Berg[6], K. Wolffenbuttel[7], W.F. Feitz[8], T.P.V.M. de Jong[9], J.C. Giltay[1], C. Wijmenga[1,10].* 1) Department of Medical Genetics, University Medical Center Utrecht, Netherlands; 2) Department of Human Genetics, Radboud University Nijmegen Medical Center, Netherlands; 3) Pediatric Urology, VU University Medical Center, Amsterdam, Netherlands; 4) Pediatric Nephrology, VU University Medical Center, Amsterdam, Netherlands; 5) Department of Human Genetics, VU University Medical Center, Amsterdam, Netherlands; 6) Department of Neurology, Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, Netherlands; 7) Pediatric Urology, Sophia Children's Hospital, Erasmus Medical Center, Rotterdam, Netherlands; 8) Pediatric Urology Centre, Department of Urology, Radboud University Nijmegen Medical Center, Netherlands; 9) Pediatric Renal Center, University Medical Center Utrecht and Academic Medical Center Amsterdam, Netherlands; 10) Department of Genetics, University Medical Center Groningen and University of Groningen, Netherlands.

Vesico-ureteral reflux (VUR) is the retrograde passage of urine from the bladder to the upper urinary tract. 8.5% of end stage renal disease in children is due to VUR. VUR is a complex genetic developmental disorder. Ectopic embryonal ureter budding has long been implicated in the pathogenesis of VUR. We performed an extensive candidate-pathway association study for primary VUR by using a two-stage, case-control design, investigating genes in the ureter budding pathway.

We recruited a Dutch VUR patient cohort (n=409). Controls (n=1446) were included from existing cohorts (e.g. blood bank). The cases were not only analyzed as one group, but we also extracted two extreme phenotype subgroups. Sub-group one consisted of clear cut primary VUR cases (~50% of the cohort); sub-group two contained patients with a duplex collecting system and VUR(~25% of the cohort).

Based on a review of the literature, we selected 44 genes known to be involved in the embryonal ureter budding pathway. A set of 567 tagging single nucleotide polymorphisms (SNPs) for these genes was genotyped in half of the case cohort and controls (stage one). The 14 SNPs that reached the lowest p value (p value cut-off: 0.005) in stage one, were genotyped in the other half of the case cohort and controls (stage two).

The results suggested associations with VUR in six genes. For four genes (gene, odds ratio (95% confidence interval)): GENE1, 0.77 (0.65 - 0.91); GENE2, 1.27 (1.07 - 1.51); GENE3, 1.28 (1.03 - 1.59) and GENE4, (0.77 (0.62 - 0.96), the effect, or trend towards the effect, was present in the joint results of both phenotype sub-groups. For GENE5, 0.80 (0.69 - 0.94), mainly sub-group one with primary VUR cases contributed to the overall effect. The GENE6 gene (1.52 (1.11 - 2.06) was only associated in sub-group two (with duplex collecting systems and VUR). With p-values not reaching the multiple-testing threshold of significance (10-5), these results warrant replication in larger cohorts. This exploratory study seems to confirm the hypothesis that common genetic variants in the ureter budding pathway do contribute to the genetic susceptibility for primary VUR.

Mutations within the hydrophobic part (h-region) of the renin (REN) signal sequence have been recently identified in three unrelated families with the autosomal-dominant inheritance of early-onset anemia, polyuria, hyperuricemia and progressive chronic kidney disease (Živná et al.; Am.J.Hum.Gen. 2009, 85:204-13). We report fourth family with this syndrome and a novel heterozygous mutation c.58T>C resulting in the amino acid substitution of cysteine for arginine in the preprorenin signal sequence (p.Cys20Arg) occurring in all affected members. The mutation occurs in the conserved polar C-terminal part (c-region) of the preprorenin signal sequence which decreases its overall hydrophobicity and alters its cleavage site score profile and cleavage site probability. In-vitro studies showed that the mutation indeed abolishes endoplasmic reticulum cotranslational translocation and post translational processing of the mutant protein. Transient expression of p.Cys20Arg preprorenin in HEK293 cells leads to massive accumulation of non-glycosylated, non-granular and thus secretion incompetent preprorenin in cytoplasm of transfected cells. We propose that this mechanism likely reduces viability of renin producing cells which leads to attenuation of renin biosynthesis and dysregulation of intra-renal RAS (renin-angiotensin system). This is reflected by low plasma renin activity, low serum aldosterone, irregular expression of RAS components and ultrastructural damage of the kidney. Treatment with fludrocortisone in an affected 10 year old child resulted in an increase in blood pressure and estimated glomerular filtration rate. Nephrologists should consider REN mutations in families with autosomal dominant inheritance of chronic kidney disease, especially if they suffer from anemia, polyuria and hyperuricemia in childhood.

Unravelling the unexpected genetic heterogeneity of nephronophthisis in the Hutterite population. *C.M. Loucks[1], A.M. Innes[1], A.W. Wade[2], K.M. Boycott[3], P. Frosk[1], C.L. Beaulieu[1], E.G. Puffenberger[4], J.S. Parboosingh[1].* 1) Dept of Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Division of Pediatric Nephrology, University of Calgary, Calgary, AB, Canada; 3) Dept of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 4) Clinic for Special Children, Strasburg, PA, USA.

Nephronophthisis (NPHP) is a genetically heterogenous group of autosomal recessive disorders characterized by renal cysts, polyuria, polydipsia, secondary enuresis and anemia. It is the most frequent genetic cause of end-stage renal disease in children and is seen in 1 in 50 000 live births in Canada. NPHP is classified as a ciliopathy due to the identification of causative mutations in 10 genes localizing to nonmotile cilia (*NPHP1-9, 11*), with the majority of cases being attributed to a recurrent homozygous deletion of *NPHP1*. Within the endogamous Hutterite population the frequency of NPHP is even higher and may approach 1 in 2750. As the majority of Hutterites are descended from 89 ancestors this was expected to be the result of a single founder mutation. The 'common' *NPHP1* deletion was found in four Hutterite NPHP patients, but five other patients were initially found to lack the homozygous *NPHP1* deletion, suggesting the presence of a second founder mutation in the population. Three of these patients are closely related, and the causative mutation was expected to lie within a homozygous chromosomal region inherited from a common ancestor. Initially, no homozygous regions were found surrounding the known NPHP genes using microsatellite markers, suggesting the possibility of a novel locus, but a 10K SNP array revealed an apparent homozygous region surrounding *NPHP1*. Sequencing *NPHP1* in these patients showed a single base pair deletion, resulting in a premature stop codon in the final exon expected to disrupt normal cell-cell junctional targeting of the encoded protein. Interestingly, these three patients who appeared homozygous on the SNP array were found to be compound heterozygotes for the large 'common' deletion and the single base pair deletion, while the two remaining patients did not carry either *NPHP1* mutation, indicating that at least one more NPHP mutation is present in the population. A 10K SNP array on one of these patients revealed multiple stretches of homozygosity including one surrounding *NPHP3*. Sequencing of *NPHP3* is underway, and if a mutation is not found consideration will be given to genes in other homozygous regions implicated in renal dysfunction and/or expressed in the ciliary proteome. Identifying the full spectrum of mutations causing NPHP in the Hutterites will allow for more comprehensive clinical genetics service for this population and will further our understanding of the complexities of ciliopathies in this population.

Identification of a chromosomal locus associated with recessive Primary Ciliary Dyskinesia in a Bedouin family. *M. Mazor[1,2], S. Alkrinawi[3], V. Caspi[2], E. Manor[4], J.C Beck[5], V. Sheffield.[5], M. Aviram[3], R. Parvari[1,2].* 1) Developmental human Genetics, Ben Gurion University, Beer-Sheva, Negev, Israel; 2) The National Institute for Biotechnology in the Negev, Israel; 3) Pediatric Division Soroka medical Center, Beer-Sheva, Israel; 4) Institute of Genetics, Soroka Medical Center, Beer Sheva 84105 and Faculty of Health Sciences, Ben Gurion University of the Negev, Beer Sheva 84101, Israel; 5) Dept. of Pediatrics - Division of Medical Genetics; Howard Hughes Medical Institute, University of Iowa, Iowa City, IA 52242, USA.

Primary ciliary dyskinesia is a rare autosomal recessive genetic disorder, caused by inherited defects of ciliary structure and function. The clinical features reflect the distribution of dysmotile cilia and include neonatal and chronic respiratory distress due to lack of coordinated ciliary movement. In approximately half of PCD patients, there is apparent randomization of left-right axis development, or situs inversus totalis proposed to result from defective function of embryonic nodal cilia. We have characterized a consanguineous Bedouin family from the Negev, who has two siblings diagnosed with situs inversus and respiratory symptoms and numerous healthy siblings. Linkage to the 13 genes known to be associated with the disease was negated. Further genome wide linkage analysis using the Affymetrix GeneChip mapping 250K array and microsatellite markers was performed. Homozygosity mapping identified a chromosomal region larger than 16cM. Genotyping the region by analyzing polymorphic markers to all family members has defined a locus of 30Mb on chromosome 18q with a Lod score of 3.0 for multipoint analysis. Prioritizing genes for search of the mutation and initial sequencing, was preformed according to the databases of proteome collections, and derived from evolutionarily distant organisms which combines independently assembled ciliary, basal body and centrosome. Identification of additional genes involved in cilia function will provide new insights into the molecular mechanisms of the cilia and help to develop much needed novel techniques to diagnose subjects with PCD.

Deleterious mutations in *RRM2B* causing severe mitochondrial DNA depletion in infancy. *S. Seneca[1,2], J. Smet[3], R. Van Coster[3], W. Lissens[1,2], S. Van Dooren[1], M. Bonduelle[1,2], I. Liebaers[1,2], L. De Meirleir[4,2].* 1) Center for Mediacal Genetics, UZ Brussel, Brussels, Belgium; 2) Vrije Universiteit Brussel (VUB), Brussels, Belgium; 3) Division of Paediatric Neurology and Metabolism, University Hospital Ghent, Ghent, Belgium; 4) Division of Paediatric Neurology, UZ Brussel, Brussels, Belgium.

Mitochondrial DNA (mtDNA) copy number reduction, known as the mitochondrial DNA depletion syndrome (MDS), is a common cause of severe mitochondrial disorders of infancy and early childhood. MDS results from defects in nuclear encoded factors involved in mtDNA maintenance and within the past years mutations in the *POLG1*, *DGUOK*, *MPV17*, *PEO1*, *SUCLG1*, *TK2* and *SUCLA2* genes have proven to be implicated in the pathogenesis of this disorder. The clinical phenotypes associated with the different gene alterations vary considerately but present either as a hepatocerebral or a myopathic syndrome. We have identified a homozygous p.E85 deletion in exon 3 of the *RRM2B* gene in a neonate. The patient, born to first-cousin Caucasian parents, presented with lactic acidosis, severe hypotonia, deafness, blindness and hyperammonemia. Muscle biopsy showed RRF, a combined respiratory chain defects and massive subcomplexes of ATP synthase both with traditional spectrophotometry and BN-PAGE. Western blotting using antibodies against selective OXPHOS subunits indicated the preservation of nuclear encoded complex II. She died at 2 months of age. Mutations of the *RRM2B* gene, encoding the cytosolic R2 subunit of a p53 controlled ribonucleotide reductase (p53R2), have been reported to cause severe depletion of muscle mtDNA by Bourdon et al. 2007. Indeed, < 5% residual amount of mtDNA was measured in muscle tissue of our patient. Aberrations in these 8 genes count only for a minority of all MDS cases. It is expected that other genes involved will be identified.

A genetic risk factor behind chronic obstructive pulmonary disesase (COPD). *J. Klar[1], P. Blomstrand[2], J. Badhai[1], B. Schemkel[2], C. Brunmark[3], H. Falk Håkansson[3], C. Sollie Brange[3], B. Bergendahl[2], N. Dahl[1].* 1) Department of Genetics and Pathology, Rudbeck Laboratory, Uppsala University and University Hospital, Uppsala, Sweden; 2) Department of Clinical Physiology, Ryhov County Hospital, Jönköping, Sweden; 3) AstraZeneca R&D, Lund, Sweden.

Chronic obstructive pulmonary disease (COPD) is a complex disorder and one of the leading causes of death in developed countries. The disease results from major remodelling of the airspace and changes in the lung epithelium. In contrast to asthma, which is defined by a reversible airflow obstruction, COPD is defined by a fixed obstruction, although it may be difficult to differentiate between the two diseases. The most important risk factor for the development of COPD is cigarette smoking, but only a minority of smokers will develop COPD, which implies that genetic factors may be involved. Familial aggregation of lung function as well as clustering of COPD within families supports a genetic contribution to pulmonary function. Despite tremendous efforts to understand the genetics behind COPD, most genetic factors remain obscure with the exception of α1-antitrypsin deficiency.

We have identified two families segregating irreversible obstructive lung disease. Affected family members have a moderate COPD from spirometry measures. The phenotype is associated with mutations causing reduced fibroblast growth factor (FGF) levels. Our findings show that impaired pulmonary function is associated with mutations affecting FGF levels and the results provide a direct connection between FGF signalling and COPD.

microRNA processing is dysregulated by mutations associated with Pulmonary Arterial Hypertension. *K.M. Drake[1], S.A. Comhair[2], S.C. Erzurum[2], M.A. Aldred[1].* 1) Genomic Medicine Institute, Lerner Research Institute, Cleveland Clinic, Cleveland, OH; 2) Department of Pathobiology, Lerner Research Institute, Cleveland Clinic, Cleveland, OH.

Hereditary pulmonary arterial hypertension (PAH) is a progressive lung vascular disease caused by mutations in the bone morphogenetic protein (BMP) pathway, primarily the gene encoding the BMP type-II receptor (BMPR2), or less commonly activin receptor-like kinase 1 (ACVRL1), endoglin (ENG) or Smad-8 (gene symbol: SMAD9). microRNAs (miRs) are small, non-coding RNA molecules that negatively-regulate gene expression. Recently, BMP signaling was shown to regulate a subset of miRs, including miR-21, via a non-canonical Smad-1,5-mediated pathway. We hypothesized that mutations of BMP pathway genes in PAH patients result in the dysregulation of microRNA biogenesis. Control pulmonary artery endothelial (PAEC) and smooth muscle (PASMC) cells were treated with short-interfering RNA (siRNA) pools targeting specific genes of the BMP pathway. BMP stimulation induced a 2-3-fold increase of miR-21 in wild-type cells. This was abrogated by siRNA knockdown of BMPR2 or ACVRL1/ENG. Cells from explant lungs of two patients with heterozygous BMPR2 mutations showed no induction of miR-21, confirming that PAH mutations directly disrupt miR biogenesis. Remarkably, siRNA knockdown of SMAD9 also blocked miR-21 induction, despite only a modest blunting of canonical BMP signaling through Smad-4. These results were also confirmed in a third patient line carrying a germline SMAD9 mutation. Our data suggest that patients with BMP-pathway mutations have a primary defect in BMP-dependent microRNA processing and that this is more profound than effects on canonical BMP signaling. We are currently undertaking Illumina-GA sequencing to characterize the complete spectrum of miR dysregulation in PAH cells and to define their gene targets. To date we have identified and validated three additional miRs that are regulated in the same manner. Collectively, these miRs regulate key processes such as apoptosis, angiogenesis and response to hypoxia, suggesting that defects in their regulation may play an important role in pathogenesis of PAH.

2272/F

The regulation and the role of miR-154 microRNA family in Lung Fibrosis. *J. Milosevic[1], P. Kusum[1], M. Magister[1], A. Bais[2], P.V. Benos[2], E. Rabinovich[1], N. Kaminski[1].* 1) Dorothy P. and Richard P. Simmons Center for Interstitial Lung Disease, Division of Pulmonary, Allergy and Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, PA; 2) Department of Computational Biology, University of Pittsburgh, Pittsburgh, PA.

Rationale: Idiopathic pulmonary fibrosis (IPF) is a progressive interstitial lung disease of unknown origin characterized by abnormal activation of developmental pathways. We have previously demonstrated significant and biologically relevant down-regulation of microRNAs in IPF. In this study we focus on the role and regulation of up-regulated microRNAs in IPF. Methods and Results: We analyzed the expression of microRNAs in IPF lungs and identified 46 significantly ($p<0.05$) up-regulated microRNAs in IPF samples. Impressively, 23 of the 46 increased microRNAs were localized at the chromosome 14q32 microRNA cluster. The miR-154 gene family was over represented among the up-regulated microRNAs with 11 members significantly increased. We validated changes in expression of intergenic miR-154, miR-154*, miR-134, miR-299-5p, miR-410, miR-382, miR-409-3p, miR-487b and intronic miR-127 by qRT-PCR. We ruled out differential methylation of this region using Agilent Human CpG Islands Microarray methylation arrays and EpiTYPER MassARRAY (Sequenom). Computational analysis of the upstream region of the intergenic and intronic miR cluster revealed 8 SMAD binding elements within 5kb upstream of miR-154 and 82bp upstream of miR-127. TGF-B1 stimulation of normal human lung fibroblast (NHLF) caused significant up-regulation of 11 miRNAs from chr14q32 (miR-132, miR-127-3p, miR-299, miR-154, miR-409-3p, miR-376c, miR-376b, miR-487b, miR-411, miR-323-3p) suggesting that the up-regulation of this cluster is at least in part caused by TGF-B1. Transfection of lung fibroblasts with members of miR-154 family caused increases two fold in cell proliferation and three fold in cell migration as measured by (^{3}H) thymidine incorporation and Boyden chamber assays respectively. Conclusion: The concordant up regulation of members of the miR-154 family, regulation by TGF-B1, and their role in proliferation and migration highlight this family as a potential regulator of the lung phenotype in IPF.

2273/F

The microRNA profile of Idiopathic Pulmonary Fibrosis has a developmental signature. *K.V. Pandit[1], J. Milosevic[1], P.V. Benos[2], G. Schatten[3], J. Hagood[4], N. Ambalavanan[5], N. Kaminski[1].* 1) Dorothy P. & Richard P. Simmons Center for Interstitial Lung Disease, PACCM, School of Medicine, University of Pittsburgh; 2) Department of Computational Biology, School of Medicine, University of Pittsburgh;; 3) Department of Obstetrics, Gynecology, and Reproductive Sciences, University of Pittsburgh School of Medicine, Pittsburgh; 4) Department of Pediatrics, University of California San Diego; 5) Department of Pediatric Neonatology, University of Alabama Birmingham.

INTRODUCTION: Idiopathic pulmonary fibrosis (IPF) is a chronic lethal lung disease resulting in respiratory failure and death within 3-5 years from diagnosis. Since it has been reported that IPF lungs are enriched with genes associated with lung development, we analyzed the microRNA expression patterns in IPF lungs and compared it to that of fetal lungs. METHODS AND RESULTS: RNA from 12 control lungs and 13 IPF lungs was hybridized on Agilent microRNA microarrays. 51 microRNAs were decreased and 45 increased in IPF lungs compared to controls. The expression of 34 microRNAs was confirmed by real time PCR. Among the decreased microRNAs were let-7, the miR-26, miR-29 and miR-30 families and the miR-17~92 cluster. Among increased microRNAs were members of the miR-154 and miR-199 families. Pathway analysis revealed targets of these microRNAs to be enriched with genes associated with developmental pathways. We proceeded by analyzing the microRNA profile of human fetal lungs and found it to be significantly similar to IPF lungs. To demonstrate a gradual shift in microRNA profile during the course of lung development, we analyzed the microRNA repertoire of post-natal mouse lungs at different time points since almost 90% of alveolar development in mice takes place after birth. The microRNAs decreased in IPF gradually increased in the developing mouse lung and vice versa. These observations were also supported by the analysis of their predicted and proven targets. We identified that change in microRNA patterns of expression eliminated key anti-fibrotic regulatory step and created multiple feed forward loops. CONCLUSIONS: Aberrant activation of embryological pathways regularly repressed in the adult life may explain the persistent nature of the disease. Our results indicate that the cumulative effect of the changes in microRNA expression in IPF is a global profibrotic transcriptional regulatory environment. The understanding of this regulatory environment would allow us design interventions that will disturb the pro-fibrotic balance in IPF lungs and potentially not only stop fibrosis but in some cases allow its reversal.

2274/F

Differences in average age of onset, locus heterogeneity & penetrance between Familial Pulmonary Arterial Hypertension & Familial Interstitial Pneumonia can predict the success of linkage and whole exome sequencing in discovering disease causing alleles. *J.A. Phillips[1,2], J.D. Cogan[1], E.D. Austin[1], E.K. Larkin[2], C.R. Markin[2], W.E. Lawson[2], J.H Newman[2], J.E. Loyd[2], T.S. Blackwell[2].* 1) Dept Ped; 2) Dept Med, Vanderbilt Univ Sch Med, Nashville, TN.

Familial Pulmonary Arterial Hypertension (FPAH) & Familial Interstitial Pneumonia (FIP) are AD with ages of onset (AO) of ~35 & >50yrs. In FPAH we used linkage analysis (LA) to map the BMPR2 locus which causes >80% of families. The later AO in FIP results in affected sibs with few other affected generations & 3 genes (SFTPC, TERC & TERT) cause <20% of families. Since LA is less robust in FIP, whole exomic sequencing (WES) is attractive to identify candidate loci. The number of WES variants are problematic because FIP pedigrees are limited in proving which are causal because average sharing of 50% of the genome by sibs & locus heterogeneity (LH). **Hypothesis:** Differences in AO & LH in FPAH & FIP affect the utility of LA & WES to detect disease genes. We compared numbers of affected generations; living affected & at risk relatives; informativeness of the most distant affected relatives' DNAs; & informative meioses for LA between FPAH & FIP pedigrees. We reviewed the 6 FPAH pedigrees we used to map FPAH & compared them to the 6 best of our 235 FIP families based on informativeness & available DNAs. We compared our FPAH & FIP pedigrees by 1) median & interquartile ranges, 2) exact non-parametric Wilcoxon tests of distributions of at risk relatives, affected generations, & living affecteds; 3) odds of DNAs from the 2 most distantly related, affected family members to share WES variants, & 4) the number of potentially informative meioses for LA. **Results:** Our FIP kindreds have more living at risk members (14 vs. 6, p=0.04). Potentially informative meioses were lower in FIP (2 vs. 5.5 in FPAH; p=0.002). Numbers of affected generations & DNAs from affecteds were less different in FIP vs FPAH (2 vs. 2.5; P=0.11 & 2 vs. 3.5; P=0.08, respectively). The probability DNAs from the 2 most distant affected relatives to share WES variants was 0.09 in FPAH vs. 0.25 (p=0.11) in FIP. Comparison of the numbers of affecteds/all at ≥50% risk suggests that the penetrance of FIP is ~2.4 fold less than FPAH in the pedigrees studied. **Conclusions:** Our data indicate that our best FIP pedigrees are less informative for LA & allele sharing studies to map disease loci than our FPAH kindreds due to later AO, reduced penetrance & greater potential LH. We plan to combine WES to identify candidates; analyze sharing of candidates between affected but distantly related family members, & perform surrogate phenotyping such as measuring telomere length to facilitate FIP gene discovery.

2275/F

Decreased dyskerin levels as a novel mechanism of telomere shortening in X-linked dyskeratosis congenita. *E.M. Parry[1,2], S.S. Lee[3], J.A. Phillips 3rd[4], J.E. Loyd[5], P. Duggal[6], M. Armanios[1,2].* 1) MSTP Program, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Oncology, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Predoctoral Training Program in Human Genetics, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Department of Pediatrics, Vanderbilt University School of Medicine, Nashville, TN; 5) Department of Medicine, Vanderbilt University School of Medicine, Nashville, TN; 6) Department of Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD.

Idiopathic pulmonary fibrosis (IPF) is progressive and fatal, yet its pathophysiology remains poorly understood. Mutations in the genes encoding the essential components of the telomerase enzyme, hTERT, the telomerase reverse transcriptase and hTR, the telomerase RNA, underlie inheritance in 8-15% of IPF families. Dyskeratosis congenita (DC) is a premature aging syndrome characterized by short telomeres. Individuals with DC suffer early mortality from organ failure in aplastic anemia, liver cirrhosis and IPF. An X-linked form of DC is caused by mutations in DKC1 which encodes dyskerin, a ribonucleoprotein that is essential for the stability and biogenesis of hTR. We identified a four generation IPF family with features of DC. Affected males showed the classic mucocutaneous features of DC and died prematurely from IPF. Although we could not find any sequence or splicing variants, genome wide analysis of 16 individuals across four generations identified significant linkage at the DKC1 locus (LOD 3.3). To examine the possibility that a regulatory sequence is mutated, we examined the known regulatory elements of DKC1 but identified no variants. However, quantitation of dyskerin protein levels identified a 50% reduction in affected males. The decrease in dyskerin levels segregated with the very short telomere phenotype, diagnostic of DC. Confirming a dyskerin defect, the decrease in dyskerin protein in affected individuals was associated with a reduction in hTR levels. This family study identifies decreased dyskerin protein levels, in the absence of coding mutations, as a novel mechanism of disease in X-linked forms of familial IPF-DC. Our data indicate that intact dyskerin levels are critical for telomerase RNA stability and for in vivo telomere maintenance. Characterizing the regulatory elements that control DKC1 transcription can elucidate genetic elements that predispose to IPF and other syndromes of telomere shortening.

Absence of Cyclophilin B Causes Autosomal Recessive Osteogenesis Imperfecta but does not Impair Type I Collagen Peptidyl-Prolyl Isomerization. *A. Barnes[1], E. Carter[2], W. Cabral[1], M. Weis[3], W. Chang[1], E. Makareeva[4], S. Leikin[4], C. Rotimi[5], D. Eyre[3], C. Raggio[2], J. Marini[1].* 1) BEMB, NICHD/NIH, Bethesda, MD; 2) Hospital for Special Surgery, New York, NY; 3) University of Washington, Seattle, WA; 4) SPB, NICHD/NIH, Bethesda, MD; 5) NHGRI/NIH, Bethesda, MD.

Osteogenesis imperfecta, or brittle bone disease, is a genetic disorder characterized by bone fragility and growth deficiency. Recently, recessive forms of osteogenesis imperfecta have been shown to be caused by mutations in the three genes coding for components of the collagen 3-hydroxylation complex. This complex post-translationally hydroxylates a single residue in type I collagen, Pro986, as well as residues on types II and V collagen. Null mutations in *CRTAP* or *LEPRE1* lead to severe/lethal forms of OI with white sclerae and rhizomelia (types VII and VIII OI). Collagen synthesized by patient fibroblasts has minimal Pro986 hydroxylation, but is overmodified, indicating delay in collagen folding. In a pair of Senegalese siblings born to consanguineous parents, we identified a homozygous mutation in the start codon of *PPIB*, which encodes cyclophilin B (CyPB) the third member of the 3-hydroxylation complex. These children are ambulatory with moderate OI and white sclerae, but without rhizomelia or severe growth deficiency. Proband fibroblast RNA had 55% of the normal level of *PPIB* transcripts by real-time RT-PCR. On Western blot of fibroblast lysates, no CyPB protein was detectable using 3 antibodies to full protein, C-terminal half and final 15 residues or after treating proband cells with a proteasome inhibitor. Both CRTAP and P3H1 protein levels were reduced to half of normal levels, suggesting that complex stability is decreased. Immunofluorescence microscopy confirmed these findings in vivo. CyPB is a well-known peptidyl-prolyl cis-trans isomerase which is thought to be involved in the rate-limiting step of type I collagen folding. Therefore, we examined the proband's steady-state type I collagen protein as well as the levels of lysyl and 3- and 4-prolyl hydroxylation in the collagen helix. Pro986 hydroxylation was normal in proband collagen, indicating that the complex can complete its collagen modification function in the absence of CyPB. Surprisingly, steady-state collagen from our proband was not overmodified, with normal lysyl and 4-prolyl hydroxylation levels, in contrast to collagen synthesized by cells with recessive defects in *CRTAP* or *LEPRE1*, or with recessive *PPIB* mutations which allow synthesis of misfolded CyPB. Therefore, the complete absence of CyPB does not appear to delay collagen folding, strongly suggesting that there is redundancy for collagen isomerization, or CyPB may not be the major type I collagen folding isomerase.

Clinical features and abnormal *ALK2* activity in case of fibrodysplasia ossificans progressiva (FOP) with an *ALK2* (G356D) mutation. *H. Furuya[1], H. Arahata[1], E.I. Araki[1], N. Fujii[1], Y. Fukumaki[2], T. Katagiri[3].* 1) Department of Neurology, National Oomuta Hospital, Oomuta, Fukuoka, Japan; 2) Division of Human Molecular Genetics, Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 3) Division of Pathophysiology, Research Center for Genomic Medicine, Saitama Medical University, 1397-1 Yamane, Hidaka-shi, Saitama 350-1241, Japan.

Fibrodysplasia ossificans progressiva (FOP) is a rare autosomal dominant congenital disorder characterized by progressive heterotopic bone formation in muscle tissues. A common mutation among FOP patients has been identified in *ALK2* (R206H), which encodes a constitutively active bone morphogenetic protein (BMP) receptor. Recently, a unique mutation of *ALK2* (G356D), was identified to be a novel mutation in a Japanese FOP patient who showed rigid spine, baldness, sensorineural hearing loss, and hypodactyly accompanied by abnormal ectopic ossification. Over-expression of *ALK2* (G356D) induced phosphorylation of Smad1/5/8 and activated Id1-*luc* and alkaline phosphatase (ALP) activity in myoblasts. However, the overexpression failed to activate phosphorylation of p38, ERK1/2, and CAGA-*luc* activity. These *ALK2* (G356D) activities were weaker than those of *ALK2* (R206H), and they were suppressed by a specific inhibitor of the BMP-regulated Smad pathway. These findings suggest that *ALK2* (G356D) induces heterotopic bone formation via activation of a BMP-regulated Smad pathway. The quantitative difference between *ALK2* (G356D) and *ALK2* (R206H) activities may have caused the phenotypic differences in these patients, which may also give a clue to better understanding of the pathophysiology of FOP.

Two novel *COL1A1* mutations in Chinese pedigrees with osteogenesis imperfecta type I. *M. Gu[1,2], W. Xu[1], X. Wu[1], X. Chen[1], Z. Wang[1,2].* 1) Dept Med Gen, Shanghai Jiao Tong Univ Sch Med, Shanghai, China; 2) E-Institutes of Shanghai Universities, Shanghai Jiao Tong Univ Sch Med, Shanghai, China.

Osteogenesis imperfecta (OI) is an autosomal dominant or recessive disorder characterized by osteoporosis, dentinogenesis, blue sclera and hearing loss. Studies have shown that the vast majority of affected individuals have mutations in either of the two genes, *COL1A1* and *COL1A2*, that encode the chains of type I procollagen. In our study, a three-generation family was ascertained through initial identification of a proband from Shanghai. Another family from Inner Mongolia was also ascertained. After informed consent was signed, all affected individuals and family members were evaluated by experienced orthopedists. The diagnosis was made based on family history, physical and radiographic examinations. The diagnostic criteria were based on Sillence's OI classification. Peripheral blood samples were collected and genomic DNA was extracted from all family members by using QIAamp DNA blood mini kit (Qiagen). Then, the members of two pedigrees were genotyped firstly with microsatellite markers at the two known loci of OI. Linkage analysis showed that the affected individuals in these families have high LOD scores within the region of 17q11.2-22, where the *COL1A1* gene is located. After screening *COL1A1* for mutations by direct sequencing, we identified two mutations. One was a TG deletion in exon 28 which leads to the frameshift mutation of *COL1A1* and converts a codon to a premature stop codon in c.1959, producing a stop codon in exon 29 and decreasing the amount of collagen I. Thus the truncated protein (p.Gly632ThrfsX21) was produced. The other one was a splicing mutation that converted the splice-acceptor site in intron 8 from AG to GG. These mutations were found in all affected individuals but unaffected relatives and 100 unrelated normal individuals were not observed. The two mutations appeared to be novel, which were neither reported in literature nor registered in Osteogenesis Imperfecta & Ehlers-Danlos syndrome variant databases (http://www.le.ac.uk/genetics/collagen). In conclusion, we identify a novel frameshift mutation (c.1896_1897 del TG) and a novel RNA-splicing mutation (c.643-2A>G) in *COL1A1* resulting in OI type I. The detailed molecular and clinical features will be useful for extending the evidence for genetic and phenotypic heterogeneity in OI type I.

2279/F

CANT1 does not account for all Desbuquois dysplasia cases but is directly involved in proteoglycan synthesis. *C. Huber[1], A. Rossi[2], R. Merrina[1], M. Fradin[1], B. Abdulibdeh[3], Y. Desbuquois dysplasia is characterized by short stature, joint laxity, scoliosis, advanced carpal ossification and hand anomalies including delta phalanx or extra ossification center. Studying 9 Desbuquois families with characteristic hand anomalies, we have identified 7 mutations in the Calcium-Activated Nucleotidase 1 gene (CANT1) which encodes a soluble UDP-preferring nucleotidase. Among the 9 families, nonsense mutations were identified in 4 and all children presented an early death due to cardio-respiratory failure. In the 5 other families, we identified 3 missense mutations located in the region encoding the 7th nucleotidase conserved region and changing Arg300. Using RT-PCR analysis, we observed a specific CANT1 expression in chondrocytes. We also found electron-dense material within distended rough endoplasmic reticulum in Desbuquois patient fibroblasts. Following this study, we have collected the samples of 16 additional Desbuquois families. Among them, 2 had characteristic hand anomalies and we identified two mutations in CANT1 (p.R300H and a novel mutation p.I374N) present at the homozygous state. The 14 other families were consanguineous and CANT1 was excluded by linkage analysis. Because Desbuquois dysplasia shares phenotypic features with Diastrophic dysplasia and recessive Larsen syndrome, which are due to SLC26A2 or CHST3 mutations, we excluded these two genes in 13/14 patients with no CANT1 mutation but we found an homozygous CHST3 mutation (p.L259P) in 1/14 patient. Remembering that SLC6A2 and CHST3 encode proteins involved in proteoglycan sulfation, we made the hypothesis that CANT1 deficiency may interfere with the availability of UDP-sugars needed for proteoglycan synthesis. Fibroblasts from two Desbuquois patients and four controls were therefore double labeled with [35S]sulfate and [3H]glucosamine. Surprisingly, in the patient cells glycosaminoglycan (GAG) synthesis was almost normal under basal conditions when compared to the controls, but significant reduced GAG synthesis was observed in presence of β-D-xyloside, a compound that increases GAG synthesis acting as a chain initiator. These data suggest that CANT1 plays a role in proteoglycan metabolism and supports its involvement in the rate of GAG synthesis. We conclude that Desbuquois dysplasia is a genetically heterogeneous condition. On going studies will hopefully lead to the identification of another disease gene presumably also involved in proteoglycan synthesis.

2280/F

Expansile panostotic high turnover bone disease with massive jaw tumor formation associated with a unique 12 bp duplication in RANK. *S. Mumm[1], A.L. Schafer[2], I.H. El-Sayed[2], M.S. Anderson[2], E.C. Hsiao[2], F.V. Schaefer[3], M.T. Collins[4], P. Andreopoulou[4], M.P. Whyte[1], D.M. Shoback[2].* 1) Washington University School of Medicine and Shriners Hospital for Children, St. Louis, MO; 2) University of California, San Francisco, CA; 3) Center for Genetic Testing at Saint Francis, Tulsa, OK; 4) National Institute of Dental and Craniofacial Research, NIH, Bethesda, MD.

A 27-year-old man was transferred to the UCSF Otolaryngology Service for management of a bleeding, basketball-size, mandibular tumor. Born in Mexico, he was deaf and mute, and was "bow-legged" but active as a child. Family history was negative for bone disease. Puberty occurred normally, but he developed difficulty straightening his limbs, multiple fractures, and a bony tumor on his chin. At age 18 yrs, all limbs were misshapen. As the mandibular mass grew, the diagnosis of McCune-Albright syndrome (MAS) was considered. The mass protruded from the oral cavity and extended to the lower ribs. Other bony defects included a maxillary mass and serpentine limbs. There were no café-au-lait spots. Laboratory results included serum Ca 7.1 mg/dL, PO4 2.4 mg/dL, albumin 1.7 g/dL, PTH 91 ng/L, 25(OH)D 11 ng/mL, and alkaline phosphatase 1760 U/L (nl 29-111). There was no clinical or biochemical hyperfunctioning endocrinopathy. Radiography of the limbs showed medullary expansion and cortical thinning with severe bowing. The patient underwent mandibular mass excision, 5 months later partial maxillectomy, and subsequently further maxillary debulking. Histopathology showed curvilinear trabeculae of woven bone on a background of hypocellular fibrous tissue. After surgery and vitamin D supplements, bone-specific alkaline phosphatase was >575 mcg/L (nl 8.4-29.3), C-telopeptide 1644 pg/mL (nl 87-1200), 1,25(OH)2D 45, and intact FGF23 60 pg/mL (nl 10-50). In samples of affected bone and leukocyte DNA, site-specific enrichment mutation analysis followed by sequencing for codon 201 of GNAS showed no mutation, making MAS and panostotic fibrous dysplasia of bone especially unlikely. We searched for mutations in the three major proteins [RANK (receptor), RANKL (ligand), and OPG (osteoprotegerin, decoy receptor)] in the "receptor activator of nuclear factor-κB" (RANK) signaling pathway. No exon or splice site mutations in the genes encoding RANKL or OPG were found, but a unique 12 bp tandem duplication in the signal peptide of RANK was detected. The elevated bone turnover, reflected in the biochemical markers and disorganized bone histology, is likely due to amplified RANK signal transduction, although this phenotype seems different from those reported previously with increased RANK signaling and in-frame duplications in the signal peptide of RANK [familial expansile osteolysis (18 bp dup), expansile skeletal hyperphosphatasia (15 bp dup), early onset Paget disease (27 bp dup)].

2281/F

MLPA analysis of *LRP5* in children with recurrent fractures. *A. Saarinen[1, 2], M. Mäyränpää[3], C. Laine[1, 3], R. Vijzelaar[4], A.E. Lehesjoki[1, 5], O. Mäkitie[1, 3].* 1) Folkhalsan Inst Genetics, Biomedicum Helsinki, Helsinki, Finland; 2) Dept of Medical Genetics, University of Helsinki, Finland; 3) Hospital for Children and Adolescents, Helsinki University Hospital, Finland; 4) MRC-Holland, Amsterdam, The Netherlands; 5) Neuroscience Center, University of Helsinki, Finland.

Background: Mutations in the low-density lipoprotein receptor-related protein 5 gene (*LRP5*) have been associated with high and low bone mass. While homozygous *LRP5* mutations cause osteoporosis-pseudoglioma syndrome (OPPG), characterized by severe osteoporosis and blindness, heterozygous mutations have been associated with reduced bone mass. LRP5 functions as a plasma membrane receptor in the Wnt signaling pathway. We previously described *LRP5* mutation analysis in 66 children with recurrent fractures. In this study we further analyzed the role of *LRP5* in these children by searching for possible exonic deletions or amplifications using multiplex ligation-dependent probe amplification (MLPA).

Methods: The novel Salsa MLPA P285 *LRP5* probemix (MRC-Holland) was used to look for possible exonic amplifications or deletions. This kit contains 38 specific probes for each of the 23 exons for *LRP5* and each of the 4 exons of *DKK1*, an inhibitory protein of Wnt signaling. Furthermore, an additional probe for the *LRP5* p.G171V alteration, associated with a high bone mass phenotype, was included.

Results: The MLPA analysis did not detect any exonic deletions in *LRP5* or *DKK1* in these patients. Several possible amplifications in *LRP5* were detected, but these could not be confirmed by PCR.

Conclusions: Genomic deletions in *DKK1* or *LRP5* are not frequent alterations underlying recurrent fractures in children. The existence of possible exonic *LRP5* amplifications will need to be verified in further studies.

2282/F

How different FGFs contribute to Apert Syndrome phenotype. *E. Yeh, R.D. Fanganiello, D.Y. Sunaga, M.R. Passos-Bueno.* Department of Genetics, Institute of Bioscience, São Paulo, São Paulo, Brazil.

Apert syndrome (AS) is characterized by craniosynostosis and limb abnormalities and is primarily caused by p.S252W mutations in FGFR2, which lead to prolonged ligand-receptor engagement and violation of FGFR2 ligand binding specificity. This mutation compromises the patient even after birth, particularly by a high rate of post-surgical cranial resynostosis. Despite a large literature on FGF-FGFR signaling, we still have unanswered questions concerning the pathways activated by each FGF, the effect of this mutation on cellular function and how the mutation ultimately cause the phenotype. By evaluation of cellular behavior in periosteal fibroblastoid cells from the coronal suture of AS p.S252W patients (n=3) and from matched controls (n=3) we observed that p.S252W mutation is associated with excessive proliferation and enhanced migration in the presence of FGF2 and FGF10. These cells also have increased osteogenic potential, which is inhibited by FGF2 and FGF10. Furthermore, we show that FGFs 2 and 10 trigger different downstream signaling pathways in AS cells and the most relevant pathways are associated with CNS development and inflammatory diseases, respectively. Since appropriate inflammation is involved in wound healing in adult humans and given that the recurrence of suture fusion after surgical repair in AS patients implies a rapid wound healing, this analysis indicates the role of FGF10 in $FGFR2^{+/S252W}$ periosteal cells as a starter and all the altered cell behavior we observed in response to FGF2 and FGF10 are very likely involved in the resynostosis process, as these ligands are expressed in the sutures even after birth. Overall, the new correlations between cellular functions and transcriptome alterations in the presence of the p.S252W mutation can partly explain the high rate of cranial resynostosis after surgical intervention.

2283/F

Craniosynostosis diagnosed by custom molecular microarray (ARRAY CGC). *P. Tavares[1], A. Lopes[1], L. Lameiras[1], L. Dias[1], L. Ramos[2], E. Galhano[3], L. Nunes[4], M. Costeira[5], P. Vidal-Ríos[6], J. Sá[1,2], P. Rendeiro[1], H.G. Santos[1], A. Palmeiro[1].* 1) Clinical Director, CGC Genetics, Porto, Portugal; 2) Hospital Pediatrico de Coimbra EPE, Coimbra, Portugal; 3) Maternidade Bissaya Barreto EPE, Coimbra, Portugal; 4) Centro Hospitalar de Lisboa Central EPE, Lisboa, Portugal; 5) Centro Hospitalar de Alto Ave EPE, Guimarães, Portugal; 6) Complejo Hospitalario de Santiago de Compostela, Santiago de Compostela, Spain.

Introduction: Craniosynostosis is a condition of variable aetiology characterized by premature closure of calvarial skull bones. With many sutures closing prematurely, the skull cannot expand to accommodate the growing brain, which leads to several consequences, including developmental delay, mental retardation and vision and hearing problems can also appear. Most cases are diagnosed during the neonatal period but many cases are detected sooner by ultrasound during the prenatal period. Because this disorder is clinically heterogeneous, some carriers are not detected until late in infancy or only detected after the birth of an affected child. The major conditions, Muenke, Pfeiffer, Apert, Crouzon, Jackson-Weiss, and Seathre-Chotzen-like Syndromes, are related with mutations located in the different genes of the Fibroblast Growth Factor Receptors (FGFR) 1, 2 and 3. Carpenter syndrome was also included, in spite of being a rare condition, to improve the differential diagnosis of craniosynostosis. The molecular characterization of the major forms is of main interest to establish an accurate diagnosis, particularly during the neonatal period and to assess the familial recurrence risk. Method: Using new custom microarray panel (Arrays CGC - Patent Pending) that contains a panel of 10 point mutations identified in 4 main genes involved on syndromic craniosynostosis, FGFR1 (Pfeiffer), FGFR2 (Apert, Crouzon Jackson-Weiss and Pfeiffer), FGFR3 (Muenke and Seathre-Chotzen-like syndrome) and RAB23 (Carpenter), it is possible to identify the molecular basis of the most frequent and severe forms. We report here our experience using this new methodology. Results: We analyzed 9 cases (8 peripheral blood and 1 amniotic fluid) and in two we detected the c.866A>C (p.GIn289Pro) mutation in heterozygozity in the FGFR2 gene and the c.755C>G (p.Ser252Trp) in the FGFR2 gene. Conclusion: This approach drastically reduces turnaround time (one week after DNA extraction), maintaining accuracy and liability independently of the sample type. Faster diagnostic is achieved, allowing early decision-making process in patient management, particularly in prenatal diagnosis.

2284/F

FAM83H Mutations Cause ADHCAI and Alter Intracellular Protein Localization. *JW. Kim[1,3], SK. Lee[1], KE. Lee[1], Z.H. Lee[1], TS. Jeong[2], YH. Hwang[1], S. Kim[2].* 1) Department of Cell and Developmental Biology & Dental Research Institute School of Dentistry, Seoul National University, Seoul, Korea; 2) Department of Pediatric dentistry Pusan National University Dental Hospital Beomeo-Ri, Mulgeum-Eup, Yangsan-Si, Gyeongsangnam-Do, Korea; 3) Department of Pediatric Dentistry & Dental Research Institute School of Dentistry, Seoul National University, Seoul, Korea.

Mutations in family with sequence similarity 83 member H (FAM83H) gene cause autosomal dominant hypocalcification amelogenesis imperfecta (ADHCAI). We performed mutational analyses on two Korean families with generalized ADHCAI and identified the disease-causing mutations. Mutations in family 1 (g.3115C>T, c.1993C>T, p.Q665X) and family 2 (g.3151C>T, c.2029C>T, p.Q677X) introduced nonsense codons in exon 5, the last coding exon. All ADHCAI-causing mutations terminate translation directly or by shifting the reading frame in the FAM83H coding region from Ser287 to Glu694, with mutations near Glu694 causing a milder, more localized phenotype. We tested the hypothesis that FAM83H truncation mutations alter the intracellular localization of the expressed protein. Wild-type FAM83H and p.E694X mutant FAM83H fused to GFP localized in the cytoplasm of HEK293T cells, but p.Q677X mutant FAM83H fused to GFP localized exclusively in the nucleus. We conclude that nuclear targeting of truncated FAM83H contributes to the severe, generalized enamel malformations in patients with ADHCAI, while truncated FAM83H localized to the cytoplasm functions partially and results in a milder, localized enamel defects. This work was supported by a grant from the Korea Science and Engineering Foundation (KOSEF) grant funded by the Korea government (MEST) (No. R01-2008-000-10174-0(2010)) and by the Korea Research Foundation Grant funded by the Korean Government (KRF-2008-313-E00597), the Science Research Center grant to Bone Metabolism Research Center (2009-0063266) funded by the Korean Ministry of Education, Science and Technology.

Novel mutations in the HPS1 gene among Puerto Rican patients. *C. Carmona-Rivera[1], R.A. Hess[1], K. O'Brien[2], G. Golas[2], E. Tsilou[3], J.G. White[4], W.A. Gahl[1,2], M. Huizing[1].* 1) Med Gen Branch, NIH/NHGRI, Bethesda, MD; 2) Office of Rare diseases,NIH/NHGRI, Bethesda, MD; 3) Oftal Gen Vis Func Branch, NIH/NEI, Bethsda, MD; 4) Dept of Laboratory Medicine, U. Minnesota, Minneapolis, USA.

Hermansky-Pudlak Syndrome is a disorder of oculocutaneous albinism and platelet storage pool deficiency. Eight different disease causing genes have been identified, whose gene products are thought to be involved in the biogenesis of lysosome-related organelles. HPS type 1 (HPS-1) is the most common HPS subtype in Puerto Rico, with a frequency of 1:1,800 in the northwest of the island due to a founder mutation, i.e., a 16-base pair duplication in exon 15 of the HPS1 gene (c.1472_1487dup16; p.H497QfsX90). We identified three Puerto Rican HPS-1 patients who carried compound heterozygous HPS1 mutations. One patient was heterozygous for c.937G>A, causing a missense mutation (p.G313S) at the 3' splice junction of exon 10. This mutation resulted in activation of a cryptic intronic splice site causing an aberrantly spliced HPS1 mRNA that included 144-bp of intronic sequence, producing 11 novel amino acids followed by a stop codon. The other two patients were heterozygous for the previously reported c.972delC in HPS1, resulting in a frameshift and a premature stop codon (p.M325WfsX6). These findings indicate that, among Puerto Ricans, other HPS1 mutations apart from the 16-base pair duplication should be considered in the analysis of this population.

Case Reports of TGM1 Mutations in Iranian Patients with Lamellar Ichthyosis. *S. Ardalan Khales[1], S. Ardalan Khales[1], M. Houshmand[2], A. Farajieilanjegh[1].* 1) Medical Genetic Laboratory of Special Medical Center, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology, Tehran, Iran.

Autosomal Recessive Congenital Ichthyosis (ARCI) is a rare, heterogenous keratinization disorder of the skin, classically divided into two clinical subtypes, lamellar ichthyosis (LI) and nonbullous congenital ichthyosi-formis erythroderma (NCIE). Lamellar Ichtyosis is caused by mutations in the TGM1 gene that encodes the transglutaminase 1 enzyme, which is critical for the assembly of the cornified cell envelope in terminally differentiating keratinocytes. TGM1 is a complex enzyme existing as both cytosolic and membrane-bound forms. Moreover, TGM1 is proteolytically processed, and the major functionally active form consists of a membrane-bound 67/33/10-kDa complex with a myristoylated and palmitoylated amino-terminal 10-kDa membrane anchorage fragment.. In this study all 14 coding exons of TGM1 gene by using of PCR-Sequencing method in three Iranian patients with different phenotypes were investigated that a homozygote mutation (G218S) in exon 4 and three heterozygote mutations (R37K, D58N, D86N) in exon 2 were observed. The mutation (D86N) was shown in two patients simultaneously. KEY WORDS: TGM1, Lamellar, Ichthyosis, ARCI, NCIE.

2287/F

Novel *PCDH19* mutations causing EFMR. *S. Jamal[1,2], RK. Basran[1,2], S. Newton[1], Z. Wang[1,2], JM. Milunsky[1,2,3].* 1) Ctr Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Department of Pediatrics, Boston University School of Medicine; 3) Department of Genetics and Genomics, Boston University School of Medicine.

Epilepsy and Mental Retardation Limited to Females (EFMR) [MIM 300088] was first described in 1971 (Juberg et al.) in fifteen related females with early onset grand mal seizures and mental retardation. Although EFMR demonstrates X-linked inheritance, it follows an unusual pattern by sparing transmitting males and affecting only heterozygous females. In 2008, mutations within the protocadherin 19 (*PCDH19*) gene located at Xq22 were implicated as causative of EFMR (Dibbens, et al.). The EFMR phenotype is typically characterized by seizure onset in infancy and varying degrees of intellectual impairment. Sequence analysis of *PCDH19* gene: During a 12 month period (May 2009-May 2010), the Center for Human Genetics/ Boston University School of Medicine sequenced the *PCDH19* gene of 33 female patients with developmental delay and early onset epilepsy. We identified 5 patients (15% yield) with novel *PCDH19* sequence aberrations. Amongst the mutation-positive patients, exon 1 mutations (c.78delG, c.213delA, c.434-435insG, c.729C>A (p.Y243X)), were found in 80% (4/5) of patients. Two of the exon 1 mutation-positive patients were within the extracellular cadherin (EC) domain 1, whilst the remaining two mutations were in EC domain 2 and 3. The remaining patient had a mutation (c.2490-2493delTTTT) within exon 4 of the PCDH19 gene. To date, maternal and paternal samples of 3 of the 5 positive cases were negative; thus demonstrating the de novo nature of these alterations. More patients need to be studied to establish whether genotype-phenotype correlations exist. Clinical assessment of mutation-positive patients: Ages ranged from 3 years to 19 years all of whom had seizure onset in infancy requiring the use of multiple antiepileptic drugs. They also had varying degrees of intellectual impairment along with the presence of autistic features. Clinical history of the mutation-negative patients will also be reviewed to further characterize the pertinent features of EFMR. Prior to the identification of the causative gene, EFMR was more easily identified in large pedigrees where the phenotype occurred in multiple affected females connected through unaffected males, while in smaller families, the condition may be under recognized. With the recent availability of clinical testing for *PCDH19*, we recommend testing of this gene in females with early onset epilepsy, autistic features, and intellectual impairment, irrespective of family history.

2288/F

A nonsense mutation in the FMR1 gene causing classical fragile X syndrome. *K. Gronskov[1], K. Brondum-Nielsen[1], A. Dedic[1], H. Hjalgrim[2].* 1) Kennedy Ctr, Glostrup, Denmark; 2) Danish Epilepsy Centre, Dianalund, Denmark.

Fragile X syndrome is a frequent cause of inherited mental retardation. It is caused by lack of FMR1 gene product. The most common cause is an expansion of a CGG repeat located in the 5' UTR of FMR1. If the number of CGG repeats exceeds 200, the repeat and the CpG islands in the promoter region are methylated which abolish transcription. Only a few cases of patients with intragenic point mutations in FMR1 have been reported and routine analysis of patients referred for fragile X syndrome includes solely analysis for repeat expansion. We describe here a patient with classical clinical symptoms of fragile X syndrome; Southern blot analysis showed no expansion, however Western blot analysis showed no FMR1 product. Subsequently sequencing of the FMR1 gene revealed a substitution in exon 2, c.80C>A, causing a nonsense mutation p.Ser27X. The mother was a heterozygous carrier of the mutation, and presented with mild mental retardation. This shows that in patients with typical symptoms of fragile X syndrome, in whom no expansion is detected, further studies including sequence analysis of the FMR1 gene should be performed.

2289/F

***FMR1* premutation and fibromyalgia.** *M. Mila[1,2], J. Blanch[3], I. Madrigal[1,2], D. Martinez[1], C. Badenas[1,2], A. Collado[4], J. Carbonell[3], L. Rodriguez-Revenga[1,2].* 1) Gen Service, Hosp Clinic, Barcelona, Spain; 2) CIBER de Enfermedades Raras (CIBERER), Barcelona, Spain; 3) Rheumatology Department, Hospital de Mar, Barcelona, Spain; 4) Rheumatology Department, Hospital Clinic. Barcelona, Spain.

Within the past few years, there has been a significant change in identifying and characterizing the *FMR1* premutation associated phenotypes. The premutation has been associated with elevated *FMR1* mRNA levels and slight to moderate reductions in FMRP levels. Furthermore, it has been established that ~ 20% of female premutation carriers present primary ovarian insufficiency and that FXTAS occurs in 16.5% of female premutation carriers and in 45.5% of premutated males older than 50 years. Besides primary ovarian insufficiency and FXTAS, new disorders have recently been described among individuals (especially females) with the *FMR1* premutation. Those pathologies include thyroid disease, hypertension, seizures, peripheral neuropathy, and fibromyalgia. Among fragile X families we have detected that more than 18% of females with the *FMR1* premutation present fibromyalgia. In the present study we have screened 200 DNA samples from the National DNA bank of Spain corresponding to women with a clinical diagnosis of fibromyalgia for *FMR1* CGG repeat expansion. Results showed two females carrying *FMR1* premutation alleles, giving a frequency of 1%. This frequency is much higher than the one reported in the Spanish population (1/411 females are found to be *FMR1* premutation carriers) indicating that *FMR1* gene could be one of the genes implicated in the etiology of fibromyalgia. ACKNOWLEDGMENTS This work was supported by FIS 09-00413. The CIBER de Enfermedades Raras is an initiative of the ISCIII.

Sandhoff disease: A novel mutation in the HEXB gene. *H. Aryan[1], M. Hushmand[1,2], O. Aryani[1].* 1) Genetic, Special Medical Center, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology, Karaj-Tehran, Iran.

Sandhoff disease is a rare, genetic, lipid storage disorder resulting in the progressive deterioration of the central nervous system which is an autosomal recessive lysosomal storage disorder due to mutations in HEXB, the gene coding for the b-subunit of b hexosaminidases A and B. Both Hex A and Hex B activities are deficient in Sandhoff disease. The classic infantile form of the disease has the most severe symptoms. The first signs of symptoms begin before 6 months of age and the parents' notice when the child begins digressing in their development. Our case was a child with low activity of both Hex A and Hex B enzyme. We used sequencing method to detect mutations in the HEXB gene. Sequencing results showed a homozygote deletion T (c.183 delT) in our patient. Materials and Methods: Preparation of Genomic DNA: DNA of fresh blood samples prepared from patients was extracted using flexigene DNA extraction kit. DNA Amplification and Direct Sequencing: Both exonic and intron/exon junctions of Genomic DNA amplified by PCR considering that each region amplified by two pairs of primers specifically. The reaction were performed in 50 µl volume of 4µl Genomic DNA, 1µl of each primer (10nm), 1µl MgCl2, 0.5 µl dNTP and 0.2 µ Taq polymerase. Amplification was done in a Thermal Cycler (Techne) for an initial denaturation 5min at 95°C and 32cycles, that each cycle consist of a denaturation 40s at 95°C, 40s annealing 50-60°C and extension 30s at 72°C, which followed by a final extension 10min at 72°C. These amplified PCR samples sequenced using ABI3370 (MacroGen, Korea). Result: Our case was a 2 year- old- male child with progressive cerebella ataxia and psychomotor retardation. Biochemistry analyses of hexosaminidase A and B in this patient showed a low activity in hexosaminidase B. Patient admitted with blindness and cherry-red macular spots, seizures, and myoclonus. In this study we used direct sequencing for detection of mutation.Direct sequencing of PCR products of exons and splicing sites for Hexb gene showed that the patient was homozygote for c.183del T (n.513 del T) in exon 4 (leading to stop codon in codon 206, exon 5). His parent blood was used to confirm this mutation. Sequencing results for his parent showed heterozygote state for the mentioned mutation.

ACVRL1 germinal mosaicism with two mutant alleles in a family with Hereditary Haemorrhagic Telangiectasia associated with PAH. *M. EYRIES[1,4], F. COULET[1,4], F. PIRES[1], M.C. WAILL[1], B. GIRERD[2], D. MONTANI[2], M. HUMBERT[2], P. LACOMBE[3], J. ROUME[3], F. SOUBRIER[1,4].* 1) Laboratoire d'Oncogénétique et d'Angiogénétique moléculaire , Groupe Hospitalier Pitie-Salpetriere, Paris, France; 2) Centre National de Référence de l'hypertension pulmonaire sévère, Service de pneumologie, Hôpital Antoine Béclère, Université Paris-Sud 11, INSERM U999, Clamart, France; 3) Service de Génétique, Hôpital Ambroise Paré, Boulogne, France; 4) Université Pierre et Marie Curie (UPMC), Paris, France.

Pulmonary Arterial Hypertension (PAH) and Hereditary Hemorrhagic Telangiectasia (HHT) are distinct clinical entities caused by germline mutations in genes encoding members of the TGF-β/BMP superfamily: BMPR2 in PAH and ACVRL1, ENG, or SMAD4 in HHT. When PAH and HHT co-exist within the same family, ACVRL1 mutations predominate. We report a remarkable ACVRL1 germinal mosaicism characterized by the presence of two mutant alleles in a woman initially diagnosed with PAH at age 21. She also met the Curaçao diagnostic criteria for HHT based on additional findings of telangiectases and epistaxis. Mutation analysis of ACVRL1 identified two closely located heterozygous deleterious mutations within exon 10: c.1388delG (p.Gly463fsX464) and c.1390del (p.Leu464X). DNA of the index case's parents was not available because they were deceased. However, they did not have any sign of the disease, like the four sisters of the index case, suggesting that mutations found are both neomutations. We performed allele-specific PCR analysis to quantify the two mutant alleles in lymphocytes of the index case demonstrating that c.1388delG is the predominant mutation suggesting that the mutational event leading to this mutation occurs earlier than the one leading to the c.1390del. Both mutant alleles were detected by direct sequencing in lymphocytes, buccal swab, urine sediments and hair roots of the patient indicating a mosaicism affecting ectoderm and mesoderm derivatives. The two mutations were transmitted independently to the three sons of the index case. One son received the c.1388delG and two sons received the c.1390del. They all present symptoms of HHT with various intensity but genotype/phenotype correlation is not currently interpretable because of their young age. The presence of these two distinct alterations results probably from two successive mutational events that occurred very early during embryogenesis. The proximity of the two mutation sites might be explained by their localisation within a palindromic region of 6 bp. These regions are known to form conformational structures that favour deletion of DNA. This is the first known report of ACVRL1 germinal mosaicism characterized by the presence of two mutant alleles responsible for HHT.

2292/F

Common splicing mutation in *CCM2* in the Ashkenazi Jewish population. *C.J. Gallione[1], A. Solatycki[2], D.A. McDonald[1], I.A. Awad[3], J.L. Weber[2], D.A. Marchuk[1].* 1) Dept Genetics, Duke Univ Medical Ctr, Durham, NC; 2) PreventionGenetics, Marshfield, WI; 3) Section of Neurosurgery, University of Chicago Pritzker School of Medicine, Chicago, IL.

Cerebral Cavernous Malformations (CCM) are vascular malformations of the central nervous system consisting of clusters of dilated vessels, leading to stroke, seizures and focal neurological deficits. CCM occurs sporadically and as an autosomal dominant trait. Three genes have been identified for inherited CCM, and mutations in one of these three genes are identified in the majority of CCM families. Routine genetic testing for CCM in six unrelated patients self-reporting as Ashkenazi Jewish revealed the same 2-base pair change in *CCM2*, c.30+5_6delinsTT, however the significance of this variant was unclear since it does not occur within the canonical splice donor site. Furthermore, aberrant splicing of the first exon of a gene can be difficult to predict, precluding simple assay design for experimental validation of the putative splicing defect. We have confirmed this difficulty by showing that RT-PCR from patient blood with this mutation does not exhibit an aberrantly spliced variant. However, using a common polymorphic SNP in exon 2 to track the fate of the two alleles, we show that the RT-PCR product consists of only one allele. Both alleles are present in RT-PCR products from normal individuals harboring the same common SNP, confirming that the loss of one allele is due to the *CCM2*, c.30+5_6delinsTT variant. These data provide proof that this sequence variant is the causative mutation in these families. We are currently examining SNP haplotypes surrounding *CCM2* exon 1 to determine whether this mutation has arisen from a founder in the Ashkenazi Jewish population. The results of this study could lead to a rapid genetic test for CCM in individuals of this population.

Isolated ectopia lentis: report of a new deletion in the *ADAMTSL4* gene and evidence for genetic heterogeneity of the autosomal recessive form of the disease. *N. Hanna[1,2], G. Sultan[3], C. Muti[2], B. Grandchamp[2], L. Gouya[1,2], S. Funtowiez[2], D. Lacombe[4], H. Dollfus[5], C. Baudouin[3,6], G. Jondeau[2], C. Boileau[1,2,7].* 1) Laboratoire de Génétique moléculaire, Hôpital Ambroise Paré, AP-HP, Université Versailles-Saint Quentin en Yvelines, Boulogne, France; 2) Centre de Référence Marfan, Hôpital Bichat, AP-HP, Paris, France; 3) Service d'Ophtalmologie, Hôpital Ambroise Paré, AP-HP, Boulogne, France; 4) Service de Génétique Médicale, Hôpital Pellegrin, CHU de Bordeaux, Université Bordeaux II, France; 5) Centre de Référence pour les Affections Rares en Génétique Ophtalmologique (CARGO) et Service de Génétique Médicale, Hôpitaux Universitaires de Strasbourg, Strasbourg, France; 6) Centre Hospitalier National d'Ophtalmologie des Quinze-Vingts, Paris, France; 7) Inserm U781, Hôpital Necker-Enfants Malades, Paris, France.

Ectopia lentis (EL) is characterized by partial or complete displacement of the lens. Often associated with systemic diseases (such as homocystinuria, Marfan syndrome or Weill-Marchesani syndrome) it can also appear as an isolated condition with autosomal dominant (ADEL, OMIM#1296000) or autosomal recessive (AREL, OMIM#225100) inheritance. ADEL has been associated with mutations within the *FBN1* gene, while only two mutations have been identified to date in the *ADAMTSL4* gene in families with AREL (Ahram *et al*., 2009; Greene *et al*., 2010). To evaluate the contribution of *ADAMTSL4* gene mutations to isolated EL, we studied 12 French probands negative for homocystinuria and with no mutation within the *FBN1* gene. Bidirectionnal sequencing of the 17 coding exons of the gene was performed. When available, family studies were performed and regional haplotypes were constructed with 9 microsatellite makers flanking the gene at 1q21.3. An unreported and identical homozygous frameshift deletion was found in 2 unrelated probands: c.767_786del, p.Gln256ProfsX38. Family analysis showed that the mutation was carried on two different haplotypes, one proband carrying the two haplotypes. In the 10 remaining EL probands, no mutation was identified in the *ADAMTSL4* gene to explain the EL phenotype. Interestingly, one of these probands belonged to a small French family of Gypsy origin with 4 affected children. None of the affected children were haplo-identical thus demonstrating exclusion of the gene locus. In the same way, linkage was also excluded to the *FBN1* gene. In conclusion, in a small sample of EL probands, only 2/12 (16 %) of EL cases were related to a mutation in the coding sequence of the *ADAMTSL4* gene. Furthermore, we report a family with AREL unlinked to either of the known genes associated with EL. This family demonstrates the existence of further genetic heterogeneity in isolated ectopia lentis.

The maternal pattern of X-chromosome inactivation as a parameter for evaluating the contribution of X-chromosome mutations to mental retardation in males. *A.M. Vianna-Morgante, K.N. Coqueti, P.A. Otto.* Departamento de Genética e Biologia Evolutiva, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brazil.

Nearly a third of obligate carriers of mutations causative of X-linked mental retardation (XLMR) have been reported to have extreme X-inactivation skewing (≥ 90:10) in peripheral blood cells, compared to about 2% of their non-carrier relatives (Plenge et al., Am J Hum Genet 71:168, 2002). Selective advantage of cells with the non-mutated allele on the active X chromosome would explain this skewing. Based on these findings, we used the pattern of X-inactivation in mothers of mentally retarded boys as a parameter to evaluate the frequency of XLMR among non-familial cases. To determine the X-inactivation pattern in these women, we investigated the methylation status of the *AR* alleles in blood cells. We selected 100 boys with moderate to severe mental retardation of unknown cause, who had normal karyotypes and tested negative for fragile X syndrome; their mothers were heterozygous for the polymorphic CAG repeat of the *AR* gene, a requisite of the X-inactivation assay. Ten women (10%) had completely skewed X-inactivation (100:0), a frequency significantly higher (P = 0.0001; Fisher exact test) than the frequency reported for adult women from the general population (1.7%; 95% CI = 0.0068 - 0.0345; Amos-Landgraf et al., Am J Hum Genet 79:493, 2006). Assuming that every mother with completely skewed X-inactivation is a carrier of an X-chromosome mutation that causes mental retardation in her son, the frequency of XLMR in our sample of 100 boys is 10% (95% CI = 0.0490 - 0.1762), the fragile X syndrome being excluded. Although these figures are quite in agreement with previous estimations of the frequency of XLMR among mentally retarded men, they might be an underestimation, when it is taken into account that only about a third of obligate carriers of XLMR mutations have highly skewed X inactivation. Financial Support: FAPESP (CEPID 9814254-2) and CNPq.

The Greek mitochondrial genome does not harbor deafness-causing mutations. *H. Kokotas[1], M. Grigoriadou[1], G.S. Korres[1], E. Ferekidou[1], D. Kandiloros[2], S. Korres[3], M.B. Petersen[1].* 1) Department of Genetics, Institute of Child Health, 'Aghia Sophia' Children's Hospital, Athens, Greece; 2) B' Department of Otorhinolaryngology - Head and Neck Surgery, Athens University Medical School, Attikon Hospital, Athens, Greece; 3) A' Department of Otorhinolaryngology - Head and Neck Surgery, Athens University Medical School, Hippokration Hospital, Athens, Greece.

Hearing impairment is one of the most common sensory handicaps with a frequency of at least 1/1,000, whereas at the age of 80 years more than 50% of the elderly have developed hearing loss severe enough to impair communication. Mitochondria harbor their own DNA, known as mtDNA, encoding certain essential components of the mitochondrial respiratory chain and protein synthesis apparatus. MtDNA mutations have an impact on cellular ATP production and many of them are undoubtedly a factor that contributes to sensorineural deafness, including both syndromic and non-syndromic forms. Mitochondrial mutations are present in less than 1% of the children with prelingual deafness, but are more frequent at a later age. In the Caucasian population at least 5% of postlingual, non-syndromic hearing impairment is due to known mtDNA mutations in some studies, representing the most frequent cause of hearing loss after the 35delG mutation in the GJB2 gene encoding connexin 26 in some populations. The use of aminoglycoside antibiotics can cause hearing loss in genetically susceptible individuals. Hot spot mutation regions for deafness mutations are the MTRNR1 gene, encoding the 12S rRNA, the MTTS1 gene, encoding the tRNA for Ser(UCN), and the MTTL1 gene, encoding the tRNA for Leu(UUR). Specific mtDNA mutations are usually involved in either non-syndromic or syndromic cases; however there are mtDNA mutations that have been reported to cause deafness in both syndromic and non-syndromic cases. The fact that scientists usually perform tests in either a cohort of patients with syndromic or a cohort of non-syndromic patients but rarely in a combined cohort means that there is a chance of mtDNA mutations to go undetected in several deafness cases. For this reason, we investigated the MTRNR1 A1555G mutation, the MTTL1 A3243G mutation, and the MTTS1 A7445G, 7472insC, and T7510C mutations in the Greek population, by testing 513 unrelated cases suffering either from prelingual or postlingual, bilateral, sensorineural, syndromic or non-syndromic deafness using PCR-RFLP protocols. The homoplasmic A1555G mutation was detected in two familial cases, one of which was found negative and the other heterozygous for the common GJB2 35delG mutation. None of the cases presented with the A3243G, A7445G, 7472insC, or T7510C mutations. We conclude that the A1555G mutation is rather uncommon in the Greek population and that in general, the Greek mtDNA is void of deafness-causing mutations.

Gene expression profiling in facioscapulohumeral muscular dystrophy muscles. *F. Rahimov[1], O.D. King[2], L.C. Warsing[3,4], J. Chen[2], K. Hanger[2], R.J. Bloch[5], J.B. Miller[2], C.P. Emerson, Jr.[2], K.R. Wagner[3,4], L.M. Kunkel[1,6].* 1) Division of Genetics, Children's Hospital Boston, Boston, MA; 2) Boston Biomedical Research Institute, Watertown, MA; 3) The Johns Hopkins University, School of Medicine, Baltimore, MD; 4) Kennedy Krieger Institute, Baltimore, MD; 5) University of Maryland School of Medicine, Baltimore, MD; 6) Howard Hughes Medical Institute.

Facioscapulohumeral muscular dystrophy (FSHD) is a progressive myopathy caused by deletions of integral number of repeat elements within the subtelomeric macrosatellite element D4Z4 on chromosome 4q35. However, the underlying mechanism by which FSHD arises is poorly understood. We performed global transcriptome profiling of mature muscle tissues collected from affected and unaffected individuals from 14 cohorts using the Affymetrix GeneChip® 1.0 ST array and RNA sequencing approaches. We identified a number of differentially regulated genes between affected and unaffected muscle tissues. In addition, we performed high-throughput quantitative real-time RT-PCR analysis on 46 growth and differentiation marker genes and several candidate genes residing on chromosome 4q35 in muscle tissues and primary cell lines derived from these tissues using the Fluidigm Biomark System. The putative biomarker genes identified in this study will be valuable for understanding the molecular etiology of FSHD and assessing the success of clinical trials for this disease.

Rescue from the lethal phenotype of Herlitz junctional epidermolysis bullosa by spontaneous read-through of a nonsense mutation. *F. Pacho, H. Schneider.* Department of Pediatrics, University of Erlangen-Nuremberg, Erlangen, Bavaria, Germany.

Mutations in the laminin-332 genes, LAMA3, LAMB3 and LAMC2, are known to cause junctional epidermolysis bullosa (JEB). Patients carrying a nonsense mutation in both alleles of any of these genes normally die in infancy due to widespread skin wounds, loss of fluid, cells and proteins, and severe infections. In a child with JEB and compound-heterozygous LAMA3 nonsense mutations as typically seen in the lethal Herlitz type of JEB, we observed clinical and molecular rescue due to spontaneous premature termination codon (PTC) read-through. RNA from keratinocytes of this patient was shown to include a full-length transcript with the PTC, which partially escaped nonsense-mediated mRNA decay. Translation of the mRNA is expected to result in a truncated laminin α3 protein lacking approximately 40 amino acids of the laminin globular domain 1 and the entire globular domains 2 to 5. The truncated α3 chain may be able to associate with laminin chains β3 and γ2 to laminin-332, but would lack binding sites for integrins responsible for tight adhesion of the basal keratinocytes to the underlying dermis. Analysis of skin biopsies and a continuous improvement of the patient's condition indicated, however, that translational read-through allowed deposition and accumulation of laminin-332 molecules with a full-length α3 chain in the epidermal basement membrane, outweighing laminin-332 turnover. To elucidate this phenomenon, various PTCs surrounded by their natural neighbouring codons were cloned between an ATG codon and an EGFP reporter gene and introduced into 293 cells by retroviral gene transfer. FACS analysis revealed significant reporter gene expression despite the PTC mutation only for the genetic context of our patient. Gene expression could be reduced to background levels by replacing the base before, or the 1st or 2nd base behind the UGA. Site-directed mutagenesis was used to identify genotypes allowing PTC read-through. The genetic context of the naturally occurring mutation of our patient is close to a hypothetical consensus sequence for maximum PTC read-through. These findings provide clues for the prediction of PTC read-through in human genetic disease.

2298/F

Different mutations in three Jewish families with Darier's disease. *L. Peleg[1], M. Karpati[1], B. Amichai[2].* 1) Danek Gertner Human Genetic Inst, Sheba Medical Ctr, Ramat Gan, Israel; 2) Dept Dermatology, Huzot Clinic, Clalit health Service, Ashkelon, Israel.

Darier's disease (DD) is an autosomal dominant skin disorder characterized by loss of adhesion between epidermal cells and abnormal keratinization. The disease has a world wide distribution with a varied prevalence. Defects in the sarco/endoplasmic reticulum Ca2+ ATPase type 2 underlie DD. The encoding gene ATP2A2 is positioned on chromosome 12q23-24. To date about 150 mutations had been identified in familial and sporadic cases. The aim of this study was to identify the genetic defect in patients from three unrelated Jewish families with DD. DNA was extracted and PCR was carried out to amplify the exons and flanking intron region of the ATP2A2 gene. The amplified fragments were then sequenced using ABI 3130 XL Genetic Analyzer. Two novel mutations were identified in two families: a C®T substitution at position 391, altering arginine 131 to stop codon was identified in three members of an Ashkenazi family. An A to C change at position 530 altering glutamine 177 to proline was found in four patients of an unrelated Ashkenazi family. These mutations were not found in 50 healthy individuals of the same ethnic origin. Codons 131 and 177 are located in a highly conserved cytoplasmic β-strand domain and thus are candidates to actually be disease causing. Two other mutations in codon 131 were already reported in non-Jewish patients. In the third family of a Tunisian extraction, Asparagine 767 was change to Serine (A2300G). That mutation was already reported as a disease causing mutation in European and Japanese patients. The existence of different mutations in three Jewish families verify the previously published reports that most mutations in that gene are private.

Identification of recombinant alleles using Quantitative Real-time PCR: Implication for Gaucher disease. *A. Velayati, M.A. Knight, B.K. Stubblefield, E. Sidransky, N. Tayebi.* Section on Molecular Neurogenetics, Medical Genetics Branch/ NHGRI, NIH, Bethesda, MD.

Background: Gaucher disease is an autosomal recessive disorder caused by the deficiency of glucocerebrosidase. The glucocerebrosidase gene (GBA) is located in a very gene-rich region on chromosome 1q 21. The presence of contiguous, highly homologous pseudogenes for both GBA and metaxin 1 at this locus increases the likelihood of DNA rearrangement. We describe an easy method to identify and analyze recombinant alleles in patients with Gaucher disease. Methods: Genomic DNA from twenty patients with Gaucher disease known to carry recombinant GBA alleles and five controls were studied. Six different probes for either the GBA gene or pseudogene were designed to identify DNA rearrangements, as well as copy number variation within the GBA locus. Quantitative real-time PCR using TaqMan probes was performed on genomic DNA, and β-globin was co-amplified as an internal control. Southern blot analyses using the restriction enzyme HincII and direct sequencing were performed to confirm the real-time results. Results: GBA fusions and duplications could be detected in all the cases, corresponding to the Southern blot results. Different sites of recombination could also be distinguished. Conclusion: Quantitative real-time PCR is a sensitive and rapid method to detect fusions and duplications in patients with recombinant GBA alleles. Since this technique is faster and cheaper than Southern blotting, it can be applied as a suitable method in diagnostic laboratories. Keywords: Gaucher disease, glucocerebrosidase, recombinant alleles.

2300/F

KCNQ2 and KCNQ3 mutations in familial and sporadic cases of Benign Familial Neonatal Convulsions. *N.E. Verbeek[1], M. Poot[1], F.E. Jansen[2], D. Lindhout[1], M.J.A. van Kempen[1].* 1) Medical Genetics Dept; 2) Neuropediatrics Dept, University Medical Center Utrecht, Utrecht, Netherlands.

Background: Benign neonatal epilepsy (EBN) is an autosomal dominantly inherited epilepsy syndrome, characterized by seizure onset in the first week postnatally, spontaneously resolving within a few months. In the vast majority of patients, psychomotor development is normal, but seizures may recur in up to 15% of patients later in life. EBN is caused by mutations in the voltage-gated potassium channel subunit gene KCNQ2 (20q13.3) or KCNQ3 (8q24). The majority of reported mutations was found in KCNQ2 (92%). This is possibly due to a lower number of patients being analysed for KCNQ3 mutations. Purpose of this study is to determine the frequency of KCNQ2 and KCNQ3 mutations in EBN families and sporadic cases.

Methods: MLPA- and sequence analysis of the KCNQ2 and KCNQ3 gene was performed in patients with neonatal seizures. Larger deletions were analysed with Infinium humanhap300 SNP-array (Illumina, San Diego, USA).

Results: In total 62 probands were referred to our laboratory with the indication EBN. In this cohort 42 patients were confirmed clinically to have (possible) benign neonatal seizures (26 were familial cases and 16 were sporadic). In 16 families and 9 sporadic cases mutations in the KCNQ2 gene were detected, consisting of missense, splice-site, frameshift or nonsense mutations, and large deletions (ranging from 49 to 479 kbp containing one to 14 annotated genes). Additional analysis in 10 KCNQ2-negative probands (3 familial and 7 sporadic) revealed missense mutations in the KCNQ3 gene in 2 families and 2 sporadic cases.

Conclusions: KCNQ2 or KCNQ3 mutations were found in 69% of familial or sporadic cases. Mutation detection in neonates with (possible) benign neonatal seizures can prevent superfluous diagnostic procedures, provided DNA diagnostics has a short turn-around-time. In sporadic patients 82% were KCNQ2 and 18% were KCNQ3 mutations, which is higher than previously reported. Besides missense, splice-site, frameshift and nonsense mutations, large deletions comprise a substantial portion (16%) of KCNQ2-mutations, in KCNQ3 only missense mutations are found suggesting distinct mechanisms of etiopathogenesis.

2301/F

"Pseudoheterozygosity " in Autosomal Recessive Diseases. *H. Reznik-Wolf[1], A. Abu-Horowitz[1], Y. Bar-Joseph[1], M. Dushnitzki[1], B. Davidov[3], M. Frydman[1,2], H. Yonath[1,2], E. Pras[1,2].* 1) D Gertner Inst of Hum Genetics, Sheba Medical Ctr, Ramat-Gan, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Israel; 3) Institute of Medical Genetics, Rabin Medical Center, Israel.

In most autosomal recessive diseases the mutations can be identified in both genomic DNA (gDNA) and coding DNA (cDNA). Rarely, a single mutation is identified in gDNA in heterozygous state, while in the cDNA the mutation is found in a hemizygous state. A baby boy with severe lactic acidosis due to complex I deficiency, passed away at 5 months of age. cDNA, extracted from his fibroblasts, revealed a homozygous mutation (R228Q) in *NDUFS2*. The genomic DNA from the parents was studied to assure their carrier state. Surprisingly, the mother did not carry the mutation, and was found to be homozygous for the wild type allele. Study of gDNA from the deceased child identified the mutation in heterozygous state. Comparing the gDNA and cDNA sequences revealed that the maternal allele was not expressed in the child's fibroblasts. The mother was found to be homozygous for all polymorphic markers and SNPs in the gene. Subsequent prenatal diagnosis performed with flanking and intra-genic polymorphic markers, identified that the fetus carries the same maternal allele as the deceased child, but a different paternal allele. A baby girl was born two years ago and she is healthy and developing well. We are still trying to identify the presumed regulatory maternal mutation. When only one mutation is found in an individual affected by an autosomal recessive disorder, the possibility of a mutation that affects expression should be considered.

2302/F

The Variant Spectrum of the Wilson Disease Gene, *ATP7B*, in Costa Rica. *D. Bugbee[1], C. Centeno-Cerdas[2], M. Sandi[3], A. Leal[3], D.W. Cox[1].* 1) Department of Medical Genetics, University of Alberta, Edmonton, Canada; 2) Department of Biochemistry School of Medicine, University of Costa Rica, San Pedro, Costa Rica; 3) Human Genetics Section School of Biology, University of Costa Rica, San Pedro, Costa Rica.

Wilson disease (WND) is an autosomal recessive copper deposition disorder that presents with hepatic and/or neurological signs anywhere from 3 to 70 years of age. The gene causing Wilson disease was identified in 1993 as *ATP7B*. A P-type ATPase, ATP7B excretes excess copper from the liver into the bile. Variation of the *ATP7B* gene can lead to protein products with decreased copper transport and trafficking activity. Decreased protein function results in a toxic copper buildup within several tissues that is fatal if untreated. To date, 644 gene variants have been identified, of which, over 500 are possibly disease causing as summarized within the Wilson Disease Database (http://www.wilsondisease.med.ualberta.ca/database.asp). Identification and classification of this variation is important to better understand its impact on protein function, copper accumulation, and in turn, Wilson disease. We have examined the specific variations of *ATP7B* found in Costa Rican patients. We partially/fully sequenced the *ATP7B* gene in a series of 26 WND patients from 18 different families. Possible disease causing variants (DV) M1I, M645R, M665I, L708P, I1184T, H1207R, and N1270S were all identified. M645R, M665I, L708P, and N1270S have Mediterranean origins. N1270S is the most frequent DV being 57.5% of all DVs found in the patient set. M1I and I1184T are novel to this study. I1184T is a polar to nonpolar amino acid change in the ATP loop which is predicted to be disease causing by the algorithm SIFT (Sorting Intolerant From Tolerant). The effect of the start site M1I variant is unknown, but might alter the translational initiation site in favour of an available downstream methionine located at c.97-c.99 (M33). Since this start codon is in-frame it is possible that a shorter ATP7B translation product is produced. The identification of these variants will help disease diagnosis in the Costa Rican population, and further adds to the variation spectrum of *ATP7B*.

2303/F

An Analysis of DNA Sequence Variation in the C2ORF71 Gene. *P.I. Sergouniotis[1,2], Z. Li[1], D.S. Mackay[1], L.A. Ocaka[1], G.A. Wright[2], S.R. Devery[2], A.T. Moore[1,2], A.R. Webster[1,2].* 1) UCL Institute of Ophthalmology, London, EC1V 9EL, United Kingdom; 2) Moorfields Eye Hospital, London EC1V 2PD, United Kingdom.

Mutations of *C2ORF71* have been recently reported to be associated with autosomal recessive (AR) retinitis pigmentosa (RP) in humans and defects in vision in zebrafish. The C2ORF71 gene is located on 2p23.2, is conserved in euteleostomi but has no evident paralogues. In humans, it is a 2-exon gene, predicted to encode a 1288 amino acid protein of unknown function that is expressed mainly in the photoreceptor cells of the retina. We sought to determine the prevalence of mutations in *C2ORF71* in cohorts of probands with progressive AR retinal dystrophy.

A combination of High Resolution DNA melting analysis (HRM) and automated DNA sequencing was used to screen *C2ORF71* in 286 affected unrelated individuals. Among them, 95 are affected with AR early onset retinal dystrophy and 191 are affected with AR adult onset retinal disease. 151 European and 40 South Asian control DNAs were also screened in a similar fashion.

Overall, 40 DNA sequence variants were detected. Among them, 28 were novel with 17 changes found in controls (8 missense, 7 synonymous, 2 other). Importantly, 11 novel variants (6 missense, 5 synonymous) in 20 alleles were detected in our cohort of patients but not in controls. Only one proband was compound heterozygote but segregation analysis revealed her unaffected father to be homozygous for one of the putative mutations. Average heterozygosity of the *C2ORF71* coding region, a measure of the probability of non identity of two randomly chosen chromosomal sites, was found to be 2.12×10^{-3}. This value is 12 to 700 times greater than that of three other retina disease genes examined in the similar fashion (*ABCA4, VMD2* and *EFEMP1*).

HRM is an economical, fast and sensitive PCR-based method for detecting DNA sequence variants. However, on two occasions, misincorporation of nucleotides during the PCR process prior to HRM was observed, reducing the specificity of the method. *C2ORF71* is a highly polymorphic gene with many rare variants, and this confounds mutation detection. Further analysis will determine the spectrum of retinal disease caused by mutations in *C2ORF71* and distinguish true pathogenic alleles from the high background of polymorphism elucidating the role of this rare cause of RP in the visual process.

2304/T

Tafazzin mRNAs of Barth Syndrome Individuals. *I. Gonzalez, A. Manolakos, V. Funanage, S. Kirwin.* Biomedical Research, Nemours/AI duPont Hospital for Children, Wilmington, DE.

Barth syndrome (BTHS, OMIM 302060) is due to mutations in the tafazzin (TAZ) gene located on Xq28. The tafazzin protein is an acyltransferase involved in the remodeling of cardiolipin, a component of the inner mitochondrial membrane. The phenotype includes dilated cardiomyopathy or left ventricular noncompaction, 3-methylglutaconic aciduria, neutropenia, skeletal myopathy, and growth delay. Biochemically, tetralinoleoyl cardiolipin is dramatically reduced and monolysocardiolipin accumulates. This study sought to determine how mutations affect TAZ mRNA quantities and alternative splice variants. To accomplish this, we used PAXgene tubes to collect blood samples from Barth syndrome individuals at the 2008 Barth Syndrome International Conference. Several studies were carried out: correlation of tafazzin splice variant distributions with the particular mutation of each subject; comparison of the proportions of splice variants between BTHS and healthy subjects; comparison of the mRNAs from bloods collected in PAX tubes with those of bloods collected in EDTA tubes; comparison of the splice variant distributions in EDTA bloods under simulated shipping delay conditions with those processed on the day of collection. For several samples we were able to compare tafazzin mRNAs from blood samples collected in PAX tubes with the mRNAs of blood cells that were cultured for 3 days in a previous study. We used FAM-labeled PCR primers to study splice variant distributions by capillary electrophoresis fragment analysis. As in our earlier study, where variants were cloned and sequenced, we found that besides the four main splice variants there is a large number of fragments that (by size) correspond to previously identified alternatively and incompletely spliced mRNA forms. PAXgene tube collection is claimed to yield mRNAs that represent the living condition as the mRNAs are stabilized from the moment of blood draw, and we found differences between this set of mRNAs and those from EDTA bloods and from cultured cells. We also found dramatic changes in mRNAs from EDTA bloods processed on the day of collection and those processed on the 3rd day, which would represent the effect of shipping delays. This study shows that TAZ mRNA requires immediate stabilization after blood draw in order to yield the most reliable results; this result is likely applicable to other mRNAs.

2305/T

Digenic inheritance in Arrhythmogenic Right Ventricular Dysplasia (ARVD) identified by Multiplex Targeted High Throughput Sequencing. *J.L. Blouin[1], S. Nikolaev[2], A. Munoz[2], S.E. Antonarakis[1,2], S. Fokstuen[1].* 1) Dept Genetic Medicine, Univ Hosps Geneva, Switzerland; 2) Genetic Medicine and Development, University of Geneva School of Medicine; Switzerland.

Cardiomyopathies and arrhythmias are common, seemingly monogenic autosomal dominant cardiac disorders. They are considered as primary cause of sudden cardiac death in young adults. These diseases are characterized by a remarkable genetic and allelic heterogeneity, which makes it difficult to unravel the causative mutation in a diagnostic laboratory. To circumvent these limitations, we used the new molecular diagnostic possibilities based on targeted high throughput sequencing of multiplexed barcoded samples. Five patients suffering from different monogenic cardiac disorders were analysed: 1 ARVD with a known pathogenic mutation (c.148_151delACAG) in exon 1 of Plakophilin-2 (*PKP2*) as a positive control, 2 long-QT syndromes and 2 hypertrophic cardiomyopathies (HCM) without known mutations. We designed a capture microarray that includes all exons of 132 genes involved in cardiovascular mendelian disorders (1 Mbp genomic region). Genomic DNA of the 5 patients were barcoded and mixed in equimolar amounts. Sequencing with paired-end 38 bp reads was performed in a single lane of a Illumina GAII, and data analysis was performed by MAQ software. Small coding indels, nonsense and non-synonymous variants probably damaging by Polyphen were scored and subjected to validation by Sanger sequencing. Potentially pathogenic novel variants were confirmed in 4 patients. First, in the patient known to have a causative mutation in *PKP2* gene, an additional nonsense variant (p.Lys991X) was found in Voltage-Gated Sodium Channel type V (*SCN5A*) gene. Mutations in *SCN5A* have mainly been described in long-QT and Brugada syndromes but have so far not been associated with ARVD. To our knowledge, this is the first report of a case of non-desmosomal digenic inheritance in ARVD. Second, a missense variant (p.Arg281Gln) in Acid Alpha-Glucosidase (*GAA*) gene (glycogen storage disease) was found in a patient diagnosed with HCM. Third, a missense variant (p.Met1384Ile) was detected in the Fibrillin (*FBN1*) gene (Marfan syndrome) in a 8 year old patient with long-QT syndrome. Finally, one patient with long-QT has a missense variant (p.Arg1860Ser) in *SCN5A* gene. Our results demonstrate that multiplex targeted high throughput sequencing holds considerable promises for molecular diagnosis of highly heterogeneous monogenic disorders in clinical practice, and allows a better understanding of the complexity of mendelian disorders.

Initial presentations of genotype-positive individuals with MYBPC3 gene mutation prior to left ventricular hypertrophy. *H. Wang[1, 2, 3], B. Xin[1], L. Nye[1], C. Troyer[1], S. De[4], A. Borowski[4], J. Thomas[4], W. Tang[4, 5].* 1) DDC Clinic for Special Needs Children, Middlefield, OH; 2) Department of Pediatrics, Rainbow Babies & Children's Hospital, Cleveland, OH; 3) Department of Molecular Cardiology, Cleveland Clinic, Cleveland, OH; 4) Department of Cardiovascular Medicine, Heart and Vascular Institute, Cleveland Clinic, Cleveland, OH; 5) Lerner Research Institute, Cleveland Clinic, Cleveland, OH.

Hypertrophic cardiomyopathy (HCM) is typically inherited in an autosomal dominant pattern with a variable age of onset and prognosis. We have recently reported over 20 Old Order Amish children with severe neonatal HCM caused by a novel homozygous mutation c.3330+2T>G in the cardiac myosin-binding protein C (MYBPC3) gene in the Ohio Amish population. This mutation in the splice-donor site of MYBPC3 intron 30 results in a frame-shift which leads to production of a truncated protein. It is estimated that approximately 1500 individuals carry this HCM-causative mutation in the community, which represents a very unique opportunity for us in further understanding of the condition, its development, diagnosis and prevention. In this study, we focused on the initial presentations of the genotype-positive individuals with MYBPC3 gene mutation, before they developed left ventricular hypertrophy (LVH). One hundred and three genotype-positive individuals were identified from high-risk families, and 57 individuals, twelve years-old or older, completed a questionnaire. They demonstrated various clinical complaints, including dizziness or lightheadedness (30%), heart racing or fluttering (35%), skipped heart beat (26%), easily tired (30%), shortness of breath (25%) and chest pain (30%). However, there were no significant differences in cardiac-specific biomarkers (including B-type natriuretic peptide levels and cardiac troponin I levels) as well as inflammatory biomarkers (including high-sensitivity C-reactive protein and myeloperoxidase levels), when we compared 55 genotype-positive individuals with 67 genotype-negative individuals. Echocardiogram was performed in 41 consecutive genotype-positive individuals. Of these, 6 were felt to have possible phenotype expression, with 4 having echocardiographic features of HCM and 2 having concentric LVH. The remaining 35 individuals' echocardiograms were compared with 30 healthy controls. There were minimal differences in conventional 2D and Doppler derived parameters of systolic and diastolic function between the genotype-positive carriers and healthy controls, although the regional reductions in basal septal strain were observed the genotype-positive carriers. We concluded that the genotype-positive individuals with MYBPC3 gene mutation may have significant clinical manifestations before the left ventricular hypertrophy is developed, and we need to develop strategies to effectively follow up this cohort in our future study.

2307/T

Molecular genetic spectrum in Korean patients with Long QT syndrome. *SY. Kim[1], EJ. Bae[2], CI. Noh[2], YJ. Hyun[1], SI. Cho[1], SW. Seo[1], H. Park[1], SH. Song[3], SS. Park[1].* 1) Department of Laboratory Medicine, Seoul National University Hospital, Seoul, Korea; 2) Department of Pediatrics, Seoul National University Children's Hospital, Seoul, Korea; 3) Department of Laboratory Medicine, Seoul National University Bundang Hospital, Seongnam, Korea.

The Long QT syndrome (LQTS) is an inherited arrhythmic disorder causing serious cardiovascular mortality. To date, at least 12 genes are known to cause the LQTS which principally encode cardiac ion channels. This study aimed to identify the mutation spectrum of Korean LQTS patients in the major causative genes *KCNQ1, KCNH2, SCN5A, KCNE1, KCNE2*, and *CACNA1C*.

We enrolled 39 unrelated Korean LQTS patients showing QTc interval of 470 ms or more prolongation, and their 46 familial members. Each gene was analyzed using comprehensive molecular genetic methods: direct sequencing for point mutations, multiplex ligation-dependent probe amplification for exonal deletion or duplication, and RT-PCR for the splicing site mutations. The significance of novel variants was assessed by familial segregation analysis, allelic frequency in normal control subjects, in silico prediction of the effect on protein function, and interspecies conservation of the amino acid.

Seventeen Korean probands (43.6%, 17/39) carried mutations in one of the genes: nine (52.9%, 9/17) with *KCNQ1* mutations, four (23.5%, 4/17) with *SCN5A* mutations, three (17.6%, 3/17) with *KCNH2* mutations, and one with *CACNA1C* mutation. Two de novo mutations were identified in the *KCNQ1* and *SCN5A*, respectively. Two rare syndromic patients were molecularly confirmed through this study: one proband was diagnosed with the autosomal recessive, Jervell and Lange-Nielsen syndrome. One was diagnosed with Timothy syndrome. Seven novel causative mutations were identified: p.Gln359_Lys362dup, p.Gly48SerfsX36, and splicing mutation p.V307V in the *KCNQ1*; p.Q1476K, p.W1345C, and p.R121W in the *SCN5A*; p.R20P in the *KCNH2*. Mutations were identified in 20 family members (43.5%), therefore appropriate management was provided for them.

This study identified molecular genetic characteristics of LQTS in Korean population previously unexplored. The *KCNQ1* was the most important gene in Korean patients. The *SCN5A* mutations had higher proportion in Korea than in western countries. No mutational hotspot region was observed. The genetic characteristics of Korean LQTS will be helpful for the diagnosis, appropriate medical therapies, and genetic counseling for the patients and their family members. This study also provides better understanding the worldwide spectrum of LQTS.

2308/T

A new locus for syndromic Thoracic Aortic Aneurysms and Dissections maps to chromosome 15q. *I.M.B.H. van de Laar[1], R.A. Oldenburg[1], J. Roos-Hesselink[2], B. de Graaf[1], I. Frohn-Mulder[3], Y. Hoedemaekers[1], M. Kros[4], P.M. Pattynama[5], S.M. Bierma-Zeinstra[6], E.H.G. Oei[5], B.A. Oostra[1], M.W. Wessels[1], A.M. Bertoli-Avella[1].* 1) Clinical Genetics, Erasmus Medical Centre, Rotterdam, Netherlands; 2) Department of Cardiology, Erasmus Medical Center, Rotterdam, the Netherlands; 3) Department of Pediatric Cardiology, Erasmus Medical Center- Sophia, Rotterdam, the Netherlands; 4) Department of Pathology, Erasmus Medical Center, Rotterdam, the Netherlands; 5) Department of Radiology, Erasmus Medical Center, Rotterdam, the Netherlands; 6) Department of General Practice, Erasmus Medical Center, Rotterdam, the Netherlands.

Background: Aortic aneurysms represent a leading cause of cardiovascular morbidity and mortality. Thoracic aortic aneurysms and dissections (TAAD) are a main feature of connective tissue disorders such as Marfan syndrome, Loeys-Dietz syndrome and vascular Ehlers-Danlos syndrome. Methods: We characterized the clinical spectrum of a large Dutch family with syndromic TAAD. Thirty family members had an extensive physical and cardiologic examination. Histological examinations of aneurismal aortas were performed. We carried out a genome-wide linkage analysis using Affymetrix 250k SNP arrays to localize the disease gene. Mutation analysis in functional candidate genes in the linkage interval is ongoing. Results: We describe a new syndromic form of TAAD with tortuosity throughout the arterial tree, skeletal, connective tissue anomalies and mild craniofacial features. Twenty-two patients were identified from whom 12 had aneurysms of the thoracic aorta (9 patients) or other arteries involving the pulmonary, splenic, common iliac, mesenteric, renal and vertebral artery. Aortic dissections and/or rupture occurred in mildly dilated arteries. Associated (congenital) heart defects were found as well. All patients had striking joint abnormalities, including early-onset intervertebral disc degeneration, osteochondritis dissecans and osteoarthritis (OA). We therefore name this syndrome TAAD/OA. Subsequently, we mapped its genetic locus to chromosome 15q with a significant multipoint LOD score of 3.6. All 12 patients with arterial aneurysms and 10 patients with a spectrum of skeletal and connective tissue anomalies were sharing the 15q21-q24.2 disease haplotype. Conclusions: We characterized the clinical spectrum of a new TAAD syndrome, TAAD/OA. The clinical phenotype overlaps with known syndromes such as Marfan syndrome, Loeys-Dietz syndrome and vascular type Ehlers-Danlos syndrome. Our data provide evidence for a new TAAD locus. Identification of the disease gene will give insight into the pathogenesis of arterial aneurysms and osteoarthritis.

2309/T

The Genetic Contribution to Hypothyroidism in a South Tyrolean Population. *C.B. Volpato[1], A. De Grandi[1], M. Facheris[1,2], C. Minelli[1], C. Pattaro[1], M. Gögele[1], A.A. Hicks[1], P.P. Pramstaller[1,2,3].* 1) Institute of Genetic Medicine, European Academy Bozen/Bolzano (EURAC), Bolzano, Italy Affiliated Institute of the University Lübeck, Germany; 2) Department of Neurology, Central Hospital, Bolzano, Italy; 3) Department of Neurology, University of Lübeck, Germany.

Thyroid hormones (THs) have important roles in growth and development. The key regulator of thyroid function is thyroid-stimulating hormone (TSH). Serum TSH is a indicator of thyroid function and the best assay to check thyroid function and clinically define hypothyroidism. In order to look for genes contributing to hypothyroidism we have used linkage followed by association under the linkage peaks. We used a South Tyrolean population (Italy) in whom the founder-population structure can simplify genetic analysis of complex traits. Samples from 1336 individuals were collected and genotyped with 1000 microsatellites and Illumina HumanHap300 SNP microarrays. To define individuals with hypothyroidism we used two accepted cutoff criteria (from the literature): TSH values over 3.0 mU/l for sub-physiological hypothyroidism, and over 4.60 mU/l for clinically-defined hypothyroidism. Merlin software was used for non-parametric genome wide linkage analysis. Two set of pedigrees were built, with 46 families (2 to 11 affected) using TSH >3.0 mU/l and 18 families (2 to 5 affected) using TSH >4.6 mU/l respectively. Linkage analysis with both criteria revealed overlapping linkage peaks in two regions, most notably at 6q26-27 where SNP association under the linkage peak identifies PDE10A as a gene of interest. Therefore, using a combination of microsatellite linkage and SNP association we have identified novel association to a gene that is involved in hypothyroidism in our South Tyrolean sample. The presence of linkage over PDE10A in families with clinical hypothyroidism supports the argument that functional variants within this gene contribute to the pathogenesis of abnormal thyroid function.

2310/T

Kallmann Syndrome in Finland. *J. Tommiska[1,2], K. Vaaralahti[1], E.-M. Laitinen[2], M. Tervaniemi[1], L. Valanne[3], T. Raivio[1,2].* 1) Institute of Biomedicine/Physiology, University of Helsinki, Helsinki, Finland; 2) Children's Hospital, Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Radiology, Helsinki University Central Hospital, Helsinki, Finland.

Kallmann syndrome (KS) is a clinically and genetically heterogeneous disorder comprised of isolated hypogonadotropic hypogonadism (IHH) and absent sense of smell (anosmia). KS results from disturbed intrauterine migration of gonadotropin-releasing hormone (GnRH) neurons to the hypothalamus. The exact incidence of KS is currently unknown. In familial KS (~40% of KS), autosomal dominant, autosomal recessive, and X-chromosomal recessive modes of inheritance have been described. Defects in 7 genes (*KAL1*, *FGFR1*, *FGF8*, *PROKR2*, *PROK2*, *NELF*, *CHD7*) have been shown to underlie KS. A heterozygous mutation in *FGFR1* is found in ~10% of cases. However, causative gene defect(s) can be identified in only ~30% of patients. We examined the nationwide incidence of KS in Finland. In addition, 30 probands (25 males; 5 females) were phenotyped in detail and analyzed for mutations in the coding regions of *KAL1*, *FGFR1*, *FGF8*, *PROKR2*, *PROK2*, and *NELF*. Three patients were also screened for mutations in *CHD7* due to phenotypic features associated with CHARGE syndrome. Between 1976 and 1987, among 767 778 newborns, 15 KS subjects were retrospectively identified giving a KS incidence of 1 in 51 000. A difference existed between the incidences in males (12/392 900) and females (3/374 878) (P=0.04). The phenotypic spectrum of the 30 probands ranged from severe hypogonadism with complete absence of puberty to reversal of IHH following androgen exposure. Importantly, all 5 females carried an *FGFR1* mutation and had severe IHH. Overall, 3 mutations in *KAL1* (C157CfsX46, R262X, g.2357_2360delAgta) and 9 in *FGFR1* (W4X, G48S, T82TfsX28, R209H, K321RfsX13, S436YfsX3, R609X, E670A) were detected. Mutant receptors G48S and E670A displayed impaired MAPK signaling *in vitro*, and were associated with variable olfactory and reproductive phenotypes in the families. No mutations were found in *PROKR2*, *PROK2*, *FGF8*, *NELF*, or *CHD7*, which may reflect the special genetic features of the Finnish population. Eighteen of 25 male probands (72%) remained without identified mutations, and 7 of them had severe IHH. This, together with the lack of mutations in any of the known KS genes apart from *FGFR1* and *KAL1*, implies the existence of previously undescribed gene(s) underlying KS in Finnish men. Indeed, sex-dependent penetrance of the mutations in KS genes yet-to-be discovered could explain the higher incidence of KS in males, as well as the *FGFR1* mutations as the sole cause of KS in Finnish females.

2311/T

Proline-rich domain of MYO15A is necessarily for hearing and stereocilia maintenance. *Q. Fang[1], J. Bird[2], A.A. Indzhykulian[3], M. Mustapha[1,4], S.M. Jones[5], I.A. Belayantseva[2], D.F. Dolan[1], T.B. Friedman[2], G. Frolenkov[3], S.A. Camper[1].* 1) University of Michigan Medical School, Ann Arbor , MI; 2) National Institute of Deafness and Communication Disorders, Rockville, MD; 3) University of Kentucky, Lexington, KY; 4) Stanford University, Palo Alto, CA; 5) East Carolina University, Greenville, NC.

Mutations in unconventional myosin *Myo15a* are responsible for profound congenital deafness and vestibular dysfunction in shaker 2 (*sh2*) and shaker 2J (*sh2J*) mice (Probst et al, 1998; Anderson et al, 2000). The *sh2* mutation likely inactivates the motor ATPase, while the *sh2J* deletion truncates the C-terminal PDZ ligand that is important for binding whirlin and transporting it to stereocilia tips (Belyantseva et al., 2005). As a result, stereocilia are abnormally short in both *sh2* and *sh2J* mutants. Mutations in the human ortholog, *MYO15A*, cause deafness *DFNB3* (Wang et al, 1998). Alternatively spliced transcripts predict multiple isoforms of MYO15A that include a large, evolutionarily conserved proline-rich N-terminal domain (Liang et al, 1999). The N-terminal domain is encoded solely by exon 2, and mutations in this exon have been linked to deafness in humans. Elegant studies in cochlear explants have shown that isoforms lacking the proline-rich N-terminal domain are sufficient to rescue stereocilia elongation and whirlin transport (Belyantseva et al, 2005). To test whether the proline-rich region has a distinct function, we generated a mouse model that recapitulates a human mutation in the proline-rich domain using knock-in technology. Knock-in mutants were profoundly deaf, but differ from *sh2* and *sh2J* mice in both hair bundle morphology and the absence of circling behavior. Vestibular evoked response testing did reveal subtle vestibular abnormalities. Cochlear stereocilia appear to develop normally with whirlin localized at their tips, but the stereocilia are not maintained, implicating the proline-rich region in preservation of the hair bundle. Classic genetic analysis of compound heterozygous mice containing different combinations of *Myo15a* mutant alleles revealed no evidence of allelic complementation for hearing or hair bundle maintenance, consistent with the functional importance of full length MYO15A isoforms containing the proline-rich domain for normal mammalian hearing. In conclusion, this new isoform-specific *Myo15a* mutant mouse suggests a novel function for the proline-rich N-terminus that is more critical for auditory function than for vestibular function.

2312/T

Examination of Gene Expression Patterns Associated with PMP22-related Auditory Dysfunction. *M.J. Kovach, T.A. Carver, T. Walker.* Biological & Environmental Sci, Univ Tennessee, Chattanooga, TN.

Characterization of genes responsible for deafness, and their expression patterns, can help dissect the molecular events underlying both deafness and normal hearing. A variant of Charcot-Marie-Tooth (CMT1E) disease associated with deafness, has been linked to point mutations in the PMP22 gene. Although PMP22 is largely expressed in Schwann cells responsible for nerve myelination, PMP22 mRNA has also been detected in a variety of non-neural tissues, including the cochlea and lungs, at critical times of tissue development. This widespread expression suggests a more universal biological function for the PMP22 protein. The mouse homolog of PMP22, Gas3, was first isolated as a Growth Arrest Specific gene. In non-neural tissues, Gas genes are induced during periods of growth arrest and downregulated at terminal differentiation. Gas genes are thought to function during the intervening period where cells committed to a particular lineage continue to divide at a reduced rate. Not surprisingly, Gas genes are known to regulate gene expression, apoptosis and timing of cell division. Thus, PMP22 appears to play a role in nerve myelination and cell growth regulation of non-neural tissues. This dual expression is consistent with both neural and cochlear hearing loss in CMT1E patients. This study examines the involvement of PMP22 in cochlear development, where we propose it acts as a transcriptional regulator of genes important to normal ear functions. We hypothesize that a mutation in PMP22 leads to abnormal gene expression patterns that characterize the deafness phenotype. The Trembler-J mouse was chosen as a model for PMP22-associated auditory dysfunction to study gene expression patterns at critical developmental time points. Lung tissue was used as a non-neural surrogate for the cochlear labyrinth. Tissues were collected from normal and TrJ mice throughout development and gene expression profiles were characterized by differential display and qRT-PCR. Thus far, ~100 differentially expressed transcripts have been identified and classified according to cellular function, 55% of which are homologs or family members of genes in the human cochlear library. Divergent patterns of PMP22 cochlear localization and expression are seen at the D7/D14 developmental transition. In the TrJ mouse, this transition is associated with an upregulation of genes involved in signal transduction and membrane/cytoskeletal processes, and downregulation of genes involved in cell cycling.

Disruption of the histone H3 acetylation gene, MYST4, leads to Noonan syndrome and hyperactivated MAPK signaling. *C. Thiel[1], M. Kraft[1], A.K. Voss[2, 3], T. Thomas[2, 3], I. Goehring[1], B.N. Sheikh[2, 3], L. Gordon[2], H.S. Scott[2, 3], G.K. Symth[2, 3], I.C. Cirstea[4], M.R. Ahmadian[4], U. Trautmann[1], M. Zenker[1], M. Tartaglia[5], A.B. Ekici[1], A. Reis[1], H.-G. Doerr[6], A. Rauch[1, 7].* 1) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany; 2) Walter and Eliza Hall Institute of Medical Research, Parkville, Melbourne, Australia; 3) Department of Medical Biology, University of Melbourne, Parkville, Australia; 4) Institute of Biochemistry and Molecular Biology II, Heinrich-Heine University Medical Center, Düsseldorf, Germany; 5) Dipartimento di Ematologia, Oncologia e Medicina Molecolare, Istituto Superiore di Sanità, Rome, Italy; 6) Division of Paediatric Endocrinology, University Hospital for Children and Adolescents, Erlangen; 7) Institute of Medical Genetics, University of Zurich, Schwerzenbach-Zurich, Switzerland.

Only recently awareness is rising that the genetic information of an individual is not only encoded by its nucleotide composition, but also based on the so called epigenome by means of epigenetic modifications of DNA and histones. By chromosomal breakpoint mapping in a patient with a Noonan syndrome phenotype encompassing short stature, blepharoptosis and attention deficit hyperactivity disorder, we identified haploinsufficiency of the histone acetyltransferase MYST4 as the underlying cause. Using acetylation, whole genome expression and chromatin immunoprecipitation studies in the patient, MYST4 siRNA cell lines and the querkopf mouse model we find that H3 acetylation is important for neural, craniofacial and skeletal morphogenesis, mainly by specifically regulating the MAPK signaling pathway. This further elucidates the complex role of histone modifications in mammalian development and adds a new pathomechanism to the phenotypes resulting from misregulation of the Ras signaling pathway.

2314/T

Expression profiles of SPG11 and SPG15 proteins, involved in hereditary spastic paraplegia with thin corpus callosum. *R.P. Murmu[1], E. Martin[1], P.S. Denora[1], M.P. Muriel[1], K.H. El Hachimi[1,2], T. Esteves[1], J. Fernandez[1], A. Dauphin[1], C. Duyckearts[1], A. Brice[1], G. Stevanin[1,2].* 1) CR-icm, INSERM / UPMC UMR_S975, NEB, Paris, France; 2) EPHE, Paris, France.

Hereditary spastic paraplegias (HSP) are genetically inherited and clinically diverse neurodegenerative disorders which are due to degeneration of the corticospinal tract and of additional syndrome-specific structures. Truncating mutations in the SPG11 and SPG15 genes cause complicated spastic paraplegia due to loss of the functions of spatacsin and spastizin, respectively. We explored the intracellular and tissue localisations of these proteins by using specific polyclonal anti-spatacsin (SPG11) and anti-spastizin (SPG15) antisera that we developed. We observed expression of both proteins in human and rat nervous systems, particularly strong in cortical and spinal motor neurons as well as in sensory neurons and retina. Both proteins were also expressed ubiquitously in embryos. In cultured cells, these two proteins had similar diffuse punctate, cytoplasmic and sometimes nuclear (spastizin) distributions. They partially co-localized with protein-trafficking vesicles, mitochondria or cytoskeleton. This study of the endogenous expression of spatacsin and spastizin shows similarities in their expression patterns that could account for their overlapping clinical phenotypes. The findings of our study are expected to shed light into the functions of these proteins which may provide insight into mechanisms underlying the degeneration of corticospinal tract in hereditary spastic paraplegias.

2315/T

Is 8860 variation a rare polymorphism or associate as a secondary effect of HCM disease? *M. Houshmand[1,2], M. Montazeri[2], N. Kuchekian[1].* 1) Medical Genetic, Special Medical Center, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology, Tehran, Iran.

mtDNA defects, both deletions and point mutations, have been associated with hypertrophic cardiomyopathies (HCM). The aim of this study was to establish a spectrum for mtDNA mutations in Hypertrophic cardiomyopathy (HCM) Iranian patients. HCM is widely accepted as a pluricausal or ultifactorial disease. Because of the linkage between energy metabolism in the mitochondria and cardiac muscle contraction, it is reasonable to assume that mitochondrial abnormalities may be responsible for some forms of HCM. Point mutations and deletions in the two hot spot regions of mtDNA were investigate by PCR and Sequencing methods. Some unreported point mutations have been founded in this study but no deletion was detected. Meanwhile some of these point mutations have been investigated among HCM patients for the first time. A8860G transition was presented in high proportion that resulted to the doubt that if this rare polymorphism associate as a secondary effect of HCM disease.

2316/T

Sorting defects of mutant CLC-Kb in Bartter syndrome. *E.J. Kamsteeg[1], R.D.A. Weren[1], J. Schoots[1], J.H. Robben[2], N.V.A.M. Knoers[1], H. Scheffer[1], P.M.T. Deen[2], L.H. Hoefsloot[1].* 1) Human Genetics, Radboud University Medical Center, Nijmegen, Netherlands; 2) Physiology, Radboud University Medical Center, Nijmegen, Netherlands.

Bartter syndrome (BS) is an autosomal recessive disorder characterized by renal salt wasting and hypokalaemic metabolic alkalosis. The primary defect is a reduced NaCl reabsorption in the thick ascending limbs of Henle's loop. Bartter syndrome type 3 (BS3) is caused by mutations in CLCNKB, encoding the renal chloride channel CLC-Kb. This chloride channel functions in the basolateral plasma membrane and transports chloride from the cell's interior to the interstitium. CLCNKB has many non-pathogenic variants, making detected missense variants difficult to interpret. Defects of these variants may include a disturbed subcellular sorting or defective gating. Analysis of these variants in polarized epithelial cells is a valuable tool to assess their sorting properties. Here, we present the analysis of the subcellular distribution of eleven CLC-Kb missense variants in such cells. CLC-Kb needs the scaffolding protein barttin to reach the basolateral plasma membrane. Therefore, barttin was stably-expressed in the polarized renal epithelial MDCK type II cells. These cells were then transiently transfected with GFP-tagged CLC-Kb encoding constructs and subjected to imunnofluorescence studies and confocal laser-scanning microscopy. Of the eleven variants, six (S113T, V170M, A204T, M427V, G465R and R595Q) were transported to the basolateral plasma membrane, like wt-CLC-Kb. Three others (P124L, G164R en L656P) were retained intracellularly, and colocalized to a major extend with an endoplasmic reticulum (ER) marker. The last two variants (G433E and C626Y) showed a unexpected staining of the nucleus, although the latter also is expressed in the basolateral plasma membrane. These data indicate that a subset of the CLC-Kb variants is properly sorted to the basolateral plasma membrane. These variants may reflect non-pathogenic variants, or pathogenic variants that are functionally impaired (i.e. defective gating). However, another subset is retained in the ER, as is common with misfolded membrane proteins, such as CFTR or AQP2. Finally, two other variants were missorted to the nucleus. The mechanism causing nuclear missorting remains to be determined. Altogether, studying the subcellular distribution of CLC-Kb variants in polarized cells is a valuable additive tool to test their pathogenicity.

2317/T

Insulin like growth factor-1 receptor gene (IGF1R) mutations in patients with intrauterine growth retardation (IUGR) and postnatal catch-up growth failure. *M.J. Kang[1], K.J. Kim[1], M. Hong[1], E.J. Seo[1,2], J.Y. Park[1], G.H. Kim[1,2], H.Y. Jin[3], B.H. Lee[1,2,3], S.M. Lee[4], H.W. Yoo[1,2,3].* 1) Genome Research Center for Birth Defects, University of Ulsan College of Medicine, Asan Medical Center Children's Hospital, Seoul, Korea; 2) Medical Genetics Clinic and Laboratory,University of Ulsan College of Medicine, Asan Medical Center Children's Hospital, Seoul, Korea; 3) Department of Pediatrics,University of Ulsan College of Medicine, Asan Medical Center Children's Hospital, Seoul, Korea; 4) Department of Pediatrics, Hanyang University Guri Hospital, Seoul, Korea.

The mutations in the *IGF1R* genes are associated with intrauterine growth retardation (IUGR) and postnatal growth failure. Here we report three patients from two unrelated Korean families with *IGF1R* mutation and their clinical and molecular genetic characteristics. All three patients showed unexplained IUGR (birth weight <-1.5 SDS) and persistent short stature (<-2.0 SDS). *IGF1R* gene analysis identified a novel heterozygous mutation of c.420delC (p.Ala110fsX20) in exon 2, resulting in a frame-shift with premature termination of IGF1R protein in family 1 with autosomal-dominant inheritance pattern. The expression of IGF1Rβ protein is reduced in patients' fibroblasts compared to that in control cell lines. Both IGF-1-induced autophosphorylation of P-Tyr of IGF1R and phosphorylation of downstream signaling protein, Akt were enhanced in a dose-dependent manner, but less efficiently in patients' fibroblasts than in control fibroblasts. Array CGH of chromosome 15 also identified a heterozygous deletion of 15q26.2 to 15qter, a region including *IGF1R*, in a sporadic case in family 2. This study demonstrates functional perturbation of the signaling pathway associated with cell growth in patients with *IGF1R* mutation, which should be included in differential diagnosis in familial IUGR patients without catch-up growth.

SMC1A MUTATIONS CAUSING CORNELIA DE LANGE SYNDROME AFFECT THE RECRUITMENT OF TRANSCRIPTION FACTORS. *A. Musio, S. Menga, L. Mannini.* Inst Tecnologie Biomed, CNR, Pisa, Italy.

Cornelia de Lange syndrome (CdLS, MIM#s 122470, 300590, 610759) is a rare disease characterised by mental and growth retardation, facial dysmorphism and limb abnormalities. It has been shown that CdLS is caused by mutations in cohesin and cohesin regulatory genes. Mutations in NIPBL, SMC1A and SMC3 genes have been identified in about 60% of CdLS patients. NIPBL is involved in the loading of cohesin onto chromatin, whereas SMC1A and SMC3 code for proteins belonging to the core cohesin complex. NIPBL mutations include point mutations, deletions and insertions, causing a null allele. SMC1A and SMC3 mutations are missense or small in frame deletions. Beyond its structural function in maintaining sister chromatid cohesion, cohesin plays additional roles distinct from its basic role. Depletion of cohesin genes leads to chromosome aberrations, whereas mutations are associated to colorectal cancer, suggesting that cohesin is a genome stability caretaker. In addition, experimental evidence obtained in Drosophila, Saccharomyces cerevisiae, zebrafish and mammalian cells highlight a key role of cohesin in transcription regulation.At this point, mounting evidence indicates that CdLS is owed to gene expression dysregulation by a cohesin-dependent mechanism. However, the underlying molecular mechanism is still poorly understood. Taking these facts into consideration, it was particularly fascinating to explore whether the gene transcription machinery was somehow affected by SMC1A mutations. We report here that SMC1A mutations impair the assembly of transcription complex initiation in the promoter regions and that the recruitment of RNA polymerase II, TATA box Binding Protein and TFIIB transcription factor is deficient in CdLS cell lines, therefore affecting the key step in the transcription process. Supported by Tuscany Region grant (A.M.).

Exploring the role of miR-590 in Williams Beuren syndrome. *G. Merla[1], V.A. Gennarino[2], C. Fusco[1], L. Micale[1], B. Augello[1], M.G Turturo[1], E.V. D'Addetta[1], S. Banfi[1], A. Calcagni[1], M.N. Loviglio[1].* 1) Laboratory of Medical Genetics, IRCCS "Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy; 2) TIGEM, Telethon Institute of Genetics and Medicine, Naples, Italy.

Williams Beuren syndrome (WBS) is a recurrent genomic disorder caused by hemyzygosity of 28 contiguous genes at 7q11.23. Patients with WBS have a characteristic constellation of medical and cognitive findings. Despite a significant advance in the last years still much has to be learnt in order to further translate the knowledge into a better care of patients. We investigated the role of miR-590, the only miRNA located within the WBS deleted region. Preliminary results showed that both miR-590-5p and miR-590-3p miRNA strands are downregulated in cell lines of WBS patients. Because individual miRNAs regulate the expression of multiple target genes, we speculated that the downexpression of miR-590 in WBS has strong influences on the generation of a number of WBS phenotypes because of an altered control of its target genes. This project moved from the idea that if we can modulate the action of such miRNA, we will find a possible "large spectrum" therapeutic target for WBS. In order to asses the biological pathways controlled by miR-590, and to identify the set of its putative target (PTs) genes, we exploited global transcriptome analysis in cells following overexpression and inactivation of miR-590. Preliminary, by qPCR, luciferase assays, and western blot analysis, we have validated a set of predicted miR-590 PTs identified by querying HOCTAR a recently developed software for miRNA target prediction. We are now performing functional assays on some selected PTs to assess their biological relevance on WBS. The results of these comprehensive analyses on miR-590 will be presented.

Calvarial Osteoblasts from Infants with Nonsyndromic Craniosynostosis Exhibit Increased Osteogenic Potential. *S.A. Boyadjiev Boyd[1], M.L. Decaris[2], C. Horner[2], A. Bhat[2], E. Cherkez[1], G. Yagnik[1], J. Liu[1], G.J. Boggan[3], T. Tollefson[4], C. Senders[4], M.L. Cunningham[5], J.K. Leach[2].* 1) Dept Pediatrics Gen, SOM, UCD Med Ctr, Sacramento, CA; 2) Dept. of Biomedical Engineering, University of California Davis, Davis, CA; 3) Dept. of Neurosurgery, University of California Davis, Sacramento, CA; 4) 4Dept. of Otorhinolaryngology, University of California Davis, Sacramento, CA; 5) Dept. of Pediatrics, Division of Craniofacial Medicine, University of Washington, Seattle, WA.

Nonsyndromic craniosynostosis (NSC), the premature fusion of one or more cranial sutures, is a clinical condition with accelerated ossification. Its causes remain unknown and it is unclear if NCS occur due to innate osteoblast defect or due to abnormal signaling from the surrounding tissues. We hypothesized that sutural and perisutural osteoblasts from infants with NSC have greater osteogenic potential as compared with control calvarial osteoblasts. Control osteoblasts and osteoblasts from infants with sagittal, metopic or coronal NSC were seeded on tissue culture plastic and cultured in media containing osteogenic supplements in 1% (hypoxic), 5% (normoxic), or 21% O2 (ambient air) for up to 14 days. Osteogenic potential was determined by quantifying intracellular alkaline phosphatase activity (ALP), cellular proliferation by DNA content, mineral deposition by von Kossa staining, and changes in gene expression by qPCR. For all oxygen tensions examined, NSC osteoblasts exhibited significantly higher levels of osteogenic differentiation ($p<0.05$). We detected significantly more mineralized nodules in NSC osteoblasts as compared to control osteoblasts at all oxygen tensions, with cells cultured in 5% O2 exhibiting the largest nodules. Osteoblasts from NSC patients demonstrated ALP levels that were significantly higher than control cells for all culture conditions. A markedly increased expression of osteogenic genes was also observed for cells from NSC patients. Our data demonstrate that NSC osteoblasts exhibit increased osteogenic potential compared to control osteoblasts under a variety of oxygen tensions. We suggest that NSC osteoblasts harbor genetic variants that determine more robust osteogenic maturation program as compared to control osteoblasts.

Further characterization of cell lines harbouring an unmethylated full mutation of the *FMR1* gene. *E. Tabolacci[1], L. Borrelli[1], S. Lanni[1], U. Moscato[2], P. Chiurazzi[1], G. Neri[1].* 1) Inst Medical Genetics, Catholic Univ, Rome, Italy; 2) Institute of Public Helath, Catholic Univ, Rome,Italy.

Fragile X syndrome (FXS, OMIM #300624) is the commonest cause of inherited mental retardation, due to mutation of *FMR1*, an X-linked gene containing a CGG repeat in its promoter region. Expansion of this sequence beyond 200 repeats (full mutation) and consequent epigenetic changes cause the transcriptional inactivation of *FMR1* and lack of the FMRP protein. Rare individuals of normal intelligence, carrying an unmethylated full mutation (UFM), have been observed and the epigenetic modifications in their *FMR1* gene were characterized [Pietrobono et al., 2005; Tabolacci et al., 2008]. These cell lines are very rare, possibly representing the status of FXS cells before epigenetic silencing. CTCF (CCCCTC-binding factor), a zinc-finger protein which binds to the chromatin insulators, is an important regulator of the transcription of genes harbouring trinucleotide repeats, playing an important role in the barrier activity of insulators. We started to investigate the role of CTCF in regulating *FMR1* gene expression and observed that the amount of CTCF bound to *FMR1* was slightly higher in the UFM cell lines, compared to normal controls, while in the FXS cells this amount was low. On the other hand, knock-down experiments with anti-CTCF siRNA, transfected into normal and UFM fibroblasts demonstrated a 50% reduction of *FMR1* transcript, both sense and antisense (AS-FMR1), with respect to untreated controls. After CTCF knock-down, the epigenetic analysis of the *FMR1* promoter region demonstrated a reduction of H3-K4 methylation and an increase of H3-K9 methylation. These results suggest that CTCF is a key modulator of the *FMR1* transcription, given that its depletion causes *FMR1* transcript reduction and the transition to a heterochromatin organization. Further experiments are in progress to study the effect of CTCF knock-down on DNA methylation, including the boundary region recently described by Naumann et al. (2009), and on FMRP level. We have also identified antisense FMR1 RNAs (AS-FMR1) in different regions of the *FMR1* promoter both in controls and in UFM cell lines, but not in FXS cell lines. The AS-FMR1 levels were approximately 7-fold overexpressed in UFM cells relative to normal controls and absent in FXS cell lines. The elucidation of the mechanism sparing UFM males from inactivating their full mutation is important for planning therapeutic attempts at converting methylated into unmethylated full mutations, restoring the expression of the *FMR1* gene.

2322/T

Genetic structure and subcellular targeting of the hereditary spastic paraplegia gene REEP1. *J. Price[1], J. Huang[1], G. Montenegro[1], T. Deconinck[2,3], M. Pericak-Vance[1], G. Wang[1], P. de Jonghe[1], S. Züchner[1].* 1) Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami; 2) Molecular Genetics Department, Flanders Interuniversity Institute for Biotechnology, University of Antwerp, Antwerp, Belgium; 3) Division of Neurology, University Hospital Antwerp, Antwerp, Belgium.

Previously, we have shown that mutations in REEP1 cause hereditary spastic paraplegia (HSP) type 31. REEP1 is now considered the third most common HSP gene and genetic testing is frequently carried out according to the reported gene annotation. REEP1 is a protein of unknown function, but a controversy has emerged whether it is localized in mitochondria or the endoplasmic reticulum. We studied the genetic structure of REEP1 and identified additional exons and alternative isoforms. Sequencing analysis was carried-out at these novel exons in a large sample of HSP index patients. In-vitro experiments were performed at transiently transfected cell lines. We identified two novel missense mutations in two of the new REEP1 exons, which would have been missed by conventional testing approaches. Interestingly, at least one new isoform is missing the mitochondrial targeting signal at the N-terminal end of REEP1. In cell culture experiment we found differential subcellular targeting of REEP1 with isoform2a localizing to mitochondria and isoforms1 and 2b localizing to the ER. The identification of additional coding exons inREEP1 has important consequences for genetic testing in SPG31. Future genetic tests should include these novel coding exons. The subcellular localization of REEP1 is significantly different in the expressed isoforms. How this relates to the pathology of SPG31 will be an important part of future functional studies.

Cloning of Copper binding protein from Indian Childhood Cirrhosis liver revealed Arg 72 variant of p53: New insight in pathophysiology. *R. Prasad[1], N. Sharma[1], G. Kaur[2], B.R. Thapa[3].* 1) Department of Biochemistry, Postgraduate Institute of Medical Education and Research (PGIMER), Chandigarh, India; 2) Department of Physiology, Government Medical College and Hospital (GMCH), Chandigarh, India; 3) Division of Pediatric Gastroenterology, Postgraduate Institute of Medical Education and Research (PGIMER), Chandigarh, India.

Indian Childhood Cirrhosis (ICC) is a disease of abnormal copper metabolism which is commonly characterized by swelling and degeneration of liver cells along with the presence of orcein staining deposits of copper. Erstwhile, we identified and characterized a ~ 50KDa copper binding protein from ICC liver (Prasad R, Kaur G, Mond R, Walia BNS. Pediatr.Res.44:673-681, 1998). We now report the identification of p53 cDNA encoding the 50 kDa copper binding protein by isolating a cloned DNA complementary to copper binding protein mRNA. A basic local alignment research tool (BLAST) search of cDNA revealed that it belongs to Arg 72 variant of p53. Genetic analysis of p53 gene in 14 ICC patients divulged Arginine form of p53 at codon 72 in both homozygous and heterozygous forms. Immunofluorescence and Immunohistochemistry analysis documented a marked expression of p53 protein in ICC liver. p53 antibodies were also detected in the plasma of ICC patients. On functional characterization, expression of p53 cDNA transfected in Hep G2 cell lines was significantly augmented with increasing extra cellular copper concentration. On Immunohistochemistry, p53 was localized in both cytoplasm and nucleus of transfected Hep G2 cells. Marked apoptotic potential of Arg 72 p53 was demonstrated by increased expression of CD95 in ICC liver. Taken together, the findings of the present study deduce that Arg form of p53 at codon 72 is found in ICC patients and it gains marked apoptotic potential when copper concentration is increased which could be prominent predisposing genetic factor in the pathogenesis of ICC.

2324/T

Clinical, molecular and functional characterisation of autosomal recessive bestrophinopathy (ARB). *A.E. Davidson[1,2], I.D. Millar[3], P.D. Brown[3], A.T. Moore[1,4], G.C.M. Black[2], A.R. Webster[1,4], F.D.C. Manson[2].* 1) Genetics, Institute of Ophthalmology, UCL, London, United Kingdom; 2) Genetic Medicine, The University of Manchester, Manchester, United Kingdom; 3) Faculty of Life Sciences, The University of Manchester, Manchester, United Kingdom; 4) Moorfields Eye Hospital, London, UK.

We aim to characterise the clinical presentation and molecular pathophysiology of ARB.

BEST1 mutations were sought in patients with a diagnosis of ARB. Probands underwent ophthalmic examination, ISCEV-standard electrophysiology, autofluorescence imaging and spectral domain optical coherence tomography. Cellular localisation and protein stability of pathogenic bestrophin-1 isoforms was determined by immunofluorescence and the addition of proteasomal and lysosomal protease inhibitors followed by western blotting in a transiently transfected epithelial model system. Chloride channel function was measured by whole-cell patch-clamping in transiently transfected HEK293 cells.

All ARB patients had biallelic *BEST1* mutations. The ocular phenotype associated with ARB includes central visual loss, hyperautofluorescent confluent subretinal lesions, abnormal EOG light rise, abnormal full-field ERGs, and hyperopic refraction. This disorder is also often associated with angle closure glaucoma and cystoid macular oedema. Using an epithelial model system we demonstrate that ARB missense isoforms are mis-localised away from the basolateral cell membrane, displaying a perinuclear reticular pattern typical of the endoplasmic reticulum (ER). Mutant ARB isoforms also had reduced stability compared to wildtype bestrophin-1 and were rapidly degraded via a proteasomal dependant route. Whole-cell patch-clamping demonstrated that all ARB mutant isoforms investigated had a significantly reduced chloride conductance compared to wildtype bestrophin-1.

Patients with ARB have a distinct but variable autosomal recessive ocular phenotype. The majority of ARB bestrophin-1 isoforms are not correctly trafficked to the cell surface and are retained within the ER where they are degraded via a proteasomal dependant route, thus providing an explanation for the lack of chloride-specific currents. This work is the first comprehensive functional characterisation of missense bestrophin-1 isoforms that occur in either the homozygous or compound heterozygous states. The localisation and proteasomal data presented here suggests that ER associated degradation (ERAD) of mutant bestrophin-1 isoforms is the disease mechanism underlying most of the ARB genotypes, and supports our previous hypothesis that ARB represents the null bestrophin-1 phenotype in humans.

A mutation in the 3'UTR of the HDAC6 gene abolishing the post-transcriptional regulation mediated by hsa-miR-433 is linked to a new form of dominant X-linked chondrodysplasia. *B. Arveiler[1,2], D. Simon[1], M. Barillot[1], V. Godard[1], N. Dagoneau-Blanchard[1], C. Blanchard[1], C. Rooryck[1,2], T. Barnetche[1], M. Marche[1], I. Burgelin[1], I. Coupry[1], B. Laloo[3], A. Tingaud-Sequeira[4], M. André[4], A. Knoll-Gellida[4], N. Chassaing[5,6], B. Gilbert-Dussardier[7], P. Babin[4], K. Massé[8], C. Grosset[3], D. Lacombe[1,2].* 1) Human Genetics Laboratory, Univ Victor Segalen Bordeaux 2, Bordeaux, France; 2) CHU de Bordeaux, Bordeaux, France; 3) INSERM U889, Bordeaux, France; 4) Laboratoire de Physiologie des Poissons, Bordeaux, France; 5) INSERM U563, Toulouse, France; 6) CHU de Toulouse, Toulouse, France; 7) CHU de Poitiers, Poitiers, France; 8) CNRS UMR 5164, Bordeaux, France.

A family with dominant X-linked chondrodysplasia was previously described. The disease locus was ascribed to a 24 Mb interval in Xp11.3-q13.1. We have identified a variant (c.*281A>T) in the 3'UTR of the HDAC6 gene that totally segregates with the disease. The variant is located in the seed sequence of hsa-miR-433. Our data showed that, in MG63 osteosarcoma cells, hsa-miR-433 down-regulated both the expression of endogenous HDAC6 and that of an eGFP-reporter mRNA bearing the wild-type 3'UTR of HDAC6. This effect was totally abrogated when the reporter mRNA bore the mutated HDAC6 3'UTR. The HDAC6 protein was found to be overexpressed in thymus from an affected male foetus. Concomitantly, the level of total alpha-tubulin, a target of HDAC6, was found to be increased in the affected foetal thymus, whereas the level of acetylated alpha-tubulin was found to be profoundly decreased. Skin biopsies were obtained from a female patient who presented a striking body asymmetry with hypotrophy of the left limbs. The mutated HDAC6 allele was expressed in 31% of left arm-derived fibroblasts, whereas it was not expressed in the right arm. Overexpression of HDAC6 was observed in left arm-derived fibroblasts. Altogether these results strongly suggest that this HDAC6 3'UTR variant suppressed hsa-miR-433-mediated post-transcriptional regulation causing the overexpression of HDAC6. This variant is likely to constitute the molecular cause of this new form of X-linked chondrodysplasia. This represents to our knowledge the first example of a skeletal disease caused by the loss of a miRNA-mediated post-transcriptional regulation on its target mRNA. We shall present our current work heading towards deciphering the physiopathology of the disease. Data presented will concentrate on the phenotype of fibroblasts expressing the mutated HDAC6 allele, on the expression pattern of HDAC6 during development in X. laevis, D. rerio and the mouse, and on the overexpression of HDAC6 in these models.

Identification and functional consequences of a recurrent NLRP12 missense mutation in periodic fever syndromes. *I. Jéru[1, 2, 3], G. Le Borgne[1, 2], E. Cochet[3], H. Hayrapetyan[4], P. Duquesnoy[1], G. Grateau[5], A. Morali[6, 7], T. Sarkisian[4], S. Amselem[1, 2, 3].* 1) U.933, INSERM, Paris, France; 2) Université Pierre et Marie Curie-Paris6, UMR S_933, Paris, F-75012 France; 3) AP-HP, Hôpital Trousseau, Service de Génétique et d'Embryologie médicales, Paris, F-75012 France; 4) Center of Medical Genetics and Primary Health Care, Yerevan, 375010 Armenia; 5) AP-HP, Hôpital Tenon, Centre de référence Amyloses d'origine inflammatoire et Fièvre méditerranéenne familiale, Service de Médecine Interne, Paris, F-75020 France; 6) Centre Hospitalier-Universitaire Nancy-Brabois, Hôpital d'Enfants, Centre de compétence des maladies digestives rares et inflammatoires de l'enfant, Vandoeuvre-les-Nancy, F-54500 France; 7) INSERM, U954, Vandoeuvre-Les-Nancy, F-54505 France.

Introduction. Recently, two first disease causing-mutations (a nonsense and a splice site mutations) have been identified in the NLRP12 gene in patients with a clinical manifestations evocative of cryopyrinopathies, which correspond to a subgroup of periodic fever syndromes (PFS). The diagnosis of PFS remains often difficult since there is no pathognomonic sign of these disorders, and since the majority of patients corresponds to sporadic cases precluding intrafamilial segregation analyses. The majority of mutations identified in PFS genes corresponds to missense variations, whose deleterious effect remain often questionable. In addition, since PFS genes are expressed at low levels in peripheral blood mononuclear cells, the effect of sequence variants can hardly be assessed by the study of endogenous proteins. To further test the involvement of NLRP12 in PFSs, we screened this gene in patients with symptoms of genetically-unexplained cryopyrinopathies. The functional consequences of the identified missense variation was subsequently assessed. Methods. NLRP12 was screened for mutations by direct sequencing. Functional assays were performed in HEK293T cells stably expressing the pro-apoptotic protein ASC and pro-caspase 1, in order to determine the consequences of normal and mutated NLRP12 proteins on speck formation, caspase 1 signaling, and NFKB activation. Results. A heterozygous NLRP12 missense mutation involving a CpG site (c.1054C/T, p.Arg352Cys) was identified in exon 3, which encodes the nucleotide-binding site (NBS) of the protein, in two patients originating from different countries and carrying different NLRP12 haplotypes. The mutation, which does not alter the inhibitory properties of NLRP12 on NFKB activation, increases speck formation and activates caspase 1 signaling. Conclusions. Given the rarity of known NLRP12-associated disorders, the identification of this new NLRP12 molecular defect contributes to the delineation of the clinical spectrum associated with mutations in this gene and underlines the importance to screen NLRP12 in patients presenting with unexplained PFSs. This study also demonstrates by means of functional assays the deleterious effect of this recurrent missense mutation; in this regard, the gain of function associated with this NBS mutant on speck formation and caspase 1 signaling is consistent with the patients' inflammatory phenotype.

Defining the phenotypic specificity of Schimke immuno-osseous dysplasia: A hypothesis. *M. Morimoto[1,2], K.S. Cho[3,4], C. Myung[1], K. Beirnes[1], D. Leung[1], A. Fam[1], K. Choi[1,2], Y. Huang[1], C. Huang[3], S. Lou[3], A.K. Gormley[5], Z. Yu[6], D. Parham[6], B. Najafian[7], C.F. Boerkoel[1,2].* 1) Child and Family Research Institute, Department of Medical Genetics, University of British Columbia, Vancouver, BC Canada; 2) Rare Disease Foundation, Vancouver, BC Canada; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) Department of Biological Sciences, Konkuk University, Seoul, Republic of Korea; 5) Department of Pediatrics, University of Oklahoma, Oklahoma City, OK; 6) Department of Pathology, University of Oklahoma, Oklahoma City, OK; 7) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN.

Objective: Schimke immuno-osseous dysplasia (SIOD), an autosomal recessive multisystem disorder, is caused by mutations in the *SMARCAL1* gene. Although the SMARCAL1 enzyme binds open chromatin diffusely and affects transcription globally, we hypothesize that its deficiency gives rise to the pathognomic features of renal failure, skeletal dysplasia, immunodeficiency, and vascular disease by differential effects on gene expression.

Methods: We assessed this using an F_1 genetic screen in *Drosophila melanogaster* to measure suppression or enhancement of ectopic wing veins induced by the overexpression of SMARCAL1. Furthermore, using RT-PCR and immunoblotting, we assessed expression of key pathways in SIOD autopsy tissue and following knock down of SMARCAL1 in cultured primary cells.

Results: In the *Drosophila* model, mutations in the wingless and epidermal growth factor pathways strongly suppressed, mutations of the notch pathway strongly enhanced, and mutations in the decapentaplegic and hedgehog pathways had no effect or weakly suppressed the ectopic wing veins providing evidence that SMARCAL1 interacts differentially with developmental pathways. Furthermore, gene expression analysis in flies and SIOD patient tissues identified differentially altered gene expression. Specifically, expression of elastin in the arterial wall and lung was significantly altered and correlated with arterial and pulmonary pathology.

Conclusion: Similar to mutations of *RNA polymerase II* and general transcription factors, dysfunction of SMARCAL1 alters the expression of some genes more than others and in turn affects tissue development and maintenance. We show for the first time that alterations in gene expression cause SIOD. We hypothesize that this arises because some regions of the genome are more sensitive to SMARCAL1 dysfunction than are others.

2328/T

Defects of embryonic myosin in Freeman-Sheldon syndrome reduce force and prolong relaxation of skeletal myofibers. *A.E. Beck[1,2], A.W. Ward[3], M.J. McMillin[1,2], F.S. Korte[3], M. Regnier[3], M.J. Bamshad[1,2,4].* 1) Dept Pediatrics, Univ Washington, Seattle, WA; 2) Seattle Children's Hospital, Seattle, WA; 3) Dept Bioengineering, Univ Washington, Seattle, WA; 4) Dept Genome Sciences, Univ Washington, Seattle, WA.

Congenital contractures such as clubfoot affect ~1 of every 200-500 live births in the United States and are caused by a combination of genetic and environmental risk factors. To understand the genetic and biophysical mechanisms that cause congenital contractures, we studied single skeletal myofibers from a person with distal arthrogryposis (DA). The DAs are a group of ten autosomal dominant disorders characterized by congenital contractures of the hands and feet, most notably clubfoot and camptodactyly. We and others have discovered that DA syndromes can be caused by mutations in each of at least nine genes that encode proteins of the skeletal muscle contractile complex including: troponin I, troponin T, tropomyosin, myosin binding proteins and several myosin heavy chains. Here we report the first functional studies of skeletal myofibers from a person with congenital contractures caused by a defect of embryonic myosin. Specifically, we measured the contractile properties of individual myofibers sampled from the gastrocnemius muscle of an individual with Freeman-Sheldon syndrome (FSS) caused by a R672C *MYH3* mutation. Maximal force per cross-sectional area was reduced by more than 70% in FSS myofibers, but maximal force per myofiber was maintained as FSS myofibers were larger than control fibers. Neither cooperativity of activation nor calcium sensitivity of contraction was significantly affected. Following calcium-induced activation, time to 90% relaxation was ten-fold longer in FSS myofibers, and this effect was independent of myofiber diameter or fiber type. Relaxation time could be restored toward normal by chemically disrupting myosin-actin interactions. These observations can be collectively explained by slower turnover of actin-myosin crossbridges in FSS myofibers. Furthermore, while the expression of *MYH3* has been thought to be limited to fetal development and shortly thereafter, we found that *MYH3* mRNA and embryonic myosin protein are present in both normal fetal and adult skeletal muscle. This finding suggests that mutations in *MYH3* could affect contractility in both prenatal and adult skeletal muscle. Elucidating the mechanism of aberrant relaxation could provide important information leading to development of novel therapeutics that either mitigate severe outcomes or potentially prevent the development of contractures.

2329/T

***SLC2A13* loss of function associated with failure to thrive and developmental delay.** *C. Dias[1,2,3], J.L. Huang[1,2,3], A. Lehman[1,2,3], C. du Souich[1,2,3], S. Bhatt[4], D. Chai[1,2], P. Eydoux[1,2], P. Stankiewicz[4], C.F. Boerkoel[1,2,3].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, British Columbia; 2) Child and Family Research Institute, Children's and Women's Health Centre of British Columbia, Vancouver, British Columbia, Canada; 3) Rare Disease Foundation, Vancouver British Columbia, Canada; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The combination of profound developmental delay, failure to thrive, and epilepsy is a diagnostically challenging clinical presentation. Causes for this triad uncover insights into the biology of human growth and cognition. We present a 3 y. o boy with hypotonia, severe failure to thrive, severe developmental delay, nonspecific dysmorphic features, and seizures causing hemiparesis. He had normal metabolic and endocrine studies. Brain MRI showed normal anatomy and delayed myelination. Chromosome analysis and array comparative genomic hybridization revealed a de novo balanced translocation t(6;12)(q25.1;q12). Subsequent, analyses refined the breakpoint to intron 4 of the SLC2A13 gene, encoding a membrane channel in the Golgi apparatus, and intron 6 of LOC729178, which expresses a noncoding mRNA. Further RT-PCR studies showed nearly complete loss of mRNA transcription from the untranslocated allele of SLC2A13. Current studies focus on defining the basis for loss of expression from the normal allele. Based on its expression pattern and predicted function, we propose that deficiency of SLC2A13 causes growth restriction and delayed neurological development by affecting vesicular trafficking or protein modification. This is the first description of SLC2A13 deficiency in humans.

2330/T

ZNF750 is a nuclear protein with novel variants in its promoter & 5' UTR in psoriasis patients. *I. Cohen[1], R.Y. Birnbaum[1], A.M. Bowcock[2], K. Leibson[1], S. Sivan[1], O.S. Birk[1,3].* 1) Morris Kahn Laboratory of Human Genetics, National Institute for Biotechnology in the Negev, Ben Gurion University, Beer-Sheva, Israel; 2) Department of Genetics, Washington University School of Medicine, Saint Louis, MO, United States; 3) Genetics Institute, Soroka Medical Center, Beer-Sheva, Israel.

We previously showed that a dominant mutation in the novel zinc finger protein, ZNF750, that is located within PSORS2 locus, causes seborrhea-like dermatosis with psoriasiform elements. Furthermore, ZNF750 c.-625A>C promoter variant has been linked with familial psoriasis in Chinese patients. We now sequenced DNA samples of 250 bone-fide psoriasis patients. No mutations were found in the ZNF750 coding sequence. However, sequence variants in the ZNF750 5'-UTR were found in 3 of 250 unrelated psoriasis patients and not in 300 controls. It is yet unclear how this variation affects ZNF750 expression. To begin to understand ZNF750 function, we determined ZNF750 sub-cellular localization: HEK293 and HaCaT cells were transiently transfected with EGFP-ZNF750 constructs of full-length or of partially truncated protein, abrogating the ZNF750 NLS. Both confocal fluorescence microscopy and cellular fractionation followed by western blot analysis demonstrated that ZNF750 is expressed in the cell nucleus both in HEK293 and HaCaT cells. Removal of the nuclear localization signal of ZNF750 abrogated its nuclear localization. Our data suggest that ZNF750 5'-UTR variants might be associated with bone fide psoriasis. Although ZNF750 has a single zinc finger C2H2-like motif, its nuclear localization suggests that it might act as a transcription factor.

2331/T

Haploinsufficiency for the erythroid transcription factor KLF1 causes Hereditary Persistence of Fetal Hemoglobin. *M.A. GEORGITSI[4], J. BORG[1, 2], P. PAPADOPOULOS[3], L. GUTIERREZ[3], G. GRECH[1, 2], P. FANIS[3], M. PHYLACTIDES[5], A.J.M.H. VERKERK[6], P.J. VAN DER SPEK[6], C.A. SCERRI[1, 2], W. CASSAR[1, 2], R. GALDIES[1, 2], W. VAN IJCKEN[7], Z. OZGUR[7], N. GILLEMANS[3], J. Hereditary Persistence of Fetal Hemoglobin (HPFH) is characterized by persistence of fetal hemoglobin (HbF, $\alpha_2\gamma_2$) above 2% in adults. A few genetic loci account for the variable expression of total HbF levels, including *HBB*, *HBS1L-MYB*, and the recently identified γ-globin genes repressor *BCL11A*, however they account for <50% of cases. Ten of 29 members from a unique Maltese family presented with HPFH (HbF: 3%-20%). Genome-wide SNP array and linkage analysis data, assuming autosomal dominant inheritance, were combined with expression profile data of HPFH and normal primary erythroid progenitors (HEPs). A candidate region was mapped on chromosome 19p13.12-13. Sequencing analysis of candidate genes identified a nonsense mutation in the *KLF1* gene, p.K288X, ablating the DNA binding domain of this key erythroid transcriptional regulator. Only HPFH family members were p.K288X carriers; p.K288X was absent in the general Maltese population. Expression profiling of HPFH HEPs revealed downregulation of KLF1 target genes, including *BCL11A*, as previously seen in *Klf1 null* mouse erythroid progenitors. Lentiviral shRNA-mediated knockdown of *KLF1* in normal HEPs, followed by quantitative S1 nuclease protection assays and qPCR, showed a marked increase of *HBG1*/*HBG2* and downregulation of *BCL11A* expression, similar to the observations in HPFH carriers. Lentiviral-mediated transduction of normal HEPs with mutant (p.K288X) *KLF1* did not affect *HBG1*/*HBG2* expression level, excluding a dominant-negative role. Transduction of HPFH HEPs with full-length *KLF1* resulted in a marked increase of BCL11A protein and decrease of *HBG1*/*HBG2* mRNA levels. Chromatin immunoprecipitation assays on fetal liver HEPs and adult peripheral blood HEPs revealed consistent binding of KLF1 on one of the potential CACC sites on the proximal *BCL11A* promoter only in the adult stage. In conclusion, in addition to its established role in adult globin expression via the activation of *HBB*, KLF1 is a critical activator of the *BCL11A* gene, which represses fetal *HBG1*/*HBG2* expression in adults. These findings provide a rationale for the observed effects of *KLF1* haploinsufficiency on HbF levels and support the notion that KLF1 is a regulator of human fetal-to-adult globin switching. Since HbF mitigates the severity of both β-thalassemia and sickle-cell disease, the reactivation of *HBG1*/*HBG2* genes in adults, via attenuation of KLF1 activity, provides novel lead for molecular therapeutics of β-type hemoglobinopathies.

2332/T

Investigation of the effects of SLC4A11 (CHED2) gene depletion on corneal endothelial cell growth and proliferation. *J. Liu[1], L.W. Koh[1], R. Mohan[2], T. Aung[1,3,4], E.N. Vithana[1,3].* 1) Singapore Eye Research Institute, Singapore; 2) Mason Eye Institute and College of Veterinary Medicine, University of Missouri-Columbia, Missouri, USA; 3) Dept of Ophthalmology, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 4) Singapore National Eye Centre, Singapore.

NaBC1 protein, encoded by SLC4A11 gene, has been shown to function as an electrogenic Na/Borate co-transporter in the presence of borate in mammalian cells. In 2006, Vithana et al identified the SLC4A11 gene as the cause of a blinding cornea dystrophy, Congenital Hereditary Endothelial Dystrophy (CHED2). Herein, we aimed to identify the cellular characteristics and the gene regulation events involved in CHED2 pathology by depleting SLC4A11 in immortalized human corneal endothelial cell line (HCEC). In 2004 Park et al found reduced cell growth and proliferation in HeLa cells after 48 and 72 hours' treatment of transient siRNA specific for SLC4A11. In contrast, we found that SLC4A11 gene could not be depleted at the protein level in HCECs by transient treatment with siRNAs. Gene depletion could only be achieved by long-term and stable expression of siRNA via short-hairpin RNA (shRNA). Real-time assessment of cell growth using the XCELLigence system (Roche) consistently indicated the reduced cell number with time in SLC4A11 gene-depleted cells compared to the control. However, Ki-67 immunostaining indicated that cell proliferation is not significantly different between cells that stably express SLC4A11 targeted siRNAs and the negative control. After further analysis, we conclude that the reduction of cell number with time in SLC4A11-depleted HCECs is mainly due to the increase in cell death. We also investigated the apoptotic signaling pathways that were affected by depletion of SLC4A11 in HCECs. And we studied the role of borate on growth and proliferation in HCECs. Park et al previously demonstrated the importance of borate on growth of HeLa cells through the rescue of cell growth and proliferation by incubating siRNA treated cells with 0.5mM borate. In our study, the HCEC phenotypes due to SLC4A11 gene depletion could not be rescued by treatment with 0.5mM borate. Thus our data do not support a critical role for either borate or NaBC1 as a Na/Borate cotransporter in HCECs. NaBC1/SLC4A11 may have a different transporter role in HCECs. The Knowledge gained from this study may possibly lead to the identification of therapeutic targets and reagents applicable for CHED as well as a wide group of corneal diseases that essentially involve the maintenance/restoration of corneal clarity.

Bioinformatics and Cellular Approaches Confirm ER-Associated Protein Degradation (ERAD) as a Major Mechanism Underlying Numerous Monogenic Disorders. *B.R. Ali[1], N.A. Akawi[1], A. John[1], L. Al-Gazali[2].* 1) Department of Pathology, Faculty of Medicine and Health Sciences, UAE University, Al-Ain, Abu Dhabi, United Arab Emirates; 2) Department of Pediatrics, Faculty of Medicine and Health Sciences, UAE University, Al-Ain, Abu Dhabi, United Arab Emirates.

More than a third of all cellular proteins are targeted to the endoplasmic reticulum (ER) as a first step in their trafficking routes along the secretory pathway to their final cellular destinations. The processes of protein folding, assembly into multi-subunit complexes and export out of the ER are subjected to a stringent quality control system to ensure that only properly folded and assembled proteins exit the ER. Malfolded proteins and unassembled subunits of protein complexes are rejected by this ER quality control system and re-translocated to the cytosol for degradation by the ubiquitin/proteasome. This process has been named ERAD (ER-Associated protein Degradation) and has been implicated in the cellular mechanisms of at least 50 human monogenic diseases including cystic fibrosis. Due to the high stringency of ERAD and the large number of cellular proteins that has to pass through the secretory pathway (~8,000), we reasoned that ERAD should be implicated in the mechanisms of many more human monogenic conditions. We therefore, utilized bioinformatics and data mining approaches and found that at least 45% of all known human disease genes have an ER-targeting signal and consequently we identified many ERAD disease candidates. We experimentally validated our predictive approach experimentally by establishing that ERAD is indeed responsible for most of the loss-of-function missense mutations in the genes involved in a number of the identified ERAD disease candidates including Robinow syndrome, Acromesomelic Dysplasia type Maroteaux and SMED-SL.

Genotypic and phenotypic diversities in Wilson's disease. *B.H. Lee[1,2,3], J.H. Kim[2], K.J. Kim[2], J.Y. Park[2], G.H. Kim[2,3], H.W. Yoo[1,2,3].* 1) Pediatrics, University of Ulsan College of Medicine, Asan Medical Center Children's Hospital, Seoul, Korea; 2) Genome Research Center for Birth Defects and Genetic Disorders, University of Ulsan College of Medicine, Asan Medical Center Children's Hospital, Seoul, Korea; 3) Medical Genetics Clinic and Laboratory, University of Ulsan College of Medicine, Asan Medical Center Children's Hospital, Seoul, Korea.

Wilson's disease (WD) is an autosomal recessive disorder of copper metabolism. Wide genotypic-phenotypic heterogeneities have been reported, hampering the study on their correlations. This study was performed to identify factors related to genotypic-phenotypic diversities of WD in 237 unrelated Korean WD families. Presenting phenotypes were classified as hepatic (H1, H2), neurological (N1, N2, NX), and asymptomatic (ASx), modifying the guidelines by Ferenci et al *(Liver Int 2003;23:139-42)*. Presenting phenotypes in our cohort were H1 (12.2%), H2 (42.4%), N1 (21.6%), N2 (0.4%), NX (0.4%), ASx (22.4%), and other (0.4%). Onset age was youngest in patients with ASx presentation, but similar among H1, H2 and N1 patients. Liver cirrhosis was associated in 63% of N1 patients, similar as in H1+H2 patients (49%). On follow-up (average, 8.2±5.8 years), liver cirrhosis was rarest in ASx patients (4%). Decompensated cirrhosis was highest in H1 (48%) but similar between N1 (2%) and H2 (5%) patients. Favorable outcome was rarest in N1 patients (8%). Forty-seven *ATP7B* mutations including 11 novel mutations were identified in 85% of the 474 alleles. MLPA assay in *ATP7B* and analyses of *ATOX1* and *COMMD1* identified no additional mutations. Yeast complementation and growth curve assays demonstrated functional perturbation of the seven novel missense mutants. Five major mutations, p.Arg778Leu (36.5%), p.Ala874Val (9.9%), p.Asn1270Ser (8.0%), p.Lys838SerfsX35 (4.2%), and p.Leu1083Phe (4.0%), accounted for 63% of the alleles. H1 was more common (26.8% vs. 8.5%, $P = 0.006$), onset age was younger (12 vs. 15 years, $P = 0.009$), and N1+N2+NX tended to be less common (12.2% vs. 27.0%, $P = 0.06$), in patients with nonsense, frame-shifting or splicing mutations than in those with missense mutations alone. No other genotype-phenotype correlations were identified among common mutations or genotypes. In addition, widely heterogeneous presenting phenotypes were noted in patients with both mutations in a single domain of ATP7B. In conclusion, the presenting phenotype strongly affects the clinical outcome of WD, and is related, in part, to mutation type. Several common mutations unique to those of particular ethnicity should be identified to allow rapid and easy diagnosis of WD without the need for invasive intervention. More effort is needed to identify genetic defects in those without *ATP7B* mutation and the factors related to genotypic-phenotypic heterogeneity.

Hirschsprung's disease and common variants in genes involved in enteric neural crest cell proliferation and migration. *T. Carter[1], J. Troendle[1], D. Kay[2], M. Browne[3,4], P. Romitti[5], M. Conley[1], D. Kuehn[1], M. Caggana[2], C. Druschel[3,4], L. Brody[6], J. Mills[1].* 1) Division of Epidemiology, Statistics, and Prevention Research, Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, Bethesda, MD; 2) Division of Genetics, Wadsworth Center, New York State Dept of Health, Albany, NY; 3) Dept of Epidemiology and Biostatistics, School of Public Health, University at Albany - State University of New York, Albany, NY; 4) Congenital Malformations Registry, New York State Dept of Health, Troy, NY; 5) Dept of Epidemiology, The University of Iowa College of Public Health, Iowa City, IA; 6) Genome Technology Branch, National Human Genome Research Institute, NIH, Bethesda, MD.

INTRODUCTION: Hirschsprung's disease results from failure of neural crest cells to colonize the embryonic gut. The differentiation and survival of neural crest-derived enteric neurons require RET signaling. Rare mutations in RET are present in familial (50%) and non-familial (15%) cases but common RET variants have also been associated with Hirschsprung's disease. The aim of this study was to determine if common variants in other genes that regulate enteric neural crest cell proliferation and migration also play a role in Hirschsprung's disease. We examined single nucleotide polymorphisms (SNPs) in candidate genes (ASCL1, HOXB5, PHOX2B, PROK1, PROKR1) which, when mutated in animals, block embryonic enteric neural crest cell proliferation and migration. METHODS: We conducted a nested case-control study of 305 Hirschsprung's disease cases 1,216 controls selected from among all New York State live births between 1998 and 2005. Cases were identified from the New York State Congenital Malformations Registry and had no other major birth defects. Controls without major malformations were randomly selected and frequency-matched to cases by race/ethnicity. DNA was genotyped for 33 haplotype tagging SNPs in the five candidate genes and for five SNPs in RET. Logistic regression was used to calculate odds ratios (OR) and 95% confidence intervals (CI). RESULTS: PROKR1 rs4854479 was associated with being a case in non-Hispanic whites (168 cases, 668 controls) (OR: 2.08; 95% CI: 1.1, 4.1). Among Hispanic subjects (50 cases, 198 controls), associations were found for HOXB5 rs4793943 (OR: 5.6; 1.2, 26.1) and PHOX2B rs6826373 (OR: 2.6; 1.1-6.1). RET rs1864410 was strongly associated with Hirschsprung's disease among non-Hispanic white (OR: 11.9; 7.2, 19.7), Hispanic (OR: 21.0; 6.1, 72.2), and Asian (23 cases, 92 controls) (OR: 13.1; 2.7, 63.4) subgroups. These ORs represent effect estimates for subjects who were homozygous for the minor allele compared with those homozygous for the major allele. CONCLUSIONS: In addition to RET, common variants in genes regulating enteric neural crest cell proliferation and migration were associated with Hirschsprung's disease. Gene expression data in animals and humans suggest that the proteins encoded by these genes could modulate RET signaling. Our findings require confirmation but they suggest that other genes affecting enteric neural crest cell proliferation should be investigated as contributors to Hirschsprung's disease.

2336/T

Identification of a deletion of the entire *CTRC* gene in a patient with familial chronic pancreatitis. *E. Masson[1,2,4], J.M. Chen[1,3,4], P. Hammel[5], C. Le Maréchal[1,2,3,4], C. Férec[1,2,3,4].* 1) Institut National de la Santé et de la Recherche Médicale (INSERM), U613 "Génétique moléculaire et Génétique épidémiologique", Brest, France; 2) Laboratoire de Génétique Moléculaire et d'Histocompatibilité, Centre Hospitalier Régionale Universitaire (CHRU) Brest, Hôpital Morvan, Brest, France; 3) Etablissement Français du Sang (EFS) - Bretagne, Brest, France; 4) Université de Bretagne Occidentale (UBO), Faculté de Médecine et des Sciences de la Santé, Brest, France; 5) Pôle des Maladies de l'Appareil Digestif, Service de Gastroentérologie-Pancréatologie, Assistance Publique-Hôpitaux de Paris, Hôpital Beaujon, Clichy, France.

Introduction: Chronic pancreatitis (CP) is a relapsing inflammatory disease of the pancreas. More than a century ago, pancreatitis was thought to be an autodigestive disease. This hypothesis was given the strongest support in 1996, when a "gain of function" mutation in the cationic trypsinogen gene (*PRSS1*) was reported to cause hereditary pancreatitis. Thereafter, "loss of function" mutations in the trypsin's inhibitor gene (*SPINK1*) and, more recently in the *CTRC* (Chymotrypsin C) gene, have also been found to be associated with the disease. These mutations are thought to disrupt the trypsin-inhibitor balance, leading to trypsin-driven premature digestive zymogene activation cascade and pancreatic autodigestion. **Aim of the study**: Copy number variations (CNVs) in the *SPINK1* and *PRSS1* genes (large deletions and gain of copy number respectively), have been previously found to cause pancreatitis. In this study, we attempted to identify this kind of mutation in the *CTRC* gene. **Materials and methods**: The eight exons of the *CTRC* gene were screened by means of quantitative fluorescent multiplex PCR. A total of 223 unrelated CP patients including 37 patients with a positive family history and 186 young patients with idiopathic CP, participated in this study. All were recruited after our previously study published in 2008 and no *PRSS1*, *SPINK1* or *CTRC* clearly disease-causing mutations were found among them. **Results**: We have identified a large heterozygous deletion encompassing the entire *CTRC* gene in one patient with familial CP. Direct sequencing of the aberrant chromosomal junction characterized the deletion as being ~54 kb in length, with the insertion of a short Alu sequence of ~ 30 bp. Moreover, in this patient, the *CTRC* deletion was found to be co-inherited with the p.N34S variant in the unlinked *SPINK1* gene. In the context of this particular family, the *CTRC* deletion may constitute a clearly disease-causing factor, whereas the *SPINK1* variant probably acts as a disease modifier. Cascade screening of the other family members and further investigation of the genotype/phenotype relationship may shed some light on this question. **Conclusion**: This is the first time that a genomic event involving the *CTRC* gene was found to cause chronic pancreatitis.

2337/T

A linkage study for Gallbladder Disease in a South Tyrolean Population. *A. De Grandi[1], C.B. Volpato[1], C. Pattaro[1], M. Felder[4], A.A. Hicks[1], P.P. Pramstaller[1,2,3].* 1) Institute of Genetic Medicine, European Academy Bolzano, Bolzano, BZ, Italy; Affiliated Institute of the University Lübeck, Germany; 2) Department of Neurology, Central Hospital, Bolzano, Italy; 3) Department of Neurology, University of Lübeck, Germany; 4) Department of Gastroenterology, Central Hospital, Bolzano, Italy.

Gallbladder disease (GBD) is one of the major digestive diseases. The significant risk factors associated with GBD are age, gender (female), obesity, lipids, diet, parity, type 2 diabetes, medications, and ethnicity. GBD appears to be strongly related to the metabolic syndrome. Most people with gallstones, however, remain asymptomatic through their lifetimes. Inhabitants of an isolated village in South Tyrol (North Italy) were identified through a first screening phase as individuals putatively affected by cholelitiasis. They and their first-degree relatives were called for ultrasonic examination by a gastroenterology specialist and 45% of participants were diagnosed as having of gallstones, despite the majority being asymptomatic. We have reconstructed the pedigrees starting from the affected individuals through the collection in the parish archive of genealogical data of 15 generations. Different pedigree splitting parameters were used to generate either two sets of large pedigrees (444 persons in 8 pedigrees with 59 affected, and 349 persons in 17 pedigrees with 61 affected) for Simwalk 2 analysis and those of more modest sizes (320 persons in 16 pedigrees with 100 affected) for Merlin analysis. Despite changes in signal levels due to different power in the tree sets of pedigrees, overlapping linked regions on chromosomes 3, 5, 6 and 8 were observed between analyses. The maximum significant linkage values were reached using the largest pedigrees. We are currently investigating association signals within the linked regions to identify genes of interest. One such compelling candidate in one of the linked regions is one of the organic solute transporters (OST alpha). Expression of OST alpha has been reported to be significantly reduced (3.3-fold, P = 0.006) in normal-weight but not overweight gallstone carriers compared with controls, leading us to speculate that underlying mutations in this gene might contribute to GBD in this population.

2338/T

Ablation of Sbds in the murine pancreas leads to Shwachman-Diamond syndrome phenotypes. *M.E. Tourlakis[1,2], J. Zhong[2], L.L. Chen[1,2], S. Zhang[1,2], P.R. Durie[3,4], J.M. Rommens[1,2].* 1) Department of Molecular Genetics, University of Toronto, Toronto, ON; 2) Program in Genetics and Genomic Biology, Hospital for Sick Children, 101 College St. East Tower, Toronto, ON, Canada M5G 1L7; 3) Department of Pediatrics, University of Toronto, Toronto, ON; 4) Program in Physiology and Experimental Medicine, Hospital for Sick Children, Toronto, ON.

The autosomal recessive disorder Shwachman-Diamond syndrome (SDS) involves multiple systems, with exocrine pancreatic dysfunction being a major feature. More than 95% of SDS patients exhibit loss of function mutations in the essential *SBDS* gene.

We modeled SDS in the murine pancreas to understand the consequences of loss of Sbds. Mice with null or disease-associated missense (*R126T*) *Sbds* alleles in combination with a conditional allele (CKO)were investigated for pancreatic dysfunction during development. Conditional inactivation was achieved with *Cre* recombinase under control of the Ptf1a early pancreatic progenitor transcription factor. $Sbds^{CKO/R126T}$;$Ptf1a^{Cre/+}$ and $Sbds^{CKO/-}$;$Ptf1a^{Cre/+}$ pancreata displayed progressive dysplasia postnatally. Trichrome staining of mutant pancreata indicated prominent connective tissue at pre-weaning periods, with fewer total acinar cell numbers and fat infiltration at post-weaning periods, resembling presentation in SDS patients. The pancreas remained small at all time points in both models; at P30, pancreata of $Sbds^{CKO/-}$;$Ptf1a^{Cre/+}$ mice were 0.31% of total body mass compared to 0.58% of control littermates. Acinar components appeared disorganized with tubular complexes. Notably, amylase-negative cells were observed but apoptotic bodies were not evident. Consistent with clinical findings, endocrine components were spared based on insulin and glucagon immunohistochemical staining, as well as glucose tolerance testing at 6 months of age. Mutant animals did show a modest reduction in total body size suggesting nutritional deprivation.

We show that Sbds is required for normal postnatal development of the pancreas and that its loss is sufficient to recapitulate the dysfunction seen in this organ in SDS. Moreover the clear genotype-phenotype correlation of the two models confirms that the *R126T* allele is hypomorphic in nature. A building body of evidence suggests that SBDS has a role in ribosome biogenesis and/or translation. Given the level of specialization of the exocrine pancreatic proteome, we propose that acinar cells are acutely sensitive to translation disruption in the absence of functional SBDS/Sbds.

2339/T

Founder effect of glucose-galactose malabsorption in Old Order Amish. *B. Xin, A. Bright, H. Wang.* DDC Clinic for Special Needs Children, Middlefield, OH.

Glucose-galactose malabsorption (GGM) is a rare autosomal recessive disease caused by a defect in glucose and galactose transport across the intestinal brush border. Clinically, GGM is manifested by neonatal onset of watery and acidic severe diarrhea, which is fatal unless these sugars are removed from the diet. Mutations in the Na+/glucose cotransporter gene SLC5A1 have been linked with the disease. Here, we report thirty-three patients with congenital GGM from a large Old Order Amish pedigree and the associated mutations in SLC5A1 gene. Besides previously reported clinical features such as classic watery diarrhea and dehydration, we found that increased bowel sounds, distended abdomen, vigorous nursing regardless of their illness, and irritability and apathy were also part of the initial presentation in all affected individuals. The patients underwent a dramatic turnaround with an immediate cease of the diarrhea and a quick rehydration if they were correctly diagnosed and adequately managed, followed by a normal growth and development pattern afterwards; whereas a prolonged clinical course would follow if the disease was not recognized. Sequence analysis of SLC5A1 gene revealed four homozygous missense mutations, c.152A>G (p.N51S), c.1231G>A (p.A411T), c.1673G>A (p.R558H), and c.1845C>G (p.H615Q), that co-segregate with the GGM phenotype in all of the affected individuals. Neither unaffected individuals in the pedigree nor 100 ethnically matched healthy controls were homozygous for any of these mutations. These findings suggest founder effect of the SLC5A1 mutations associated with the disease in Amish and a population specific genetic testing is in need to pursue an early diagnosis which is critical for a favorable outcome.

Identification of the causative gene for Congenital Short Bowel Syndrome. *C.S. van der Werf[1], J. Paredes[2], N. Hsiao[3], T.D. Wabbersen[4], H.C. Etchevers[5], P.M. Kroisel[6], D. Tibboel[7], R.A. Schreiber[8], E.J. Hoffenberg[9], I. Ceccherini[10], S. Lyonnet[5], R. Seruca[2], G.J. te Meerman[1], S.C.D. van Ijzendoorn[3], I.T. Shepherd[4], J.B.G.M. Verheij[1], R.M.W. Hofstra[1].* 1) Genetics, University Medical Center Groningen, Groningen, Groningen; 2) IPATIMUP - Institute of Molecular Pathology and Immunology of the University of Porto, Portugal; 3) Department of Cell Biology, University Medical Center Groningen, The Netherlands; 4) Department of Biology, Emory University, Atlanta, USA; 5) INSERM, U781, Hôpital Necker-Enfants Malades, Paris, France; 6) Institute of Human Genetics, Medical University of Graz, Graz, Austria; 7) Department of Pediatric Surgery, Erasmus MC-Sophia Children's Hospital, PO Box 2060, 3000 CB, Rotterdam, The Netherlands; 8) Division of Gastroenterology, BC Children's Hospital, Rm K4-200, 4480 Oak Street, Vancouver, BC V6H 3V4; 9) Department of Pediatrics, Section of Pediatric Gastroenterology, Hepatology, and Nutrition, University of Colorado, Denver, CO, USA; 10) Laboratorio di Genetica Molecolare, Istituto Giannina Gaslini - 16148 Genova, Italy.

Congenital Short Bowel Syndrome is a rare gastrointestinal disorder characterized by an inherited markedly diminished short small intestine length at birth and malrotation. 60% of the cases are familial, as siblings are affected. Because boys and girls are both affected and in 25% of the cases the parents are consanguineous, an autosomal recessive pattern of inheritance has been suggested. The aim of our study is to identify and characterize the causative gene. Homozygosity mapping was performed using 610K SNP arrays of Illumina on 5 patients of 4 different families, including one consanguineous family with 2 affected siblings and one unaffected child. We found an overlapping homozygous region in 4 of the 5 patients. In this region a homozygous deletion concerning one exon of one specific gene was detected in one of the patients. Furthermore, a homozygous deletion in the first intron was detected in the affected siblings of the consanguineous family, this deletion co-segregates with the disease phenotype in this family. Sequencing of this gene in 3 other patients resulted in the identification of additional mutations: one patient proved to have a heterozygous frameshift mutation and a heterozygous splice site mutation, whereas 2 other patients were homozygous for a nonsense mutation and a missense mutation, respectively. To further analyze the effect of the splice site mutation, we performed an exon trapping experiment that showed that the splice site mutation indeed affects the splicing of the exon. Transfection of CHO-K1 cells with the pIRES-EGFP gene-expressing vector containing the mutant gene (missense mutation) showed abnormal localization of the mutant protein compared to the wildtype protein. Furthermore, we determined the spatial and temporal expression pattern of the gene in human embryos and fetal tissues as well as of the orthologues of the gene in zebrafish. Currently zebrafish knock down experiments are being performed and the function of the gene is being studied in a gastrointestinal epithelial cell model. Although the pathophysiology is not yet fully understood, all our findings indicate that we identified the causative gene for Congenital Short Bowel Syndrome.

Conventional mutations are associated with a different phenotype than polyglutamine expansions in spinocerebellar ataxias. *A. Durr[1,2], S. Forlani[1], C. Cazeneuve[2], C. Cagnoli[3], K.P. Figueroa[4], D. Lorenzo[5], J. Johnson[6], J. van de Leemput[6], M. Viemont[2], A. Camuzat[1], S. Benaich[1,2], A. Singleton[6], L. Ranum[5], S. Pulst[4], A. Brusco[3], E. Leguern[2], A. Brice[1,2], G. Stevanin[1,2,7].* 1) CR-icm, INSERM / UPMC UMR_S975, NEB, Paris, France; 2) APHP, Departement de Genetique et Cytogenetique, Groupe Hospitalier Pitie-Salpetriere, 75013 Paris, France; 3) Department of Genetics, Biology and Biochemistry, University of Torino, Italy; 4) Cedars-Sinai Medical Center, Los Angeles, CA, USA; 5) University of Minnesota, Minneapolis, MN, USA; 6) National Institute on Aging, NIH, Bethesda, MD, USA; 7) EPHE, Paris, France.

Autosomal dominant cerebellar ataxias comprise a wide spectrum of diseases with different clinical/neuropathological profiles. At least 30 responsible loci (SCA) have been mapped. Nucleotide repeat expansions have been identified as responsible for the disease in 10 genes including those caused by polyglutamine-coding (CAG)n repeat expansions in the SCA1-3,6,7 and 17 genes and rare forms caused by non-coding repeats in the SCA8,10, 12 and 31 genes. More recently, conventional mutations were reported in SPTBN2/SCA5, TTBK2/SCA11, KCNC3/SCA13, PRKCG/SCA14, ITPR1/SCA15/16, FGF14/SCA27 and AFG3L2/SCA28. The relative prevalence of the SCA genes and their associated phenotype was investigated in 826 index patients from families with a dominant transmission of the disease collected from 1990 to 2008 in the Pitie-Salpetriere university-hospital in Paris or through the SPATAX network (coordinator: A Durr) using standardized clinical charts. The most frequently mutated genes were SCA3 (20.4%), SCA2 (9.7%), SCA1 (7.7%), SCA7 (5.7%) and SCA6 (1.8%). Missense mutations in SCA14 (1.8%), SCA28 (1.6%), SCA13 (1.2%) and SCA5 (0.8%) were less frequent. We found SCA17 (0.2%) and SCA12 (0.2%) to be very rare, while no cases of SCA10 and SCA27 were identified. In subclinical selections, heterozygous deletions in SCA15/16 (4/76) and a non-sense mutation in SCA11 (1/77) were also detected. Genotype-phenotype correlations showed that CAG repeat expansion diseases shared a rapidly progressive and severe disease course with onset in the thirties. On the contrary, the clinical picture associated with conventional mutations in the recently identified genes was milder despite the frequent presence of marked cerebellar atrophy on MRI.

Noncoding mutations of HGF cause dysregulation of HGF and HGF/MET signalling pathways. *R.J. Morell[1], J.M. Schultz[1], S. Riazuddin[2], T.B. Friedman[1].* 1) Lab Molecular Genetics, NIDCD, Rockville, MD; 2) National Centre of Excellence in Molecular Biology, Punjab University, Lahore, Pakistan.

Hepatocyte Growth Factor (HGF) mediates a multitude of cellular pathways through a receptor tyrosine kinase encoded by the proto-oncogene MET. Expression of HGF and up-regulation of MET are characteristics of many solid tumors. Previously, we reported three noncoding germline mutations of the HGF gene associated with autosomal recessive nonsyndromic hearing loss (DFNB39). We have investigated the effects of these noncoding mutations on HGF isoform expression and on expression levels of genes in the HGF/MET signaling pathway. We established eight lymphoblastoid cell lines from individuals in four families segregating the most common DFNB39 mutation: a 3 bp deletion in a highly conserved region of intron 4 that is also transcribed as part of the 3'UTR of a novel HGF transcript (isoform 6). From each family we created a cell line from a homozygous affected individual and a heterozygous parent or sibling. We used a combination of Taqman probes that distinguish alternate splice transcripts of HGF, and SYBR Green assays of genes in various signaling pathways, in real-time PCR experiments comparing relative levels of cDNA between the homozygotes and heterozygotes. We found significant up- and down-regulation of several genes related to the MET mediated MAPK signaling pathway. Most prominently, the MAPK inhibitor SPRY2, a known regulator of cochlear development, is significantly up-regulated in homozygous cell lines. HGF isoform 6 was also significantly up-regulated in homozygous cell lines. This finding is consistent with the results of our luciferase assay which compared the effects of mutant versus wild-type 3'UTRs of isoform 6 on Renilla luciferase transcript stability. In transient transfections of HEK293 cells or NIH3T3 cells, Renilla luciferase signals persisted at significantly higher levels in cells transfected with plasmids bearing the 3 bp deletion versus those bearing a wild-type 3'UTR. We hypothesize that the 3 bp deletion affects the binding of an unknown factor and allows HGF isoform 6 to escape regulation. Overall, our experiments indicate that dysregulation of a novel short isoform of HGF leads to disruption of many genes related to the MAPK pathway. These findings will guide our evaluation of a mouse model of DFNB39 deafness.

2343/T

DFNA8/12 hearing loss in the US Population- Report of nine novel mutations in the *TECTA* gene. *M.S. Hildebrand[1], N.C. Meyer[1], C.J. Nishimura[1], H. Workmann[2], A.P. DeLuca[3,4], K.R. Taylor[3,4], B. Tompkins[3,4], C.W. Goodman[3,4], A.E. Shearer[1], P.L.M. Huygen[5], T.L. Casavant[3,4,6,7], R.J.H. Smith[1,8].* 1) Dept Otolaryngology, Univ Iowa, Iowa City, IA; 2) Department of Genetics, The Children's Medical Center of Dayton, Dayton, Ohio, USA; 3) Department of Biomedical Engineering, The University of Iowa, Iowa City, Iowa, USA; 4) Center for Bioinformatics and Computational Biology, The University of Iowa, Iowa City, Iowa, USA; 5) Department of Otorhinolaryngology, Radboud University Nijmegen Medical Centre, 6500 HB Nijmegen, The Netherlands; 6) Department of Electrical and Computer Engineering, The University of Iowa, Iowa City, Iowa, USA; 7) Department of Ophthalmology and Visual Sciences, The University of Iowa, Iowa City, Iowa, USA; 8) Interdepartmental PhD Program in Genetics, Department of Otolaryngology, University of Iowa, Iowa City, Iowa City, IA, USA.

The prevalence of DFNA8/12 hearing loss is unknown as comprehensive genetic screening in populations has not been conducted. To address this issue, we used a biased approach to determine the prevalence of DFNA8/12 mutations in autosomal dominant non-syndromic hearing loss (ADNSHL) families in the American population. In a cohort of 834 American ADNSHL families or patients, biased pre-selection was performed based on visual inspection of audiometric data. Of 72 selected families or patients, 63 (87.5%) had a DFNA8/12 audioprofile predicted by computational audioprofiling analysis. The *TECTA* gene was screened in all 72 families or patients. Nine probands were found to carry *TECTA* mutations, for a positive predictive value of 12.7%. Eight mutations were novel; one mutation (p.Arg1890Cys) has been reported in the Dutch population. The results of this study demonstrate that biased methods are effective for identification of DFNA8/12 hearing loss cases. Additionally, we have confirmed observed genotype-phenotype correlations in DFNA8/12 hearing loss and introduced new correlations that will be important in clinical management of patients. Finally, our results indicate that mutations at the DFNA8/12 locus are a common cause of ADNSHL in the American population, and that the vast majority of alleles at this locus are private mutations.

2344/T

Severe inner ear malformation and profound sensorineural hearing loss in a girl with a monoallelic *SLC26A4* mutation. *J. Samanich[1], J. Chobot-Rodd[2], J. Bent[3].* 1) Center for Congenital Disorders, Department of Pediatrics, Montefiore Medical Center, Bronx, NY; 2) Children's Evaluation and Rehabilitation Center, Albert Einstein College of Medicine, Bronx, NY; 3) Department of Otolaryngology, Montefiore Medical Center, Bronx, NY.

Background: Pendred syndrome (OMIM #274600) is an autosomal recessive condition caused by mutations in *SLC26A4*, and characterized by enlarged vestibular aqueduct (EVA), hearing impairment (HI) and goiter. However, monoallelic mutations in this gene have been associated with EVA or Mondini's dysplasia and HI, without thyroid involvement. More severe cochlear anomalies are not generally associated with *SLC26A4* mutations. Herein, we report a young girl with bilateral profound sensorineural HI and severe inner ear malformation. **Case Report**: Our patient was born full-term via cesarean section in the Dominican Republic with an unremarkable perinatal course. Prenatal history was non-contributory. Newborn hearing screening was not performed. Hearing impairment was suspected at one month of age, and was confirmed with formal testing at 26 months of age. CT scan of the temporal bones revealed marked abnormality of the inner ear structures bilaterally. She had amorphous cochlea bilaterally, with amorphous and enlarged vestibules and semicircular canals bilaterally. She had normal middle ear structures as well as external auditory canals bilaterally. At the age of three years, gross and fine motor skills were age appropriate, and speech was delayed. Family history was significant for a maternal second cousin with congenital deafness of unknown etiology. Physical examination was unremarkable, with no sign of goiter. DNA sequencing of the entire coding sequence and intron-exon borders of *SLC26A4* was performed at the Center for Genetic Testing at Saint Francis, and revealed a monoallelic mutation, c.565G>T in exon 5 (A189S). This mutation has been found in association with EVA, but not with the more severe inner ear anomalies seen in our patient. **Conclusions**: Biallelic mutations in *SLC26A4* are associated with Pendred syndrome, and monoallelic mutations have been associated with EVA and HI. We report a child with a monoallelic mutation, A189S, causing bilateral profound sensorineural HI and severe inner ear anomalies. It is possible that she has a mutation in another gene modifying her phenotype, or that there was an unidentified environmental teratogen adding to the severity of her phenotype. Additionally, it is possible that other children with similar severe inner ear anomalies have mutations in *SLC26A4*, but are not routinely tested. This report adds to the knowledge of inner ear phenotypes associated with mutations in this gene.

A Novel FLNA Mutation (c. 3686A>G/Y1229C) in Exon 22 Results in Melnick-Needles Syndrome. *G.A. Bellus[1], J. March[1], T. Futch[1], R.S. Lachman[2].* 1) Genetic & Metabolic Services, Department of Pediatrics, University of Colorado School of Medicine, Aurora, CO; 2) Ahmanson Department of Pediatrics, Cedars-Sinai Research Institute, UCLA School of Medicine, Los Angeles, CA.

Melnick-Needles syndrome (MNS)(OMIM 309350) is a rare, X-linked dominant skeletal dysplasia that is one of eight genetic disorders known to be caused by mutations in the filamin A gene (FLNA) located at Xp28. Other FLNA related disorders include: periventricular heterotopia (PVH); PVH-Ehlers-Danlos variant; otopalatodigital syndrome (OPD) type 1; OPD type 2; OPD spectrum disorder; frontometaphyseal dysplasia, chronic idiopathic intestinal pseudo-obstruction and FG syndrome. Clinical features of MNS include characteristic facial appearance (small face, full cheeks, micrognathia , prominent supraorbital ridge, exophthalmos) and skeletal features (short clavicles and scapulae, irregular ribbon-like ribs, bowing of long bones). MNS is lethal in males who inherit the condition from their mother but the phenotype is variable in females and males with spontaneous mutations. Thus far, mutational analyses of FLNA in individuals with MNS have revealed a total of 4 recurrent missense mutations that all localize to exon 22 (D1184E, A1188T, S1199L & G1176D) indicating that the MNS phenotype may be specific to mutations that alter the repeat 10 domain of the filamin A protein. We report a case of a 20 year old female with average stature who first came to medical attention at age 13 with back pain, scoilosis and mild leg length discrepancy. She was eventually referred to genetics clinic where she was noted to have mild dysmorphic facial features and radiographic skeletal findings that were typical of MNS. DNA sequencing of FLNA in this patient revealed the presence of a novel FLNA variant (c. 3686A>G/Y1229C) that was not found in either of her unaffected parents and is therefore likely to be a new mutation. Analysis of the X-inactivation pattern in blood leukocytes revealed skewing at a ratio of greater than 97:3 suggesting that skewing of X-inactivation may play a significant role in the severity of the MNS phenotype in this patient and possibly other females with MNS. Our findings support the hypothesis that the MNS phenotype is due to specific sequence changes in the filamin A repeat 10 domain.

2346/T

A Brazilian family with IBMPFD caused by p.R93C mutation in the VCP gene and literature review for genotype-phenotype correlations. *R. Fanganiello[1], V. Kimonis[2], C. Corte[3], R. Nitrini[4], M.R. Passos-Bueno[1].* 1) Dept Genetics & Evolution, Univ Sao Paulo, Sao Paulo, Sao Paulo, Brazil; 2) Division of Genetics and Metabolism, Department of Pediatrics, University of California, Irvine, CA 92868, USA; 3) Clinost, Fortaleza, Ceará, Brazil; 4) Department of Neurology, Reference Center for Cognitive Disorders, Hospital das Clínicas, University of São Paulo, São Paulo, SP, Brazil.

Inclusion body myopathy associated with Paget disease of bone and frontotemporal dementia (IBMPFD) is a progressive, rare and usually misdiagnosed autosomal dominant disorder clinically characterized by a triad of features: proximal and distal muscle myopathy, early onset Paget disease of bone (PDB) and frontotemporal dementia (FTD). It is molecularly homogeneous, caused by missense mutations in the valosin containing protein gene (VCP). We described the clinical and molecular findings of the first Brazilian family identified with IBMPFD. The proband presented with the classical clinical features. Progressive myopathy affecting the limb girdles was detected by clinical examination followed by muscle biopsy and creatine kinase measurement. PDB was suggested after bone anatomopathological examination and FTD, with features of semantic dementia, was diagnosed through clinical, neuropsychological and language evaluations. Brain magnetic resonance imaging revealed severe atrophy of the anterior temporal lobes, including the hippocampi. R93C mutation in VCP was detected by direct sequencing gene mutation screening in subject W. and in his mother, subject N, who died at 81 years of age, with a 20 years history of progressive dementia. We were not able to evaluate other members of the family but 4 more individuals diagnosed with “dementia” were reported in this family. We also present a comprehensive genotype-phenotype correlation analysis of mutations in VCP in 182 patients from 29 different families described in the literature and show that while IBM is a conspicuously penetrant symptom, independently of the protein domain harboring the mutation, PDB has a lower penetrance when associated with mutations in the AAAD1 domain and FTD has a lower penetrance when associated with mutations in the Junction (L1-D1) domain. Furthermore, the R93C mutation is likely to be associated with the penetrance of all the clinical symptons of the triad. We would like to point out that IBMPFD should be considered when the patient has at least 2 of the symptoms of the triad and mutation screening on VCP encoding gene should be suggested for confirmation of the diagnosis.

2347/T

A novel SEC23A missense mutation causing Cranio-Lenticulo-Sutural Dysplasia is involved in the MAPK signaling pathway. *S. Kim, J. Liu, E. Cherkez, S. Boyadjiev, J. Kim.* Pediatrics, UCDMC Mind Inst, Sacramento, CA.

Cranio-lenticulo-sutural dysplasia (CLSD) is an autosomal recessive disease with late-closing fontanels, cataracts, facial dysmorphisms and skeletal defects. The extracellular matrix (ECM) is a complex structural entity surrounding and supporting cells that are found within tissues. Collagens are the most abundant proteins of ECM. We have identified a patient with CLSD due to M702V mutation in SEC23A. Cultured skin fibroblasts from this new patient showed secretion defect of collagen and enlarged endoplasmic reticulum. In addition, phosphorylation of MAPK/Erk and cyclin D1 protein expression in the patient’s cells were significantly decreased, while AKT phosphorylation was significantly increased as compared to control cells. G0/G1 arrest was also shown in the patient cells. In corroboration, phosphorylation of MAPK/Erk and cyclin D1 were significantly decreased when wild type fibroblasts were transfected with sec23A 702V plasmid. Our data suggest that SEC23A exports secretory proteins involved in MAPK/Erk -related cell proliferation and cell cycle signaling pathway.

New FKBP10 patient expanding the phenotypic spectrum of this rare and severe recessive form of Osteogenesis imperfecta. *M. Le Merrer, G. Baujat, S. Dos Santos, G. Goudefroye, G. Pinto, G. Finidori, J.P. Bonnefont, A. Munnich, V. Cormier-Daire, A.S. Lebre.* Université Paris Descartes, AP-HP Hôpital Necker-Enfants Malades et Inserm U781, Départements de Génétique et d’Orthopédie et traumatologie pédiatriques, Paris F-75015 France.

Osteogenesis imperfecta (OI) is a heritable brittle bone disease presenting with clinical heterogeneity (severity from mild to neonatal lethal) and genetic heterogeneity (autosomal- dominant and -recessive forms). OI involves type I procollagen (designed as proα1(I)), a heterotrimer composed of two α1(I) and one α2(I) chains assembled in the lumen of the endoplasmic reticulum (ER). The proα1(I) triple helical domain, which is characterized by a repeating Gly-X-Y triplet, undergoes a series of posttranslational modifications in the ER. They include 3-hydroxylation of the Pro-986 residue, which is accomplished by a complex comprising cartilage-associated protein (CRTAP), prolyl 3-hydroxylase (P3H1) and cyclophilin B (CyPB), encoded by the CRTAP, LEPRE1, and PPIB genes, respectively. Chaperones, including HSP47 and the ER-resident cis-trans isomerase FKBP65 (encoded by the SERPINH1 and FKBP10 genes, respectively) assist with proper chain registration and folding of the molecules into the collagen triple helix. The majority of OI patients have dominant forms with mutations in COL1A1 or COL1A2 genes. Recently, mutations in the CRTAP, LEPRE1, PPIB, SERPINH1 and FKBP10 genes have been described in OI patients with recessive forms. In this study, we described the clinical, radiologic, and genetic features of a new FKBP10 patient originated from Turkey with a homozygous mutation in exon 6 (c.950_951dupTC, p.Gly318fs). This patient presented with progressive long bone deformities including an unusual aspect of the iliac bone with severe acetabular protrusion, narrowness of the iliac wing, no platyspondily, no dentinogenesis imperfecta and white sclera. Interestingly, bisphosphonate treatment was inefficient. We performed a meta-analysis of the literature and compared his phenotype with the other reported patients with recessive forms of OI to identify a possible clinical or radiological pattern. This report further describes the phenotypic spectrum of FKBP10 mutations and will hopefully contribute to define the hallmark of FKBP10 defect.

2349/T

***MKS1* mutations are a new cause for Joubert syndrome, expanding the genetic overlap with Meckel syndrome.** *D. Doherty[1], E.A. Otto[2], N.T. Gorden[1], J. Adkins[1], J.C. Dempsey[1], D. Knutzen[3], S. Aysun[4], M.A. Parisi[5], F. Hildebrandt[2], I.A. Glass[1].* 1) Dept Pediatrics, Univ Washington, Seattle, WA; 2) Dept of Pediatrics, University of Michigan, Ann Arbor, MI; 3) Dept Obstetrics and Gynecology, Madigan Army Medical Center, Tacoma, WA; 4) Dept of Pediatric Neurology, Hacettepe University, Ankara, Turkey; 5) National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD.

Mutations in *TMEM67/MKS3*, *CC2D2A*, *CEP290*, and *RPGRIP1L* cause both Joubert (JS) and Meckel syndromes, while *MKS1* mutations have only been reported in patients with Meckel syndrome. To determine whether *MKS1* mutations can cause the JS phenotype, we sequenced the exons and intron-exon boundaries in our large cohort of patients with JS, ascertained by the molar tooth sign on brain MRI and clinical features. We identified *MKS1* mutations in 6/190 families. In three families with known consanguinity and homozygosity at the *MKS1* locus, we identified 1) a homozygous missense mutation (c.55G>T, p.D19Y) that is predicted to be damaging, 2) a homozygous single basepair insertion (c.1528-1529insC, p.R510PfsX81) near the 3' end of the gene resulting in a frameshift that replaces the C-terminus of the protein, and 3) a homozygous mutation that removes the branch splice site in intron 3, previously described in Meckel syndrome. In three families without known consanguinity, we found 1) compound heterozygosity for a splice mutation previously reported in a fetus with Meckel syndrome (c.417G>A) and a missense mutation (c.1208C>T, p.S403L), 2) compound heterozygosity for a single basepair deletion leading to a frameshift and truncation (c.381delC, p.T127Tfs17X) and a 3-base pair deletion (c.1115_1117delCCT, p.S372del) that removes a single serine residue and is predicted to be damaging, and 3) homozygosity for the same 3-base pair deletion (c.1115_1117delCCT, p.S372del). Additional clinical features at 2-21 years of age include: kidney disease (1/6), liver disease (1/6) and abnormal ERG (1/6) but no encephalocele, polydactyly, or coloboma (optic pit in 1/6). These are the first *MKS1* mutations reported in patients with JS, confirming genetic overlap with Meckel syndrome. The mutations associated with JS may have less impact on MKS1 function, since all Meckel patients have combinations of truncating and splice mutations while most JS patients have single amino acid changes (2 patients) or combinations of single amino acid changes with truncating/splice mutations (2 patients). Based on our data, we estimate that *MKS1* mutations account for ~3% of JS and propose that *MKS1* testing should be considered in all JS patients, not just those with features of Meckel syndrome.

2350/T

Genetic variation of serotonin receptor 2A gene may influence age at onset but not cognitive performance in patients with temporal lobe epilepsy. *I. Manna[1], A. Labate[1,2], U. Aguglia[3], G. Palamara[2], L. Mumoli[1,2], A. Fratto[1,2], F. Condino[1], G. Di Palma[1], A. Quattrone[2], A. Gambardella[1,2].* 1) Institute of Neurological Sciences, National Research Council,Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 3) Regional Epilepsy Centre, Hospital of Reggio Calabria, Italy.

Serotonin (5-hydroxytryptamine or 5-HT) and its receptors, including the 5-HTR2A receptor, are important for learning and memory. There is also evidence that impairment of the 5-HT neurotransmission may be involved in the pathophysiology of temporal lobe epilepsy (TLE). In this study, we wished to explore the association of a functional single nucleotide polymorphism (SNP) at position 1354C/T of the 5-HTR2A receptor with the memory decline. We conducted a detailed neuropsychological and molecular study in a group of patients with mild nonlesional TLE. A total of 138 consecutive patients (78 female, mean age 50.2 years, SD ± 17.9; range 14 to 87) with mild non-lesional TLE were entered into the study. All patients received a diagnosis of TLE after comprehensive clinical, neuropsychological, EEG, and MR evaluations. All patients were Caucasian and were born in Italy. All gave written informed consent prior to participation in the genetic studies. Genomic DNA was isolated from each sample. The target fragment of 5-HTR2A gene was amplified by PCR. The SNPs in 5-HTR2A gene were detected by denature high performance liquid chromatography (DHPLC) combined with DNA sequencing. which predicts an amino acid substitution (His to Tyr) at residue 452. All patients had undergone a standardized neuropsychological examination, twenty-five percent (34/138) had test scores indicating verbal memory deficit (VMD), and they where divided in two groups: cognitively impaired (34) and preserved (104). We did not observe a significant differences of the 1354 C/T polymorphism between the two TLE groups, both in the comparison of genotype distribution (p= 0.177) and allele frequencies (p= 0.065). We also investigated the association between the 1354 C/T polymorphism and age at onset of epilepsy, and found that patients carrying the 1354T allele had a significant earlier onset of the disease (p= 0.006). The results of the present study demonstrate that the T allele of 5-HTR2A variant at position 1354 may influence an earlier age of onset of TLE. Nonetheless, this polymorphism has not major impact on memory functions in patients with mild TLE.

2351/T

ATP7B mutation analysis of nine Taiwanese families with Wilson disease. *S. Chang[1,4], G. Ma[1], W. Lin[1], M. Chen[1,2,3].* 1) Dept Medical Genetics, Changhua Christian Hosp, Changhua City, Taiwan; 2) Department of Obstetrics and Gynecology, National Taiwan University, Taipei, Taiwan; 3) Department of Obstetrics and Gynecology, Changhua Christian Hospital, Changhua, Taiwan; 4) Department of Life Science, National Chung Hsing University, Taichung, Taiwan.

Wilson disease (WD) is a genetically and phenotypically heterogeneous disorder of copper transport with hepatic and/or neurological symptoms. It is caused by mutations in ATP7B that result in copper storage in liver and brain. At present more than 400 ATP7B mutations have been reported in WD patients. In this study, we screened for mutations in all the coding sequences and exon-intron boundaries of the ATP7B gene in nine unrelated WD families, and the results were compared with the oneline reference sequence and normal control data. A total of 12 mutations (including 11 misssense mutaions and one nonsense muation) that were not found in the normal controls and the SNP database were found in our patinets. Almost all of these mutations have been reported in literature as disease-causing mutations, except for two novel mutations, p.D1047V and p.V1297I. All of the missense mutations lay in critical functional domains of the ATP7B protein (e.g. the transmembrane region, the transduction domain, the phosphorylation domain, the ATP-hinge region and the ATP-binding domain). Of the mutations we identified, the p.R778L mutation was found repetitively, with a carrier rate of 77.8% (in 7/9 families) and a mutant allele frequency of 38.9%, suggesting a hotspot of Taiwanese population. The mutations of p.Q1142H and p.I1148T are alos common, with frequency of 11.1%. Our results add the short list of ATP7B mutations in Chinese/Taiwanese population, and are helpful for the diagnosis and counseling of WD.

2352/T

A genome-wide association and linkage study (GWALS) identifies two loci modifying lung disease severity in Cystic Fibrosis: North American CF Modifier Consortium. *G. Cutting[1], C.F. Modifier Consortium[2].* 1) Inst Gen Med, Johns Hopkins Sch Med, Baltimore, MD; 2) North American CF Modifier Consortium (Univ of N Carolina, Case Western U, Hosp for Sick Children, Toronto, Johns Hopkins).

Cystic Fibrosis (CF) is a multi-system life-limiting disorder due to dysfunction of the CFTR gene. Progressive obstructive lung disease, the major cause of mortality in CF, is highly variable and poorly correlated with CFTR genotype. Affected twin and sibling analysis demonstrates that variation in forced expiratory volume in 1 second (FEV1), a lung function measure predictive of survival, is heritable (h2 = 0.5-0.8). To identify the genetic modifiers underlying variation in CF lung function, 3 independent studies (Genetic Modifier Study (GMS: case-control), CF Twin and Sibling Study (CFTSS: family-based) and Canadian Consortium for Genetic Studies (CCGS: population-based)) combined to form the CF Modifier Consortium. The Consortium developed a CF-specific lung function measure based on FEV1 using survival-corrected centile scores. 3,467 CF patients stratified by lung function were genotyped using the Illumina 610K SNP array. 570,748 SNPs were validated with call concordance rate of 0.9987. Association analysis of 2494 patients from the GMS and CCGS identified seven regions of suggestive significance ($p<1.8 \times 10^{-6}$). When the analysis was confined to 1978 patients with identical CFTR genotypes (F508del /F508del), a cluster of five SNPs in moderate LD ($r2>0.6$) within a suggestive region on chromosome 11p13 exceeded genome-wide significance ($p<8.8 \times 10^{-8}$). Linkage analysis of 486 sibling pairs from the CFTSS was performed using 19,566 SNPs with minor allele frequency>0.4 and $r2 <0.01$ between adjacent SNPs. A genome-wide significant peak with multipoint LOD score of 5.03 occurred on chromosome 20q13.2 and a region of suggestive linkage (LOD score= 2.6) was observed on 1q11. As the 20q13.2 region had been previously linked to a nutritional phenotype, and nutritional status is correlated with CF lung function, analysis was repeated with BMI as a covariate, resulting in an increase in LOD to 5.72 for the same region. Regional association analysis was performed using 2494 unrelated patients from the GMS and CCGS samples and 306 SNPs drawn from a 1.314 Mb 1-LOD critical region on 20q13.2. A set of SNPs in the critical region were suggestive of association, consistent with incomplete tagging of low-frequency variants. These results demonstrate that genome-wide methods are applicable to discovery of loci that modify quantitative measures of disease severity in a monogenic trait. Genes of substantial biologic relevance to CF occur at both loci.

2353/T

Frequency of point mutations and intragenic rearrangements in REEP1 responsible for SPG31. *C. Goizet[1,2], C. Depienne[1,3], A. Boukhris[1,3,4], E. Mundwiller[1], E. Fedirko[3], E. Denis[3], D. Hannequin[5], P. Charles[3,6], I. Feki[4], J.F. Pinel[7], J. Yaouanq[7], B. Fontaine[6], A. Durr[1,3,6], A. Brice[1,3,6], G. Stevanin[1,3,8].* 1) CR-icm, INSERM / UPMC UMR_S975, NEB, Paris, France; 2) Université Victor Segalen Bordeaux 2, Laboratoire de Génétique Humaine, Bordeaux, France; 3) AP-HP, Pitié-Salpêtrière Hospital, Département de Génétique et Cytogénétique, Fédération de Génétique, Paris, France; 4) Service de Neurologie, Hôpital Habib Bourguiba, Sfax, Tunisia; 5) Service de Neurologie, CHU Rouen, France; 6) GHU Pitié-Salpêtrière, Fédération des Maladies du Système Nerveux, Paris, France; 7) Hôpital Pontchaillou, Clinique Neurologique, CHU Rennes, France; 8) EPHE, Paris, France.

Hereditary spastic paraplegias (HSP) constitute a clinically and genetically heterogeneous group of neurodegenerative disorders characterized by slowly progressive spasticity of the lower extremities. Mutations in the SPG31 gene, REEP1, were initially associated with a pure dominant form of the disease. Our objective was to estimate the frequency of SPG31 in Western European HSP families, to define the spectrum of mutations in REEP1 and to describe the associated phenotypes. To this end, we sequenced all exons of REEP1 in a large panel of 177 unrelated European HSP index patients from kindreds with dominant inheritance, with either pure (n=92) or complicated (n=85) forms of the disease. They mostly originated from France. We also looked for rearrangements using a dedicated MLPA (MRC_Holland) kit. We identified 12 different heterozygous mutations in 12 different families of French origin, with either a pure or a complex phenotype; 3 affected the splicing of the gene, 2 were exon deletions, 3 were missense mutations and 3 were small indel or point mutations introducing premature stop codons. In addition, we also found a variation in the 3'UTR that might alter the binding of microRNA. The overall mutation rate in our clinically heterogeneous sample was 7.3%, and 3.5% by taking into account HSP cases with other known entities.

Genotype-phenotype correlations in subjects with X-linked hypohidrotic ectodermal dysplasia. *H. Schneider[1], J. Hammersen[1], K. Huttner[2], A. Bohring[3].* 1) Department of Pediatrics, University of Erlangen-Nuremberg, Erlangen, Bavaria, Germany; 2) Edimer Pharmaceuticals Inc., Cambridge, USA; 3) Institute of Human Genetics, University of Muenster, Germany.

Background: X-linked hypohidrotic ectodermal dysplasia (XLHED), the most common ectodermal dysplasia, is caused by EDA gene mutations. Reduced sweating is a major cause of XLHED-associated morbidity and mortality. To characterize the genotype-phenotype relationship, sweat gland function was assessed non-invasively in genotyped XLHED patients. **Subjects and Methods:** 27 male XLHED subjects aged 2 to 57 years and 17 healthy male controls aged 5 to 56 years were studied at a family conference in Germany (clinicaltrials.gov NCT01109290). Informed consent was obtained from all participants. Parameters determined included palmar sweat pore density, sweat volume produced after stimulation with pilocarpine using the Wescor 3700 device, and palmar skin conductance measured with the Med-Storm 1001 device. **Results:** Control subjects had 423 sweat pores/cm2 on average (range 294-669) and a mean sweat volume of 77 µl following stimulation (38-93 µl). In 5 of 14 XLHED children and 1 of 13 XLHED adults some sweat was detectable by the Wescor assay (1.0-11.0 µl). However, there was a clear demarcation between XLHED males and controls. Among XLHED subjects, 12/27 had neither detectable sweat pores nor inducible sweating, 13/27 showed a few sweat pores (6-113/cm2) correlating with absence of sweat or low sweat volumes (up to 11.0 µl), and 2/27 had normal sweat pore counts but reduced sweat volumes. Basal skin conductance, an indirect measure of skin hydration, was reduced (<20.0 µS) in 20 of 21 non-sweating and 1 of 6 low-sweating XLHED patients, but none of the 17 controls. Similarly, stimulated skin conductance following blood sampling was reduced (<10.0 µS) in all 21 non-sweating XLHED subjects, 3 of 6 with decreased sweating, and 4 of 17 controls. In this XLHED cohort representing 22 different EDA genotypes, exon deletions, nonsense and splice-site mutations and mutations affecting the furin cleavage site of ectodysplasin-A were consistently associated with compromised sweat gland function across all measurements. **Conclusions:** In contrast to prior reports on non-genotyped HED populations with qualitative sweat assessment, this study on XLHED males confirmed a consistent, quantifiable defect in sweat gland function as a disease biomarker, even in the setting of normal sweat pore counts. Skin conductance measurements may be useful as a screening tool, but have reduced sensitivity in detecting XLHED subjects with residual sweat gland function.

2355/T

High level deletion mosaicism in Cornelia de Lange with severe phenotype. *C. Gervasini[1], J. Azzollini[1], D. Rusconi[2], P. Castronovo[1], A. Cereda[3], M. Masciadri[4], S. Russo[4], A. Selicorni[3], P. Finelli[2], L. Larizza[1].* 1) Div Medical Genetics, Univ Milano San Paolo Sch, Milan, Italy; 2) Cytogenetics Laboratory Istituto Auxologico Italiano, Milano, Italy; 3) Ambulatorio Genetica Clinica Pediatrica Università Milano Bicocca Fondazione MBBM A.O S Gerardo Monza, Italy; 4) Molecular Laboratory Istituto Auxologico Italiano, Milano, Italy.

Cornelia de Lange (CdLS, MIM #122470, #300590, #610759) is a rare, congenital neurodevelopmental syndrome characterized by growth/mental retardation, dysmorphic face and limb reduction defects. Wide phenotypic variability is common in the CdLS patients. Mutations in NIPBL, SMC1A and SMC3 genes, encoding for a regulator and two subunits of the cohesin complex respectively, are found in 60-65% of CdLS patients. A CdLS patient with severe typical phenotype was tested by DHPLC and direct sequencing for NIPBL and SMC1A genes and found negative. The ERCC8 gene, responsible for Cockayne syndrome, was then screened as plausible candidate based on the partial clinical overlapping between the two syndromes, but no sequence alteration was detected. In order to exclude rare chromosomal rearrangements affecting the major CdLS genes, BAC-FISH was performed targeting the NIPBL gene. An asymmetric signal was apparent in a fraction of cells, suggesting a genomic deletion in mosaic condition. The finding was confirmed by aCGH analysis which showed a large deletion encompassing exons 3-23 in about 80% of the cells. This case provides the second evidence of mosaicism in CdLS and raises the issue of the variable associated clinical phenotypes. We have recently described a patient with low-level mosaicism for a point mutation who displayed a phenotype milder than predicted by a truncating mutation. Conversely the high deletion mosaicism here reported is associated with a severe presentation as attested by death of the proband at age one year. Further evidence of mosaicism could explain the clinical heterogeneity of CdLS, highlighting the likely underestimated mutation rate of known genes.

2356/T

Molecular & clinical analysis of the *retinoic acid induced 1* gene (*RAI1*) in patients with suspected Smith-Magenis Syndrome without the 17p11.2 deletion. *A.C.M. Smith[1], T. Vilboux[2], C. Ciccone-Stevens[2], J. Blancato[3], G. Cox[4,5], W. Introne[1], W.A. Gahl[1,2], M. Huizing[2].* 1) Office Clinical Dir, NHGRI/NIH, Bethesda, MD; 2) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 3) Dept. of Oncology, Georgetown University Medical Center, Washington, DC; 4) Div. of Genetics, Children's Hospital Boston and Dept Pediatrics, Harvard Medical School, Boston, MA; 5) Genzyme Corporation, Cambridge, MA.

Smith-Magenis syndrome (SMS) is a complex developmental disorder characterized by multiple congenital anomalies. The syndrome is primarily ascribed to a ~3.7 Mb de novo deletion on chromosome 17p11.2. Haploinsufficiency of multiple genes likely underlies the complex clinical phenotype. *RAI1 (Retinoic Acid Induced 1)* is recognized as a major gene involved in the SMS phenotype. Extensive genetic and clinical analyses of 36 patients with SMS-like features, but without the 17p11.2 microdeletion, yielded 5 patients with *de novo* and 5 patients with novel *familial RAI1* variants. Haplotype analysis showed two major *RAI1* haplotypes in our primarily Caucasian cohort; the novel *RAI1* variants did not occur in a preferred haplotype. RNA analysis revealed for the first time that *RAI1* mRNA expression was significantly decreased in cells of patients with the common 17p11.2 deletion, as well as in those with *de novo RAI1* variants. Expression levels varied in patients with familial *RAI1* variants and in non-17p11.2 deleted patients without identified *RAI1* defects. No correlation between SNP haplotype and *RAI1* expression was found. Two clinical features, ocular abnormalities and polyembolokoilomania (object insertion), were significantly correlated with decreased *RAI1* expression. While not significantly correlated, the presence of hearing loss, seizures, hoarse voice, childhood onset of obesity and specific behavioral aspects and the absence of immunologic abnormalities and cardiovascular or renal structural anomalies, appeared to be specific for the *de novo RAI1* subgroup. Recognition of the combination of these features may assist in referral for *RAI1* analysis of patients with SMS-like features without detectable microdeletion of 17p11.2.

2357/T

The genetic perspective from a large ethnically mixed cohort of patients with BBS. *C. Deveault[1], G. Billingsley[1], J. Bin[1], R. Theal[1], A. Vincent[1], K.J. Fieggen[3], J.L. Duncan[4], C. Bardet-Biedl syndrome (BBS) is a pleiotropic ciliopathy disorder characterized by retinal degeneration, obesity, polydactyly, renal and genital abnormalities and cognitive impairment. To date, mutations have been identified in fourteen genes (*BBS1-BBS14*) that account for ~70% of affected individuals. BBS was previously shown to genetically and clinically overlap with other ciliopathies such as McKusick-Kaufman syndrome (MKKS), Alström syndrome (ALMS), Meckel-Gruber syndrome (MKS) and Joubert syndrome (JBTS). We present the analysis of our full cohort consisting of 83 probands of varied ethnic origin (104 cases) and describe 27 unpublished novel changes and novel clinical observations.

Patients were recruited from The Hospital for Sick Children, Toronto and from collaborators abroad. Mutational analysis of *BBS1-12* used different approaches including direct sequencing, homozygosity mapping and commercially available DNA chip analysis of known mutations. Phenotype analysis was as comprehensive as possible.

Two putative disease-causing mutations (EPP=3) were identified in 62 probands (74.7%) of diverse ethnicity. Nineteen new mutations were found in 7 different BBS genes (1, 2, 4, 8, 9, 10 and 12). Eight variants of unknown significance (EPP=2) were identified. Sixteen cases were found to have more than 2 mutations (EPP=3).

In addition to having typical BBS features, most of our cases (65.4%) also showed features more characteristic of other ciliopathies. We found 53.8% that showed overlap (at least 2 or more features) with ALMS, 20.5% with MKKS and 9.0% with both. Features more typical of JBTS and MKS were also observed in a few patients. The overlap and the features were not specific to any BBS genes. These numbers for the overlapping features could be underestimated as not all clinical information was available on all features for all patients. The overlap between MKKS and BBS was previously reported to be seen in chaperonin-like genes (*BBS6*, *10* and *12*) but we also observed this in patients with *BBS2* mutations.

The analysis of larger cohorts and improved phenotyping will contribute to better defining genotype-phenotype correlations and the spectrum of disease features involved which is necessary to improved patient management.

High frequency of triallelic inheritance in individuals with Leber Congenital Amaurosis. *W. Wiszniewski[1], R.A. Lewis[1,2,3,4], D. Stockton[10], J. Peng[5], G. Mardon[1,3,6,7,8], R. Chen[1,5,8], J.R. Lupski[1,2,9].* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 3) Dept Ophthalmology, Baylor Col Medicine, Houston, TX; 4) Dept Medicine, Baylor Col Medicine, Houston, TX; 5) Human Genome Center, Baylor Col Medicine, Houston, TX; 6) Dept Neuroscience, Baylor Col Medicine, Houston, TX; 7) Dept Pathology, Baylor Col Medicine, Houston, TX; 8) Program in Developmental Biology, Baylor Col Medicine, Houston, TX; 9) Texas Children's Hospital, Houston, Texas; 10) Dept Pediatrics, Wayne State University, Detroit, Michigan.

Leber congenital amaurosis (LCA) is a clinically and genetically heterogeneous retinal dystrophy. The causes of LCA have been unraveled partially at the molecular level. At least 14 genes have been reported that, when mutated, result in LCA. To understand the roles of the known genes in LCA a group of outbred subjects from 60 apparently either recessive families, with one or more affected individuals, or isolated affected patients were evaluated. One affected individual from each family underwent comprehensive mutational analysis by direct DNA sequencing of all coding regions and splice junctions of 13 LCA genes. Mutations were indentified in 70% of individuals. CEP290 made the largest contribution to the identified mutations, providing 43% of those mutant alleles. We identified seven families in which affected individuals with two mutant alleles, sufficient to cause disease, had an additional mutation at a second LCA locus. The families with mutations in more than one gene show no evidence for a more severe ocular phenotype. Our findings suggest mutational load can be important to penetrance of the LCA phenotype.

Resistance to Thyroid Hormone: description of a new mutation in a Colombian family. *J. Campos[1], P. Duran[2], F. Salguero[3], G. Laverde[4], P. Paez[5], H. Groot[1], MC. Lattig[1].* 1) Laboratorio de Genética Humana Departamento de Ciencias Biologicas Universidad de los Andes; 2) Hospital Infantil Fundacion Cardioinfantil- Instituto de Cardiología Bogota - Colombia; 3) Facultad de Medicina Universidad de los Andes Bogota - Colombia; 4) Laboratorio de Investigacion Hormonal Bogota - Colombia; 5) Fundación Clínica el Bosque, Facultad de Medicina el Bosque Bogota - Colombia.

Resistance to Thyroid Hormone (RTH) is a group of genetic entities with autosomic dominant inheritance. This syndrome is characterized by a decreased effect of the thyroid hormones with respect to their circulating levels; thyroid function tests demonstrate a persistent elevation of the thyroxine (T4) and triyodotironine (T3) and the free fractions, with an inappropriately normal or elevated TSH. Its incidence is 1 in every 40000 births, but could be higher given the greater sensitivity of the current molecular studies. RTH is caused in the majority of cases by mutations in the thyroid hormone beta receptor (TRβ), specifically in its T3 binding site. Currently, mutations in the TRβ gene have been identified in more than 343 families suffering RTH worldwide, and of these approximately 124 have been characterized as unique in each family; i.e. these mutations have not been identified in another family. We present here the clinical history of a Colombian family with RTH and report a new mutation in exon 8 of the TRβ gene, which we have named V264L. The family also presents individuals with hypothyroidism who do not manifest the V264L mutation, therefore we believe that two separate entities are segregating in the same family, one is RTH due to the V264L mutation and the other is hypothyroidism with an unknown etiology.

2360/T

Pathogenic-Or-Not -Pipeline for prediction of disease relevance of variations and their mechanism. *M. Vihinen[1, 2], J. Härkönen[1], A. Olatubosun[1], T. Tiirikka[1], J. Väliaho[1], J. Thusberg[1].* 1) Institute of Medical Techology, Univ Tampere, Tampere, Finland; 2) Science Center, Tampere University Hospital, Tampere, Finland.

Sequencing laboratories are producing ever increasing number of sequence information, which include numerous genetic variations. Analysis of the effects of these variations has become the bottleneck in many fields of genetics, especially in clinical laboratories. As normal non-harmful variations appear at very high frequency, every individual has millions of variations. Only small portion of these are disease-related or associated. Pathogenic-Or-Not -Pipeline (PON-P) is an integrated computer tool that allows - analysis whether a variation is pathogenic or benign - and for those identified as benign the analysis of putative mechanism PON-P integrates a large number of existing tools developed by our group and others and produces a summary of the predictions. The tool allows also submissions of relative large numbers of cases. The program provides a detailed summary of the predictions and the combined end result based on machine learning approach. Currently the methods included are for annotations, identification of known SNPs, tolerance of mutations, effects to stability, aggregation and disorder tendency, as well as to protein localization. PON-P is freely available at http://bioinf.uta.fi/PON-P/.

2361/T

The inheritance of missense c.487A>G mutation in GJB2 gene in two Iranian families. *M. Falah[1], M. Houshmand[2], S. Akbaroghli[3], S. Mahmodian[1], H. Emamdjomeh[1], M. Farhadi[1].* 1) Department and Research Centre of ENT & Head and neck Surgery of Iran Medical University, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology , Tehran, Iran; 3) Tehran welfare Organization, Tehran, Iran.

Abstract: Background: Mutations in GJB2 gene are the most common cause of hereditary hearing loss. The majority of GJB2 mutations are recessive, but a few dominant mutations have been associated with hearing loss. This study introduces some new fact about M163V mutation in GJB2 gene in two Iranian families. Material and Methods: Genomic DNA of Two unrelated Iranian families with hearing loss were obtained from six family members and screened for GJB2 mutations with direct sequencing. Results: Fathers of both families showed late onset hearing impairment in third or fourth decade of the life, but hearing loss in children was early onset in both families with more severity rather than fathers. Also, one grandfather of every family showed late onset hearing loss in seven decade. The analysis of familial pedigree revealed anticipation in phenotype and autosomal dominant inheritance. There was a substitution of A to G in exon 2 at nucleotide 487(M163V). This mutation was heterozygous in fathers and children while mothers were normal. Discussion: Previously, M163V always introduced as unknown heterozygous not even as compound heterozygous. Researcher showed the produced protein of M163V failed in the formation of homotypic junctional channel. Due to other mutation in this nucleotide was reported as M163L in autosomal dominant inheritance that defects trafficking to the plasma membrane and increase cell death. Our finding can confirm the autosomal dominant inheritance of this mutation. This hypothesis was further supported by conservation of the methionine residue at position 163 across the 23 mammalian species.

2362/T

Tyrosinase-related Oculocutaneous Albinism (OCA1A/B): report of the G47D mutation in Colombia. *D. Sanabria[1], H. Groot[1], J. Guzman[2], MC. Lattig[1].* 1) Laboratorio de Genetica Humana Departamento de Ciencias Basicas Universidad de los Andes Bogota - Colombia; 2) Fundación Universitaria del Área Andina Bogota - Colombia.

Oculocutaneous Albinism (OCA) is an autosomic recessive inherited disorder characterized by lack of the pigment melanin in melanocyte-containing tissues such as hair, skin, and eyes. The enzyme tyrosinase, codified by the gene TYR, has been shown to be responsible for Oculocutaneous Albinism Type 1 (OCA1A/B). To date approximately 230 mutations have been described as responsible for OCA1A/B in different populations. The aim of this study is to further understand the history of albinism in Colombia by following the G47D mutation found in a family that lives in its capital, Bogota, and its relationship to individuals with OCA1 in the small town of Cienega - Boyaca located on the eastern Andes Mountains. The family with OCA1 in Bogota has two affected individuals, one with OCA1A and the other is diagnosed with OCA1B where both members are heterozygous for the G47D and the second mutation has not been found. Two individuals that were born and raised in the town of Cienega, diagnosed with OCA1 are homozygous recessive for the mutation G47D. After examining official town and church records of births, deaths, and marriages and by personal interviews with people from the town it could be concluded that the individuals from Cienega and the family in Bogota have a common ancestral parent who lived approximately during 1850. The G47D mutation has been previously reported on Hispanic populations such as Canary Islands, Puerto Rico, Cuba and Mexico and it is believed to have originated in the Moroccan Jew and Sephardic (Spanish) populations. Haplotype analysis is on the way to verify if the G47D mutation found in Colombia has the same founder origin as the Puerto Rican/Moroccan Jew populations.

2363/T

Co-inheritance of Beta-Thalassemia and Fragile-X Syndrome in a Turkish Family. *I. Keser[1], T. Bilgen[1], Y. Arikan[1], E. Mihci[2], O. Duman[3], A. Yesilipek[4], S. Haspolat[3].* 1) Med Biol & Gen, Med Faculty,Akdeniz Univ, Antalya, Antalya, Turkey; 2) Pediatric Genetics, Med Faculty,Akdeniz Univ, Antalya, Antalya, Turkey; 3) Pediatric Neurology, Med Faculty,Akdeniz Univ, Antalya, Antalya, Turkey; 4) Thalassemia Unit, Pediatric Hematology, Med Faculty,Akdeniz Univ, Antalya, Antalya, Turkey.

Background: Hemoglobinopathy and mental retardation are the most severe health problems in the populations. Beta-thalassemia and fragile X syndrome (FXS) are common diseases among hemoglobinopathies and inherited cause of mental retardation, respectively. In this study, we aimed to investigate and to report the co-inheritance and effect of beta-thalassemia and FXS in a Turkish family. Methods: Following the pedigree analysis, DNA extraction from peripheral blood, amplification and DNA sequencing of the beta-globin gene and fragment analysis for CGG repeats of the Fragile X Mental Retardation 1 (FMR1) gene were done for each member at risk in the family. Results: We found the expansion from premutation to full mutation of the CGG repeats of FMR1 gene and the co-inheritance of this CGG instability and codon 39 (C-T) mutation of beta-globin gene in the family with the first cousin consanguinity. While proband, 4 year old male, had full mutation and carrier for codon 39, his brother had premutation and beta-thalassemia major phenotype due to codon 39 homozygosity. Proband's father had carrier for codon 39 mutation and mother's had carrier for both codon 39 and premutation for FMR1 gene. Conclusion: Although the association of beta-thalassemia and other diseases such as Down syndrome has been reported, the co-inheritation of beta-thalassemia and fragile X syndrome had not been reported in literature. Our findings suggest that co-inheritance of both diseases which were transmitted by two different modes is important to discuss the clinical findings due to both diseases and to give genetic counseling to the families at risk.

2364/T

Identification of novel mutations in myosin VIIA gene in two Chinese families with either high- or low-frequency non-syndromic deafness. *H. Yuan[1], Y. Sun[1], J. Chen[1,2], H. Sun[1,3], J. Cheng[1], J. Li[1], Y. Lu[4], Y. Lu[1], Z. Jin[1], Y. Zhu[1], P. Dai[1], X. Liu[1,5], R. Wang[1].* 1) Institute Of Otolaryngology, Chinese PLA General Hospital, Beijing 100853, China; 2) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 3) Department of Otolaryngology, General Hospital of Chinese People's Armed Police Force, Beijing, 100039, China; 4) Department of Obstetrics and Gynecology, Chinese PLA General Hospital, Beijing 100853, China; 5) Department of Otolaryngology, University of Miami, Miami, FL, USA.

The Myosin VIIA (MYO7A) gene encodes a protein classified as an unconventional myosin. Mutations within MYO7A can lead to both syndromic and non-syndromic hearing impairment in humans. Among 340 different mutations reported in MYO7A, only five led to non-syndromic sensorineural deafness autosomal dominant type 11 (DFNA11). Here, we present the clinical, genetic, and molecular characteristics of two large Chinese DFNA11 families with either high- or low-frequency hearing loss. Affected subjects of family DX-J033 have a sloping audiogram at young ages at high frequency, and then affected all test frequencies with increased age. Affected members of family HB-S037 present with an ascending audiogram affecting low frequencies at young ages, and then all frequencies were involved, with increasing age. Genome-wide linkage analysis mapped the disease loci within the DFNA11 interval for both families. DNA sequencing of MYO7A revealed two novel nucleotide variations, c.652G>A (p.D218N) and c.2011G>A (p.G671S), in the two families. Neither of these two mutations was detected in DNA from 100 unrelated Chinese controls. Sequence alignments of MYO7A revealed that the two novel mutations are highly conserved across species and among different myosin classes. The identified mutations in MYO7A in the present study are the first reported cases to be implicated in DFNA11 in Chinese population. For the first time, we tested the Electrocochleography (ECochG) in DFNA11 family with low-frequency hearing loss and speculated that the low-frequency sensorineural hearing loss in DFNA11 family was not related to endolymphatic hydrops.

2365/T

Candidate gene approach in identification of disease-associated genes in Myofibrillar myopathy. *H. Lee[1], P. Serdaroglu-Oflazer[2], M. Olivé[3], Z. Odgerel[1], P. van der Ven[4], D. Fürst[4], L. Goldfarb[1].* 1) 1National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MarylandNINDS, NIH, Bethesda, MD; 2) Medical Faculty, Istanbul University, Istanbul, Turkey; 3) IDIBELL-Hospital Universitari de Bellvitge and CIBERNED Hospitalet de Llobregat, Barcelona, Spain; 4) Department of Molecular Cell Biology, Institute of Cell Biology, University of Bonn, Bonn, Germany.

Myfibrillar myopathy (MFM; OMIM # 601419) is a group of neuromuscular disorders caused by mutations in genes coding for sarcomeric Z-disk proteins. Dominant germline and de novo mutations in seven genes (DES, MYOT, LDB3, CRYAB, BAG3, FLNC, and FHL1) have been established as the cause of MFM, but a significant number of MFM patients failed to show disease causing mutations in routinely tested genes. Fourteen additional Z-disk associated proteins closely interacting with MFM-causing proteins are likely to be involved in MFM, although such association has not been reported yet. In order to maximize the efficiency of etiological search, we used 10K-genotyping based approach for molecular testing in large families. The family under study was a recently identified large kindred of Macedonian ancestry affected with an MFM-type myopathy. According to the family history, MFM has been transmitted in at least four consecutive generations. Segregation analysis demonstrated autosomal dominant inheritance. Genome-wide 10K single nucleotide polymorphism (SNP) genotyping was performed in 21 family members including 10 MFM patients. Linkage analysis excluded six known MFM-causing genes and 14 potential candidates (1.6 Mb in total) with LOD scores of less than -2. Suggestive linkage was found in the FLNC region which showed a seven point LOD score of 2.9. Subsequent DNA sequence analysis of the FNLC coding region was complicated by inconsistencies caused by the interference with an unknown by that time highly homologous FLNC pseudogene located on chromosome 7q32-q35, about 53.6 kilobases downstream of the functional FLNC gene in inverted orientation. Using optimized procedures, the disease-causing mutation was eventually uncovered in exon 48 of FLNC. This mutation cosegregated with the disease. In conclusion, genome wide linkage analysis in sufficiently large MFM-affected families can effectively exclude candidate genes and focus sequencing effort on a gene showing evidence of involvement.

2366/T

Identification of novel ENaC gene mutations in African patients with cystic fibrosis-like disease. *L. Mutesa Sr[1, 2], C. Verhaeghe[1], J.F. Vanbellinghen[1], V. Dhennin[3], A. Uwineza[2], H. Cuppens[4], C. Korbmacher[5], V. Bours[1].* 1) Dept Medical Genetics, Univ Liege, Belgium, Liege, Belgium; 2) Center for Medical Genetics, National University of Rwanda, Rwanda; 3) GIGA-Genomics Facility, University of Liège, Belgium; 4) Department of Human Genetics, Katholieke Universiteit Leuven, Belgium; 5) Institut für Zelluläre und Molekulare Physiologie, Universität Erlangen-Nürnberg, Germany.

The defect in chloride and sodium transport in cystic fibrosis (CF) patients is a consequence of CFTR loss of function and/or an abnormal interaction between CFTR and ENaC. A few patients were described with CF-like symptoms with a single CFTR mutation and/or an ENaC mutation. In our previous study (Mutesa L. et al., Genetic analysis of Rwandan patients with cystic fibrosis-like symptoms: identification of novel CFTR and ENaC gene variants. Chest 2009, 135:1233-1242), we have identified in small group of CF African patients several novel ENaC gene mutations in association with CFTR mutations. In the present study, we extensively performed ENaC genes sequencing of the remaining CF patients without any CFTR mutation. Several novel ENaC gene mutations were identified and some of them were located in highly conserved domains and consistent with a pathophysiological role. Our data suggest that CF-like syndrome in Africa could be associated with ENaC mutations.

2367/T

A novel NF1 gene mutation in an Italian family with neurofibromatosis type 1. *A. Gabriele[1], M. Ruggieri[2], M. Muglia[1], A. Patitucci[1], A. Magariello[1], R. Mazzei[1], F.L. Conforti[1], C. Ungaro[1], G. Di Palma[1], L. Citrigno[3], W. Sproviero[4], A. Gambardella[1,4], A. Quattrone[5].* 1) Institute of Neurological Science (ISN), National Research Council (CNR), Cosenza, Italy; 2) Department of Paediatrics, University of Catania, Catania, Italy; 3) Department of Neurosciences, Psychiatric and Anesthesiological Sciences, University of Messina, Messina,Italy; 4) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 5) Neuroimaging Research Unit, National Research Council, Catanzaro, Italy.

Neurofibromatosis type 1 (NF1) is a common autosomal dominant disorder with an estimated incidence of one in 3,500 births. Clinically, NF1 is characterized by café-au-lait (CAL) spots, neurofibromas, freckling of the axillary or inguinal region, Lisch nodules, optic nerve glioma, and bone dysplasias. NF1 is caused by inactivating mutations of the 17q11.2-located NF1 gene. We present a clinical and molecular study of an Italian family with NF1. The proband, a 10-year-old boy, showed large CAL spots and freckling on the axillary region and plexiform neurofibromas on the right side only. His father (47 years old) showed, in addition to the similar signs, numerous neurofibromas of various sizes on his thorax, abdomen, back, and shoulder. The brother and the sister of the proband presented only small CAL spots. In the examined family with NF1, a novel frameshift insertion mutation of one adenine at the nucleotide 654 (c.654 insA) in exon 4c was identified. This novel mutation creates a shift on the reading frame starting at codon 218 and leads to the introduction of a premature stop at codon 227 (PTC). The mutation was also detected in all affected members of the family but it was not found in 200 normal chromosomes. In a previous study, Toliat et al. reported a high incidence of mutations in exon 4b of the NF1 gene. Later, Griffiths et al. also reported mutations in exon 4b in addition to exons 10a, 13, 16, 31, and 37. Our data suggest that exon 4 can be considered a mutation hotspot of the NF1 gene even if it is not located in the two functional domains: Cys-Ser rich domain encoded by exons 11-17 and GAP-related domain encoded by exons 21-27a. The mutation reported in this study determines the production of an abnormal mRNA that contains a premature termination codon at codon 227. This abnormal mRNA could result in a shorter non-functional protein, or it could be disrupted by a cellular surveillance mechanism, Nonsense-mediated decay (NMD), preventing the translation of such mRNA into truncated, and potentially harmful, protein.

CHD7 mutations in CHARGE syndrome: implication for the genotype and phenotype correlation. *Y. Ke[1,2], D. Lee[1], G. Ma[1], M. Chen[1,3,4].* 1) Department of Genomic Medicine, Changhua Christian Hospital, Changhua, Taiwan; 2) Department of Pediatrics, Changhua Christian Hospital, Changhua, Taiwan; 3) Department of Obstetrics and Gynecology, and Department of Medical Genetics, College of Medicine and Hospital, National Taiwan University, Taipei, Taiwan; 4) Department of Obstetrics and Gynecology, Changhua Christian Hospital, Changhua, Taiwan.

CHARGE syndrome is a rare autosomal dominant disorder with characteristic features including Colooma, Heart malformation, choanal Atresia, Retardation of growth and/or development, Genital abnormalities and Ear anomalies with or without hearing loss, which give the name (an acronym) to this condition. The prevalence of CHARGE syndrome is in one of 10,000 live born infants. The diagnosis of CHARGE syndrome is mainly based on the clinical findings and temporal bone imaging although the diagnostic criterion for CHARGE syndrome was recently up dated and was stressed the importance of the 3C triad (Coloboma-Choanal atresia-abnormal semicircular Canals). At present, mutations in the chromodomain helicase DNA binding protein coding gene, CHD7, are known to cause CHARGE syndrome. There are approximately 60-70% of patients with CHARGE syndrome have mutation in CHD7 gene. Here, we reported on the clinical and molecular findings in five unrelated families with CHARGE syndrome. Since all of the mutations identified were different and novel, we also discussed the possible genotype and phenotype correlation for this condition.

2369/T

Discordant monochorionic diamniotic twins carrying a mosaic NF1 mutation. *J.G. Pappas[1], E. Ward[1], J.C. Allen[2], J. Xie[3], A. Poplawski[3], L.M. Messiaen[3].* 1) Dept Pediatrics,Human Gen, New York Univ Sch Med, New York, NY; 2) Dept Pediatrics, Div Ped Hematology/Oncology, New York Univ Langone Med Ctr, New York, NY; 3) Dept Genetics, Univ Alabama at Birmingham, Birmingham, AL.

We present 12 year old monochorionic diamniotic twin girls, twin A with multiple café-au-lait macules, axillary freckling and optic glioma and twin B without signs of neurofibromatosis type 1 (NF1). They were delivered by cesarean at the 35th week of gestation due to twin to twin transfusion. Both are growing and developing normally, have identical facial features and similar anthropometrics. Twin A is under treatment for optic glioma diagnosed by brain MRI. Twin B had normal brain MRI as well as multiple negative clinical examinations for signs of NF1 including skin examinations using the Woods lamp. Mutation analysis for NF1 in the blood lymphocytes revealed a truncating mutation, c.3047-3048delGT, in mosaic form in both girls. Mosaicism for this mutation was also present in both twins in a different sample, i.e. cells from saliva. The mutation was found in ~25 % of the blood cells in both twins and in ~15% of the saliva cells in twin A, versus 8-10% of the saliva cells in twin B. To the best of our knowledge this is the first description of monochorionic diamniotic twins mosaic for an NF1 mutation, with one twin clinically unaffected at age 12. Possible explanations for the discordance include occurrence of the mutation before the formation of the germ layers followed by unequal ratios of mutant cells in the resulting twins or mosaicism in the apparently unaffected twin solely in the hematopoietic cells due to twin - twin transfusion. The former possibility predicates occurrence of a mutation very early during development, before the 9th day of gestation when monochorionic diamniotic twins split. Hence, generalized mosaic NF1 would have been expected as a phenotype in both twins. Biallelic mutations in the NF1 have been proven to be associated with the different phenotypic features (Maertens O et al, 2007) and further study of other tissues from different embryonic cell layers for the distribution of the NF1 mutation may give us insights for explaining the phenotypic discordance.

2370/T

Nonsense mutations of *COL3A1* gene causing nonsense-mediated mRNA decay in two Japanese patients with Vascular type of Ehlers-Danlos Syndrome. *B. Than Naing[1], A. WATANABE[1,2], A. HATAMOCHI[3], H. MORISAKI[4], T. SHIMADA[1,2].* 1) Department of Molecular Genetics, Nippon Medical School, Tokyo, JAPAN; 2) Division of Clinical Genetics, Nippon Medical School, Tokyo, JAPAN; 3) Department of Dermatology, Dokkyo Medical University, JAPAN; 4) Department of Bioscience, National Cerebral and Cardiovascular Center, JAPAN.

Vascular type of Ehlers-Danlos syndrome (vEDS), also known as EDS type IV (MIM#130050), is a life-threatening autosomal dominant inherited disorder of connective tissue mainly caused by mutations in type III collagen, COL3A1 gene (total 52 exons). The majority of identified mutations are point mutations that result in single amino acid substitutions for glycine in the GLY-X-Y repeat of the triple helical region. About one-third of the known mutations occur at splice sites, and most result in exon skipping. The mutation of COL3A1 gene in vEDS patients have been detected by reverse transcriptase PCR (RT-PCR) direct sequencing using total RNA from patient's fibroblasts. No mutation in the COL3A1 gene using total RNA method was detected in two Japanese patients with typical clinical features of vEDS; patient 1 is a 21 year-old male with family history of sudden death of a brother at 25 years of age and patient 2 is a 43 year-old male with no family history. We analyzed known single nucleotide polymorphisms in coding region (cSNPs) using genomic DNA. Heterozygosities were found in the genomic DNA at two cSNPs (c.2244T>C and c.3613A>G) in patient 1 and one cSNP (c.2092G>A) in patient 2. These sequence discrepancies between mRNA and genomic DNA strongly suggest nonsense-mediated mRNA decay (NMD) which degradates mRNA carrying premature translation termination codons. Therefore, we analyzed the whole coding region of COL3A1 gene by PCR direct sequencing using genomic DNA. A nonsense mutation was found in each patient: c.2992C>T; p.Gln998Ter at exon 42 in patient 1 and c.4141C>T; p.Gln1381Ter at exon 51 (outside of triple helical region of COL3A1 gene) in patient 2. The level of protein expression was different in each patient. In patient 2 family, the severity differences were present within the same family because no clinical findings were detected in the mother having the same mutation. This is the first report of nonsense mutations in the COL3A1 gene which cause nonsense-mediated mRNA decay. Many nonsense mutations have been reported in other collagen genes causing diseases. Our findings indicate that cSNP analysis of genomic DNA is highly informative when mutations could not be found by standard RT-PCR of mRNA from patients having typical vEDS symptoms. Sequence discrepancies at the cSNPs between mRNA and genomic DNA suggest NMD and therefore, sequencing of the whole coding regions should be performed using genomic DNA.

2371/T

PRF1 and STX11 Mutations in Familial Hemophagocytic Lymphohistiocytosis Patients. *A. Alpman Durmaz[1], F. Ozkinay[2], B. Durmaz[1], O. Kirbiyik[1], D. Yilmaz[3], N. Cetingul[3], C. Vergin[4], H. Akin[1], H. Onay[1], C. Ozkinay[1].* 1) Department of Medical Genetics, Ege University Medical Faculty, Izmir, Turkey; 2) Department of Pediatric Genetics, Ege University Medical Faculty, Izmir, Turkey; 3) Department of Pediatric Hematology, Ege University Medical Faculty, Izmir, Turkey; 4) Department of Pediatric Hematology, Dr. Behcet Uz Pediatric Hospital, Izmir, Turkey.

Familial hemophagocytic lymphohistiocytosis (FHL) is a rare autosomal resesif hyperinflammatory syndrome characterized by fever, hepatosplenomegaly, pancytopenia, hypertriglyceridaemia, hypofibrinogenaemia, and neurological abnormalities. Mutations in Perforin, Syntaxin and Munc13-4 genes are found to be associated with FHL-2, FHL-4 and FHL-3, respectively. In this study, we analyzed the PRF1 and STX11 genes in patients with FHL. Thirty-two patients were analyzed for PRF1 mutations by DNA sequencing. Patients who were found to be normal for PRF1 mutations were analyzed for STX11 mutations. Among 51 patients sequenced for PRF1 mutations, 3 patients were found to be heterozygous for A91V and 3 patients homozygous for W374X mutations. Twenty-three of the perforin mutation negative patients were available for STX11 gene mutation analysis and 2 patients were found to be heterozygous for E115D which was not previously reported. Two patients were found to be compound heterozygous for V197M and E182E. In one of the 2 patients after parental DNA sequencing, mutations were considered to be on the same allele. These 2 mutations were not described as a mutation or polymorphism before. STX11 and PRF1 mutations play an important role in FHL patients and molecular spectrum in these genes may be different in different populations.

2372/T

ABCG2/BCRP as a major causative gene for gout. *H. Matsuo[1], T. Takada[2], K. Ichida[3,4], T. Nakamura[5], A. Nakayama[1,6], Y. Takada[7], H. Inoue[1], Y. Kawamura[1], Y. Sakurai[8], T. Hosoya[4], H. Suzuki[2], N. Shinomiya[1].* 1) Dept. Integrative Physiol., National Defense Med. College, Tokorozawa, Japan; 2) Dept. Pharm., Univ. Tokyo, Tokyo, Japan; 3) Dept. Pathophysiol., Tokyo Univ. Pharm. Life Sci., Tokyo Japan; 4) Dept. Intern. Med., Jikei Univ. School Med., Tokyo, Japan; 5) Lab. Math., National Defense Med. College, Tokorozawa, Japan; 6) Dept. Defense Med., National Defense Med. College, Tokorozawa, Japan; 7) Dept. Forensic Med., National Defense Med. College, Tokorozawa, Japan; 8) Dept. Prev. Med. Publ. Health, National Defense Med. College, Saitama, Japan.

Gout based on hyperuricemia is a common disease with a genetic predisposition. Recent genome-wide association study also showed that serum uric acid (SUA) levels and gout relates to ABCG2 gene, which is reported to locate in a gout-susceptibility locus (MIM 138900) on chromosome 4q revealed by a genome-wide linkage study. We previously reported that ABCG2 is an exporter that has polymorphic reduced functionality variants. As ABCG2 exports nucleotide analogs structurally similar to urate, these findings suggest that ABCG2 could be a urate secretion transporter and a cause of gout. Mutation analysis of 90 Japanese hyperuricemia patients in ABCG2 revealed six nonsynonymous mutations: V12M, Q126X, Q141K, G268R, S441N and F506SfsX4. ATP-dependent transport of urate was reduced by approximately half (46.7%) in Q141K, and was nearly eliminated in Q126X, G268R, S441N and F506SfsX4. Among these variants, relatively frequent two dysfunctional SNPs, Q141K (31.9%) and Q126X (2.8%), were then analyzed. Haplotype frequency analysis revealed that there is no simultaneous presence of Q126X and Q141K in one haplotype. As Q126X and Q141K are assigned to nonfunctional and half-functional haplotype, respectively, their six genotype combinations are divided into five functional groups. Gout risk of 75% function was increased with an OR of 3.02 (95% CI, 1.96-4.65; P=2.29x10-7) and that of 50% function was with an OR of 4.34 (95% CI, 2.61-7.24; P=2.23x10-9). Gout risk of £25% function was remarkably increased with an OR of 25.8 (95% CI, 10.3-64.6; P=3.39x10-21). 10.1% of gout patients had these genotypes of £25% function, while only 0.9% of control males have the same genotype combinations. In addition, genotype combinations of full function are detected in 50.8% of the control subjects but only in 21.4% of gout patients. Our function-based genetic analysis showed that combinations of dysfunctional variants are major causes for gout, thereby providing evidence for "a common disease common variant" hypothesis. We will show the latest progress on our study in this meeting.

Mutation screening in a cohort of Chinese families with hereditary nuclear cataract. *KJ. Wang[1, 2], SQ. Zhu[2], CP. Pang[1].* 1) Opthalmology & Visual Sciences, Chinese University of Hong Kong, Hong Kong, Hong Kong; 2) Beijing Tongren Eye Center, Beijing Tongren Hospital, Capital Medical University, Beijing Ophthalmology & Visual Sciences Key Lab, Beijing, China.

PURPOSE: To investigate the molecular genetic background in Chinese families with autosomal dominant nuclear cataract. METHODS: Members of thirty unrelated Chinese families with congenital nuclear cataracts and 100 unrelated individual adults without congenital cataracts were recruited for this study. All study subjects were given full ophthalmological examinations. The genomic DNA was extracted from peripheral blood leukocytes. We conducted two-point linkage analysis and sequencing of 18 cataract candidate genes to find the causative mutations. RESULTS: There were variations in the clinical phenotypes among families but all involved nuclear opacifications. Among the thirty families, six showed nuclear cataract and microcornea. Mutation analysis revealed seven causative mutations, five novel and two reported. Five families (16.7%) have affected crystalline genes, CRYAA-R116C, R116H, CRYBB2-V146M, I21N, CRYBB1- R233H. Two families (6.7%) had mutations in the GJA8 gene, I31T and S258F. These mutations co-segregated with all affected individuals in the respective families and were not observed in unaffected family members or the 100 controls. CONCLUSIONS: Mutations were identified in 7 out of the 30 families (23.3%). All these mutations involve in crystallins and connexins. The CRYBB2 mutation (V146M) was first identified in this study to be associated with congenital cataract and microcornea. Our results, with 67.7% of families not identified for mutations in reported genes, strongly indicates the genetic heterogeneity of congenital cataracts, although the crystalline genes appear to be more commonly associated with hereditary nuclear cataracts than other genes in the Chinese population.

Inheritance patterns in myofibrillar myopathy associated with a BAG3 mutation. *Z. Odgerel[1], A. Sarkozy[2], HS. Lee[1], C. McKenna[2], J. Rankin[3], V. Straub[2], H. Lochmüller[2], F. Paola[4], A. D'Amico[4], E. Bertini[4], K. Bushby[2], LG. Goldfarb[1].* 1) National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD; 2) Institute of Human Genetics, Newcastle upon Tyne, U.K; 3) Department of Clinical Genetics, Royal Devon and Exeter NHS Foundation Trust, Exeter, U.K; 4) Department of Neurosciences, Ospedale Bambino Gesu', Rome, Italy.

Myofibrillar myopathies (MFMs) are a group of heterogeneous disorders defined by disintegration of myofibrils. These disorders are known to be associated with mutations in DES, CRYAB, MYOT, ZASP, FLNC, FHL1, or BAG3. We conducted a study of the underlying mechanisms of disease transmission in three families with early onset MFM caused by BAG3 p.Pro209Leu mutation. Haplotype analysis, informative in Family 1, indicated that two affected siblings inherited the pathogenic allele from their asymptomatic father, suggesting that the father was germline mosaic. Transmission from asymptomatic parents also occurred in Families 2 and 3, although the transmitting parent could not be identified. The father of the two affected boys in Family 1 displays somatic mosaicism for the BAG3 p.Pro209Leu mutation. A recurrent transmission from an unaffected parent indicates that the mutation is present in a significant proportion of his germ cells. Somatic mosaicism for pathogenic mutations has important ramifications for counseling offered to families regarding the risk to younger children. Since the disease associated with the BAG3 p.Pro209Leu mutation starts in the childhood and results in incapacity and death before reaching reproductive age, transmission from affected individuals is unlikely.

2375/T

Molecular analysis in Belgian patients with late-onset glycogen storage disease type II. *W. Lissens, S. Seneca, S. Van Dooren, I. Liebaers.* Ctr Med Gen, UZ Brussel, Brussels, Belgium.

Glycogen storage disease type II (GSDII or Pompe disease) is an autosomal recessive disorder caused by a deficiency of the lysosomal alfa-glucosidase (GAA). Clinically, the disease represents a continuous spectrum of phenotypes from rapid progressive early-onset subtypes to late-onset milder subtypes. We present here the results of molecular analysis of all coding exons and parts of the flanking introns of the GAA gene in 16 unrelated patients, aged between 25 and 59 years, with late-onset GSDII on clinical and biochemical bases. All 16 patients were carriers of the leaky splice site mutation c.-32-13T>G (previously described as IVS1-13T>G) that is known in literature to occur at a high frequency in adult-onset patients of Caucasian origin. The mutations on the other alleles comprised 9 small deletions/insertions/duplications with c.258dupC present in 3 patients, 4 missense (3 not previously described) and one nonsense mutation, one donor splice site mutation and one deletion from I17 to I18. The independent segregation of the mutations was proven in all families. Our results confirm the high incidence of the c.-32-13T>G mutation in Caucasian patients with late onset GSDII. Therefore, mutation analysis in late-onset GSDII patients could be started by sequencing for the presence of this mutation in our population. The other mutations are scattered all-over the GAA gene; many of these mutations are insertions or deletions of a few bases. We would like to thank the Neurologists who have sent samples from their patients for molecular analysis.

Mutation Analysis of the FRAS1 and FREM2 gene in Fraser Syndrome using Roche 454 GS-FLX System. *M.J. Vogel[1], P.H.A. van Zon[1], A.M.H. Langemeijer-Ketelaar[1], I.J. Nijman[2], E.E. Voest[3], E.P.J.G. Cuppen[1,2], P.J. Scambler[4], M.M. van Haelst[1], J.K. Ploos van Amstel[1], Fraser Syndrome Collaboration Group.* 1) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 2) Hubrecht Institute-KNAW and UMC Utrecht, The Netherlands; 3) Department of Medical Oncology, UMC Utrecht, The Netherlands; 4) Molecular Medicine Unit, Institute of Child Health, London, United Kingdom.

Fraser syndrome (FS, MIM 219000) is an autosomal recessive malformation disorder characterized by cryptophthalmos, syndactyly, and abnormalities of the respiratory and urogenital tract. FS is considered to be the human equivalent of the murine blebbing mutants. In these mice mutations at five loci cause a phenotype that is comparable to FS in humans. Thus far mutations in two homologous human genes, FRAS1 and FREM2, have been identified to cause FS. FRAS1 contains 74 exons and encodes an extracellular matrix protein of 4,011 amino acids. FREM2 (FRAS1-related extracellular matrix protein 2) has 24 exons and encodes a protein of 3,169 amino acids. Recently, mutations in FREM1 were identified in patients with a congenital malformation syndrome consisting of bifid nose, renal agenesis and anorectal malformations. This condition may represent a previously unrecognized variant of FS. FREM1 has 37 exons encoding a protein of 2,197 amino acids. To date, a causative mutation has been detected in approximately 45% of the FS cases, of which the majority comprised FRAS1. Only 2 different FREM2 mutations have thus far been reported. The size of these genes makes the analysis of the genes laborious. A proper DNA-diagnostics for this syndrome is much needed as is a better insight in the genotype-phenotype relationship of Fraser Syndrome and related phenotypes. We therefore, developed a test on the 454 GS-FLX massive parallel sequencing (MPS) platform from Roche that allows simultaneously testing of large genes. Such a test could easily be expanded in the future with additional candidate genes. We have initially set up a test for FRAS1 and FREM2. This test involves 395 amplicons that cover all exons and their flanking sequences. The amplicons are pooled and subjected to MPS. We have analyzed six FS cases and identified mutations in the FRAS1 gene in three probands and FREM2 mutations in two probands. Seven out of eight of these mutations have not been reported before. Although the number of patients investigated in this study is small, the percentage of FREM2 families identified is remarkable (33%). All mutations that were identified could be confirmed by Sanger sequencing. In only one family we could not identify a pathogenic mutation in either of these two genes, although further improvement of coverage will be needed to strengthen this conclusion. In two cases the identification of the disease causing mutations led to prenatal testing.

2377/T

A COMMON PATTERN OF BRAIN MRI IMAGING IN MITOCHONDRIAL DISEASES WITH COMPLEX I DEFICIENCY. *A. Lebre[1], M. Rio[1], L. Faivre d'Arcier[1], D. Vernerey[1], P. Landrieu[2], A. Slama[2], C. Objective: To identify a consistent pattern of brain MRI imaging in primary complex I deficiency. Complex I deficiency, major cause of respiratory chain dysfunction, accounts for various clinical presentations, including Leigh syndrome. Human complex I comprises seven core subunits encoded by mitochondrial DNA (mtDNA) and 38 nuclearly-encoded core subunits (nDNA). Moreover, its assembly requires six known and many unknown assembly factors. To date, no correlation between genotypes and brain MRI phenotypes has been found in complex I deficiencies. Design and Subjects: We have retrospectively collected the brain MRI of 30 patients carrying known mutation(s) in genes involved in complex I and compared them with the brain MRI of 11 patients carrying known mutation in genes involved in pyruvate dehydrogenase (PDH) complex and 10 patients with MT-TL1 mutations. Results: All complex I deficient patients showed bilateral brainstem lesions (30/30) and the 77% (23/30) showed putaminal anomalies. Supratentorial stroke-like lesions were only observed in complex I deficient patients carrying mtDNA mutations (8/19) and necrotizing leukoencephalopathy in patients with nDNA mutations (4/5). Conversely, the isolated stroke-like images observed in patients with MT-TL1 mutations, or corpus callosum dysmorphism observed in PDH deficient patients were never observed in complex I deficient patients. Conclusion: We identified a common pattern of brain MRI imaging with signal abnormalities in brainstem and subtentorial nuclei with lactate-peak as a clue of complex I deficiency. We suggest that combining clinico-biochemical data with brain imaging can help orient genetic studies in complex I deficiency.

Mutations in quinone biosynthesis pathway results in up-regulation of CABC1 gene. *C. MEILLER, A. MUNNICH, A. ROTIG.* INSERM U781, Université René Descartes Paris V.

Quinone (CoQ10) plays a pivotal role in the mitochondrial respiratory chain (RC) as it distributes electrons between the various dehydrogenases and the cytochrome segments of the RC. CoQ10 deficiencies represent a rare cause of mitochondrial disorders. We have found CoQ10 deficiency in eight unrelated families and identified in the different patients mutations in various genes encoding enzyme of the ubiquinone biosynthesis pathway: PDSS1, PDSS2, COQ2 and CABC1. All these genes are ubiquitously expressed but their mutations are related to different clinical presentations: deafness, mental retardation and obesity for PDSS1 mutations, deafness, nephrotic syndrome, mental retardation, myopathy, ataxia for PDSS2 mutations, neonatal fatal neurological distress and liver failure for COQ2 mutations and ataxia for CABC1 mutations. The mechanisms leading to this tissue specific expression of the disease are yet unknown but it could be hypothesized that different expression level of these genes in different tissues could partially account for this feature or that specific regulations result from mutations of a specific gene. As a first step in investigating tissue-specific expression of quinone deficiency we analyzed the expression levels of all genes known or supposed to be involved in quinone biosynthesis in cultured skin fibroblasts of patients with PDSS1, PDSS2, COQ2 and CABC1 mutations. Total RNA extracted from fibroblasts of the eight patients and a control were reverse transcribed and the expression level of PDSS1, PDSS2, COQ2, COQ3, COQ4, COQ5, COQ6, COQ7, COQ8, COQ9, COQ10A, COQ10B, CABC1, ADCK1, ADCK2, ADCK4, ADCK5 genes was established by quantitative PCR. In all patients we observed a strong increase of CABC1 expression level and to a lesser extend of COQ3. CABC1 protein has a putative kinase activity based on the identification of four kinase conserved motifs in its aminoacid sequence but its biochemical function is currently unknown. It has been shown in yeast that COQ8, the counterpart of CABC1 has a regulatory function of quinone biosynthesis pathway. The up-regulation of CABC1 gene in fibroblasts of patients with quinone biosynthesis deficiency confirms the central role of CABC1 in this biosynthesis pathway. Finally, CABC1 has been shown to be a direct target of p53 and it should be hypothesized that this gene also acts as a sensor of RC deficiency.

Mitochondrial genetics and sepsis. *A. Pyle[1], S.V. Baudouin[2, 3], P.F. Chinnery[1].* 1) Mitochondrial Research Group, Newcastle University, Newcastle upon Tyne, NE2 4HH, United Kingdom; 2) Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, NE2 4HH, United Kingdom; 3) Department of Anaesthesia, Royal Victoria Infirmary, Newcastle upon Tyne, NE1 4LP, United Kingdom.

Infectious disease has had a dramatic impact on human evolution. Our genetic makeup partially determines our ability to resist infection. There is emerging evidence that mtDNA plays an integral role in the evolution of the human species. Several studies have reported changes in mitochondrial function during severe infection. Mitochondrial DNA is highly polymorphic; as a result there is considerable variation in the mtDNA genome both within and between human populations. Consequently, mtDNA is divided into a discrete number of mtDNA haplogroups. A comprehensive analysis of mtDNA haplogroups and sepsis found that patients who were haplogroup H are more likely to survive after admission to an intensive care unit. The functional cause of these associations remains uncertain but there is increasing evidence that these inherited genetic variations influence respiratory chain efficiency. Mitochondrial copy number alterations have also been found in a number of diseases, with a reduction in mtDNA copy number observed in sepsis patients. This reduction has been attributed to the reciprocal increase in blood neutrophils after infection. The mtDNA content of circulating monocytes and lymphocytes is decreased in the acute phase of sepsis. It has been suggested that mtDNA depletion could serve as a prognostic marker in acute sepsis, or directly relevant to the mechanisms of survival. The mitochondrial genome has been much less studied in patients with infection and sepsis. Here we describe a mtDNA genetic study into the polymorphic changes in sepsis patients.

2380/T

Poikiloderma with Neutropenia: delineation of novel mutations and geographic clusters. *E.A. Colombo[1], G. Roversi[2], N. Elcioglu[3], G. Fremont[4], L. Volpi[5], L. Larizza[1]*. 1) Dipartimento Medicina, Chirurgia e Odontoiatria, Università di Milano, Milano, Italy; 2) Unit of Medical Genetics, Fondazione IRCCS, Istituto Nazionale Tumori, Milano, Italy; 3) Department of Pediatric Genetics, Marmara University Hospital, Istanbul, Turkey; 4) Departement of Dermatology, Hôpital Saint-Louis, Paris, France; 5) Dipartimento di Biologia e Genetica per le Scienze Mediche, Università degli Studi di Milano, Milano, Italy.

Patients affected with Poikiloderma with Neutropenia (OMIM #604173) show persistent neutro penia, early onset poikiloderma, palmoplantar keratosis and a peculiar pachyonychia on big toes.

Recently genome-wide scan of an inbred Italian pedigree identified genetic linkage to the16q13 and targeted sequencing appointed the *C16orf57* disease gene. Three mutations of the gene were described: c.502A>G, c.504-2A>C and c.666_676+1del12: surprisingly all affect the splicing process leading to complete skipping of exon 4, exon 5 and exon 6, respectively**1**.

We herein describe three new patients with non-splicing mutations in the *C16orf57* gene: i) a French woman of NorthAfrican origin has a homozygous mutation in exon 2 c.179delC, predicting a truncated product 113 aminoacids long (p.Pro60LeufsX55). The same mutation has been just described by Tanaka in three Moroccan siblings**2**, suggesting either geographic consanguinity or founder effect. ii) Two Turkish PN boys carry a homozygous c.531delA deletion in exon 5, predicting a truncated product (p.His179-MetfsX86). They are both born from inbred families but no common ancestor and not even a common origin from a geographic isolate could be traced back.

It's not yet clear if this autosomal recessive genodermatosis results from complete haplo insufficiency or a residual protein activity is sustained by hypomorphic mutations. Delineating the mutational repertoire of the gene is one of the tools suitable to unravel its function. Including the present report only 10 out of 29 PN patients have the mutation identified**1,2**; we don't know the genetic alteration/s specific to the Navajo population**3,4** neither to the other reported Turkish patients**4,5** but it could be interesting to establish whether different ethnic groups have private founder mutations and whether the clinical phenotype is modulated by the type of mutation.

Supported by AIRC, CARIPLO NOBEL and Fondazione Peretti.

Mutation Analysis of FBN1 Gene in Marfan sydrome Probands and Patients with Marfanoid Habitus or Fibrillinopathy. *A. Kuskucu[1], K. Oztarhan[2], K. Yararbas[3], S. Gursoy[3], A. Tukun[3]*. 1) Medical Genetics, Bakirkoy Women and Children's Hospital , Bakirkoy, Istanbul, Turkey; 2) Pediatric Cardiology, Bakirkoy Women and Children's Hospital , Bakirkoy, Istanbul, Turkey; 3) Duzen Laboratory Groups,Turkey.

Marfan syndrome (MFS) is an autosomal dominant connective tissue disorder with a high degree of clinical variability, usually caused by a mutation in the fibrillin 1 (FBN1) gene. Cardinal manifestations involve the ocular, skeletal, and cardiovascular systems. Using sequencing analysis methodology, we studied the mutation spectrum in 20 probands with Marfan syndrome and related phenotypes. It is well known that mutations in the FBN1 gene cause MFS and have been associated with a wide range of milder overlapping phenotypes. A proportion of patients carrying a FBN1 mutation does not meet enough diagnostic criteria for MFS, and are diagnosed with fibrillinopathy or Marfanoid habitus. We would like to report our findings and related genotype phenotype correlations.

Genetics of Primary Dystonia. *T. Fuchs[1], K.M. Lamar[1], D. Raymond[2], R. Saunders Pullman[2], N. Sharma[3], I. Peter[1], S. Bressman[2], L.J. Ozelius[1]*. 1) Gen & Genomic Sci, Mount Sinai Sch Med, New York, NY; 2) Department of Neurology, Beth Israel Medical Center, New York, NY; 3) Department of Neurology, Massachusetts General Hospital, Boston, MA.

Primary torsion dystonia (PTD) is a movement disorder characterized by involuntary twisting, repetitive movements and abnormal postures where dystonia is the only neurological feature. Seven genes have been mapped for PTD but only two have been identified: TOR1A which is responsible for DYT1 - early onset generalized dystonia and THAP1, which is responsible for DYT6 - dystonia of mixed type. Deciphering the genetic basis of primary dystonias is a critical step in understanding the molecular pathophysiology of the disease and finding a better treatment or cure for the disease. Our program for deciphering the genetic basis of PTD comprises multiple gene discovery approaches including traditional linkage analysis and positional cloning, candidate gene association studies, genome wide association (GWAS) and next generation sequencing. Recently, using the positional cloning approach, we discovered THAP1 as the gene underlying DYT6 dystonia. An insertion/deletion mutation in this gene was shown to be causative founder mutation in Amish-Mennonite families. Additionally, THAP1 missense, nonsense and truncating mutations were found in families and sporadic individuals of diverse ethnic origins. We performed a whole genome scan and linkage analysis in a cervical dystonia family with 8 affected individuals which identified four putative linkage regions. The enriched exome libraries of these regions will be constructed and sequenced using next generation sequencing. Polymorphisms in the TOR1A/TOR1B region have been implicated as being associated with primary focal and segmental dystonia. In a cohort of subjects with either focal or segmental dystonia we found a strong association between rs3842225 SNP in TOR1A and protection from focal dystonia. In order to find additional genes involved in etiology of focal dystonias, we genotyped approximately 100 Ashkenazi Jews focal dystonia samples using Affymetirix 6.0 platform. The GWAS is being performed on these data.

Uniparental disomy and progressive clonal selection a common mechanism causing late onset β-thalassemia major? *C.L. Harteveld[1], C. Rifaldi[2], A. Giambona[3], C. Ruivenkamp[1], M. Hoffer[1], C. Borgnia-Pignatti[4], A. Maggio[3], M. Cappellini[2], P.C. Giordano[1]*. 1) Human and Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Fondazione Ospedale Maggiore Policlinico Istituto di Ricovero e Cura a Carattere Scientifico Universita di Milano, Milano, Italia; 3) U.O.C. Ematologia II con Talassemia, Azienda Ospedaliera Vincenzo Cervello Via Trabucco 180, 90146 Palermo, Italia; 4) Department of Clinical and Experimental Medicine-Pediatrics University of Ferrara, Ferrara, Italy.

We present three cases of "severe late onset β-thalassemia" in three independent subjects, all presenting with the mild phenotype of beta thalassemia minor up to adult age and developing a severe transfusion dependent phenotype in the third and fourth decade of life when a presumed homozygosity for the cd39 (C®T) mutation is observed. We demonstrate that uniparental isodisomy of part of chromosome 11p15 accounts for the observed mosaicism for the cd 39 (C®T) mutation. Clonal selection for hematopoietic stem cells containing the uniparental isodisomy for the mutant beta-globin gene during life may account for the progressive development of the disease. We base our conclusion on the fact that we have observed in all cases molecular rearrangements on the short arm of chromosome 11, together with sequences showing T/T homozygosity in the presence of a small but consistent C signal in DNA extracted from peripheral blood, from buccal mucose and from erythroid cultures. Loss of heterozygosity due to a deletion of one allele was excluded by MLPA analysis. In addition, two subjects had a father who was a carrier and a non-carrier mother and one male subject was married and had 3 children of which only one was a carrier. A similar observation for a single case was made by Chang et al., who found this in a single patient with late-onset β-thalassemia Major. Our study demonstrates that uniparental isodisomy of chromosome 11p15 is apparently more frequently associated with late-onset transfusion dependent β-thalassemia in presumed carriers at birth, representing a novel mechanism leading to this special form of beta-thalassemia and possibly in other late-onset genetic diseases. Chang et al. Haematologica 2008, 93(6):913-916.

RGR and USH2A Digenic Recessive Retinitis Pigmentosa Causes an Early Onset Stable Retinal Phenotype. *P. Bitoun[1], E. Pipiras[2], B. Benzacken[2], A. Delahaye[2].* 1) Gen Med, CHU Paris-Nord, Hopital Jean Verdier, Bondy, France; 2) Embryo-Cytogenetics and Assisted Reproductive Biology, CHU Paris-Nord, Hopital Jean Verdier, Bondy, France.

Purpose: Identification of causal genes by Molecular analysis of Retinitis Pigmentosa patients DNA allows for characterisation of disease , prognostic factors, prenatal diagnostic possibilities if indicated and possible treatment by gene replacement therapy or pharmacologic substances. A cohort of 25 RP patients was screened for recessive, dominant or X-linked RP genes mutation depending on the family history/clinical presentation using automated chip analysis. Materials and Methods: Patients were examined clinically and had ERG VEP OCT and color vision testing and gave informed consent for genotyping. For patients with a clinical or pedigree phenotype compatible with a recessive disorder The following genes were tested for a total of 584 known mutations and SNP's : CERKL, CNGA1, CNGB1, MERTK, PDE6A,PDE6B, PNR,RDH12, RGR,RLBP1, SAG,TULP1, CRB, RPE65, USH2A, USH3A, LRAT using automated genechip analysis. Results:A 19 year old young woman with early onset but slowly progressive RP and ERG photopic and scotopic anomalies was identified with a digenic mutation in both RGR and USH2A genes as follows RGR, exon 4:454 C>A which predicts H152N HET Mut. USH2A exon 12: 2137ÝG>C which predicts G713R HET Mut.She has normal hearing. RGR is an RPE retinal G-protein coupled receptor also found in Muller cells. It is a Rhodospin homolog which unlike rhodopsin binds all trans retinal converted to 11-cis retinal by light . it is implicated in recessive RP and dominant choroidal sclerosis. USH2A/ usherin is a basement membrane protein, with laminin EGF and fibronectin type III domains, found in many tissues including capillary and structural basement membranes in retina and inner ear; USH2A causes 30-40% of Usher syndrome type 2 and 10-15% of recessive RP. The putative interaction of these 2 proteins to cause the RP phenotype warrants further investigation Discussion: Digneic RP has been rarely reported in a handful of patients with RDS/Peripherin and ROM1 since 1994 as well as Peripherin 2 and ROM1 ; RHO and RP1 ans also SP4 and GNB1 rod Transducin . Digenic invovlment has also been described in albinism. Triallelism has been rarely identified in Bardet-Biedl syndrome and in digenic RP with USH2A with PDZD7. The availability of multiplex genechip analysis and next gen sequencing allows testing of multiple genes to characterise patients with digneic disorders and better understand gene interaction in the retina and their role in phenotype and pathogenesis of RP.

Molecular Characterization of Beta-Globin Gene Mutations in Filipino Beta-Thalassemia Patients. *C.L.T. Silao[1,2], M.C.C. Manuel[3], M.L.T. Naranjo[4], R.P. Laude[3], P.D. Fajardo[2], E.M.A. Melendres[2], C.D. Padilla[1,2], E.dJ. Yuson[4].* 1) Institute of Human Genetics, National Institutes of Health, Manila, Philippines; 2) Department of Pediatrics, University of the Philippines-Philippine General Hospital, Manila, Philippines; 3) Institute of Biological Sciences, College of Arts and Sciences, University of the Philippines Los Baños, Laguna, Philippines; 4) Thalassemia Center, Fe del Mundo Medical Center, Quezon City, Philippines.

BACKGROUND: Beta-thalassemia is an autosomal recessive disorder marked by deficiency or absence of synthesis of the beta-globin chain of the hemoglobin protein. It is caused by the inheritance of one or two diseased alleles of the human beta-globin gene on chromosome 11. Clinical manifestations include anemia and in extreme cases, splenomegaly, bone deformities, impaired growth, and endocrinopathies among others. This study characterizes the spectrum of beta-globin gene mutations in a Filipino population. METHODS: This involves 35 Filipino beta-thalassemia patients detected through complete blood count, red blood cell indices, and hemoglobin electrophoresis or HPLC. Genomic DNA was extracted either from dried blood spots or from whole blood using the Qiagen QIAamp DNA Blood Mini/Midi Kit. Polymerase chain reaction (PCR) analysis was used to detect the 45 kb beta thalassemia deletion and direct sequencing was done to determine other beta globin gene mutations. RESULTS: The 45 kb deletion was confirmed to be the most common mutation found. It was detected in 22/70 (31 percent) alleles analysed. This was followed by codon 67 (-TG) in 8 alleles (11 percent). CONCLUSIONS: Filipino beta-thalassemia patients show considerable heterogeneity, both phenotypically and genotypically. Obtained data were useful for genetic counseling.

Microcytic anemia in three siblings associated with a nonsense codon of STEAP3 and low expression of the normal allele. *B. Grandchamp[1,5], C. Balser[2], C. Kannengiesser[1,5], G. Hetet[1], C. Oudin[1], E. Kohne[3], C. Beaumont[4], H. Heimpel[5].* 1) Department of Biochemistry and Genetics, CHU Bichat, Paris, France; 2) Department of Hematology and Oncology, Erlenring Center, Marburg, Germany; 3) Department of Pediatrics, University Hospital Ulm, Ulm, Germany; 4) INSERM UMR 773, University Paris Diderot, Paris, France; 5) Department Internal Medicine III, University Hospital Ulm, Ulm, Germany.

Three siblings, two boys and a girl born to healthy parents from Pakistan origin had a transfusion-dependent poorly regenerative anemia and iron overload. A moderate microcytosis with distinct anisopoikilocytosis was present. All siblings had repeated viral and bacterial infections. Thalassemia, Congenital Dyserythropoietic Anemia , sideroblastic anemia and other known genetic causes were excluded and several candidate genes were sequenced from DNA of the proband. STEAP3, an iron reductase involved in the iron-transferrin endocytic cycle was found to be mutated with a premature STOP codon (c.C110X) at the heterozygous state. The same mutation was found in the 2 other affected siblings and their unaffected father. We did not detect any abnormality in the maternal alleles. Interestingly, a genome-wide expression study showed that STEAP3 displays significant allele-specific expression that is associated with SNPs in the 3' flanking region of the gene (Emilsson V et al, Nature, 2008: vol 452: 423431, supplementary 5c). We studied the relative expression of STEAP3 alleles in immortalized lymphocytes from family members after treatment the cells with emetin to prevent the degradation of the mutated allele resulting from nonsense mediated mRNA decay. We found that the relative expression of the normal allele is about twice higher in the father than in his three affected offspring. Quantitative PCR from blood RNA confirmed that STEAP3 mRNA is significantly more decreased in the affected siblings than in their father. We confirmed that STEAP3 expression in blood from healthy unrelated volunteers is highly variable, allele specific and associated to 3'UTR SNPs. Recent reports demonstrated that allele specific expression is a rather common finding that may concern 5-20% of the genes. The coinheritance of a mutated and a low-expressed normal allele has been previously reported in erythropoietic protoporphyria and in pyropoïkylocytosis and may mimic either a dominant or a recessive transmission depending on the frequency of the low expressed allele in the population. We postulate that STEAP3 deficiency leads to severe anemia in human and may result from the genotypic combination of a mutated allele and a low expressed allele.

2387/T

Pathogenetic mechanism of Diamond-Blackfan Anemia (DBA). *I. Dianzani[1], A. Aspesi[1], E. Pavesi[1], I. Boria[1], F. Avondo[1], P. Roncaglia[2], M. Caterino[3], D. Lazarevic[2], M. Ruoppolo[3], S. Gustincich[2], C. Santoro[1].* 1) Dept Med Sci, Univ Piemonte Orientale, Novara, Italy; 2) International School for Advanced Studies (SISSA/ISAS), Trieste, Italy; 3) Department of Biochemistry and Medical Biotechnologies, Università degli Studi di Napoli Federico II, Napoli, Italy.

DBA (MIM 105650) is a congenital, autosomal dominant, hypoplasia of erythroid progenitors often associated with physical malformations. Though rare this disease is interesting for hematologists because it is the prototype of pure erythroid aplasia. Half of the patients respond to steroid therapy. Non-responders require lifelong blood transfusions. DBA is the first ribosomapathy ever reported. In approximately 50% of cases it is due to heterozygous mutations in a ribosomal protein (RP) gene of the small (RPS19, RPS24, RPS17, RPS26, RPS10) or the large (RPL5, RPL11, RPL35A) subunit. The link between mutated RPs and defective erythropoiesis is unknown. To shed light on the molecular alterations responsible for the disease we compared gene and protein expression profiles in control and RP haploinsufficient cells. Differentially expressed genes were expected to reveal which pathways are impaired in DBA. We used human erythroleukemic cell line TF1 expressing inducible siRNA against RPS19, the gene most frequently mutated in DBA. This model is widely employed in DBA studies since proper amounts of bone marrow patient cells are not available and mouse models do not show a hematological phenotype. A proteomic analysis by DIGE on RPS19 downregulated TF1 cells was also performed. Results show an abnormal expression of proteins involved in cytoskeleton organization, protein synthesis and apoptosis. These variations may be due to multiple cellular mechanisms that we decided to investigate. Transcriptome analysis was performed using Affimetrix microarrays to assess whether abnormal transcription was present. Validation of a set of DIGE and microarray results were carried out by Western blot and qRT-PCR, respectively, on RPS19 downregulated cells (both TF1 and CD34+ cord blood derived cells). A previous study from our group showed that fibroblasts from patients with mutations in RPS19 presented expression anomalies as compared with control fibroblasts (Avondo et al 2009). This study showed that expression anomalies are not limited to hemopoietic cells in DBA. We have compared the expression profile from these cells and that from TF1 cells downregulated for RPS19. Notwithstanding the different cell type and model we found a common set of genes that were dysregulated: they represent a molecular signature of RPS19 deficiency, that may be used to develop a diagnostic assay.

2388/T

Identification of a Novel *C16orf57* Mutation in Athabaskan Patients with Poikiloderma with Neutropenia, Clericuzio-Type. *L. Wang[1], K. Harutyunyan[1], S. Plon[1], R. Erickson[2], A. Irvine[3], R. Bagatell[4], T. Griffin[5], T. Shwayder[6], C. Clericuzio[7].* 1) Dept Ped, 1102 Bates St., Suite 1200, Baylor College of Medicine, Houston, TX. 77030; 2) Departments of Pediatrics and Molecular and Cell Biology, University of Arizona Health Science Center, 1501 N. Campbell Ave, Tucson, AZ 85724; 3) Departments of Clinical Medicine, Trinity College Dublin and Paediatric Dermatology Our Lady's Children's Hospital Crumlin, Dublin 12 Ireland; 4) Division of Oncology, The Children's Hospital of Philadelphia, 3501 N. Civic Center Blvd., Philadelphia PA 19104; 5) Cincinnati Children's Hospital Medical Center, University of Cincinnati College of Medicine, Department of Pediatrics, 3333 Burnet Avenue, Cincinnati, Ohio 45229; 6) Department of Dermatology, Henry Ford Hospital, 3031 W Grand Blvd, Suite 800, Detroit, MI 48202; 7) Department of Pediatrics, University of New Mexico School of Medicine, MSC10 5590, Albuquerque, NM 87131.

Background: Poikiloderma with Neutropenia (PN), Clericuzio-Type (OMIM #604173) is characterized by poikiloderma, nail dystrophy, neutropenia, recurrent sinopulmonary infections, and chronic bronchiectasis. First described by Clericuzio in 1991 in 14 patients of Navajo descent, it was initially referred to as "Navajo Poikiloderma." Subsequently, it was described in non-Navajo patients and was renamed "Poikiloderma with Neutropenia." Recently, *C16orf57* was identified as the causative gene mutated in three separate PN kindreds. The purpose of the current study was to confirm the presence of *C16orf57* mutations in a small cohort of PN subjects including several subjects of Athabaskan (Navajo and Apache) ancestry. **Patients and Methods:** Nine subjects from seven kindreds were enrolled in an IRB-approved study at Baylor College of Medicine. One subject from each family was studied. Three subjects were of Athabaskan ancestry (100% Navajo, 100% Apache, and 25% Navajo, respectively). PCR amplification and sequencing of the *C16orf57* gene was performed on genomic DNA using previously published primers and conditions (Volpi et al, Am J Hum Genet 2010; 86:1-5) and included the entire coding region and conserved splice site junctions of the gene. **Results:** We identified deleterious mutations in *C16orf57* in all PN subjects analyzed in our cohort. The seven mutations consisted of deletion (2), nonsense (3), and splice site (2) mutations. Four subjects were homozygous and three subjects were compound heterozygous for mutations. The three subjects of Athabaskan ancestry all had a deletion mutation (c.496delA) which was not found in the four other non-Athabaskan subjects. The full Athabaskan subjects were homozygous for this mutation while the quarter Navajo subject was compound heterozygous for this mutation and another deletion mutation. **Conclusions:** Mutations in the *C16orf57* gene have been identified thus far in all described subjects carrying the clinical diagnosis of PN. We have identified a new mutation (c.496delA) present in all three subjects of Athabaskan descent, suggesting that this mutation represents the underlying cause of PN in this sub-population of patients.

2389/T

Characterizing expression of Proteus marker proteins in skin using immunohistochemistry. *M.J. Lindhurst[1], J.C. Sapp[1], C.R. Lee[2], L.G. Biesecker[1].* 1) GDRB, NHGRI/NIH, Bethesda, MD; 2) NCI/NIH, Bethesda, MD.

Proteus syndrome (PS) is a rare disorder that is hypothesized to be caused by a mosaic gene alteration lethal in the non-mosaic state. The phenotype of PS is highly variable. Objective diagnostic criteria have been published that has allowed for a more precise definition of the disorder. These criteria require: a mosaic distribution of lesions, a sporadic occurrence, and a progressive course of the disease plus a combination of characteristic manifestations. Characteristic manifestations include cerebriform connective tissue nevi (CCTN), linear epidermal nevi (LEN), vascular malformations, disproportionate overgrowth, and others. While it is straightforward to recognize a PS lesion in an affected patient or to recognize a histological section from a patient with PS as abnormal, a cellular phenotype had not been established. Recently, we reported the results of a micorarray experiment comparing cultured skin fibroblasts from affected PS lesions to skin fibroblasts cultured from non-PS skin. We found seven genes, *CD9*, *COL14A1*, *COL15A1*, *COL21A1*, *COL6A3*, *EML1*, and *FBN2*, that were up-regulated in the PS-affected cultures. When qRTPCR was used with a larger sample set to validate the micorarray results, *CD9*, *COL14A1*, *COL21A1*, and *EML1* showed significant differential expression. Immunohistochemistry using antibodies to CD9, COL15A1, and FBN2 showed increased staining of dermal fibroblasts and the surrounding extracellular matrix in five plantar CCTN sections from four PS patients when compared to plantar skin controls from five non-PS individuals. This staining was non-uniform within a section and varied among the PS and control sections. Presently, we are characterizing the staining in more detail to see if additional structures within the skin show any differential expression and to look for correlations between the areas with increased staining and other characteristics such as morphology or staining of other types of skin markers. In addition, we are testing antibodies to COL21A1 and COL6A3 to see if they are up-regulated in vivo. We are also examining skin biopsies taken from other areas, both affected and unaffected, of PS patients and are planning to compare the staining to other types of collagenomas and lesions found in other overgrowth syndromes. This survey will help not only in understanding the biology of skin lesions in PS, but may also lead to the development of markers that can be used to distinguish different overgrowth syndromes.

2390/T

Homozygosity Mapping is an efficient strategy for mutation identification in Consanguineous Families with a Genetically Heterogenous Disease. *R. Segel[1,2], S. Zeligson[1], T. Falik-Zaccai[3,4], S. Perlberg[1], M. Neufeld[5], P. Cohen[5], P. Renbaum[1], S. Zuckerman[1], A. Nir[2,6], E. Levi-Lahad[1,2].* 1) Medical Genetics Institute, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Hebrew University, Jerusalem, Israel; 3) Institute of Human Genetics, Western Galilee Hospital-Nahariya, Nahariya, Israel; 4) Rappaport Faculty of Medicine, Technion, Israel Institute of Technology, Haifa, Israel; 5) Department of Ophthalmology, Shaare Zedek Medical Center, Jerusalem, Israel; 6) Department of Pediatric Cardiology, Hadassah University Medical Center, Jerusalem, Israel.

Molecular diagnosis in patients with genetically heterogeneous diseases is challenging and costly. We report the use of genome-wide Homozygosity Mapping (HM) using Affymetrix 250K Nsp arrays in two families, each with a genetically heterogeneous autosomal recessive disease. The strategy was to determine homozygous regions associated with the disease, and sequence only the known disease gene(s) within such regions. We identified and sequenced only one candidate gene in each family, and identified the disease-causing mutations, which were both novel. Family 1: A consanguineous Arab family in which two siblings were diagnosed with Xeroderma Pigmentosum (XP). The diagnosis was confirmed using a functional DNA repair assay with the affected patients' cells. XP is caused by mutations in at least nine genes. HM of two affected children and their healthy brother detected eight regions of homozygosity. Only one known XP gene, ERCC5, was present in one of these homozygous regions. ERCC5 sequencing identified a novel frameshift mutation, generating a stop codon located three amino acids downstream. Family 2: A consanguineous Arab family with isolated anophthalmia. Mutations in four genes are known to cause isolated anophthalmia, but these account for only a small proportion of all cases, indicating further genetic heterogeneity. HM of three affected patients indicated one homozygous area (chr14 68,922,826 - 94,033,531), which encompasses CHX10, a known isolated anophthalmia gene. CHX10 seqeuncing revealed a novel missense mutation in a highly conserved residue. Computational analysis indicated that this mutation is likely to cause a conformational change of functional significance in the tertiary structure of the protein. Discussion: The cases described illustrate that HM is an efficient first step in pursuing molecular diagnosis for genetically heterogenous diseases in consanguineous families. In highly consanguineous populations, HM often reveals multiple regions of homozygosity, but as these cases demonstrate, this approach can still pinpoint a single gene to be sequenced from among the gene set known to be associated with a specific disease, significantly reducing the time and cost of genetic analysis in such families. Since HM is also useful in outbred populations (Hildebrandt F et al, PLoS Genet., 2009), this strategy may have general utility as well.

2391/T

The spectrum of PORCN mutations in Focal Dermal Hypoplasia in a cohort of 31 consecutive diagnostic cases. *G. Richard, I. Olivos-Glander, D. Ho, S. Bale.* GeneDx, Gaithersburg, MD.

Focal Dermal Hypoplasia (FDH) is an X-linked disorder with highly variable features due to faulty focal development of ectodermal and mesodermal tissues resulting from a block in Wnt signaling. Greater than 90% of affected individuals are females, who harbor a de novo mutation in the PORCN gene that facilitates of the secretion of Wnt signaling proteins. All affected males, and some females, are reported to be mosaic for a post-zygotic PORCN mutation. Such mosaic mutations can be challenging to detect. To date, 59 distinct PORCN mutations and 6 patients with microdeletions involving several exons or the entire PORCN gene have been published. Our clinical diagnostic laboratory has performed molecular testing for FDH in 31 individuals by sequence analysis of the PORCN gene combined with deletion testing with exon-level resolution using a custom-design microarray ('ExonArrayDx'). 10 of 26 females referred to GeneDx with a diagnosis of FDH were found to be heterozygous for a novel PORCN mutation identified by DNA sequencing. In addition, one female from a 3-generation family of affected females had a genomic deletion of the entire PORCN gene. Follow-up genome-wide aCGH was recommended to determine the exact boundaries of the genomic deletion and its gene content. The mutation spectrum in our cohort included 2 single-base pair deletions, 3 nonsense, 1 splice site, and 3 missense mutations. One of these, Gly342Asp was observed in two unrelated patients. Each of the missense variants altered highly conserved residues in the membrane-bound O-acyltransferease domain, where all previously reported missense mutations are located. No mutation or gene deletion was identified in the remaining 15 females nor any of the 5 males submitted for PORCN testing. Nevertheless, low-level mosaicism for a PORCN mutation or deletion could be missed, and analysis of DNA derived from tissues other than blood (e.g. cultured fibroblasts) was recommended. The mutation distribution we observed was comparable to earlier reports, with the majority of mutations being either gene deletions (9%) or mutations leading to premature stop of translation (55%), and the remainder (36%) being missense mutations presumably resulting in loss of protein function. This experience shows that DNA sequencing combined with gene copy number analysis is an efficient protocol for mutation identification in FDH in a clinical diagnostic laboratory, and improves the sensitivity of diagnostic testing.

Terminal Osseous Dysplasia is caused by a single recurrent mutation in the FLNA gene. *J.T. Den Dunnen[1], Y. Sun[1], R. Almomani[1], E. Aten[1], J. Celli[1], J.W.F. van der Heijden[1], H. Venselaar[2], S.P. Robertson[3], A. Baroncini[4], B. Franco[5], L. Basel-Vanagaite[6], E. Horii[7], R. Drut[8], Y. Ariyurek[1], M.H. Breuning[1].* 1) Human & Clinical Genetics, Leiden University Medical Center, Rotterdam, Netherlands; 2) NCMLS, UMC Nijmegen, the Netherlands; 3) Department of Paediatrics and Child Health, Dunedin School of Medicine, Dunedin, University of Otago, New Zealand; 4) Unit of Medical Genetics, ASL Department of Maternal and Child Health, Imola, Italy; 5) Medical Genetics, Department of Pediatrics, Federico II University, Naples, Italy; 6) Schneider Children's Medical Center of Israel and Raphael Recanati Genetics Institute, Rabin Medical Center, Tel Aviv University, Tel Aviv, Israel; 7) Nagoya 1st Red Cross Hospital, Nagoya, Japan; Yokkaichi Municipal Hospital, Yokkaichi, Japan; 8) Servicio de Pathologia, Hospital de Niños, 1900 La Plata, Argentina.

Terminal Osseous Dysplasia (TOD) is a rare X-linked male-lethal disease characterized by skeletal dysplasia of the limbs, pigmentary skin defects and recurrent digital fibroma with onset in infancy. Females have variable severity and 100% skewed X-inactivation. Mainly because only a few cases are known world-wide, attempts to identify the disease-causing gene were hitherto not successful. We applied the new possibilities of next-generation sequencing combined with exome capture to sequence all X-chromosome genes. In the female patient analysed we identified in total 351 exonic and 25 splice site variants. Combining all available information, incl. limited published linkage data, segregation, X-inactivation and computational analysis of the variants identified, a novel variant in the FLNA gene emerged as the most likely cause of the disease. The variant was on the inactivated X-chromosome and was found in all TOD cases we could analyse; 6 unrelated cases (three families and three sporadic cases). In all cases the variant segregated with the disease and it was transmitted 4 times from a mildly affected mother to a more seriously affected daughter. The mutation identified, the last nucleotide of an exon, was suspected to interfere with normal splicing. Since the variant allele was inactivated in all patient samples analysed, we were not able to analyse the effect on RNA level. However, expression was detectable when we cultured cells obtained from an archived sample; fibroma tissue surgically removed 15-year ago. In this sample, the mutation of the normal splice donor site turned out to activate an exonic cryptic site, removing the last 48 nucleotides from the exon. At the protein level this results in a loss of 16 amino acids, predicted to remove a sequence at the surface of filamin repeat 15. Mutations in FLNA are known to cause a range of diseases with partially overlapping phenotypes (see the FLNA sequence variant database we established at www.LOVD.nl/FLNA). The unique consequences of the TOD mutation we identified might explain why it results in a clearly distinct phenotype. Overall our data strongly support the conclusion that TOD is caused by a single recurrent mutation in the FLNA gene.

A comprehensive evaluation of whole genome sequence data in five HapMap individuals, inclusive of one parents-child trio. *L.T. Guey[1], M.E. Schaffer[1], J.M. Laramie[1], K. Pant[2], D. Ballinger[2], S. Lincoln[2], D.R. Cox[1], A.B. Seymour[1].* 1) Applied Quantitative Genotherapeutics, Pfizer Inc., Cambridge, MA; 2) Complete Genomics Inc., Mountain View, CA.

Whole genome sequence data was evaluated in five individuals used in the International HapMap Project (four of European ancestry [NA12878, NA12891, NA12892, NA06990] and one of African ancestry [NA18507]), three of which comprise a father (NA21891) - mother (NA12892) - child (NA12878) trio. DNA from these HapMap individuals was sequenced by Complete Genomics Inc. with a nanoarray-based short-read sequencing-by-ligation technology. The median depth of coverage by mapped reads was 45- to 52-fold across all samples and variants were called using local de novo assembly on approximately 96% of the genome for each sample. We estimated a Mendelian inheritance error (MIE) rate of 7.4x10^-6 from 20,396 trio inconsistencies, which is well above the estimated mutation rate of 1.1x10^-8. A similar MIE rate was observed when the analysis was limited to the exome, or the coding regions of the genome. MIEs were more likely to have significantly lower depth of coverage and lower “variation scores” from the assembly software. These measures could be used in future analyses to identify potential errors. Lastly, a comparison of the data with 3.7 million genotypes generated by the HapMap project showed an overall concordance rate of 99.5%. Specifically, variants called reference homozygote and non-reference homozygote had overall concordance rates of 99.9% and 99.5% respectively while variants called heterozygote had a concordance rate of approximately 98%.

Metabolic SNPs and Nicotine and Cotinine Metabolism. *A.W. Bergen[1], H.S. Javitz[1], M. Michel[1], R. Krasnow[1], D. Nishita[1], C.N. Lessov-Schlaggar[2], C.L. Sanders[3], N.J. Markward[3], E.J. Stanek[3], F.W. Freuh[3], R.D. Hockett[4], J. Kaufman[4], N. Benowitz[5], G.E. Swan[1].* 1) Center for Health Sciences, SRI International, Menlo Park, CA; 2) Department of Psychiatry, Washington University School of Medicine, St Louis, MO; 3) Personalized Medicine Research and Development, Medco Health Solutions, Bethesda, MD; 4) Affymetrix, Inc., Sunnyvale, CA; 5) Departments of Medicine, Bioengineering and Therapeutic Sciences, University of California, San Francisco, CA.

One billion individuals currently smoke tobacco worldwide and millions of individuals die each year from tobacco-related illness. All available interventions will be needed to meet the demand for effective, sustainable tobacco control, including pharmacogenetically-informed treatments for smoking cessation. Investigation of both the time course of nicotine concentration in the body (pharmacokinetics) and the response of the brain and body to nicotine (pharmacodynamics) will be part of developing such treatments. The nicotine metabolic ratio (NMR), the ratio of the nicotine metabolites trans-3'-hydroxycotinine to cotinine, is modestly associated with measures of smoking intensity and smoking cessation. We performed a pharmacogenetic study of the fixed-dose NMR utilizing the Affymetrix DMET™ Plus Assay, which interrogates over 1900 markers at 225 drug metabolizing enzyme and transporter genes, in a sample of 336 individuals (twins and siblings) from 159 sibships who have received a standardized dose of deuterium-labeled nicotine and cotinine and from whose blood samples nicotine metabolite levels were measured using liquid chromatography-mass spectrometry. The plasma NMR mean (SD) and range was 0.26 (0.13) and 0.04-0.79, respectively. We performed hierarchical linear modeling of NMR estimates adjusted for age, gender, smoking status, menopausal status, reproductive hormone use and BMI, and of twenty-two common (minor allele frequency ≥ 0.05) biallelic non-insertion-deletion polymorphisms at CYP2A6, CYP2B6, FMO3, UTG1A4 and UGT1A9, genes which are known to code for proteins involved in nicotine metabolism. We observed associations of P£0.0001 at rs28399433 (CYP2A6 -47G>T) and rs4803418 and rs4803419 (CYP2B6 IVS4+1735C>G and +2332C>T), uncorrected for multiple testing of polymorphisms or models. Retrospective power calculations from this modest study support known gene associations with the NMR, but suggest that the power to detect novel associations with substantially less impact on NMR variance is more limited.

Cellular genetic approaches to defining drug toxicity pathways. *N. Butz[1], O. Suzuki[1], B. Steffy[1], D. Scoville[1], B. Parks[2], J. Trask[2], R. Thomas[2], T. Wiltshire[1].* 1) Division of Pharmacotherapy and Experimental Therapeutics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) The Hamner Institute for Health Sciences, Research Triangle Park, NC.

Despite recent success in defining pharmacogenetically relevant gene variants, genomic determinants of drug toxicity are poorly understood. To identify quantitative trait genes critical to drug response phenotype we developed a novel high-throughput screening platform using cultured primary embryonic fibroblasts from the Mouse Diversity Panel. A library of 70 compounds (pharmaceutical drugs and environmental toxins) has been profiled for cytotoxicity utilizing high content imaging and simultaneous evaluation of cell health parameters at a single cell level across 32 mouse inbred strains. Genome-wide association analyses between observed cellular phenotypes and known genotypes were performed using haplotype association mapping to identify quantitative trait loci (QTLs) influencing cellular responses to tested compounds. This approach generated robust and reproducible results yielding significant inter-strain variation for all measured phenotypic endpoints. We have discovered a large number of QTL and successfully defined in silico high-confidence candidate genes. For instance, a locus underlying phenotypic variations in cell viability after rotenone exposure revealed a gene encoding member A3 of the ATP-binding cassette family (Abca3) involved in transport and drug response. In vitro validation of target genes using overexpression and siRNA knock down technology is currently underway. Gene enrichment analysis allowed association of these haplotypes to specific signaling pathways underlying toxicological responses. We have identified a network enriched for cell viability assay endpoints from combined set of candidate genes in 20 compounds screen that is centered on p53 as a key node, possibly indicating a common toxicity pathway.

2396/W

A genome wide association study (GWAS) to identify markers of weight gain and response to Pregabalin (Lyrica) in Fibromyalgia. *C. Hyde[1], S. John[2], P. Banerjee[3].* 1) Clinical Research Statistics, Pfizer, Groton, CT; 2) 2Human Genetics, Molecular Medicine, Pfizer Worldwide Research and Development, Groton, CT; 3) 3Human Genetics, Molecular Medicine, Pfizer Worldwide Research and Development, New York, NY.

FM is a symptomatic condition that is characterized by musculoskeletal pain, multiple tender points, disordered sleep, fatigue and represents an area of significant unmet medical need. Lyrica is an alpha 2 delta ($\alpha 2\delta$) ligand that has analgesic, anxiolytic and anticonvulsant activity and has been developed primarily for the treatment of epilepsy, relief of neuropathic pain and FM. Upon administration of Lyrica patients experience weight gain, but variability has been observed. Similarly, variability in response to the drug has also been observed, and there are currently no predictors of response. We carried out a GWAS in 1120 individuals diagnosed with FM enrolled in three clinical trials of Lyrica, genotyping 501,550 Single Nucleotide Polymorphisms (SNPs) using the Perlegen 600K chip. The aim was to determine if there are common DNA variants that would have value in predictive response to Lyrica. We analyzed four statistical models to determine whether SNPs genotyped were associated with weight gain or efficacy. No markers in any of the four models reached statistical significance on a genome-wide basis, the most significant of the p-values being in the range of p<1.0e-06. Therefore, either there are no SNPs that have an effect on weight gain or efficacy, or the largest true effects are below what we were powered to detect in this cohort of 1160 individuals. To increase confidence in our results from the first dataset, we also ran a meta-analysis with a fourth clinical trial (N=686) on the efficacy data and did not observe any markers significant at a genome-wide level (one marker - rs12143420 had a p = 4.15e-06). We also analyzed a set of candidate genes based on prior evidence of involvement in obesity (for weight gain) as well genes in the mechanistic pathway of Lyrica including the alpha 2 delta ($\alpha 2\delta$) genes. This was done to facilitate hierarchical multiple testing corrections. The set of candidate gene SNPs comprised a total of 499 SNPs for the weight gain analysis and 239 SNPs for the efficacy analysis. For both the weight gain and efficacy analysis, no SNPs were statistically significant. Thus, the CACNA2D1 and CACNA2D2 genes ($\alpha 2\delta$ genes - targets for Lyrica) are not involved in weight gain or efficacy. Based on these results, we can conclude there are unlikely to be any common DNA variants that influence weight gain or efficacy with large effect sizes that can be utilized for therapeutic intervention in the administration of Lyrica.

2397/W

Association between *GIRK3* gene polymorphisms and postoperative analgesic requirements after major abdominal surgery. *D. Nishizawa[1], M. Nagashima[2], R. Kato[2], Y. Sato[3], M. Tagami[3], S. Kasai[1], Y. Ogai[1], J. Hasegawa[1], M. Hayashida[4], K. Ikeda[1].* 1) Molecular Psychiatry Reseach, Tokyo Institute of Psychiatry, Tokyo, Japan; 2) Department of Surgery, Toho University Sakura Medical Center, Sakura, Japan; 3) Department of Anesthesiology, Toho University Sakura Medical Center, Sakura, Japan; 4) Department of Anesthesiology, Saitama Medical University International Medical Center, Hidaka, Japan.

Objectives: Opioids are commonly used as effective analgesics for the treatment of acute and chronic pain. However, considerable individual differences have been widely observed in sensitivity to opioids. To explore polymorphisms responsible for the inter-subject difference in the opiate sensitivity, we performed an association analysis focusing on the SNPs in *GIRK3*, which is the gene encoding a subtype of G protein-activated inwardly rectifying potassium (GIRK) channel, known to play a key role in transmitting the analgesic effects of opioids. **Methods**: In our initial polymorphism search, a total of ten single-nucleotide polymorphisms (SNPs) were identified in the whole exon, 5'-flanking, and exon-intron boundary regions of the *GIRK3* gene. The subjects in the association study were a total of 112 patients with written informed consent who underwent major open abdominal surgery in hospitals and were treated with analgesics including opioids after surgery. The study protocol was approved by the Institutional Review Board at each related Institute. Total genomic DNA was extracted from peripheral blood or oral mucosa samples by standard procedures and used for genotyping. **Results and Discussion**: In an association study, carrying T alleles in the C1781T SNP and in the C1817T SNP were significantly associated with decreased postoperative 24-h analgesic requirements. The total dose (mean±SEM) of rescue analgesics converted to equivalent fentanyl doses was 1.10±0.23 and 0.61±0.11 μg/kg for the C/C and combined C/T and T/T genotypes in the C1781T SNP, respectively (p=0.035), and 1.00±0.16 and 0.40±0.10 μg/kg for the C/C and combined C/T and T/T genotypes in the C1817T SNP, respectively (p=0.002), suggesting that the subjects carrying T allele in these SNPs have higher analgesic sensitivity. The results indicate that these SNPs could serve as markers that predict decreased analgesic requirements. Our findings will provide valuable information for achieving satisfactory pain control and open new avenues for personalized pain treatment.

2398/W

Polymorphisms in BCRP, MRP2 and OATP1B1 Drug Transporters Influence Cerivastatin Transport. *B. Tamraz[1,2], H. Fukushima[3], D. Kroetz[3], PY. Kwok[1,2].* 1) Cardiovascular Research Institute, UCSF, San Francisco, CA; 2) Institute for Human Genetics, UCSF, San Francisco, CA; 3) Department of Bioengineering and Therapeutic Sciences, UCSF, San Francisco, CA.

Genetic variation in drug metabolizing enzymes and membrane transporters can modulate the beneficial, as well as the deleterious, effects of drugs. In a study of patients who developed rhabdomyolysis while taking the HMG-CoA reductase inhibitor, cerivastatin, we sought to identify genetic variants that might explain the high incidence of rhabdomyolysis associated with this medication. We re-sequenced three drug transporter genes, ABCC2 (coding for MRP2), ABCG2 (coding for BCRP) and SLCO1B1 (coding for OATP1B1) involved in efflux and uptake of cerivastatin and identified 10, 4 and 7 non-synonymous coding variants in ABCC2, ABCG2 and SLCO1B1 genes respectively. These variants were suspected to have functional consequences for cerivastatin transport. To test the hypothesis that the variants in these transporters affect the transport of cerivastatin, we stably transfected HEK293 cells with plasmids containing the variants, created for all three transporters by site-directed mutagenesis, and measured the function of the transporter in in vitro cellular assays. Our data on the OATP1B1 uptake shows that 6 polymorphism and three haplotypes (2 novel) cause a significant reduction in cellular uptake of Cerivastatin compared to wild type. This cellular uptake functional data along with data on variants of MRP2 and BCRP and their influence on cellular efflux of cerivastatin in stably transfected HEK293 cell lines will be presented.

2399/W

Pharmacogenetic determinants of 6-mercaptopurine metabolites concentrations variability during maintenance therapy for children with acute lymphoblastic leukemia. *T. Adam de Beaumais[1], M. Fakhoury[1], Y. Medard[1], S. Azougagh[1], D. Zhang[1], K. Yacouben[2], E. Jacqz-Aigrain[1].* 1) Pharm Dept, Robert Debre Hosp, Paris, France; 2) Haematology Dept, Robert Debre Hospl, Paris, France.

6-mercaptopurine (6-MP) is an inhibitor of de novo purine synthesis widely used in acute lymphoblastic leukemia (ALL) maintenance treatment. Its metabolites concentrations in red blood cells (RBC) were related to the risk of toxicities and relapses. We investigated the impact of pharmacogenetic polymorphisms affecting thiopurine methyltransferase (TPMT) and inosine triphosphate pyrophosphatase (ITPA) on 6-MP metabolites concentrations variability. Their relation with hepatotoxicities occurrence during maintenance therapy was analyzed. Sixty-six children treated according to EORTC 58951 protocol were included. Genotypes for TPMT*2, *3B, *3C, ITPA 94C>A and IVS2+21A>C were performed. RBC 6-thioguanine nucleotides (6-TGN) and 6-methylated mercaptopurine nucleotides (6-MMPN) concentrations were measured by HPLC technique and their variability evaluated by mixed-models. Six patients were TPMT heterozygous (4 TPMT*1/*2, 1 TPMT*1/*3A and 1 TPMT*1/*3C). Mutated allelic frequencies were 0.07 for ITPA 94C>A and 0.13 for ITPA IVS2+21A>C. TPMT heterozygous patients had 6-TGN levels 2.25 fold higher than wild-type patients (estimation and standard error: 757±69 versus 336±34 pmol/8x108RBC; p<0.0001). Inversely, TPMT wild-type patients had 2.25 fold higher 6-MMPN concentrations than heterozygous patients (11290±1219 versus 5010±2459 pmol/8x108RBC; p=0.006). A combined effect of TPMT and ITPA 94C>A on 6-MMPN concentrations was identified: lowest 6-MMPN concentrations were observed in patients with a multilocus TPMT variant/wild-type ITPA genotype (mean ± standard deviation: 1862±1850 pmol/8x108RBC), wild-type patients for both genes had concentrations 4.5 fold higher and the highest concentrations reached for patients wild-type TPMT/variant ITPA genotype (16468±9467 pmol/8x108RBC). A 6-MMPN concentrations threshold was defined by ROC curve at 5000 pmol/8x108RBC above which there is a great risk of hepatotoxicities. Our findings support the importance of TPMT polymorphism in 6-MP concentrations variability and suggest a potentially clinically relevant combined impact of TPMT and ITPA 94C>A on 6-MMPN concentrations related to hepatotoxic risk.

2400/W

Functional impact of a common copy number variant in dexamethasone induced apoptosis. *J. Aigner[1], S. Villatoro[1], R. Rabionet[1], L. Armengol[2], E. Marti[1], X. Estivill[1].* 1) Center for Genomic Regulation, Barcelona, Spain; 2) Quantitative Genomics, Barcelona, Spain.

Structural variations including copy number variants (CNVs) have been recognized as an important source of human genetic diversity. Phenotypic effects of CNVs are commonly observed, but the functional consequences of structural variations in general, and more specifically, on sensitivity to drug treatment have been poorly assessed so far. In the present study we describe the functional analysis of a 45-kb deletion CNV, and the genotype-based different consequences after treatment with the glucocorticoid dexamethasone. Glucocorticoids are steroidal anti-inflammatory agents that are widely used to treat several clinical diseases, including inflammatory and autoimmune diseases, organ transplantation and cancer. The 45-kb CNV deletion affects two genes of the same family, BTNL8 and BTNL3 and results in a new, in-frame, fusion mRNA (BTNL8*3). The presence of the CNV affects the expression levels of several genes, e.g. MMP9, FPR1, PDGFRB and PML, including down-regulation of both, BTNL3 and BTNL8, and the neighboring gene BTNL9. These three affected genes belong to the family of butyrophilin-like proteins, which are expressed in haematopoetic-linage cells. Expression of all three mRNAs was significantly induced after dexamethasone treatment in lymphoid cell-lines. Moreover, cells homozygous for the wild-type allele showed a significant increase in dexamethasone-induced apoptosis rate and over-expression of GFP-BTNL9 fusion-protein in (-/-) cells was sufficient to rescue this phenotype. BTNL9 has been shown to be upregulated in acute lymphoblastic leukemia and in germinal center B-cell like-type of diffuse large B cell lymphoma. For both cancers, glucocorticoids are an important component of the standard treatment protocols. Therefore, BTNL8*3 and BTNL9 protein expression status may provide useful clinical information in terms of clinical outcome of lymphoid malignancies and numerous other diseases following treatment with dexamethasone.

PharmGKB: A decade of catalyzing pharmacogenomics research. *K. Sangkuhl[1], M.W. Carrillo[1], L. Gong[1], J.M. Herbert[1], C.F. Thorn[1], M. Gong[1], F. Liu[1], R. Tang[1], R. Whaley[1], M. Woon[1], T.C. Truong[1], T. Zhou[1], R.B. Altman[1,2], T.E. Klein[1].* 1) Department of Genetics, Stanford University, Palo Alto, CA; 2) Department of Bioengineering, Stanford University, Stanford, CA.

The Pharmacogenomics Knowledge Base (http://www.pharmgkb.org) marked its 10th anniversary as the NIH supported public online resource devoted to disseminating pharmacogenomics knowledge and data to catalyze research and support hypothesis generation. PharmGKB curates knowledge to capture more complex relationships between genes, variants, drugs, diseases and pathways. Popular features are the very important pharmacogene (VIP) summaries and drug-centered pathways, many of which have been published. PharmGKB's variant-mining project focuses on functional annotation of polymorphisms with pharmacogenomic relevance. PharmGKB is committed to mapping genetic variants to a common framework, providing uniform access to all polymorphisms and support search and sorting operations. These variant annotations are the foundation for our efforts recently published in clinically annotating an entire human genome. PharmGKB's user interface is tailored to provide easy direct access to knowledge and information for genes, drugs, variants, pathways, and diseases. The website also provides excellent educational material including a summary of well known pharmacogenetics pairs of gene-drug relationships and a web-based tool for teaching high school students about pharmacogenomics. To highlight the translation of pharmacogenomics findings into clinical practice the Clinical Pharmacogenomics page catalogues drugs with pharmacogenomic information in the context of FDA-approved drug labels.

Lastly, the PharmGKB has continued its role in consortia as an independent broker to accept, integrate and curate disparate data into a form that facilitates analyses and subsequent dissemination for use by the global research community as well as providing guidance to clinicians for pharmacogenetic tests to be used in the clinic. Current consortia involve (1) determining the role of CYP2D6 genetic variation as a predictor of breast cancer recurrence and survival in postmenopausal women (ITPC), (2) discovering new genetic variants that are important for warfarin dosing using genome wide association studies (IWPC-GWAS), and, (3) creating, curating, reviewing, and updating written summaries and recommendations for implementing specific pharmacogenomic tests and practices (CPIC).

Genetic and environmental influences on cognitive response of healthy volunteers to topiramate. *E.T. Cirulli[1], D.K. Attix[2,3], K.N. Linney[1], V. Dixon[2,3], J.M. McEvoy[1], R.A. Radtke[2], D.B. Goldstein[1].* 1) Center for Human Genome Variation, Duke Univeristy School of Medicine, Durham, NC; 2) Neurology, Department of Medicine, Duke University Medical Center, Durham, NC; 3) Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC.

Topiramate is an antiepileptic drug with marked, specific and well-characterized effects on cognition. However, only certain individuals appear to experience these side-effects; furthermore, only certain aspects of cognition, such as verbal fluency and working memory, seem to be affected. Taken together, these observations indicate both that there may be a genetic component influencing response to topiramate and that the identification of genetic variants contributing to this response may provide information about the biology behind the specific aspects of cognition that are affected. Topiramate has been shown to affect cognition within two hours of taking the first dose. Here, to characterize individual responses to an acute dose of topiramate, we have administered a 100 mg dose of topiramate to 158 healthy volunteers; two hours later they were administered a battery of eleven standardized cognitive tests. All subjects had taken this same battery without topiramate an average of one year prior, and a control group of 206 subjects took the battery twice without topiramate. Using the control data to build regression models predicting the amount of change between tests expected for each individual who took topiramate, we calculated the difference between the observed change and the expected change for each individual for each test and then performed principal component analysis. The first principal component was taken as a measure of the overall response of the individual to topiramate. We were clearly able to show the strong effect of topiramate on cognition in this controlled setting. However, individual response to topiramate varied widely. We found that weight and ethnicity had an impact on this response, but that gender, age, education and baseline intelligence did not. Furthermore, the majority of the variability in response could not be explained by covariates, implying that genetic variants play a role. Nevertheless, a genome-wide association study of response in this cohort did not find a significant association with any common variants, although this result is not unusual given the relatively small sample size. Further work will involve both an expansion of the sample size for the genome-wide association study, with the hope to find common variants affecting this phenotype, and whole-genome or whole-exome sequencing of some study participants to find rarer variants influencing this adverse drug reaction.

Identifying Subtypes of Patients with Neovascular Age-Related Macular Degeneration by Genotypic and Cardiovascular Risk Characteristics. *M. Feehan[1], R. Durante[1], J. Hartman[1], M. DeAngelis[2].* 1) Observant LLC, 1601 Trapelo Rd., Ste 255, Waltham MA 02451; 2) Ocular Molecular Genetics Institute, Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston, MA 02114.

One of the challenges in the interpretation of research showing associations between environmental and genotypic data with disease outcomes such as neovascular age-related macular degeneration (AMD) is understanding the phenotypic heterogeneity within a patient population vis-à-vis any risk factor associated with the condition. This is critical when considering the potential therapeutic response of patients to any probative drug developed to treat the condition. We evaluated a sample of patients with neovascular AMD, that in previous published studies had been shown to be at elevated risk for the condition through environmental factors such as tobacco consumption and strongly associated genetic variants including the complement factor H gene (CFH) on chromosome 1q25 and variants in the in ARMS2/HtrA serine peptidase 1 (HTRA1 and) gene(s) on chromosome 10q. We conducted a segmentation analysis of these patients, and in a multivariate model factors such as tobacco consumption failed to differentiate subtypes of patients. Rather, 4 meaningfully distinct clusters of patients were identified that were most strongly differentiated on their cardiovascular (CV) health status (histories of dyslipidemia and hypertension) and the alleles of the marker rs1049331 for ARMS2/HTRA1. These results have significant personalized medicine implications for drug developers attempting to determine the effective size of the treatable AMD population. Patient suptypes or clusters may represent different targets for development (based on genetic pathways in AMD and cardiovascular pathology), and also treatments developed that may elevate cardiovascular risk, may be ill advised for particular the clusters identified.

2404/W

Maternal Smoking, Drug-Metabolizing Gene Variants, and Risk for Gastroschisis. *M.M. Jenkins[1], M.L. Gallagher[1], J. Reefhuis[1], J.S. Witte[2], S.A. Rasmussen[1], T. Hoffmann[2], D.A. Koontz[1], C. Sturchio[3], A. Smith[3], P. Richter[1], E.J. Lammer[4], M.A. Honein[1], the National Birth Defects Prevention Study.* 1) Centers for Disease Control and Prevention (CDC), Atlanta, GA; 2) University of California, San Francisco, CA; 3) Battelle contractor to CDC, Columbus, OH; 4) Children's Hospital Oakland Research Institute, Oakland, CA.

Maternal smoking during pregnancy is one proposed risk factor for gastroschisis, but reported associations have been modest, suggesting that differences in genetic susceptibility might play a role. We analyzed 6 infant and maternal polymorphisms in 4 genes (*CYP1A1*, *CYP1A2*, *CYP2A6*, and *NAT2*) that code for drug-metabolizing enzymes to determine the potential effect they have on gastroschisis risk. Maternal interview data and cytobrush-derived DNA from a multi-site, population-based case-control study of major birth defects were used. Control infants were a sample of live-born infants with no major birth defects. Infants had estimated dates of delivery between Oct 1, 1997 and Dec 31, 2003. This analysis included 192 case families and 1687 control families with available DNA specimens from the infant and/or mother. Included specimens had DNA concentrations ≥0.1ng/µl. Families with any genotypes that were inconsistent with Mendelian inheritance were excluded. Genotyping of 6 variants was completed on genomic DNA using Pyrosequencing® technology. Genotyping call rates were 99-100%. Logistic regression models stratified by periconceptional smoking status (any or none) and adjusting for maternal age at birth (continuous), maternal race-ethnicity (White, Hispanic, other), and periconceptional alcohol use (any or none) were used to estimate adjusted odds ratios (ORs). Preliminary results provide no evidence of modifying effects of maternal or infant drug-metabolizing gene variants on risk of gastroschisis among mothers who reported smoking; some gene effects were observed among nonsmoking mothers. Decreased ORs were observed among nonsmoking mothers who had or whose infant had the *CYP1A2*1F* CC or AC genotype compared with nonsmoking mothers who had or whose infant had the AA genotype (OR_{mother} 0.6, 95% confidence interval [CI] 0.4-0.9; OR_{infant} 0.5, 95% CI 0.3-0.8). Increased ORs were observed among nonsmoking mothers who had the *NAT2*6* AA or GA genotype compared with nonsmoking mothers who had the GG genotype (OR 1.5, 95% CI 1.0-2.4), and among nonsmoking mothers whose infants had the *CYP1A2*1C* AA or GA genotype compared with nonsmoking mothers whose infant had the GG genotype (OR 1.9, 95% CI 1.0-3.6). Preliminary results suggest some direct gene effects among nonsmoking mothers. Although no interaction between smoking and these genetic risk factors was observed, effect of smoking frequency was not assessed. Further analyses will include family based methods.

Development and Implementation of a Broad-Based ADME Genotyping Assay. *A.M.K. Brown[1,2], Y. Renaud[1,2], C. Ross[3], M. Hansen[4], U. Zanger[5], J-C. Tardif[1,2], M.S. Phillips[1,2].* 1) Montreal Heart Institute Pharmacogenomics Centre, Montreal, QC, Canada; 2) Université de Montréal, Montreal, QC, Canada; 3) University of British Columbia, Vancouver, BC, Canada; 4) Illumina, Inc. San Diego, CA; 5) Dr. Margarete Fischer-Bosch Institute of Clinical Pharmacology, Stuttgart, Germany.

The testing of evidence based functional markers in drug metabolism genes, such as those identified by the pharmaADME initiative (www.PharmaADME.org) or those included on many commercially available products, can serve as a valuable tools in drug development. However, a more thorough list of variants in genes involved in Absorption, Distribution, Metabolism and Excretion (ADME) is required if one wishes to investigate the inter-individual variability observed in the response to medications. In order to address this need, we have created a custom genotyping panel that uses unique assay designs to query key ADME genes. These well know genes and pathways are associated with pharmacokinetic mechanisms; however there has been little effort to interrogate a large number of these genes simultaneously with a single investigative tool. The assay consists of two types of variation, functional markers with known consequences and haplotype tags that account for blocks of linkage disequilibrium. This panel design can be used in two different ways, functional markers can be used to screen populations to make evidence based decision (i.e. stratification in clinical trials) and tag markers can be used to uncover novel genotype-phenotype correlations. The panel was developed using a rigorous development process which involved multiple phases of testing. The final assay designs incorporate novel assay conversion strategies to overcome areas of genomic interference, such as regions of homology and underlying polymorphisms. The present assay consists of 3000 markers with a conversion rate of 97.4%. To validate the assay, we recently screened 150 liver samples that have been extensively genotyped both using a genome-wide approach, and for many functional markers in ADME genes. Furthermore these livers have been phenotypically characterized for ADME enzyme activity, gene expression levels and many clinically relevant lab values. We will present novel genotype-phenotype correlations observed in these samples. The assay has also been used in studies involving chemotherapeutic agents and lipid lowering drugs and will continue to have broad applicability in any study or clinical trial that would benefit from the evaluation of an extensive list of ADME genes.

2406/W

The Application of Pharmacogenetics in Clinical Medicine and Drug Development. *L. Zhang.* CDER, Food and Drug Administration, Silver Spring, MD.

Pharmacogenetics (PGx) enables clinicians to prospectively identify patients most likely to derive benefit from a drug, with minimal likelihood of adverse events. Polymorphisms in drug metabolizing enzymes, drug targets, and disease pathogenesis genes provide substantial knowledge about the mechanisms of inter-individual differences in therapeutic response and toxicity. Moreover, PGx transforms the way clinical trials are conducted by allowing for the selection of a more homogeneous study population, thereby reducing the size and cost of drug design. Over 50 PGx biomarkers have now been included on FDA-approved drug labeling. In addition, FDA encourages opportunities through Voluntary Exploratory Data Submission (VXDS) and Biomarker Qualification program to identify new PGx evidences that may expedite the drug development process. PGx applications consist of next-generation sequencing, candidate approach, genome wide association study (GWAS), expression analysis and biological validation etc. The session will present some PGx exploratory case studies which have impact on clinical practice and drug discovery strategy.

Genome wide association analysis of rheumatoid arthritis patients treated with anti-TNF medication. Results of the DREAM registry. *MJH. Coenen[1], M. Umicevic-Mirkov[1], SH. Vermeulen[1,2], EJM. Toonen[1], A. Lee[3], F. Batliwalla[3], W. Kievit[4,8], H. Scheffer[1], T. Jansen[5,8], EJ. Knijff-Dutmer[6,8], TRDJ. Radstake[4], MAFJ. van de Laar[7,8], P. Barrera[4], PLCM. van Riel[4,8], PK. Gregersen[3], B. Franke[1].* 1) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 2) Department of Epidemiology, Biostatistics, and HTA, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3) The Feinstein Institute for Medical Research, Manhasset, New York; 4) Department of Rheumatology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 5) Department of Rheumatology, Medical Centre Leeuwarden, Leeuwarden, The Netherlands; 6) Department of Rheumatology, Gelderse Vallei Hospital, Ede, The Netherlands; 7) Department of Rheumatology, University Twente & Medisch Spectrum Twente, Enschede, The Netherlands; 8) on behalf of the Dutch Rheumatoid Arthritis Monitoring registry.

Background: Treatment strategies blocking tumour necrosis factor (TNF) have proven very successful in patients with rheumatoid arthritis (RA). However, a relevant subset of patients does not respond for reasons that are unknown. There are currently no means of identifying these patients prior to treatment start.

Objective: We aimed at identifying genetic factors predicting anti-TNF treatment outcome in patient with RA using a genome-wide association approach.

Methods: We selected patients with RA treated with antibodies directed against TNF (anti-TNF) from the Dutch Rheumatoid Arthritis Monitoring (DREAM) registry. Disease activity scores (DAS) 28 at baseline and after 14 weeks were available of 449 patients. Single nucleotide polymorphisms (SNPs) were genotyped using the Illumina HumanHap550-Duo BeadChip or the Human660W-Quad. Association analysis using the DAS28 change as outcome was performed using the whole genome association analysis toolset in PLINK.

Results: 511.499 SNPs passed quality control. No findings passed the threshold for genome-wide significance (p-value £$1x10^{-8}$). 53 SNPs showed suggestive association (uncorrected p-value <10^{-4}) with DAS28 change. Eight of the top ten associated SNPs were located in the following genes; *SCARA5, QKI, EP400, LPHN3, ATXN7, MYO1E* and *HDAC9*. Candidate genes that can be linked to anti-TNF or RA are *EP400* and *HDAC9*. EP400 plays a role in cell death, one of the working mechanisms of anti-TNF therapy; HDAC9 has a proposed function in hematopoiesis. In addition, endogenous HDAC activity is thought to regulate Th1 and 2 responses.

Conclusions: The genome wide association approach is a potent tool for the identification of new candidate biomarkers predicting anti-TNF response. However, our suggestive findings need to be replicated in larger, independent patient cohorts before any conclusions about the association of these SNPs with treatment outcome can be drawn.

A Genome-Wide Association Study of Bronchodilator Response in Four Asthma Drug Trial Cohorts. *B.E. Himes[1,2,3,4], A.C. Wu[5], J. Lasky-Su[2], B. Klanderman[2], J. Ziniti[2], J. Senter-Sylvia[2], R. Lazarus[2], J.J. Lima[6], C.G. Irvin[7], S.P. Peters[8], K. Tantisira[2], A.A. Litonjua[2], S.T. Weiss[2,4].* 1) Div Hlth Sci & Tech, Harvard Med Sch, Boston, MA; 2) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 3) Children's Hospital Informatics Program, Boston, MA; 4) Partners Center for Personalized Genetic Medicine, Boston, MA; 5) Department of Population Medicine, Harvard Pilgrim Health Care and Harvard Medical School, Boston, MA; 6) Nemours Children's Clinic, Center for Pharmacogenomics and Translational Research, Jacksonville, Florida; 7) Vermont Lung Center, Department of Medicine and Physiology, University of Vermont, Burlington, Vermont; 8) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC.

Asthma is a chronic inflammatory airway disease with well-established heritability that affects over 300 million people around the world. The most common medications used for the treatment of asthma are β_2-agonists (e.g. albuterol). The effect of β_2-agonists is commonly assessed using the bronchodilator response (BDR) test, which measures reversible airway obstruction and aids in the diagnosis of asthma. The physiological response to a bronchodilator is a complex trait that is heritable and partly under genetic control. We performed a genome-wide association (GWA) study of BDR using measures at randomization of 1,196 non-Hispanic white subjects with mild to severe asthma from four drug trial cohorts: the Childhood Asthma Management Program (CAMP), the Leukotriene Modifier or Corticosteroid Salmeterol study (LOCCS), the Effectiveness of Low Dose Theophylline as an Add-on Treatment in Asthma trial (LODO), and a medication trial conducted by Sepracor, Inc. After stringent quality-control filters were applied, data for 469,884 single nucleotide polymorphisms (SNPs) were used to measure the association of SNPs with BDR using a linear model as implemented in PLINK. Covariates included for adjustment were age, gender, height, study cohort, and the top four eigenvectors calculated in EIGENSOFT to account for residual population stratification among subjects. Of the top 15 SNPs with the lowest p-values (ranging from 2.9×10^{-5} to 2.7×10^{-6}), one is within an intron of *CRISPLD2*, a lung development gene that promotes matrix assembly, one is within an intron of *SPAT2SL*, a gene that is highly expressed in bronchial epithelial cells, and one is near *ANXA1*, a gene that is highly expressed in bronchial epithelial cells, lung, and fetal lung and is part of a family of Ca^{2+}-dependent phospholipid binding proteins that is thought to have anti-inflammatory activity. Replication of these association results is ongoing in two additional cohorts of asthmatics. To date, this is the largest genetic study of BDR that has been performed, and its results suggest that there is promise in gaining a better understanding of the biological mechanisms of differential response to β_2-agonists through GWA studies.

2409/W

DRD2 Single Nucleotide Polymorphisms are associated with nicotine dependence in an urban population of African American smokers. *B. Arrey[1,4], P. Karla[1], C. Williams[2], S. Wilson[3], L. Ricks-Santi[2,4], T. Mason[4], M. Abbas[4], V. Apprey[4,5], G. Bonney[4,5], W. Anthony[1], G. Dunston[4,6].* 1) Pharmaceutical Sciences, Howard University, Washington, DC; 2) Cancer Center, College of Medicine, Howard University, Washington, DC; 3) Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 4) The National Human Genome Center, Howard University, Washington, DC; 5) Community and Family Medicine, Howard University, Washington, DC; 6) Microbiology, Howard University, Washington, DC.

Statement of Purpose: This study addresses tobacco-related health disparities by exploring the genetics of nicotine dependence. The dopamine receptor D2 (DRD2), which binds dopamine neurotransmitters and influences the pleasure intensity signals transmitted to the brain, is involved in nicotine dependence. DRD2 single nucleotide polymorphisms (SNPs) have been associated with dopamine receptor expression. Recent studies have shown the association of SNPs in the 3' untranslated region of this gene with nicotine dependence. The TaqA1 allele in DRD2/ANKK1, occurs more frequently in populations of African descent. Our laboratory utilizes SNPs in candidate genes to investigate the functional significance of common variants in health disparities. Therefore, we investigated the association of DRD2 SNPs with nicotine dependence in African Americans. Methods: We used Restriction Fragment Length Polymorphism (RFLP) and Pyrosequencing to examine the association between several DRD2 SNPs (rs6274; rs6276; rs6279 and rs1800497/Taq1A with nicotine dependence in a cohort of 519 African American current smokers in the Baltimore, MD-Washington, DC metropolitan area. Clinical symptoms of nicotine dependence were defined in accordance with the Diagnostic and Statistical Manual of Mental Disorders. Results: We report a significant association of rs1800497 with heavy smoking (OR=0.48 95% CI: 0.25-0.93; p=0.03) and the frequency of smoking (OR=0.16, 95% CI: 0.16-1.11; p=0.05). Additionally, rs6276 was associated with frequency of smoking (OR=0.24, 95% CI: 0.06-1.05; p=0.02) while rs6279 was associated with overall clinical nicotine dependence(OR=0.46, 95% CI: 0.11-0.74); p= 0.01). Conclusions: These data provide evidence for an association between DRD2 SNPs and nicotine dependence in African Americans. Identification of SNPs associated with nicotine dependence may be instructive in the design of genotype-based clinical diagnosis and targeted intervention in the emergence of personalized genomic medicine for diverse population.

2410/W

Variants of the *NR3C1* gene associated with glucocorticoid response to patients with nephrotic syndrome. *T. Ozeki[1], T. Mushiroda[1], N. Kamatani[2], Y. Nakamura[1,3].* 1) Laboratory of Pharmacogenetics, RIKEN Center for Genomic Medicine, Yokohama, Kanagawa, Japan; 2) Statistical Analysis, RIKEN Center for Genomic Medicine, Yokohama, Kanagawa, Japan; 3) Laboratory of Molecular Medicine, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Nephrotic syndrome (NS) is characterized by proteinuria, hypoalbuminemia, edema, and hyperlipidemia. There is a considerable variability in the sensitivity to glucocorticoids (GCs) for NS among individuals. About 10% of NS patients show GC-resistant and refractory NS. GCs exert their effect by binding to GC receptor (GR), forming a complex that translocates to the nucleus, then regulate the expression of target genes by interaction with a cis-element, GC-responsive element (GRE). The genetic variations of *NR3C1* encoding the GR have been reported to affect GC sensitivity. Thus, we investigated associations of SNPs of the *NR3C1* gene with GC response to patients with NS.

From the registered samples in the BioBank Japan Project, we obtained 172 NS patients diagnosed as a minimal-change NS or a membrane nephropathy. The subjects included 43 patients with GC-resistant or refractory NS, and 129 patients who achieved remission. We genotyped 40 tag-SNPs of the *NR3C1* gene by means of multiplex PCR-based Invader assays.

Among the SNPS screened, 4 SNPs (rs41423247, rs174047, rs33388 and rs10482634) on the *NR3C1* gene showed significant association with GC-resistant and refractory NS after the correction of multiple testing, and rs12709096 revealed the lowest *P*-value for association ($P = 1.72 \times 10^{-6}$, odds ratio = 6.1 (95% CI = 2.9-12.9)). Our findings should facilitate development of a genetic test to identify individuals at risk for the GC-resistant and refractory NS.

Suppressive effects of black seed oil on ovalbumin induced acute lung remodeling in E3 rats. *M. B. Raza Asim[1, 2], M. Shahzad[3], X. Yang[1, 2], Q. Sun[1, 2], F. Zhang[1, 2], Y. Han[1, 2], L. Shemin[1, 2].* 1) Genetics and Molecular Biology, SChool of Medicine, Xi'an Jiaotong university, Xi'an, shaanxi, China; 2) Key Laboratory of Environment and Genes Related to Diseases (Xi'an Jiaotong University) , Ministry of Education, P.R. China; 3) Department of Pharmacology, University of Health Sciences, Lahore 54600, Punjab, Pakistan, Pakistan.

Abstract Both the seed and oil of Nigella sativa (black seeds) have been used as traditional medicine for centuries to treat asthma, bronchitis, rheumatism and other related inflammatory diseases. Lung remodeling in allergic asthma is the structural alteration of lung tissues due to the deposition of different types of collagen and cell proliferation. In this current study, we examined whether pure black seed oil (BSO) has inhibitory effect on acute lung remodeling in ovalbumin induced asthma model in E3 inbred rats. Rats were randomly divided into three groups; Control, OVA and BSO. Two weeks after intraperitoneal sensitization, the rats were subjected to intranasal challenge to ovalbumin (OVA) and treated intraperitoneally with pure black seed oil for seven days after each challenge. The collagen deposition, goblet cell hyperplasia and infiltration of inflammatory cells were determined by Masson's Trichome, Periodic acid-Schiff, and hematoxylin and eosin staining respectively. The activities of total arginase, ODC and proline level were determined by photometry. HPLC was used to determine the level of polyamine in lung homogenate of experimental rats. The mRNA expression of arginase I, endothelin1, MMP3 and growth factors such as TGF- β, FGF2, VEGF was determined by real time RT-PCR. The administration of pure black seed oil suppressed inflammatory cells infiltration in the airways, collagen deposition and goblet cell hyperplasia. The activity of total arginase and ODC, proline and polyamines levels in the lung homogenate were suppressed after treatment in the lungs of asthmatic rats. Black seed oil treatment abrogated the endothelin1, MMP3, TGF-β, FGF2 and VEGF mRNA expression in the lung of OVA challenged rats. In conclusion, black seed oil suppressed the OVA induced acute lung remodeling by attenuating endothelin1, MMP3, factors related to remodeling, total arginase activity and its downstream products such as proline and polyamine. These results show that Black seed oil might be useful for the treatment and future research for allergen-induced lung remodeling.

ACTG DACS 250: Mitochondrial Genetic Variation Is Associated with CD4 T Cell Recovery in HIV-infected Persons Initiating Antiretroviral Therapy. *B. Grady[1], D.C. Samuels[1], G.K. Robbins[3], D. Selph[1], J.A. Canter[1], R.B. Pollard[4], D.W. Haas[2], R. Schafer[5], S. Kalams[2], D. Murdock[1], M.D. Ritchie[1], T. Hulgan[2].* 1) CHGR, Vanderbilt Univ, Nashville, TN; 2) Division of Infectious Diseases, Department of Medicine, Vanderbilt Univ, Nashville, TN; 3) Division of Infectious Diseases, Massachusetts General Hospital, Harvard Medical School, Boston, MA; 4) Department of Internal Medicine, University of California Davis, Sacremento, CA; 5) Division of Infectious Diseases, Department of Medicine, Stanford University, Stanford, CA.

Mitochondrial genetic variation has been associated with many aspects of HIV infection, ranging from time to progression to AIDS to adverse effects from antiretroviral therapy (ART). In this study, we used the GeneChipR Human Mitochondrial Resequencing Array v2.0 (Affymetrix, Inc., Santa Clara, CA, USA) to obtain full mitochondrial DNA sequence data from U.S.-based adult participants in the AIDS Clinical Trials Group (ACTG) study 384 and examine links between mitochondrial DNA variants and the extent of CD4 T cell recovery with ART. Variation in the mitochondrial genome could influence apoptotic activity in cells with certain mitochondrial DNA variants which might lead to reduced CD4 T cell recovery during ART. In ACTG 384, data on CD4 T cell count was available at baseline, and 48 and 96 weeks after ART initiation on 423 participants, 30% of which self-identified as non-Hispanic black. The primary outcome was CD4 T cell count as an absolute change from baseline at 48 weeks dichotomized at a 100 cell increase. A race-stratified analysis of mitochondrial DNA variants with a minor allele frequency greater than 1% showed several variants associated ($P < 0.05$ before Bonferroni correction) with both increased and decreased magnitude of CD4 cell recovery. The most significantly associated mitochondrial DNA variant was found in the stratum of (self-identified) non-Hispanic blacks and indicated a primary association between the African L2 subhaplogroup and decreased magnitude of CD4 cell recovery ($P = 0.002$, Odds Ratio = 0.022). In addition to variants tagging the L2 subhaplogroup, there were other mitochondrial DNA polymorphisms not associated with haplogroup status which warrant follow up in a replication set. We plan to continue study of the effect of mitochondrial genetic variation on CD4 T cell recovery utilizing additional data from the ACTG cohort and other populations. Findings from these studies have the potential to improve ART outcomes in patients by enhancing prognostic information and improving treatment decisions.

2413/W

Gene expression studies of TRANK1, a candidate gene for bipolar disorder, demonstrate marked upregulation after chronic valproate treatment. *X. Jiang, J. Wendland, W. Coronal, S. Detera-Wadleigh, F.J. McMahon.* Genetic Basis of Mood and Anxiety Disorders, National Institute of Mental Health, National Institutes of Health, US Dept. of Health and Human Services, Bethesda, MD.

Previous studies have implicated TRANK1 in the etiology of bipolar disorder (Wellcome Trust Case Control Consortium 2007; Secolin et al. 2010), and in an accompanying abstract Wendland et al (WCPG 2010) report genome-wide significant association between common variants near TRANK1 and bipolar disorder. TRANK1 (also known as lupus brain antigen1, LBA1) encodes a tetratricopeptide and ankyrin repeat containing protein of unknown function that is highly expressed in brain and other tissues. To explore the biology of TRANK1 and its possible relationship to the pathophysiology of bipolar disorder, we carried out several in vitro gene expression studies. First, we investigated the effect of mood stabilizing drugs, lithium and valproate (VPA), on TRANK1 expression in cultured cell lines. We found that VPA increased LBA1 expression in a time and concentration dependent manner. This held true in SH-SY5Y, HEK 293, and HeLa cell lines, despite highly variable levels of expression at baseline. While 0.5 mM VPA increased TRANK1 expression only slightly at 24 h, 3 mM VPA increased TRANK1 mRNA expression more than 10- fold after 72 h of treatment. In contrast, 2 mM lithium had no effect on TRANK1 even after up to 72 h of treatment. In order to survey the biological impact of changes in TRANK1 expression, we conducted gene expression array studies with HeLa cell lines in which siRNA-mediated knockdown of TRANK1 achieved >70% loss of expression. We used the Illumina HumanHT-12_v3 BeadChips. Analysis revealed differential expression of many genes that are involved in diverse cellular processes. This preliminary work suggests that TRANK1 expression is markedly upregulated by chronic VPA and has an impact on downstream signaling pathways that may be involved in the pathogenesis of bipolar disorder.

Scanning variations in genes related to anesthetic disorder by using custom resequencing array. *S. Levano[1], Ph. Demougin[2], M. Singer[1], A. Urwyler[1], Th. Girard[1].* 1) Departments of Anaesthesia and Biomedicine, University of Basel, Switzerland; 2) Life Sciences Training Facility, Pharmazentrum, Basel, Switzerland.

In anesthesia field there are two inherited pharmacogenetic disorders that are worthy of consideration; butyrylcholinesterase (BCHE; MIM# 177400) deficiency due to its high incidence and malignant hyperthermia (MH; MIM# 145600) due to the fatal consequences. While the hot spots of BCHE mutations are few, the presence of multiple mutations is frequent in this gene. Today the genetic basis of MH lies in the RYR1 and CACNA1S causative mutations. About 70% and 1% of MH cases are linked to RYR1 and CACNA1S mutations. Despite the early hypothesis of RYR1 hot spots, today it is known that the mutations are spread along the whole coding region, which comprises more than 15,000 nucleotides. Our and other genetic groups have exhaustively examined the two principal genes, RYR1 and CACNA1S, encompassing an extensive collection of detected mutations. Taking this information into account, we have realized the need for an intensive mutation-detection approach. Recently, we have established a resequencing DNA array that contains 153 exons of the three genes (RYR1, CACNA1S, and BCHE) and serves as a detection tool for the simultaneous and highly specific identification of variants. We compared the results of the array with the dideoxy sequencing results, which were previously obtained. Array data was analyzed using Affymetrix GeneChip Sequencing Analysis software v4.1 (GSEQ). For further analysis and statistics we used a SQL database (MySQL) and own perl-scripts. Five different quality scores (QS0 to QS4) were used to analyze the resequencing arrays. The QS value affects the stringency for calling the correct bases. As we require very low false negatives to avoid missing a causative mutation, the array data were tested with different QS values at the lower end. The genetic data, obtained from 130 DNA samples in about 66 DNA arrays, is currently being analyzed. From our preliminary results, the error rate is 0.003-0.028 at QS4 and 0.008-0.056 at QS0. The overall call rate ranges from 83 to 99% at quality scores QS4 and QS0, respectively. The averages of cross hybridization in unused places ranged from 1 to 2.66% at QS4 and QS1, respectively.

2415/W

Genetic Predictors of Relapse in Major Depressive Disorder. *G. Laje[1], S. Paddock[1], A.J. Rush[2], F.J. McMahon[1].* 1) Intramural Research Program, National Institute of Mental Health, Bethesda, MD; 2) Duke-National University of Singapore, Singapore.

Major depressive disorder (MDD) will become the second greatest cause of disability in the next decade. Only a fraction of patients with MDD respond to antidepressant treatment and even fewer achieve full symptomatic remission. Moreover, of those patients who respond to treatment about one third relapse. Some predictors of relapse have emerged such as incomplete remission and stressful life events, however, to date, genetic predictors have been elusive. The Sequenced Treatment Alternatives to Relieve Depression study (STAR*D) offered up to one year of follow up treatment for those patients who improved on a specific treatment strategy (n=862). We defined relapse as those patients who reported a QIDS-SR total score <11 at the first follow-up visit, had at least one additional follow-up visit, and reported a QIDS-SR score of 11 or more at any follow-up visit (n=255). Those whose QIDS-SR score remained <11 at all follow-up visits were used as the comparison group (n=430). A candidate gene study was conducted with 780 SNPs representing 68 genes in neurotransmitter, neurotrophin, and other pathways. Results were adjusted for population stratification and Bonferroni-corrected for multiple testing. The marker rs2251388 was associated with relapse (OR: 1.82, X2=4.12, unadjusted p-value: 3.8e-5, adjusted p-value: 0.03). This is an intronic marker on GRIK1 in chromosome 21. This gene encodes the gluR5 subunit of the glutamate-kainate receptor, known to regulated by stress and corticosteroids. We conclude that genetic variation in GRIK1 is associated with relapse of depressive symptoms.

2416/W

Genome-wide association study identifies genetic determinants of warfarin responsiveness for Japanese. *P.C. Cha[1], T. Mushiroda[2], A. Takahashi[3], M. Kubo[4], S. Minami[5], N. Kamatani[3], Y. Nakamura[1].* 1) Laboratory Molecular Medicine, Institute of Medical Science, University of Tokyo, Japan; 2) Research Group for Pharmacogenomics, RIKEN Center for Genomic Medicine, Japan; 3) Laboratory for Statistical Analysis, RIKEN Center for Genomic Medicine, Japan; 4) Laboratory for Genotyping Development, RIKEN Center for Genomic Medicine, Japan; 5) Department of Bioregulation, Nippon Medical School, Kawasaki, Japan.

Warfarin is a commonly-used anticoagulant, whose dose needs to be determined for each individual patient owing to large inter-individual variability in its therapeutic dose. Although several clinical and genetic variables influencing warfarin dose have been identified, uncovering additional factors is critically important for safer use of warfarin. Through a genome-wide association study, we identified SNP rs2108622 (*CYP4F2*) as a genetic determinant of warfarin responsiveness for Japanese. Stratifying subjects who have been pre-classified according to genotypes of SNP rs10509680 (*CYP2C9*) and SNP rs9923231 (*VKORC1*), based on their genotypes of rs2108622 allowed identification of subjects who require higher dose of warfarin. Besides, incorporating genotypes of rs2108622 into warfarin dosing algorithm that considers age, body surface area (BSA), status of amiodarone co-administration, and genotypes of SNPs in the *CYP2C9* and *VKORC1* genes improved model's predictability. In this study, association of *CYP4F2* with warfarin dose of Japanese has been established for the first time. Besides, a warfarin dosing algorithm that incorporates genotypes of rs2108622 and amiodarone co-administration status has been suggested for the first time for the Japanese. Finally, our study also implied that common SNPs other than those in the *CYP2C9*, *VKORC1*, and *CYP4F2* genes that show strong effect on therapeutic warfarin dose might not exist.

2417/W

Association study of Melanocortin-4 receptor gene polymorphisms with antipsychotic induced weight gain. *N.I. Chowdhury[1], A.K. Tiwari[1], R.P. Souza[1], S.A. Shaikh[1], H.Y. Meltzer[2], J.A. Lieberman[3], D.J. Mueller[1], J.L. Kennedy[1].* 1) Neurogenetics, Centre for Addiction & Mental Health, Toronto, Ontario, Canada; 2) Psychiatric Hospital at Vanderbilt University, Nashville, TN, USA; 3) New York State Psychiatric Institute, Columbia University Medical Center, New York City, NY, USA.

Introduction Antipsychotic induced weight gain results in the metabolic syndrome in schizophrenia patients. Single nucleotide polymorphisms (SNPs) located downstream, including rs17782313, of the Melanocortin- 4 receptor (MC4R) gene have been associated with body mass index and waist circumference in healthy human populations. These findings have been replicated in obese and paediatric populations. Thus, we hypothesized that candidate single-nucleotide polymorphisms near MC4R can influence the antipsychotic-induced metabolic syndrome in schizophrenia patients. **Methods** Four tagged SNPs (rs2229616, rs17782313, rs11872992, rs8087522) were analysed in 224 patients who underwent treatment for chronic schizophrenia and were evaluated for antipsychotic induced weight gain for up to 14 weeks. Our refined sample consisted of 67 African Americans and 87 European Americans on clozapine/olanzapine, prospectively. We compared weight change (%) across genotypic groups using analysis of variance and covariance for the three tagSNPs ($r2 \geq 0.8$) near the MC4R gene. Variants were genotyped using ABI TaqMan assays. **Results** The rs2229616 was monomorphic in our population. No significant genotypic or allelic associations were found between rs11872992 and rs17782313 polymorphisms and weight gain ($p > 0.05$). A trend towards association was found between rs8087522 and weight gain in patients of European Ancestry taking either olanzapine/clozapine ($p = 0.088$). The haplotype comprised of rs8087522-rs11872992-rs17782313 was nominally significant. **Conclusion** In this study we suggest that the polymorphisms near and within the MC4R gene may be associated with antipsychotic-induced weight gain in chronic schizophrenia patients. However these observations were made in a relatively small patient population. These results need to be replicated in larger sample sets. *Corresponding author: Dr. James Kennedy Neurogenetics Department 250 College Street Toronto, Ontario M5T 1R8 Phone: (416) 535-8501 ext. 4987 Fax: (416) 479-4666.

A novel CYP2C9 mutation in a warfarin hyper- sensitive patient. *C. Ciccacci[1], N. Paolillo[1,2], M. Falconi[3], D. Di Fusco[1], F. Oteri[3], V. Forte[4], A. Desideri[3], G. Novelli[1], P. Borgiani[1].* 1) Department of Biopathology and Diagnostic Imaging, Section of Genetics, School of Medicine, Tor Vergata University, Rome, Italy; 2) IRCCS C. Mondino Institute of Neurology, Foundation, Pavia, Italy; 3) Department of Biology, Tor Vergata University, Rome, Italy; 4) Azienda Policlinico Tor Vergata, Center of Haemostasis and Thrombosis, Rome, Italy.

Warfarin (Coumadin) is a worldwide prescribed anticoagulant, largely utilized for the long term treatment and prevention of thromboembolic events. It is known that the interindividual variability in the warfarin dosing is a multifactorial character and both environmental and genetic factors influence the dose necessary for the therapeutic effect. The genes resulted to be more involved in warfarin dosing are CYP2C9 and VKORC1 and, more recently, CYP4F2. Anyway, this common variability can not explain the abnormal warfarin dose response in rare individuals with very high warfarin sensitivity or resistance. Here we report the case of an Italian patient with very high warfarin-hypersensitivity. The patient, an 81 years man that started anticoagulant therapy for atrial fibrillation, required only 2.25 mg/week to achieve therapeutic effect; this dose is definitely underneath the normal variability. In order to elucidate the molecular basis of his very high warfarin sentitivity, we conducted a pharmacogenetic analysis. In a first phase, we analyzed the common polymorphisms in VKORC1, CYP2C9 and CYP4F2 genes, already known to be associated with warfarin dosing. Anyway these common polymorphisms could not explain the very low dosing of our patient since he resulted a mix of low dosing and high dosing polymorphic variants. We hypothesized that this hyper-sensitive patient could present some other rare genetic variant. For this reason we searched for rare variations by direct sequencing of the entire coding regions of VKORC1, CYP2C9 and CYP4F2 genes. We found a novel mutation in the CYP2C9 gene, never described before, that, by means of ARMS Pcr, resulted to be in cis with CYP2C9*2 allele. This new mutation, c.374G>T, produces an aminoacid change in the enzyme, from arginine to leucine in position 125 of the protein. In order to clarify the structural/functional role of this mutation we have carried out electrostatic calculation studies on the basis of previous papers that have shown the relevance of the electrostatic interactions for the cytochrome function. Our results indicate the presence of an electrostatic potential alteration on the enzyme surface which can lead to a significant decrease of the recognition between the cytochrome and its redox partner NADPH P450 reductase. In conclusion this new rare variation causes an electrostatic alteration in the enzyme that may explain the warfarin hyper-sensitivity observed in this patient.

2419/W

Inclusion of CYP2C19*4 (c.1A>G) and *17 (g.-806C>T) for Clopidogrel Responsiveness Genotyping. *R.J. Desnick, S. Martis, Y. Kasai, R. Kornreich, S.A. Scott.* Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY.

Clopidogrel is a commonly prescribed antiplatelet prodrug that requires oxidation to its active metabolite by the cytochrome-P450 superfamily, most notably CYP2C19. Although the drug is standard of care in most patients undergoing percutaneous coronary intervention, the response to clopidogrel varies widely among individuals, in part due to inherited CYP2C19 alleles that impair enzymatic activity. The most commonly studied CYP2C19 variant is *2 (c.681G>A), which generates an aberrant splice site and results in a truncated and non-functional enzyme. CYP2C19*2 carriers have reduced responsiveness to clopidogrel with significantly increased risks of stent thrombosis, stroke, myocardial infarction, and death following treatment. In addition, the CYP2C19*17 (g.-806C>T) allele recently has been associated with increased CYP2C19 transcription, enhanced clopidogrel response and an increased risk of bleeding; however, the frequency of CYP2C19*17 has not been established in various ethnic groups. We previously reported the CYP2C19*2-*8 allele frequencies for the Ashkenazi Jewish (AJ) population which were similar to those in the general Caucasian population. To determine the frequency of additional variant CYP2C19 alleles in the AJ population and to assess the impact of including *17 in testing panels, we genotyped 180 AJ individuals, who previously had undergone CYP2C19*2-*8 testing, for CYP2C19*2-*10, *13, and *17 using the Osmetech® 11 allele panel. The frequencies of CYP2C19*1, *2, *4, and *17 were 0.622, 0.150, 0.022 and 0.206, respectively, and no other tested alleles were detected. Complete concordance between *2 and *4 was observed between the two genotyping panels. However, the frequency of extensive metabolizers (*1/*1) changed from 69% to 40% by inclusion of CYP2C19*17, which also resulted in 29% of AJ individuals being reclassified as ultrarapid metabolizers (*1/*17 or *17/*17). Notably, all CYP2C19*4 carriers were also *17 carriers, suggesting a *4/*17 genotype. However, all *2/*4 individuals also were *17 carriers, indicating that *4 (c.1A>G), a null allele, can occur on a *17 background (*4-*17). Thus, these findings identify a novel *4-*17 allele that would significantly alter the interpretation of CYP2C19 genotyping when testing for *17 without *4. These results underscore the importance of including both *4 and *17, in addition to the commonly tested *2 and *3, when assessing CYP2C19 for clopidogrel response among cardiovascular patients.

Evaluating the benefits of using genetic information to design clinical trials. *Y. Hu[1], L. Li[2], N. Bing[2], K. Song[3], M. Nelson[2], M. Ehm[2], G. Abecasis[1], D. Waterworth[3], C. Spino[1], J. Whittaker[4], H. Kang[1].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI, 48105; 2) GlaxoSmithKline, RTP, NC, USA; 3) GlaxoSmithKline, Upper Merion, PA, USA; 4) GlaxoSmithKline, Harlow, UK.

Designing a clinical trial for disease prevention is a complex and costly endeavor focused on identifying patients most likely to develop a disease in a short timeframe and then following these patients. Given that the GWAS era has produced many replicated genotype phenotype signals and that resequencing studies are poised to add to that bank of information, it is natural to ask whether these genetic findings be used, in conjunction with clinical information, in the design of prevention trials. We develop a general framework that explores the potential benefits of enriching the clinical trial sample by selecting individuals with greater genetic risk. Our framework takes into account screening and recruitment costs for each potential trial participant, follow-up costs for subjects who meet genetic or other screening criteria, and the current state of knowledge about trait-specific susceptibility variants, as exemplified by type 1 diabetes (T1D), type 2 diabetes (T2D), cardiovascular disease and age-related macular degeneration (AMD). These diseases differ in their genetic architecture: a number of markers robustly associated with T2D and cardiovascular disease only contribute small changes in disease risk; whilst loci with large effect size T1D and AMD have been shown to be effective in predicting disease risk. Using published data in conjunction with several proposed designs for prevention trials, we quantify the potential benefits -- in terms of trial cost and duration -- of incorporating genetic data in conjunction with clinical information in trials for a T1D, T2D, AMD and cardiovascular disease. Our results illustrate settings where incorporating genetic information will reduce the sample size by up to 20% to 37%; even with current sets of robustly associated loci, but considerable reduction of total trial cost may be achieved only in T1D and AMD. We also show these benefits may be further increased as the list of robustly associated markers for each trait grows. Our investigation illustrates that while current studies have the power to identify markers associated with disease risk, developing further resources such as combined clinical/genetic datasets to assess disease risk in the time dimension along with close collaboration between clinical trial scientists and geneticists will be required to translate this genetic information into the clinical trial context.

Genome wide association analysis of elevated alanine aminotransferase levels in pazopanib treated patients. *L. Huang[1], B.H. Reck[1], V.L. Goodman[2], Z. Xue[1], C.F. Spraggs[1], V.E. Mooser[1], L. Pandite[2], C.F. Xu[1].* 1) GSK R&D: Genetics Division, Harlow, UK, North Carolina and Pennsylvania, USA; 2) GSK R&D: Oncology Research and Development, North Carolina and Pennsylvania, USA.

Pazopanib (Votrient™, GlaxoSmithKline) is an oral angiogenesis inhibitor that was approved by the US Food and Drug Administration for the treatment of patients with advanced renal cell carcinoma (RCC). However, elevations in alanine aminotransferase (ALT) have been observed in patients exposed to pazopanib. To evaluate the potential genetic effect for the observed increases of ALT, genome wide association analysis (GWAS) was performed using data from participants of two clinical studies for RCC. Genetic markers from the Illumina Human 1M Beadchip were analyzed. Maximum on-treatment ALT was analyzed for association with each SNP as a continuous variable in a quantitative trait analysis (QTA) and as a binary variable according to predefined thresholds in a case-control (CC) analysis. The effect of population stratification was minimized using genetic ancestry estimates obtained by principal component analysis. GWAS was performed on a genetically determined European ancestry cluster, which was composed of 240 patients, including 42 cases and 97 controls. None of the markers met the threshold of genome-wide significance ($P \leq 10^{-8}$). Two hundred and eight markers from 60 genes and intergenic regions had a P-value $\leq 10^{-4}$ in either QTA or CC analysis. Although some markers with modest effects on pazopanib related ALT elevation were identified among the GWAS markers investigated in this study, polymorphisms with a large effect for association with ALT elevation were not revealed. Results from this analysis suggest that multiple genetic factors, each with a modest or small effect, may contribute to the observed ALT elevation in pazopanib-treated patients.

Cyclosporine Pharmacogenetics in Transplantation: Preliminary Results from a Multicenter Consortium. *P. Jacobson[1], A. Brearley[2], A. Israni[3], R. Leduc[4], D. Schladt[4], A. Matas[5], V. Lamba[6], W. Guan[4], R. Mannon[7], W. Oetting[8], DeKAF Investigators.* 1) Experimental and Clinical Pharmacology, University of Minnesota, Minneapolis, MN; 2) Clinical and Translational Science Institute, University of Minnesota, Minneapolis, MN; 3) Department of Medicine, Hennepin County Medical Center, Minneapolis, MN; 4) Division of Biostatistics, University of Minnesota, Minneapolis, MN; 5) Department of Surgery, University of Minnesota, Minneapolis, MN; 6) Department of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN; 7) Division of Nephrology, University of Alabama at Birmingham, Birmingham, AL; 8) Department of Experimental and Clinical Pharmacology and Institute of Human Genetics, University of Minnesota, Minneapolis, MN.

Background: Cyclosporine (CSA) is a common immune suppressant used in organ transplantation. Genetic variants within of the cytochrome (CYP) P450 family of genes and multidrug resistant (MDR1) genes have been extensively studied for their effect on CSA metabolism and pharmacokinetics. The majority of these studies have either not established an association or the associations have been weak. We have analyzed CSA pharmacogenomics in a large, well characterized cohort of kidney transplant recipients to identify genetic variation associated with CSA levels. Methods: CSA pharmacogenetics were studied through a multicenter consortium in the U.S. and Canada in 325 adult kidney transplantation recipients. CSA trough concentrations were measured in each patient as part of clinical care twice in weeks 1-8 posttx and then once in each of months 3, 4, 5 and 6 posttransplant. CSA trough concentrations (n=5101) were normalized for CSA dose and weight. CSA doses were adjusted to maintain whole blood concentrations in the therapeutic range as defined by the enrolling center. Recipient DNA was genotyped using a customized Affymetrix SNPChip containing 2724 single nucleotide polymorphisms (SNP) of which around 1000 were from drug absorption, distribution, metabolism and excretion (ADME) genes. Results: Mean±sd age and weight of the recipients were 50.36±13.79 yrs and 82.45±19.49 kg, respectively. 259 recipients were Caucasian and 66 were nonCaucasian. There were 202 male and 123 female recipients. Median (IQR) CSA troughs and daily dose were 173 ng/mL (136-220) and 350 mg (250-400), respectively. Time posttransplant, center and age were important factors towards log transformed CSA troughs. In repeated measures regression analysis, adjusted for the above factors, the top associated SNP towards troughs was within CYP3A7 (rs2687140, p=2.34x10-3) although it was not significant after controlling the false discovery rate at 20%. ATF6 (activating transcription factor 6, rs2271012) was the top SNP (p=1.33x10-3) after adjustment for rs2687140 and above factors. No MDR1 SNPs were found to be significant. Conclusion: We found the CYP3A7 SNP to be associated with a reduction in troughs whereas the ATF6 SNP was associated with an increase in troughs. These novel variants may further explain the substantial interpatient variability in CSA concentrations and will be validated in our accruing cohort of over 2000 patients.

A Pharmacogenetic Approach to the Selection of Fabry Patients for Pharmacological Chaperone Therapy. *E. Katz[1], M.C. Della Valle[1], X. Wu[1], K. Mascioli[1], K. Chang[1], D. Greene[1], R. Schiffmann[2], D.J. Lockhart[1], K.J. Valenzano[1], E.R. Benjamin[1].* 1) Amicus Therapeutics, Cranbury, NJ; 2) Baylor Research Institute, Dallas, TX.

Fabry disease is an X-linked lysosomal storage disorder caused by mutations in the gene (*GLA*) that encodes α-galactosidase A (α-Gal A), and is characterized by pathological globotriaosylceramide (GL-3) accumulation. More than 600 pathogenic *GLA* mutations have been reported, of which more than 60% are missense. The iminosugar AT1001 (migalastat hydrochloride, 1-deoxygalactonojirimycin) is a pharmacological chaperone for α-Gal A that is currently in clinical development as a therapy for Fabry disease. AT1001 selectively binds α-Gal A, thereby increasing physical stability, lysosomal trafficking, and total cellular activity of some mutant forms (defined as "responsive"). As such, Fabry patients expressing responsive mutant forms of α-Gal A have the potential to benefit from AT1001 treatment. Thus, we have developed a single, systematic approach to select male and female patients that may be candidates for AT1001 therapy. First, each of 449 known Fabry disease-causing missense and small in-frame insertion and deletion mutations were individually engineered into *GLA*, expressed in HEK-293 cells, and tested for response to incubation with AT1001 after 4 to 5 days. Concentration-dependent increases in α-Gal A levels were seen for ~60% of the mutant forms. Next, to identify the subset most likely to respond to AT1001 *in vivo*, criteria were developed that consider the magnitude of the enzyme response to a clinically-relevant AT1001 concentration. Mutant forms that met the *in vitro* criteria were generally found to be responsive *in vivo* as measured in white blood cells (WBCs) from male patients orally administered AT1001 during Phase 2 clinical trials. Those that did not meet the *in vitro* criteria showed very limited or no *in vivo* α-Gal A response. A similar level of consistency for a larger number of mutant forms was observed between the HEK-293 cell results and responses measured in lymphoblasts derived from male patients. To date, 189 mutant forms of α-Gal A have been identified that meet the specified criteria. Taken together, these results suggest that a pharmacogenetic reference table comprised of AT1001-responsive mutant forms of α-Gal A and the corresponding *GLA* mutations can be used to select male and female Fabry patients for pharmacological chaperone therapy based on genotype.

Replication of Association of the NTRK2 gene with Lithium Response in Bipolar Disorder in a Prospective Sample. *J. Kelsoe[1,2], S. Leckband[1,2], A. Demodena[1,2], R. McKinney[1,2], T. Shekhtman[1,2].* 1) Dept Psychiatry, MC 0603, Univ California, San Diego, La Jolla, CA; 2) Dept Psychiatry, VA San Diego Healthcare System, La Jolla, CA.

Lithium is the oldest mood stabilizer medication and the gold standard for treatment of bipolar disorder. Lithium responders comprise a clinically distinct subset of bipolar disorder patients many of whom have a excellent response to the drug. The identification of genes that predict response would be invaluable in guiding clinicians in treatment selection. 92 lithium responders and 92 non-responders were identified by retrospective review of research interviews and medical records. A SNP (rs1387923) 3' of the gene for the Trkb neurotrophin receptor (NTRK2) was associated to response (p=0.006). This association was observed only in patients who had predominantly euphoric rather than dysphoric mania. Though retrospective assessment of response is easier, a prospective trial is more definitive. We now report initial results from a prospective trial of lithium response. 77 subjects were entered into a clinical trial the goal of which was to stabilize the patients on lithium monotherapy over 3 months and then follow them for 2 years. In this initial analysis, total time in the study was examined using Cox proportional hazard survival analysis. After incorporating several clinical co-variates, the same allele of the same SNP in NTRK2 also showed association in the prospective sample (X2=14.1, p=0.028). These data provide further support for the role of NTRK2 in lithium response.

Gene expression changes in peripheral blood as potential biomarkers of antidepressant exposure. *M.A. Kennedy[1], J.A. Harley[1,2], K. Doudney[1], M. Allington[1], L. McNoe[3], J. Pearson[4], M. Black[3], P.R. Joyce[2,4].* 1) Dept Pathology, University of Otago, Christchurch, Christchurch, New Zealand; 2) Department of Psychological Medicine, University of Otago, Christchurch, New Zealand; 3) Department of Biochemistry, University of Otago, Otago School of Medical Sciences, Dunedin, New Zealand; 4) Department of the Dean, University of Otago, Christchurch, New Zealand.

The actions of antidepressants depend on the promotion of neurogenesis and modulation of synaptic plasticity, which require modification of gene expression in the brain. Changes induced in the brain by these drugs may be reflected by expression differences in a more readily sampled tissue, the blood. To identify peripheral blood gene expression changes produced by antidepressants, we have used a rat model and delivered citalopram, paroxetine, haloperidol (a non-antidepressant control) or vehicle for 12 days via subcutaneously implanted osmotic minipumps. RNA was isolated using PAXgene blood RNA collection tubes, quantified, labelled and hybridised to rat whole genome expression arrays (Affymetrix Rat gene 1.0-ST). Analysis was carried out using the R package aroma.affymetrix (significance for differential expression was set at a false discovery rate p-value of <0.05) and tools from the Broad Institute Gene Pattern webserver (www.broadinstitute.org/cancer/software/genepattern/index.html). Significant transcript expression differences were detected between paroxetine, citalopram and haloperidol treated and vehicle-only treated samples which include genes involved in neuronal signalling and development. A total of 23 transcripts were altered by both SSRIs and not by haloperidol. These have become candidates for further investigation within our laboratory. We aim to use these preliminary data to guide analysis of peripheral blood mRNA samples from human patients initiating treatment with antidepressants, and to begin evaluating them as potential blood-based biomarkers for drug exposure and perhaps treatment.

Association between Polymorphisms in CYP2D6 and ABCC2 and Clinical Outcomes of Adjuvant Tamoxifen Therapy for Breast Cancer Patients. *K. Kiyotani[1], T. Mushiroda[1], C.K. Imamura[2], N. Hosono[3], T. Tsunoda[4], M. Kubo[3], Y. Tanigawara[2], F. Aki[5], K. Hirata[6], Y. Takatsuka[7], M. Okazaki[8], S. Ohsumi[9], T. Yamakawa[10], M. Sasa[11], Y. Nakamura[1,12], H. Zembutsu[12].* 1) Laboratory for Pharmacogenetics, RIKEN Centor for Genomic Medicine, Yokohama, Japan; 2) Dept. of Clinical Pharmacokinetics and Pharmacodynamics, School of Medicine, Keio University, Tokyo, Japan; 3) Laboratory for Genotyping Development, RIKEN Centor for Genomic Medicine, Yokohama, Japan; 4) Laboratory for Medical Informatics, RIKEN Centor for Genomic Medicine, Yokohama, Japan; 5) Itoh Surgery and Breast Clinic, Kochi, Japan; 6) 1st Dep. of Surgery, Sapporo Medical University, Sapporo, Japan; 7) Dept. of Breast Surgery, Kansai Rosai Hospital, Hyogo, Japan; 8) Sapporo Breast Surgical Clinic, Sapporo, Japan; 9) Dept. of Breast Oncology, Shikoku Cancer Center, Ehime, Japan; 10) Yamakawa Breast Clinic, Kochi, Japan; 11) Tokushima Breast Care Clinic, Tokushima, Japan; 12) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

The clinical efficacy of tamoxifen is suspected to be influenced by the activity of drug-metabolizing enzymes and transporters involved in the formation and elimination of its active forms, endoxifen and 4-hydroxytamoxifen. The purpose of this study was to investigate associations of polymorphisms in transporter genes as well as CYP2D6 to clinical outcome of patients with tamoxifen treatment. We studied 282 patients with hormone receptor-positive, invasive breast cancer receiving tamoxifen monotherapy. We investigated the effects of allelic variants of CYP2D6 and haplotype-tagging single nucleotide polymorphisms (tag-SNPs) of ABCB1, ABCC2 and ABCG2, which are possibly involved in the transport of tamoxifen or its metabolites, on recurrence-free survival using the Kaplan-Meier method and Cox regression analysis. We measured plasma concentrations of endoxifen and 4-hydroxytamoxifen in 98 patients receiving tamoxifen at a dose of 20 mg/day. CYP2D6 variants were significantly associated with shorter recurrence-free survival (P = 0.000036; hazard ratio 9.52 [95% CI 2.79-32.45] in patients with 2 variant alleles vs without variant allele). Among 51 tag-SNPs in transporter genes, a significant association was found at rs3740065 in ABCC2 (P = 0.00017; hazard ratio 10.64 [95% CI 1.44-78.88] in patients with AA vs GG genotypes). The number of risk alleles of CYP2D6 and ABCC2 showed cumulative effects on recurrence-free survival (P = 0.000000055). Patients carrying 4 risk alleles had 45.25-times higher risk compared to those with 0 or 1 risk allele. CYP2D6 variants were associated with lower plasma levels of endoxifen and 4-hydroxytamoxifen (P = 0.0000043 and 0.00052), whereas no significant difference was found among ABCC2 genotype groups. These results suggest that polymorphisms in CYP2D6 and ABCC2 may be important predictors for the clinical outcome of tamoxifen treatment for individual breast cancer patients.

2427/W

Disentangling baseline and on-treatment total bilirubin associations with UGT1A1*28. *L. Li[1], S.A. Bacanu[1], J.C. Whittaker[2], M.R. Nelson[1].* 1) GlaxoSmithKline, RTP, NC; 2) GlaxoSmithKline, Harlow, UK.

UGT1A1*28 is a common TA repeat polymorphism in the promoter region of the uridine diphosphoglucuronyl transferase. The TA7 allele causes an elevation in unconjugated and total bilirubin levels (Gilbert's syndrome). With the availability of UGT1A1*28 genotypes and total bilirubin (TBL) measurements from clinical trial participants for five compounds investigated in GSK, we could demonstrate that the *28 allele explains about 8% of the variation in pretreatment (baseline) TBL. Given its effect on baseline TBL, it would be important to differentiate the influence of the genotype on TBL levels in response to drug treatment from the drug independent effect. This is challenging, particularly when the comparator/placebo arm has not been genotyped or has limited sample size. We carried out a simulation study to assess whether commonly used analysis models can differentiate the drug-independent and dependent effects. Estimates of minor allele frequency and effect size on baseline TBL from the clinical trials are used to simulate drug-independent effects on TBL levels. We find that for analysis of maximum on-treatment TBL level as the endpoint, using baseline as a covariate (Model I) does not remove the background genotype effect and results in a very high false positive rate for drug-dependent effect. However, by analyzing change from baseline (i.e. subtracting baseline from the maximum on treatment TBL) as the endpoint without including baseline as a covariate (Model II), the analysis correctly removes the genetic association with baseline and correctly controls the type 1 error rate. In the analysis of the five GSK compounds, Model I results in significant genetic associations in four out of five compounds whilst Model II only identifies one compound, pazopanib, with statistically significant association. Pazopanib is the only one of the examined drugs known to be an inhibitor of UGT1A1. These results suggest that the *28 allele interacts with pazopanib to cause increases in TBL levels beyond those expected from the drug and genotype effects, separately. We recommend that where genotype is highly correlated with baseline, analyses should be carried out with both change from baseline and the commonly used approach in which baseline is included as a covariate and their results should be carefully compared. Genotyping markers of interest in the placebo/comparator arms can also help to facilitate the interpretation of results.

2428/W

Genome-wide association analysis of serum amyloid-A and statin response. *X. Li[1], Y.I. Chen[1], X. Su[1], K. Wojnoonski[2], J. Smith[3], M. Rieder[3], D. Nickerson[3], R.M. Krauss[2], J.I. Rotter[1].* 1) Cedars-Sinai Medical Center, Los Angeles, CA; 2) Children's Hospital Oakland Research Institute, Oakland, CA; 3) University of Washington, Seattle, WA.

Purpose: To identify genetic determinants of variation in plasma concentration of serum amyloid-A (SAA), a sensitive marker of inflammatory activity, and its response to statin treatment. Methods: Plasma SAA, lipids and C-reactive protein (CRP) levels were measured at baseline and after 6 wk treatment with simvastatin 40 mg/day in 566 Caucasian subjects in the Cholesterol/Atherosclerosis Pharmacogenetics Study. Genotyping was performed in about half the subjects using Illumina 317K beadchips and in the remaining subjects using Illumina 610K beadchips. Further imputation to ~2.5 million SNPs was peformed using BIMBAM v0.95. After excluding SNPs with minor allele frequency <0.05 and/or with poor imputation quality, ~2.1 million SNPs were available for the final analysis. Under the additive model, a linear model analysis (SNPTEST 1.15) was performed with log transformed SAA values and adjustment for age, gender and body mass index (BMI). Results: For baseline SAA, we identified two regions (11p15.1-p14 and 5q22.1) with 44/2 SNPs reaching genome-wide significance ($p<5\times10^{-8}$). Several candidate genes, such as SAA1, SAA2 and SAA4, are clustered at 11p15.1. The minor allele of the top SNP, rs4638289, located near 5' of the SAA1 gene, was associated with increased SAA with a p value of 2.1×10^{-20}. Two haplotype blocks were identified for these significant SNPs: one contained top 4 SNPs including rs4638289; the other one consisted of the remaining positive SNPs in this region. In addition, a candidate gene in 5q22.1, SLC25A46, has previous been reported to be associated with cardiac function (Vasan et al, 2009). After statin treatment, mean log transformed SAA decreased minimally overall (-0.02 ± 0.78 ng/mL in log-transform). This was significantly associated with reductions of CRP ($p<0.001$). No SNP associations with SAA response to simvastatin reached genome-wide significance, although 11 SNPs exhibited associations of $p<10^{-6}$ significance. Notably at 11p15.1, rs4638289 was associated with SAA response with a borderline p value of 0.06. Conclusions: Using GWAS, we have identified 2 regions associated with variation in SAA level, one of them containing a cluster of genes encoding SAA proteins. No loci were predictive of SAA change with statin treatment at the genome-wide level of significance. In addition, we have shown that statin-induced decreases in SAA are associated with decreases in CRP.

2429/W

CYP2D6 genetic polymorphism in fluoxetine and amitriptyline antidepressant response. *M. Lopez[1], E. Peñas-LLedo[2], H. Trejo[3], P. Dorado[2], J. Guerrero[3], M.E. Alonso[3], A. LLerena[2].* 1) Sistemas Biologicos, Univ Aut Metropolitana, Mexico City DF, Mexico; 2) 2Clinical Research Centre (CICAB), Extremadura University Hospital and Medical School, Badajoz, Spain; 3) National Institute of Neurology and Neurosurgery Manuel Velasco Suárez. Mexico City. Mexico.

CYP2D6 is involved in the metabolism of many antidepressants. It is characterized by a high individual variability in catalytic activity mainly due to more than 75 CYP2D6 alleles that determine metabolizer status. The role of CYP2D6 genetic polymorphism in the metabolism of amitriptyline and fluoxetine was previously demonstrated [LLerena et al, 2004]. Herein, we analyzed the relevance of CYP2D6 genetic polymorphism for the clinical response to the antidepressant drugs fluoxetine and amitriptyline. Sixty-five patients (DSM-IV) diagnosed with Major Depression and a score equal or greater than 17 on the Hamilton-Depression (HAM-D) were prospectively studied. They were treated either with fluoxetine or amitriptyline under antidepressant monotherapy. Informed written consent was obtained from all patients. Clinical Response was evaluated with HAM-D. Patients were evaluated every month. A two months period evaluation is reported here. Patients with a 50% decrease on HAM-D were considered as "responders". CYP2D6 genotyping was assayed by PCR-RFLP and RT-PCR. A first month evaluation showed that 49 out of the initial 65 remained (16 dropped-out) in the study and second month evaluation showed that 41 patients remained (8 more dropped-out). Among responders there were 56.6% and 60% to fluoxetine, and 50% and 70% to amitriptyline, at first and second follow up evaluations, respectively. Responders were characterized by presenting one or two CYP2D6 active genes. Furthermore, the number of active genes was related to better clinical response to both drugs. The percentage of responders was higher for those with two active genes than for patients carrying just one: (a) fluoxetine, 81 % vs.18 % at first month; 87% vs. 13% at second month; (b) amitriptyline, 60 % vs.40 % at first month; 83% vs. 17% at second month. All Ultrarapid metabolizers (n=3 UMs; those with more than two CYP2D6 active genes) were found to drop out during the first month. The only Poor Metabolizer patient in the study (PM; with none CYP2D6 active genes) was found among "non-responders" in both follow-up evaluations. The number of CYP2D6 active genes seems to be related to clinical response to the antidepressant drugs amitriptyline or fluoxetine. Among responders, the frequency of patients carrying two CYP2D6 active genes is higher than those with one copy. Moreover, UMs and PMs were not found in this group.

Pharmacogenomics of Alzheimer's disease (AD): association of two novel genes (TAP1 and CYP7B1) in the ADME panel with efficacy of acetylcolinesterase inhibitors drugs. *F. Martinelli Boneschi[1], G. Giacalone[1], S. Lupoli[1,6], P. Brambilla[1], F. Esposito[1], G. Magnani[2], F. Caso[2], E. Coppi[2], C. Vismara[2], D. Galimberti[3], E. Scarpini[3], M. Franceschi[4], F. Macciardi[6], G. Forloni[5], G. Comi[1], D. Albani[5].* 1) Laboratory of genetics of complex disease, INSPE, Scientific Institute San Raffaele, Milan, Italy; 2) Department of Neurology, Memory disorder Unit, INSPE, Scientific Institute San Raffaele, Milan; 3) Department of Neurology, Ospedale Policlinico, Università degli studi di Milano, Milan, Italy;; 4) Department of neurology, Fondazione Multimedica, Castellanza, Italy; 5) Istituto di ricerche farmacologiche Mario Negri, Milan, Italy; 6) Dept of Science & Biomedical Technologies, School of Medicine, Università degli Studi di Milano.

Acetylcholinesterase inhibitors (AChI) are still today the mainstay of drug treatment for Alzheimer's disease (AD). They work by inhibiting the breakdown of acetylcholine, an important neurotransmitter associated with memory, by blocking the enzyme acetylcholinesterase. However, their effect is partial and limited to a subgroup of AD patients who are difficult to identify a priori. Our aim was to identify genetic markers predictive of response to AChI treatment in a cohort of AD-treated patients. A whole-genome case-control association study (WGAS) has been performed on 183 AChI-treated AD patients enrolled at several memory disorder clinics located in the North of Italy. Genotyping has been performed using the Illumina® Human660K BeadChip. Mean age at onset of the disease was 72 years, female:male ratio was 1.4:1, and baseline mini mental state examination (MMSE) was 20.4. AD patients have been classified into responders (R) and non-responders (NR) to treatment based on the change of MMSE during a 1-year treatment period. A parallel candidate-gene approach has been used to investigate the role of 8.037 SNPs present in the coding regions of 267 ADME (Absorption, Distribution, Metabolization, Excretion) genes (www.pharmaadme.org). SNPs have been tested for association after filtering for minimum allele frequency, Hardy-Weinberg equilibrium in controls, and genotyping failure with a logistic regression model of MMSE change during the treatment period as dependent variable. SNPs have been ranked based on their allelic association p value with the dependent variable. Among the top 10 SNPs, one is located in the coding region of the TAP1 gene and two in the CYP7B1 gene (p-values of 1.5*10-4, 7.7*10-4 and 8.1*10-4 respectively). The CYP7B1 gene catalyzes the synthesis of neurosteroids, such as dehydroepiandrosterone (DHEA) which are elevated in postmortem prefrontal cortex and temporal cortex of AD patients compared with cognitively intact control subjects. The TAP1 gene is a member of the MDR/TAP subfamily involved in multidrug resistance, and it is also implicated in the transport of antigens from the cytoplasm to the endoplasmic reticulum for association with MHC class I molecules, supporting the role of inflammation in the AD ethiopathogenesis and response to treatment. Replication of these three SNPs and additional ones identified using the WGAS approach is ongoing in an independent cohort of AD patients, using SEQUENOM® technology.

2431/W

Cytochrome-P450 Copy-Number Profiling among Caucasian, African-American, and Hispanic Individuals Identifies a Novel CYP2E1 Duplication Allele. *S. Martis[1], R. Vijzelaar[2], L. Edelmann[1], R. Kornreich[1], R.J. Desnick[1], S.A. Scott[1].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) MRC Holland, Willem Schoutenstraat 6, Amsterdam, The Netherlands.

The polymorphic cytochrome-P450 (CYP450) system is a superfamily of over 50 hemoproteins which are the major enzymes involved in drug metabolism and bioactivation. Inherited genetic variation among the different CYP450 genes is common in all racial, demographic and ethnic groups and contributes to disease susceptibility and interindividual differences in drug response, including adverse drug reactions. In addition to single nucleotide polymorphisms, copy-number variation also influences CYP450 activity, particularly for CYP2D6; however, little is known about the role of copy-number variation among other CYP450 family members. To determine if other CYP450 genes have common deletion or duplication alleles, multiplex ligation-dependent probe amplification (MLPA) with probes (three to five per gene) that interrogated CYP1A1, CYP1A2, CYP1B1, CYP2A6, CYP2B6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, CYP3A4, and CYP3A5 was performed on over 90 DNA samples each from anonymous Caucasian, African-American, and Hispanic individuals. Among the CYP450 genes studied, copy-number variation was identified in CYP2A6 (19q13.2), CYP2B6 (19q13.2), CYP2D6 (22q13.2), and CYP2E1 (10q26.3). Specifically, among Caucasians, African-Americans and Hispanics, the frequencies of CYP2A6 deletion were 0.6%, 3.8% and 1.4%, and the frequencies of CYP2D6 deletion were 1.7%, 6.9% and 2.8%, respectively. CYP2B6 deletion was also identified among African-Americans (0.6%), possibly representing the recently described CYP2B6*29 partial deletion allele. Moreover, among Caucasians, African-Americans and Hispanics, the frequencies of CYP2A6 duplication were 0%, 0.8% and 0%, and the frequencies of CYP2D6 duplication were 3.5%, 6.9% and 2.1%, respectively. Interestingly, CYP2E1 duplication (MLPA probes at exons 5, 6, and 8) was found among 3.5%, 3.1% and 4.2% of Caucasian, African-American, and Hispanic individuals, respectively. To our knowledge, this is the first report of a CYP2E1 duplication allele, with a carrier frequency of ~1 in 14 among Caucasians, African-Americans, and Hispanics. Given CYP2E1 is involved in the metabolic activation of numerous hepatotoxic and procarcinogenic compounds, CYP2E1 duplication may have an important role in the development of certain chemically-mediated cancers and the risk for tumor development.

2432/W

Frequency of trinucleotide repeat variants in the promoter of the thiopurine S-methyltransferase gene. *M. Mikula, A. Buller Burckle, W. Sun, B. Crossley, C. Strom.* Dept Molecular Genetics, Quest Diagnostics Nichols Inst, San Juan Capistrano, CA.

Thiopurine S-methyltransferase (TPMT) catalyses the S-methylation of thiopurine immunosuppressants. At least 22 variants in the TPMT gene decrease methylation activity, which increases the risk for myelosuppression. However, 1-2% of Caucasians have ultra-high TPMT enzyme activity, which can lead to treatment resistance and hepatotoxicity. In vitro studies indicate that a trinucleotide repeat element in the promoter is responsible for the ultra-high TPMT activity in some individuals. Variants with 5 [(GCC)5] or 7 [(GCC)7] GCC repeats have been observed to result in ultra-high TPMT activity, while (GCC)6 is associated with normal TPMT activity. The goal of this study was to generate frequency data for the general U.S. population, since such data have not been reported. Fluorescent PCR was utilized to detect the described variants [(GCC)5-7]. Our genotypic analysis revealed 2 additional variants of unknown significance in the same region of the TPMT promoter: (GCC)8 and a 9-bp deletion (-6327_-6319delCGCCGCCGC). All variants were confirmed by DNA sequencing. A total of 1571 de-identified clinical specimens previously submitted to our laboratory for cystic fibrosis (CF) screening (n = 1393) or beta globin sequencing (n = 178) were analyzed for variation in the GCC repeat region of the TPMT promoter. Promoter variants were detected in 17 (1.08%). Of these, 5 were heterozygous for the (GCC)7 variant and 2 were heterozygous for (GCC)5 (7/1571 = 0.45%); 10 were heterozygous for variants of unknown significance, including (GCC)8 (n=1) and a 9-bp deletion (n=9). The rest (1554/1571=98.9%) were wild-type [(GCC)6]. (GCC)8 and the 9-bp deletion affect the number of GCC repeats in the TPMT promoter. Our data indicate that the carrier frequency for variants affecting the GCC repeats at -6329 in the TPMT promoter is approximately 1.0%, while the frequency of variants with known function ([GCC]5 and [GCC]7) is around 0.4%. Further studies are necessary to determine the effect of the novel variants on TPMT activity.

2433/W

CYP2D6 and CYP2C19 gene testing in psychiatric practice: A report from the Pharmacogenetics Research Clinic in Toronto. *D.J. Mueller, J.E. Sturgess, A.K. Tiwari, O. Likhodi, J.L. Kennedy.* Neurogenetics Section, Centre for Addcition and Mental Health, Toronto, ON, Canada.

Antipsychotic and antidepressant medication are widely used for psychiatric conditions such as schizophrenia or anxiety disorders including obsessive-compulsive disorder (OCD). Two polymorphic enzymes, CYP2D6 and CYP2C19, metabolize a large number of these medications. Functional polymorphisms in these enzymes can confer altered enzymatic activity, potentially leading to toxic or subtherapeutic drug levels. As part of our AmpliChip © Study, 39 individuals with OCD were genotyped for CYP2D6 and CYP2C19. Abnormal CYP2D6 activity (i.e. non-extensive metabolizer) was significantly associated with non-response to antidepressants. Two individuals who were ultrarapid metabolibzers (UM) failed to respond with 9 antidepressants and showed only repsonse with two trials, and one individual who was poor-responder did not respond to any SSRIs trial (p = .006). This data, including a thorough chart review, show that CYP2D6 non-extensive metabolizers are significantly more likely to have complicated medication histories and suggest that genotyping could have aided in selecting medications and dosages, potentially improving treatment outcome. As part of a new study at our Pharmacogenetics Research Clinic, the first set of patients with a diagnosis of schizophrenia and mood disorders with complicated medication histories have been enrolled prospectively and genotyped for CYP2D6 and CYP2C19. At study entry, patients are asked for consent for the genetic testing of their liver enzyme activities. Patients are assessed of current and previous treatment response and occurrence of side effects. After 6 weeks, the physicians are provided with an interpretation of the genotypic results and informed about the potential clinical implications which they will then discuss with their patients. The physicians are asked to complete a questionnaire evaluating the usefulness of the genotypic information provided by the study. After 12 weeks, the clients are assessed again to monitor potential adjustments of medications and their overall treatment outcome. Overall, physicians have returned excellent feedback that the genotyping results have been very helpful in allowing them to either select medications their patients are likely to better tolerate, or to adjust doses based on geneotype results and serum levels. Our findings suggest that CYP2D6 and CYP2C19 genotyping provides useful information that help physicians to improve pharmacotherapy for individual patients.

2434/W

Pharmacogenetics of functional variants that influence the warfarin and irinotecan response in the Azorean population (Portugal). *T. Pereirinha[1], M.J. Brilhante[1], C.C. Branco[1,2], R. Cabral[1,2], L. Mota-Vieira[1,2].* 1) Mol Gen & Pathol Unit, Hosp Divino Esp Santo PD, EPE, Azores Islands, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal.

Genetic polymorphisms in genes encoding drug metabolizing enzymes, transporters and targets are known to play an important role in response to therapeutic drugs. Since pharmacogenomic information could predict drug dose and toxic effects, there is a clinical interest in improving strategies for individualized therapy. Here, we analyzed pharmacogenetically relevant genes that influence warfarin (*CYP2C9* and *VKORC1*) and irinotecan (*UGT1A1*) response, in 170 healthy blood donors from the anonymized Azorean DNA bank. Genotyping was performed by real-time PCR and fragment analysis using capillary electrophoresis. For warfarin response, the allele variants CYP2C9*2 (C430T) and CYP2C9*3 (A1075C) presented a frequency of 20.3 and 5.9%, respectively. Five genotypes were observed: CYP2C9*1/*1 (57.1%), CYP2C9*1/*2 (25.3%), CYP2C9*1/*3 (8.2%), CYP2C9*2/*2 (5.9%) and CYP2C9*2/*3 (3.5%). Regarding the *VKORC1* gene (G1639A), we identified 51 (30.0%) wild-type individuals, 96 (56.5%) heterozygous and 23 (13.5%) homozygous for the variant 1639A that corresponds to a frequency of 41.8%. The joint analysis of *CYP2C9* and *VKORC1* revealed that 68 individuals (40.0%) will need intermediate and/or low doses of warfarin if treatment is started, distributed as follows: *i*) 48 (28.2%) cases for intermediate doses (*1*1-AA®11, *1*2-GA®24, *1*3-GA®7, *2*2-GG®3 and *2*3-GG®3 individuals), and *ii*) 20 (11.8%) cases for lower doses (*1*2-AA®7, *1*3-AA®3, *2*2-AA®2, *2*2-GA®5 and *2*3-GA®3 individuals). For irinotecan response, the most relevant variant UGT1A1*28 is associated with low enzymatic activity. Inheritance of this variant was described to be a risk factor for irinotecan toxicity, leading to adverse reactions (myelosuppression or diarrhea). The results demonstrated that Azoreans show a frequency of UGT1A1*28 (30.9%) similar to other European populations. Two other rare variants - UGT1A1*36 and *37 - was also detected with low frequency (0.3%). The presence of these alleles, characteristic of African populations, is in agreement with the genetic makeup of the admixed Azorean population. Currently, we are analyzing other pharmacogenetic variants in order to improve individualized treatment of Azorean patients (lmotavieira@hdes.pt, Funded by the Azores Government, M 1.2.1./I/002/2008).

2435/W

The Serotonin Receptor Gene 5HTR2A and Drug Response in OCD. *M. Richter[1, 2, 3], V. Sinopoli[4], K. Witheridge[1], O. Likhodi[2], E. Burroughs[1], J. Kennedy[2, 3].* 1) Psychiatry, Sunnybrook Health Sciences Centre, Toronto, ON, Canada; 2) Neurogenetics Section, Centre for Addiction & Mental Health, Toronto, ON, Canada; 3) University of Toronto, ON, Canada; 4) McMaster University, Hamilton, ON, Canada.

Introduction: Pharmacogenetics is a valuable tool for reducing potential genetic heterogeneity in complex psychiatric illnesses, while also raising the prospect of personalized medicine in the future. Both these functions may be particularly important in the context of obsessive-compulsive disorder (OCD), a complex, chronic, and frequently severe psychiatric disorder. OCD is typically treated with serotonin re-uptake inhibitors (SRIs) but effectiveness of medication is limited. The serotonin 2A receptor gene (5HTR2A) is believed to be involved in selective serotonin reuptake inhibitor (SRI) response in depression, and thus is an interesting pharmacogenetics candidate in OCD. Method: This study examined retrospective treatment data for N=120 individuals with DSM-IV OCD. The 5HTR2A variants rs6314, rs6313, rs2296972, rs4941573, rs6305, and rs7997012 were genotyped and tested for association with response to any SRI medication (sertraline, fluoxetine, fluvoxamine, paroxetine, citalopram, and clomipramine). Individuals were grouped into those who improved following an adequate trial of one or more of these medications as compared with those who reported “minimal”, “no change” or “worsening” in response to medications tried. Results: No association was identified between the tested polymorphisms and response to any SRI. When considering the SRIs individually, the rs6305 G/G genotype appeared to confer greater likelihood of response to clomipramine (p=1.3 x 10-5). Analysis was suggestive of association between the A allele of rs4941573 and reduced response to fluvoxamine (p=0.052), when individuals who reported response to supoptimal trials were included in the analysis. Conclusions: Further work is needed with larger samples and ideally prospective drug response data. However although inconclusive, these results support a possible role for 5HTR2A and drug response in OCD.

Germline Genetic Variation Underlying Resistance to Cisplatin and Carboplatin Treatment in the Yoruba Population. *A.L. Stark[1], H.E. Wheeler[2], W. Zhang[3], P.H. O’Donnell[2], R.S. Huang[2], M.E. Dolan[2].* 1) Dept Human Gen, Univ Chicago, Chicago, IL; 2) Section of Hematology/Oncology, Department of Medicine, Univ Chicago, Chicago, IL; 3) Institute for Human Genetics and Dept of Pediatrics, University of Illinois College of Medicine, Chicago, IL.

Cisplatin and carboplatin are platinating chemotherapeutics used to treat a variety of cancers including testicular, gynecologic, and lung cancer. Interindividual and inter-ethnic variation in cellular sensitivity and clinical response has been observed for both drugs. To elucidate the genetic component contributing to this variation, we investigated cellular susceptibility to these agents in five different HapMap lymphoblastoid cell line populations (CEU I/III, YRI I/III, ASW, ASN, DEN) and found that LCLs derived from the Yoruba (YRI) population were the least sensitive to both drugs (p<0.001). Utilizing 120 unrelated YRI cell lines (phases I and III) of HapMap, we performed a genome-wide association study to identify genetic variants associated with response. At a permissive p-value cutoff of p<0.0001, we found 80 SNPs that associated with both agents in the YRI population, which is significantly more than expected by chance. Forty-one of the 80 SNPs are eQTLs (p<0.0001), demonstrating that over half of the overlap signal represent this functional class. Eight of these 41 SNPs (~20%) are eQTLs with over 10 transcripts suggesting they are master regulators. We are currently performing a functional genome-wide association study to prioritize the gene targets of these master regulators for molecular validation. Identifying germline genetic variation in the Yoruba population allows for the identification of variants underlying resistance to these drugs with the possibility that allele frequency differences explain inter-ethnic differences. This work, ultimately, may lead to a better understanding of resistance to carboplatin and cisplatin treatment.

Joint effects of common genetic polymorphisms and regular medication on long-term survival in humans. *S. Ukraintseva, K. Arbeev, L. Arbeeva, A. Kulminski, I. Akushevich, I. Culminskaya, D. Wu, A. Yashin.* Duke University, Durham, NC.

Long-term effects of medication on survival may differ dramatically when genes are taken into account. We studied the effects of ACE and APOE common polymorphisms on long-term survival of individuals regularly treated with drugs that potentially interact with these polymorphisms. We evaluated joint effects of ACE D/I polymorphism and ACE inhibitors, as well as APOE e2/e3/e4 polymorphism and cholesterol-lowering drugs (CHLD), on survival in Framingham Heart Study original and offspring cohorts (10,333 individuals, 53% females). These particular polymorphisms and drugs were selected because of their implication in number of pharmacogenetic and aging studies so that we could hypothesize favorable effects of some gene-drug combinations on longevity. We evaluated age-patterns of survival in following groups of individuals: (i) with ACE D/D, D/I and I/I genotypes; (ii) regularly treated with ACE inhibitors; (iii) combinations of (i) and (ii); (iv) with and without APOE e4 allele; (v) regularly treated with CHLD; (vi) combinations of (iv) and (v). Results. 1) ACE and ACE inhibitors. There was no significant difference in survival among individuals with different ACE genotypes. Regular intake of ACE inhibitors in medical history modestly but significantly ($p<0.01$) improved total survival. When both medication and genotype were taken into account, ACE inhibitors improved survival of D/D and D/I (but not I/I) carriers more substantially compared to situation when drug was considered alone. 2) APOE and CHLD. Individuals with APOE e4 allele had slightly worse survival than those without it. CHLD significantly ($p<0.0001$) improved total survival in both sexes, so that 60% of women taking CHLD survived to age 85 compared to 40% of those not taking it (40% and 20% of men respectively). When both gene and drug were considered, the favorable effect of CHLD on survival was more pronounced for those with e4 allele. Conclusion. When gene-drug interaction is taken into account, favorable effect of ACE inhibitors on survival strengthens for D allele and disappears for I/I genotype carriers, while treatment with CHLD compensates adverse effects of APO e4 allele on survival (possibly providing protection against AD, as some studies suggest). Significant gene-drug interaction effects on long-term survival observed in this study stress importance of pharmacogenetic studies for understanding/revealing possible anti-aging effects of chronic medication in some genotypes.

2438/W

Effect of Genetic Variation in LAT1 and LAT2 on Toxicity in Multiple Myeloma Patients Receiving High-Dose Melphalan and Autologous Stem Cell Transplant. *M.J. White[1], J. Giglia[2,3], C. Holt[1], S. Brandt[2,3], S.M. Williams[1].* 1) Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Vanderbilt-Ingram Cancer Center, Nashville, TN; 3) Tennessee Valley VA Healthcare System, Nashville TN.

Multiple myeloma, the second most common cancer of the blood in the United States, is characterized by an overproduction of abnormal plasma cells in the bone marrow. It is frequently treated with high-dose melphalan (HDM) in association with autologous stem cell transplantation. Although HDM is an effective treatment, it has mucositis as a common dose-limiting side effect. Mucositis, or inflammation of the mucous membranes of the digestive tract, causes severe pain and in extreme cases oral ulceration, leading to inability of the patient to ingest food or liquid. In some cases, intravenous feeding (total parenteral nutrition or TPN) is required. The aim of this study was to assess whether genetic variation in two candidate genes, LAT1 (L-type amino acid transporter 1) and LAT2, associates with this adverse drug reaction, so that adequate treatment could be implemented prior to HDM. These two candidates were selected because LAT1 is important in the transport of melphalan into cells and LAT2 has been hypothesized to serve the same role. Patients receiving HDM were recruited at the Vanderbilt University Medical Center, the Nashville Veterans Administration Medical Center, and the Veterans Administration Medical Center in San Antonio, TX. Cases of clinically severe mucositis were defined by requirement for TPN; controls did not require TPN. In total, 87 Caucasian subjects were enrolled, including 49 cases (29 of whom were male) and 38 controls (32 males). Thirty-two tag SNPs were genotyped and 28 passed quality control (8 in LAT1 and 20 in LAT2). One SNP in LAT1 (rs4240803) provided evidence of association in the total data set (OR= 2.48; 95% CI 1.15-5.68 p= 0.015). Association appeared to be stronger in males alone (OR= 3.62; 95% CI 1.32-11.29.68 p=0.006). Haplotype analyses in LAT1 revealed that all significantly associating haplotypes included this SNP, supporting its role in TPN predisposition and, by inference, severe oral mucositis. Results from LAT2 showed this gene was less strongly associated with TPN use following HDM, although some analyses did suggest a weak association with several SNPs in this gene. Our results support a role of LAT1 genetic variation in risk for developing severe oral mucositis following HDM treatment for multiple myeloma, especially in male patients. This suggests that membrane transport of melphalan is a key factor in clinical toxicity, and is subject to genetic variation.

2439/W

Inhaled Corticosteroid Treatment Modulates the Effect of Polymorphisms on Bronchodilator Response in Asthmatics. *A.C. Wu[1,2], B.E. Himes[3,4,5,6], J. Lasky-Su[6], K. Tantisira[6], S.T. Weiss[5,6].* 1) Department of Population Medicine, Harvard Medical School and Harvard Pilgrim Health Care, Boston, MA; 2) Children's Hospital, Boston Division of General Pediatrics, Boston, MA; 3) Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA; 4) Children's Hospital Informatics Program, Boston, MA;; 5) Partners Center for Personalized Genetic Medicine, Boston, MA; 6) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

Inhaled corticosteroids and β2-agonists are the two most commonly used medications for asthma. Single nucleotide polymorphisms (SNPs) appear to influence a patient's response to inhaled corticosteroids and β2-agonists. Because the effect of treatment with inhaled corticosteroids is synergistic with the effect of β2-agonists and a patient's response to both medications is genetically influenced, we hypothesized that inhaled corticosteroids could influence the effect of multiple SNPs associated with bronchodilator response across the genome. Our goal was to assess whether treatment with inhaled corticosteroids modulates the measured association of SNPs with bronchodilator response in a population of subjects with asthma using a genome-wide association approach. Our primary population is composed of subjects from the Childhood Asthma Management Program (CAMP), a clinical trial that followed asthmatic children for four years. Genome-wide SNP genotyping for 561 Caucasian CAMP subjects and their families was performed on Illumina's HumanHap550 Genotyping BeadChip (Illumina, Inc., San Diego, CA). Before frequency and genotyping pruning, there were 516,512 SNPs. SNPs were excluded for missing genotype in more than 5% of subjects, having minor allele frequency (MAF) less than 5%, having Hardy-Weinberg equilibrium p-values among controls less than 0.001. After frequency and genotyping pruning, there were 449,540 SNPs. We conducted a gene by environment analysis in PLINK with inhaled corticosteroid treatment as the environmental exposure and bronchodilator response as the outcome measure. We found that the regions of SNPs that are most significantly associated with bronchodilator response while accounting for inhaled corticosteroid treatment are in chromosomes 19 and 8, with 12 SNPs having a gene by environment interaction p-value of <1E-05. We conclude that treatment with inhaled corticosteroids appears to modify the effect of SNPs on bronchodilator response. We have identified SNPs that appear to modify this effect in the CAMP population. We are replicating these findings in an independent population.

Distribution of CCR-5Δ32, CCR2-64I and SDF1-3'A alleles that modulate drug-response and HIV infection among Jordanians. *K.H. Alzoubi[1], O.F. Khabour[2], L.J Abu-Haweleh[2].* 1) Clinical Pharmacy, Jordan University of Science and Technology, Irbid, Jordan; 2) Medical laboratory Sciences, Jordan University of Science and Technology, Irbid, Jordan.

Chemokine receptors are involved in the entry process of the HIV virus into the cells and the subsequent development of AIDS. In this study, genotype distribution patterns of polymorphisms in chemokine receptor genes, CCR5 (CCR5-Δ32), CCR2 (CCR2-64I), and SDF-1 gene SDF1-3'A (the only ligand for CXCR4) that affect drug-response against HIV were evaluated among Jordanians. A total of 540 subjects were randomly selected from all the 12 Jordanian provinces. Polymorphisms were genotyped using PCR sequencing and PCR-RFLP technology. Six individuals were found to carry CCR5-Δ32 allele (0.6%) in heterozygous genotype. The frequencies of CCR2-64I and SDF1-3'A were 17.5 % and 34.2% respectively. No significant difference in the mutant allele distribution of the CCR5 (CCR5-Δ32) and CCR2 (CCR2-64I) polymorphisms was noticed through the different parts of Jordan ($P > 0.05$). However, the genotypes of SDF-1 gene showed significantly different distribution with enriched homozygous mutant genotype in the middle of Jordan ($P < 0.05$).

PREVALENCE OF CYP3A4*18, GSTM1 0/0 AND GSTT1 0/0 : A PRELIMINARY STUDY OF GENE POLYMORPHISM AS BIOMARKERS FOR DRUG THERAPY IN FILIPINOS. *C.G. Boado[1], A.P. Baluyot[1], E.A. Banzon[1], M.R. Bernal[1], R.B. Bio[1], J.G. Apostol[1], M.J. Manansala[1], R.M. de Guia[2,3].*
1) Department of Pharmacy, University of Santo Tomas,España, Manila 1015; 2) Department of Biochemistry, University of Santo Tomas,España, Manila 1015; 3) Research Center for the Natural Sciences, University of Santo Tomas,España, Manila 1015.

Introduction: The inter-patient difference in drug metabolism is documented to be attributable to heritable genetic variations in the nucleotide sequence and deletion of genes coding for these DMEs involved in drug transport, metabolism and action. The finding of the existence variant alleles and knowledge about their genotypic/allelic frequency in specific ethnic groups are important to lead to individualized drug dosing and improved therapeutics. This study aimed to detect SNP in CYP3A4 and the homozygous deletion (0/0) of GSTM1 and GSTT1 in a Filipino population. Methodology: One-hundred and forty two Filipino subjects were genotyped of the CYP3A4*18 SNP by using PCR-RFLP with HpaII endonuclease and the GSTM1 0/0 and GSTT1 0/0 by basic PCR with β-globin as internal positive control, all were followed by AGE. Results: The sample DNA pool conformed to the Hardy-Weinberg equilibrium ($\chi 2$=0.01685) based on the gathered genotype frequencies. In the group of 142 sample DNAs, the frequency of the CYP3A4*18 variant allele found in the Filipino population was 0.01056. The percentage of GSTM1 0/0 observed was 64.08%, while that for GSTT1 0/0 was 48.59% Conclusions: Relative to studies done in other countries, the frequency of the variant allele of the CYP3A4*18 using the Fisher Exact Test was not significant higher to the Japanese, Korean and Malaysian studies. The percentage of GSTM1 0/0 observed in Filipinos was significantly higher than Indians, Chinese, Japanese and Koreans and Caucasians while that of the GSTT1 0/0 was not significantly lower than Chinese, Japanese and Koreans. Frequencies of the GSTM1 0/0 and GSTT1 0/0 in this study were higher to that reported previously in the Filipino population.

2442/F

Cloacal Dysgenesis Sequence: elucidating the mechanism of multiple malformations using fetal imaging, genetic testing and autopsy. *A. Robichaux[1], D. Niyazov[2], W. Robichaux[3], A. Kenney[4].* 1) Maternal & Fetal Medicine, Ochsner Clinic Foundation, New Orleans, LA; 2) Dept Pediatrics, Ochsner Clinic Foundation, New Orleans, LA; 3) Dept Pathology, Ochsner Clinic Foundation, New Orleans, LA; 4) Dept Radiology, Ochsner Clinic Foundation, New Orleans, LA.

Cloacal dysgenesis sequence (CDS) is a rare disorder characterized by a phallus-like structure, smooth perineum, and absence of urethral, vaginal, and anal openings. Renal dysgenesis, oligohydramnios and pulmonary hypoplasia are typical associated findings. We present a patient with multiple congenital anomalies which were investigated during the various periods of gestation using ultrasound (US), magnetic resonance imaging (MRI), biochemical and chromosomal studies, and autopsy with gross and microscopic examinations. The proband's parents were 3rd cousins who previously had a child with Zellweger syndrome (ZS). At 16 weeks of their 2nd pregnancy, severe fetal bladder distension was detected on US. Fetal MRI showed oligohydramnios and megacystitis. Clear fluid was aspirated from the bladder and amniotic fluid was mildy decreased. Karyotype and 105K oligo array on amniocytes revealed a normal female. Due to the 25% chance for ZS and one report of ZS with genitourinary anomalies, the amniotic fliud was sent for very long chain fatty acids and plasmalogens which were negative. At 27 weeks, the fetus developed ascites and oligohydramnios. A repeat MRI showed two oval structures of unclear origin, dysplastic kidneys, hypoplastic lungs and dilated sigmoid colon. The proband was delivered at 34 weeks and died shortly after birth. The autopsy showed severe ascites, anorectal atresia, dilated sigmoid colon with meconium and microcalcifications, ambiguous genitalia, urethral stenosis, two large cystic structures, two ovaries, multicystic kidneys and pulmonary hypoplasia. A 135K oligo array on the postmortem tissue was negative. CDS occurs due to a failure of migration and fusion of the urorectal septum with the cloacal membrane thus affecting urogenital and anorectal development. In our proband the urethral stenosis resulted in the bladder outlet obstruction, megacystitis, hydroureters and renal dysplasia. The bladder ruptured and ascites with oligohydramnios ensued, causing pulmonary hypoplasia. The two large cystic structures with ovaries on each side most likely represented a bladder and uterus as one entity which was once reported. The anorectal atresia and dilated meconium-filled sigmoid colon with microcalcifications may have occurred in parallel with genitourinary malformations. In conclusion, we demonstrate how the various diagnostic modalities can be utilized to explore the mechanism of malformations in CDS, which may aid in elucidating its etiology.

2443/F

Aneuploidy Detection by QF-PCR of STR Markers on the Applied Biosystems 3500 Genetic Analyzer. *V. Bansal[1], S. Jordan[2], C. Davidson[1], A. Pradhan[1], A. Felton[1], N. Duxbury[2], S. Higgins[2].* 1) Applied Biosystems, Foster City, CA,; 2) Gen-Probe Life Sciences, Abingdon, UK.

Normal human somatic cells are euploid and contain a diploid (2N) set of autosomes and a pair of sex chromosomes. Cells that do not contain an exact diploid set are termed aneuploid and, therefore, either lack or contain additional chromosomes. Common types of aneuploidy are monosomy (the loss of one sex chromosome) and trisomy, three copies of a given chromosome in a diploid cell. In early pregnancy, samples of amniotic fluid (AF), chorionic villi (CVS), or umbilical cord blood can be analyzed for aneuploidy using the molecular technique quantitative fluorescence PCR (QF-PCR). Analysis of short tandem repeat (STR) markers using QF-PCR is a common strategy employed in clinical research laboratories for the detection of chromosomal aneuploidy. Here we demonstrate performance equivalent between the Applied Biosystems 3130*xl* Genetic Analyzer and the new Applied Biosystems 3500 Genetic Analyzer for the detection of aneuploidy. A reference panel of samples was amplified with reaction mixes from each of the *TrueScience*™ Aneuploidy STR Kits: STR-Plus, STR-XY, STR-13, STR-18, STR-21. The reference panel of 95 samples and a negative control comprised of 45 female samples (47%) and 50 male samples (53%) with gDNA obtained from four different sources CVS (88%), cell-lines (5%), AF (4%), and whole blood (2%). Six aneuploidies were assessed consisting of 18 trisomy 18 samples (19%), 16 trisomy 21 samples (17%), 7 trisomy 21 samples (7%) , 3 Turner syndrome samples (3%) , 1 sample each of Triplo-X and Klinefelter syndromes (1%), and 49 wild type samples (52%). The *TrueScience*™ STR-Plus assay determined the correct genotype for 100% of the samples that passed sizing and reaction quality controls. There was a 100% correspondence between the results obtained on the 3130xl Genetic Analyzer and the new 3500 Genetic Analyzer for the *TrueScience*™ STR-Plus assay. The follow up individual chromosome kits (*TrueScience*™ STR-13, STR-18, STR-21, and STR-XY assays) determined the correct genotype for 100% of the samples that passed sizing and reaction quality controls with a 100% correspondence between the results obtained on the 3130*xl* Genetic Analyzer and the 3500 Genetic Analyzer. The advanced capabilities of the 3500 Series Genetic Analyzers demonstrated performance equivalence with 3130 Series for the detection of chromosomal aneuploidy.

Determination of the origin of extra chromosome material on 15p region in an amniotic fluid sample using MFISH techniques. *V. Catala[1,2], C. Garrido[1], Z. Sarrate[3], M. Martin[3], E. Masip[1], E. Cuatrecasas[1], A. Serés-Santamaría[1], F. Vidal[3].* 1) Prenatal Genetics, Barcelona, Catalonia, Spain; 2) Unitat de Biologia Cellular i Genética Médica. Departament de Biologia Cellular, Fisiologia i Immunologia. Facultat de Medecina. Universitat Autònoma de Barcelona, Catalonia, Spain; 3) Unitat de Biologia Cellular. Departament de Biologia Cellular, Fisiologia i Immunologia. Facultat de Biociències. Universitat Autònoma de Barcelona, Catalonia, Spain.

The amniotic fluid sample of the second pregnancy from a 32 years patient was refered to our lab without increased risk indication. The pregnancy was achieved after the transfer of two frozen embryos, coming from a donor sperm ICSI cycle, because the couple has both male and female infertility factors. The previous pregnancy with fresh embryos ended with the birth of a chromosomally normal child. The sample of amniotic fluid obtained by amniocentesis at 16 weeks of gestation, had a normal result after an aneuploidy screening using FISH (Multicolor AneuVysion Probe Kit, Abbott Molecular). The conventional cytogenetic study showed the presence of extra material on the short arms of one chromosome 15 in 72% mosaicism. The extra material was C-banding and Ag-NOR negative, and had no hybridization with D15Z1, D15Z4 and DYZ1 DNA probes (Abbott Molecular). The SpectraVysion MFISH Assay (Vysis) was applied to determine the origin of the extra chromosome 15 material. The results obtained indicated that the small fragment was derived from chromosome 3. Subtelomeric regions probes of chromosome 3 were applied (Abbott Molecular) and an extra signal of the 3p region was observed on the 15p region, which confirmed the result obtained by MFISH. The final karyotype was 46, XX,der(15)t(3;15)(p24.3;p12)[48]/46,XX[19].ish der(15)(D15Z1-, wcp+;,D3S4559+). A fetal blood sample was obtained, and the same translocation between chromosomes 3 and 15 was observed in 96% of the analyzed metaphases. Extensive fetal ultrasound at 20 weeks of gestation revealed a heart disease. The couple decided for the termination of pregnancy. Fetal tissues for cytogenetic analysis were not available.

2445/F

Aneuploid products of conception confer increased risk to subsequent conceptuses. *K.A. Eickholt[1], D.P. Agamanolis[1,2], J.M. Malone[1], R.V. Lebo[1,2].* 1) Department of Pathology, Akron Children's Hospital, Akron, OH; 2) Northeastern Ohio Universities College of Medicine, Rootstown, OH.

Aneuploidy, defined as an abnormal copy number of whole normal chromosomes in one cell, occurs frequently in conceptuses and reduces viability. Culturing chorionic villus cells that remain viable long after other cells in products of conception enabled karyotyping nearly all submitted products of conception samples. The pathologic appearance of the dissected fetal villi did not correlate with the chromosomes as suggested earlier for a more targeted group of viable abnormalities. This study found normal appearing villi in products of conception with 45,X, trisomies of chromosomes 2, 6, 9, 11, 12, 13, 14, 15, 16, 18, 21, 22, and X, triploidy, tetraploidy, and the more complex karyotypes: 48,XX+15,+21, 48,XX+2,+5, 48,XX+16,+21 48,XXX/47,XX+2/46,XX, and 47,XY+15/94,XXYY+15,+15. Furthermore, this study of 345 products of conception revealed that a large proportion of conceptuses with chromosome aneuploidy conferred a previously unreported increased risk of a second aneuploid conceptus to women of any reproductive age. This is in contrast to prior studies that found an increased risk of viable trisomy 13, 18, or 21 in conceptuses with these three trisomies sampled by CVS or amniocentesis, but no increased risk when found in products of conception (Warburton et al. 1980, 2004). Furthermore, our study found that all aneuploidies including monosomy X, the most common trisomy 16, and trisomy 22 confer an increased risk of another aneuploid conceptus. Of interest, a mother with a trisomy 3 POC and a fragile site on band 9q12 subsequently conceived a conceptus with an unbalanced translocation 92,XXXX,t(9;17)(q12;p13) karyotype including a breakpoint involving the fragile site. These results suggest that prudent obstetrical practice would karyotype all products of conception and follow an aneuploid conceptus with an offer to prenatally karyotype any subsequent conceptus regardless of maternal age.

Additional Chromosome Copy Number has Minor Influence on Expression of Genes Present on Trisomic Chromosomes in Humans. *J.A. Gebbia, T. Dunn.* CytoGenX, Stony Brook, NY.

Utilizing a high through-put proteomic screen, amniotic fluid was analyzed from patients pregnant with a fetus diagnosed with trisomy 21, 18 or 13 and age-matched, gestational control patients pregnant with a fetus of normal karyotype. Over 800 unique proteins were identified in amniotic fluid revealing a distinct proteomic profile for each trisomy and normal control samples. Most proteins detected to be increased or decreased in trisomic samples, relative to control samples, were found to be encoded on chromosomes other than those present in trisomic form. The presence of an additional chromosome copy of 21, 18, or 13 only effected the expression of a small number of genes present on each respective trisomic chromosome, indicating the expression of most genes present on trisomic chromosomes are not directly influenced by extra copy number. These results suggest only a few genes present on trisomic chromosomes may be responsible for the increased or decreased expression of a cascade of gene products encoded on other chromosomes which cause the phenotypes observed in patients diagnosed with a trisomy.

2447/F

Failure of spermatogenesis in distal Xp nullisomy might be associated with miss-conjunction of sex chromosomes. *Y. Kido[1], S. Sakazume[1], K. Obata[1], N. Murakami[1], Y. Ooto[1], K. Shimojima[2], T. Yamamoto[2], T. Nagai[1].* 1) Deartment of pediatrics, Dokkyo Medical University Koshigaya Hospital, Koshigaya, Japan; 2) Institute for Integrated Medical Sciences, Tokyo Women's Medical University, Tokyo, Japan.

Introduction Generally patients with Xp nullisomy have been known to be infertile, but the precise mechanism of infertility is not uncovered. We experienced 2 patients with Xp nullisomy and determined the breakpoints by STS analysis. Their infertility could not be explained by their deleted genes. We hypothesized that miss-conjunction of their sex chromosomes is associated with their infertility. **Patients** Patient 1 is a 19-year-old male with normal mentality, normal puberty, height of 161 cm (-1.7 SD), hypoplastic mid-face, ichthyosis, hypospadias, and cardiac anomaly (aortic regurgitation). His karyotype by G-banding analysis was 46, XY. Detailed analysis revealed interstitial deletion: the telomeric and centromeric breakpoints were between DXS6837 and DXS6834, between DXS237 and DXS278, respectively. Patient 2 is a 15-month-old boy with mild mental retardation (unable to stand up by himself, no meaningful words, not understanding his own name), height of 68 cm (-3.5 SD), hypoplastic mid-face, ichthyosis, and hypogenitalism (micropenis, hypoplastic scrotum, undescended testes). His karyotype by G-banding analysis was 46,Y,der(X)t(X;Y)(p22.3;q12)mat. **Discussion** Generally patients with Xp nullisomy show various symptoms associated with their karyotypes and many symptoms are explained by deleted genes. Most of all reported patients with Xp nullisomy involving pseudoautosomal region (PAR) were infertile. In contrast, patients with interstitial deletion conserving PAR were fertile. In our patients none of the deleted genes were known to be associated with spermatogenesis. Only *KAL1* gene close to the breakpoints is related to fertility but *KAL1* gene was not deleted in both of them. The main genotypic difference between our two patients was that only patient 1 had PAR. Usually, patients with Xp nullisomy have defect of a pseudoautosomal region and cause miss-conjunction of their sex chromosomes, resulting in oligo- or azoo-spermia. This suggests that patient 1 is fertile and patient 2 is infertile. **Conclusion** The development of spermatogenesis may be related to the existence of PAR.

2448/F

Diagnostic benefit of comprehensive prenatal MLPA testing of fetuses with large NTs. *M.V.E. Macville[1], L.M.H. Houben[1], M.A.A. Lennarts[1], K. Herzberg[1], N.D. Muntjewerff[2], Y.H.J.M. Arens[2], S.G.M. Frints[2], A.B.C. Coumans[3], C. Willekes[3], J.P.M. Offermans[3], D. Veersema[3,4], C.E.M. de Die[2], J.J.M. Engelen[1].* 1) Cytogenetics Unit/Clin Gen, Maastricht Univ Med Ctr, Maastricht, Netherlands; 2) Clinical Genetics, Maastricht Univ Med Ctr, Maastricht, Netherlands; 3) Obstetrics and Gynecology, Maastricht Univ Med Ctr, Maastricht, Netherlands; 4) Diagnostic Center, Eindhoven, Netherlands.

In a case-control cohort of 1576 prenatal samples, 90 (5.7%) presented with a heart-outflow defect or a nuchal translucency (NT) larger than 3.5 mm, including hygroma colli and hydrops. We investigated the diagnostic benefit of testing this cohort with MLPA probe sets P036/P070 and P245 for, respectively subtelomeric imbalances and 21 microdeletion syndromes compared to MLPA P095 alone for common aneuploidies. All samples were karyotyped by GTG-analysis in a routine cytogenetic diagnostic work-up. Subtelomeric imbalances and microdeletions detected by MLPA were confirmed by FISH. Parental blood was available to identify familial copy number variations without clinical consequence. MLPA was performed in duplo on uncultured samples to produce a result in 4-7 days after the invasive procedure. In 6 of 90 samples, one or more MLPA test failed due to inferior DNA quality (6.7%). In the remaining 84 samples, we found 22 aberrant results (26%). Nineteen were detected with MLPA P095 and P036/070 comprising of trisomy 21 (n=9), trisomy 18 (n=4), trisomy 13 (n=2) and monosomy X (n=4). Two were detected by MLPA P036/070 alone, being an autosomal unbalanced translocation and a cryptic terminal deletion 9p. These 21 aberrations were also visible in GTG analysis. One aberration was a microdeletion 9q22.3 that presented with a NT 4 mm as the sole ultrasound finding, that was only detected by MLPA P245 and not by the other methods. FISH and experimental SNP-array analysis further delineated the 9q22.3 deletion. We conclude that prenatal cytogenetic diagnostics benefits from MLPA P036/070 testing with respect to detection of common aneuploidies and subtelomeric imbalances. Targeted testing for microdeletion syndromes may be disputable, although - in a relatively small cohort - it has detected one case that would otherwise not be discovered. The 62 samples with normal MLPA- and GTG-analyses are eligible for a 2.7M SNP-array testing which provides the largest genomic coverage (including subtelomeric regions) for copy number variant detection at this time. In contrast to array-based testing, MLPA testing is fast an cheap. It is easy to implement because it requires equipment that is present in most of today's clinical genomic laboratories. Therefore, in terms of time- and cost-effectiveness, multiple MLPA tests may be utilized preceeding traditional karyotyping to provide a rapid and comprehensive result.

Prenatal Diagnosis of 9p Duplication Syndrome. *A. Singer[1], R. Gobozov[1], C. Vikler[2].* 1) Dept Clinical Gen Unit, Barzilai Med Ctr, Tel Aviv, Israel; 2) Institute of Medical Genetics, Wolfson Medical Ctr, Holon, Israel.

In 1970, Rethore' et al. reported the first patients with duplication of 9p as ''trisomy 9p syndrome.'' Since than, a large number of patients (more than 150) have been described with duplication of various segments of 9p. Because of that, the term ''duplication 9p syndrome'' instead of ''trisomy 9p syndrome'' is used. Most of the reported patients had only partial duplication rather than the whole arm duplication of 9p. Clinical findings include growth and mental retardation, ear anomalies, hypertelorism, prominent or globular nose, downturned corners of the mouth, and hand-foot anomalies. It is the one of the most frequent autosomal anomalies with long survival rate. Usually 9p duplication is derived from familial translocation. Only 16 cases have been reported as de novo 9p duplication or partial duplication. Ultrasound imaging during pregnancy of fetuses carrying 9p duplication can be easily missed since dysmorphic features typical to this syndrome are hard to detect.. Thus far there is no report of prenatal diagnosis of 9p duplication. We report a case of a fetus with 9p duplication detected during pregnancy. The proband is a healthy 27 years old woman. NT measured at 12 weeks gestation was 2.2mm. Integrated (first and second trimester) test showed a 1:9100 risk for Down syndrome. Ultrasound at 20 weeks gestation, revealed a 6.9 mm nuchal thickness with no other anomalies. Fetal cardiac echo was normal. Amniocentesis was performed and showed a fetal karyotype 46,XY(9p+). CGH-A analysis of the fetus' DNA diagnosed a 8.5 Mb gain from 9p24.2-9p23. The parents chose to terminate the pregnancy. This is the first case reporting prenatal diagnosis of 9p duplication syndrome associated with increased nuchal thickness.

Downs Syndrome: Indian scenario. *S. Komandur[1], R. Chikkala[1], S. Kuruganty[2].* 1) Department of Cytogenetics, Vijaya Diagnostics, Hyderabad, India; 2) Innova Childrens' Hospital, Tarnaka, Hyderabad, India.

In developed countries, prenatal screening for Down Syndrome is a general practice to identify Downs inutero. But in India, prenatal testing is warranted only in cases falling in the high risk group. This leaves less room for options like termination and increased incidence of Downs cases. We, in our clinic evaluated patients of suspected Downs syndrome. Their age ranged between 7 days to 8 years. The maternal age at the time of birth ranged between 20 yrs to 25 yrs. None of the mothers had the screening for Downs prenatally. Karyotyping was performed on 30 GTG banded metaphases for each of these patients. The karyotypes were 47, XY, +21 / 47, XX, +21 / 47, XX, +21, 21p+ / 46, XY, t (21; 21). We conclude that screening of every pregnant woman for Down syndrome must be made as a mandate instead of following it a s a ritual for only high risk groups, to identify Downs inutero. This would leave an informed choice to the couple whether to continue with the pregnancy.

An Exon 1 Deletion in OTC Identified Using Chromosomal Microarray Analysis in a Mother and Her Two Affected Deceased Newborns: Implications for the Prenatal Diagnosis of Ornithine Transcarbamylase Deficiency. *F. Quintero-Rivera[1], J. Deignan[1], J. Peredo[2], W.W. Grody[1], B. Crandall[2,4], M. Sims[2], S.D. Cederbaum[2,3,4].* 1) Pathology & Laboratory Medicine; 2) Pediatrics; 3) Human Genetics; 4) Psychiatry,David Geffen School of Medicine at University of California Los Angeles, UCLA, Los Angeles, CA.

Objectives. To describe the outcome of two consecutive pregnancies with a clinical presentation of ornithine transcarbamylase deficiency who initially lacked a molecular diagnosis. To demonstrate the importance of analyzing copy number changes in the management of cases with normal or inconclusive DNA sequencing results. To report the smallest intragenic deletion of the OTC gene. Methods. Oligonucleotide SNP array-based Chromosomal Microarray Analysis (CMA) was performed from the mother's peripheral blood. Polymerase Chain Reaction, PCR, and sequencing were done using DNA extracted from newborn screening blood spots. Results. A 119-kb deletion on Xp11.4 was detected in the phenotypically normal mother including the 5'UTR, exon 1, and part of intron 1 of the OTC gene. PCR identified the same deletion in the DNA from the two deceased male newborns. Amplification and sequencing of the deletion breakpoint in the mother revealed that it was larger than predicted by the CMA results. Conclusions. In patients with a clinical and biochemical presentation of OTC deficiency and negative OTC sequencing, CMA should be performed as a reflex test to look for deletions. PCR confirmation of CMA results should be performed when possible to precisely determine the deletion breakpoints for future use in molecular prenatal diagnosis.

2452/F

Siblings with primary congenital glaucoma. *D. Albu, E. Severin, M. Dumitrescu, C. Albu.* Dept Human Genetics, Carol Davila Univ Med & Pharm, Bucharest, Romania.

Usually glaucoma develops in older adults but primary congenital glaucoma (PCG) is observed at birth or in early infancy, and is an important cause of visual loss in children. The aims of the study were to analyze clinical and genetic features of PCG in a family with 2 affected sons and to detect if the unborn child of the pregnant mother inherited the disease-causing mutation. Case presentation: A family of Romany ethnic group with unaffected parents and their 2 sons affected by PCG were investigated clinically and genetically. Ophthalmic examination included: ophthalmoscopy, tonometry, perimetry and gonioscopy. DNA samples from all family members were analyzed for mutations in CYP1B1 gene. The mother is affected by severe myopia. The two sons (aged 9 and 17 years, respectively) are affected by PCG. Age of onset was in the first two month of life for both brothers. The sibs shared similar PCG phenotype and the missense mutation E229K identified in homozygous form in exon 2 from the CYP1B1 gene. The mother being pregnant again asked for genetic counseling. Prenatal diagnosis for PCG was performed and included cytogenetic and DNA analysis. Ultrasound examination of the pregnant woman revealed a singleton pregnancy with enlargement of the eye. Karyotype of the fetus indicated a normal female (46, XX) but DNA analysis confirmed the CYP1B1 mutation. Conclusion: We suggest genetic counseling and prenatal molecular testing for all family cases. This will further help in the prevention of childhood blindness.

2453/F

Seroprevalence of Toxoplasma gondii in south Indian women: Urgent Need for Genetic Characterization. *Y.C. Murthy, J. Smita Rao, T. Sunitha, G. Shilpa Reddy, A. Jyothy.* Institute of Genetics and Hospital for Genetic Diseases ,Osmania University, Begumpet, Hyderabad-500016, India.

Statement of Purpose: Toxoplasma gondii represents a serious parasitic infectious threat to humans globally. Especially, pregnant women exposed to T.gondii carry great risk of transmitting the infection to fetus which could lead to severe congenital anomalies or fetal loss. The genetic interaction between this parasite and the human host is believed to play influential role in the generation of potent antibody responses during the process of infection transmission and pathogenesis. In geographically diverse countries like India, the seroprevalence of T.gondii infections is increasing in women with adverse obstetric complaints. Although strong association exists between the magnitude of toxoplasmosis infections and the related genotypes, very little is known about its genetic characterization in this country. Clonal lineages of T.gondii have already been reported from several countries which indicated its great genetic diversity. Till date, no description was made that highlighted the connection between the seroprevalence and the genetic characterization/ genetic diversity of human T.gondii from India. Therefore, the main objective of this study was to determine the seroprevalence of T.gondii in south Indian women with Bad Obstetric History and Repeated Abortions and relate it with its genetic diversity. Method: Between October 2006 and May 2010, 370 serum samples were obtained from women attending the antenatal clinic with complaints of Bad Obstetric History and Repeated Abortions at Institute of Genetics, Hyderabad. They were serologically tested for Ig G and Ig M antibodies specific for T.gondii antigens by commercially available ELISA kit (Euroimmun, Germany). Results: Of the 370 women tested, 95(25.6%) had positive Toxoplasmosis IgG antibodies and 65 (17.5 %)had positive Toxoplasmosis IgM antibodies. Conclusions: This study hypothesizes that increased seropositivity to toxoplasmosis could be due to its genetically varied nature in our geographical region. There is an urgent need for defining the population structure of human T.gondii in India as this could enable to better understand its regional distribution, immunopathogenesis and prevent the congenital defects at the earliest.

2454/F

Cleft Lip and Palate, Annular Pancreas and Multiple Spinal Segmentation Anomalies - A new syndrome? *R. Teitelbaum[1,4], P. Shannon[2], L. Bonafe[3], N. Okun[4], D. Hui[4], D. Chitayat[1,4].* 1) Prenatal Diagnosis and Medical Genetics, Mount Sinai Hospital, Toronto, ON, Canada; 2) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, ON, Canada; 3) Division of Molecular Pediatrics, Centre Hospitalier Universitaire Vaudois, Switzerland; 4) Department of Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, ON, Canada.

Vertebral segmentation abnormalities are etiologically a heterogeneous disorder. A midline cleft lip and palate is an uncommon finding and usually associated with brain abnormalities. The combination of a midline cleft lip and palate and vertebral segmentation abnormalities, to the best of our knowledge have not been reported. We report a case with these findings pointing towards the possibility of a GDF6 gene dysfunction. The mother was a 33-year-old G5P2L2 of Trinidad/Indian descent and her husband was 32-years-old and of Caucasian descent. The couple was healthy and non-consanguineous. This was their first pregnancy together. The family history was non-contributory. The pregnancy was uncomplicated apart from first trimester bleeding. There was no history of exposure to teratogens. The NT was measured at 12 weeks gestation and was 2.2mm. A detailed fetal ultrasound at 22 weeks gestation revealed midline cleft lip and a suggestion of a cleft palate in a male fetus. The couple elected to terminate the pregnancy and a stillborn fetus was born with normal growth for gestational age. Autopsy showed a large bilateral cleft lip and palate, annular pancreas and multiple vertebral segmentation anomalies. These included duplication of the lateral vertebral elements (right C7), wedge-shaped hemivertebra (C6,C7), accessory ossification centre between the bodies of C7-T1, duplication of left lateral vertebral elements between L1 and L2, eccentric ossification (L1,L2,L3), and 11 ribs on right 12 on left with a large cervical rib. Investigations including chromosome analysis and Microarray analysis were normal and male. The findings in the fetus raised the possible diagnosis of spondylocostal dysostosis spectrum (type 1-4) associated with DLL3, MESP2, LFNG, HES7 gene mutations. However, the spine X-rays were not consistent with this diagnosis. The findings may also be consistent with GDF6 gene mutation. This gene is a member of the bone morphogenetic protein (BMP) family and the TGF-beta super family of secreted signaling molecules. It is required for normal formation of some bones and joints in the limbs, skull, and axial skeleton and gives a variety of phenotypes with vertebral segmentation anomalies, including "kippel-Feil" forms. Results of mutation analysis for this gene are pending.

2455/F

Rapid Screening Chromosomal Aneuploidies Using Array-MLPA. *J. Yan[1,2], M. Xu[1], C. Xiong[1], DW. Zhou[1], ZR. Ren[1], Y. Huang[1,2], M. Mommersteeg[3], R. van Beuningen[3], YT. Wang[4], SX. Liao[4], F. Zeng[1,2,5], Y. Wu[1,3], YT. Zeng[1,2].* 1) Institute of Medical Genetics, Shanghai Children's Hospital, Shanghai Jiao Tong University, Shanghai, Shanghai, China; 2) Key Lab of Embryo Molecular Biology, Ministry of Health, and Shanghai Lab of Embryo and Reproduction Engineering, Shanghai, Shanghai, China; 3) PamGene International BV, 's-Hertogenbosch, The Netherlands; 4) Medical Genetic Institute of Henan Province,the People's Hospital of Henan Province, Zhengzhou, Henan, China; 5) Institute of Medical Sciences, Shanghai Jiao Tong University School of Medicine, Shanghai, Shanghai, China.

Cultured karyotype analysis has been considered as a reliable detector of fetal abnormalities. However, its sensitivity depends on the number of cells established in a particular culture. To determine whether array-based multiplex ligation-dependent probe amplification (array-MLPA) can be used in clinical diagnostic settings for screening the common aneuploidies, we designed 116 universal tag-probes covering chromosome 13, 18, 21, X, Y and 8 control autosomal genes. We then performed MLPA and hybridized the MLPA products on 4-well flow-through microarray system. We further determined the chromosome copy numbers by analyzing the relative signals of the chromosome-specific probes. In a blind study of 161 peripheral blood and 12 amniotic fluid drawn samples, we correctly identified 76 of 80 nonmosaic aneuploidy cases, especially 11 amniotic fluid drawn samples and all of the normal controls by array-MLPA. Additionally, we detected two chromosome X monosomy mosaic cases, in which the mosaic rate estimated by the chromosome copy numbers on array-MLPA were basically consistent with the results from the karyotyping. Moreover, we found five sex aneuploidies by array-MLPA, in which the abnormalities could not be clearly identified by the karyotype analysis. Our study demonstrates the success and potential power of array-MLPA in a clinical diagnostic setting for rapid chromosomal aneuploidy screening.

2456/F

Analysis of the Noonan/CFC/Costello syndrome genes in fetuses with abnormal ultrasound findings and a normal karyotype. *H.G. Yntema, W.M. Nillesen, M. Schepens, M. Ruiterkamp-Versteeg, H. Scheffer, B.H.W. Faas, I. van der Burgt.* Dept Human Genetics 417, Radboud Univ Nijmegen Med Ctr, Nijmegen, Netherlands.

Noonan syndrome is an autosomal dominant disorder characterized by short stature, congenital heart defects, distinctive facial features, and a variable degree of intellectual deficits. The disorder is genetically heterogeneous and shows clinical overlap with cardio-facio-cutaneous (CFC) and Costello syndrome. Currently, germline mutations in 10 genes have been described: *PTPN11*, *KRAS*, *SOS1*, *RAF1*, *SHOC2*, *NRAS*, *BRAF*, *MAP2K1*, *MAP2K2*, and *HRAS*. Lee *et al*. (Clin Genet 2009;75:190) recently described *PTPN11* mutations in 9% of fetuses with cystic hygroma and increased nuchal translucency (NT). Because of these findings we offered *PTPN11* testing in a routine DNA diagnostic setting for fetuses with a normal karyotype and an increased NT. Parallel testing for mutations in *KRAS* was performed upon request. This study showed a mutation frequency of 16% in fetuses tested for *PTPN11* and *KRAS* [Houweling *et al*. (2010) Prenat Diagn 30:284]. In our DNA diagnostics laboratory, until now the DNA of 70 fetuses has been investigated for mutations in *PTPN11*, *KRAS*, *SOS1*, and *RAF1*. In 11 fetuses (16%) a de novo mutation has been identified in either *PTPN11* (n=5), *KRAS* (n=1), *SOS1* (n=1), or *RAF1* (n=4). We conclude that in this cohort *RAF1* mutations are as frequent as *PTPN11* mutations. *KRAS* and *SOS1* mutations are less frequent, but still have a mutation frequency of 1.5%. As prenatal diagnosis is dealing with a limited time frame, it is very important to establish a fast DNA diagnostic protocol for small amounts of DNA isolated from uncultured amniocytes. To decide which genes should be included in such a protocol we analysed all 10 Noonan/CFC/Costello syndrome genes in DNA of 78 fetuses with increased NT (>3.5 mm), cystic hygroma, hydrops fetalis or congenital heart disease - with or without ventricular megaly and/or renal abnormalities- and a normal karyotype. Our results suggest that prenatal analysis of all 10 genes should be offered to fetuses with specific ultrasound abnormalities and a normal karyotype. However, since these abnormalities are often detected at 20 weeks of gestation, leaving only a limited time frame for analysis, DNA mostly has to be extracted from uncultured amniocytes, providing only limited amounts of DNA. This makes analysis of all genes very difficult. The results of our studies and the difficulties in establishing a good DNA diagnostic protocol will be discussed.

2457/F

Endoreduplicated Throphoblast cells in cervix of women with normal pregnancies. *A. Amiel[1,2,3], M. Fejgin[1,3,4], P. Tsipouras[5], M. Liberman[3], N. Pery[3], F. Tafas[5], S. Sifakis[6].* 1) Genetics Institute, Meir General Hospital, Kfar Saba, Israel; 2) Bar Ilan University, Ramat-Gan, Israel; 3) Monaliza Medical, Kfar-Saba, Israel; 4) Sackler School of Medicine,Tel Aviv University; 5) Ikonisys Inc, 5 Science Park, New Haven, CT 06511, USA; 6) Department of Obstetrics-Gynecology, University Hospital of Heraklion, Crete, Greece.

Background: Fetal cells represented by the Extra Villous Trophoblast (EVT) obtained from the cervix are important source materials for Non-Invasive Prenatal Diagnosis (NIPD). Fetal cells are present in the uterine cavity from the 5th to the 12th weeks of pregnancy. Objective: In this study we estimated the False Positive Rate (FPR) of aneuploid trophoblast cells in normal pregnancies that appeared in the cervix during the 5-13 weeks of pregnancy. Methods: in the process of assessing the FPR of the procedure, samples were obtained from normal 21 female and 15 male pregnancies. FISH was done with X, Y and two 21 probes. Thirty six normal pregnancies with gestational age from 5-12th week were examined. Results: In the female cases with a mean of 15.2 tetraploid cells per case were found, with a range of 0-52 cells per case (based on the finding of 4 signals for X and 21 chromosomes), while in the male cases a mean number of 2.0 tetraploid cells were found with a range of 0-5 cells per case (based on 4 signals of Y and 21 chromosomes) . Those cells were 2 to 3 times larger than the usual normal cells seeing in the cervix. Conclusion: It is well known in the literature, that EVT tend to form endoreduplication in their nuclei to the ploidy level of 4c-8c DNA. It is of importance that those cells may represent a normal phenomenon of trophoblast cells in the cervix as they appear in normal pregnancies.

Fragile X prenatal diagnosis of 1,055 pregnancies from 1991-2010. *S. Nolin, A. Glicksman, X. Ding, N. Ersalesi, W.T. Brown, C. Dobkin.* New York State Institute for Basic Research in Developmental Disabilities, Department of Human Genetics, Staten Island, NY.

We have performed fragile X prenatal studies for 1055 pregnancies of women with intermediate, premutation or full mutation alleles from 1991-2010. The studies included 884 chorionic villus and 179 amniotic fluid samples. For 8 pregnancies, both amniocytes and chorionic villi were analyzed due to: unusual findings (3), maternal cell contamination (1), or other technical difficulties (4). The expanded allele was transmitted in 514 (49%) pregnancies with expansion to a full mutation in 221 (20.9%). No maternal age effect was observed in the risk of expansion to full mutation. Five of 53 (9.4%) allele transmissions with 45-49 repeats were unstable as were 12 of 48 (25%) with 50-54 repeats. While most unstable transmissions of intermediate alleles were modest increases of 1 to 4 repeats, a 54 repeat increased to 85, and a 53 repeat decreased to 33 repeats. Contractions in repeat size were observed for 15/514 (2.9%) pregnancies in women carrying alleles of 52 to 150 repeats. The smallest contraction was a loss of two repeats from 54 to 52 repeats and the largest was a loss of 68 repeats from 150 to 82 repeats. Among transmissions of normal maternal and paternal alleles, there were 6 unstable alleles including one normal maternal, 4 normal paternal alleles and 1 intermediate paternal allele. To confirm the prenatal studies DNA from cord blood was analyzed for 19 amniotic fluid and 92 chorionic villus samples. Analyses of the cord blood confirmed all of the prenatal studies which identified 62 normal, 11 intermediate, 27 premutation and 11 full mutation alleles. Among the cases analyzed, one woman with three alleles of 30, 80 and 110 repeats had 3 pregnancies: 1 with a full mutation expansion and 2 with contractions to 57 and 59 repeats. A second woman with three alleles of 23, 49 and 74 repeats transmitted a 49 repeat allele to her fetus. A comparison of prenatal transmissions from women with or without a family history of fragile X suggests greater instability for alleles in families known to have a history of fragile X.

Phenotype analysis and gene expression profiling in adult offspring in a mouse model of chronic maternal protein deprivation reveals a role for cohesins in developmental programming. *A. Sanchez-Valle[1], B. Sadikovic[1], H. Sangi-Haghpeykar[2], L. Chen[2], M. Fiorotto[3], I. Van den Veyver[1,2].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Obstetrics and Gynecology, Baylor College Med, Houston, TX; 3) Pediatrics (Nutrition), Baylor College Med, Houston, TX.

Epigenetic changes are thought to underlie the developmental programming of adult-onset metabolic syndrome resulting from a suboptimal intrauterine environment, but the exact molecular mechanisms and identity of altered genes remain incompletely understood. We studied C57BL/6J mice, which are predisposed to obesity and glucose intolerance as a sensitive model for developmental programming. We fed female C57BL/6J dams a maternal low-protein (MLP; 8%) or control diet (20%) starting 4 weeks prior to mating. Litters were culled to 6 on postnatal day 3 (P3) and male pups weaned to lab chow (TD91352) on P21 and single-housed. Offspring were sacrificed at P21and P365 and organs were dissected and snap-frozen. The MLP group had significantly lower body weight at P21 (N=36 MLP; N= 25 controls) and over time (N=17 MLP; N=19 controls) ($p<0.001$). Kidney ($p<0.001$), heart ($p<0.05$), liver ($p<0.01$) weights were also lower at P21 (N=8 MLP; N=6 controls), but not after adjusting for body weight. There was no difference at P365. All absolute hindleg muscle weights and those adjusted for tibia length ($p<0.001$) were lower at P21 in the MLP group (N= 19 MLP; N=8 controls). Standardized weight differences persisted at P365 for soleus ($p<0.01$), gastrocnemius ($p<0.05$) and tibialis anterior ($p<0.05$) (N=8 MLP; N=10 controls). RNA from liver at P365 (n=3 for each diet) was hybridized to Affymetrix Mouse Gene 1.0 ST Arrays. Data was analyzed with Partek Genomic Suites followed by Ingenuity Pathway Analysis. We found 521 upregulated and 236 downregulated genes in the MLP group (one-way ANOVA; $p<0.01$, 1.5 fold change). Genes with the most significantly altered expression include *SMARCA5, ATRX, ARID4b* involved in chromatin regulation; *SMC3, SMC1a, SMC5, SMC6, NIPBL*, and *PCM1* involved in cohesins and chromatin regulation; *TOPI, TOP2B, SMARCA5, MED21*, and *REV3L* involved in transcriptional regulation; and *TMF1, ROCK1, ACP1*, and *ARID4b* involved in adult onset disorders. Quantitative RT-PCR analysis on 10 genes validated our findings. The changes in expression of genes involved in the cohesin complex is a novel finding that suggests a role for altered higher-order chromatin structure as an epigenetic mechanism to stabilize long-term global alterations in transcription. These mechanisms can ultimately be responsible for predisposition to adult onset diseases such as hypertension and diabetes.

Autophagy is activated in the placenta of pre-eclampsia model mouse. *R. Akaishi[1], T. Yamada[1], I. Furuta[1], M. Morikawa[1], T. Yamada[1], H. Yamada[2], K. Nakayama[3], K. Nakayama[4], T. Yoshimori[5], H. Minakami[1].* 1) Department of Obstetrics; Hokkaido University Graduate School of Medicine; 2) Department of Obstetrics and Gynecology, Kobe University; 3) United Centers for Advanced Research and Translational Medicine, Tohoku University; 4) Department of Molecular and cellular biology, Medical institute of Bioregulation, Kyushu University; 5) Department of Genetics, Osaka University Graduate School of Medicine.

Autophagy is an intracellular bulk degradation system used to recycle the majority of proteins and some organelles. It is activated in response to nutritional deprivation and intracellular stress. Yeast Atg9p is the first integral membrane protein shown to be essential for the cytoplasm to vacuole targeting (Cvt) pathway and autophagy. *ATG9A* and *ATG9B* are identified as human genes homologous of yeast Atg9p. In human adult tissues, *ATG9A* was ubiquitously expressed, whereas *ATG9B* was highly expressed in placenta (trophoblast cells) and pituitary gland. Moreover, *ATG9B* is a vertebrate-specific gene that may have gained critical roles in mammalian-specific developmental events, such as placentation, through rapid evolution. On the other hand, *ATG9B*, is a long variant of *NOS3AS*, regulates *NOS3* post-transcriptionally. The *NOS3* locus has been suggested to be associated with a number of diseases including pre-eclampsia (PE). In this study, we hypothesized *ATG9B* may play critical roles in mammalian-specific developmental events, such as placentation and may have some roles in the mechanism of PE. Mouse placentas were analyzed to investigate the hypothesis of the function of *ATG9B* with related genes. We collected placentas from wild type mice (C57B/L6J: WTm) and PE model mice ($p57^{KIP2}$ knockout mouse: PEm) on 13.5 days post coitum (dpc), 15.5 dpc and 17.5 dpc. We performed quantitative RT-PCR to measure the expression of *Atg9a* and *Atg9b*, *Nos3* and quantified the amount of microtubule-associated protein light chain 3 -II (LC3-II) and Atg9b protein by immunoblot analysis. *Atg9b* proved to increase with advancing gestational days. *Atg9b* was more highly expressed in PEm than WTm. The expressions of *Nos3* did not change during gestation in WTm, while those of *Nos3* were significantly elevated at 13.5dpc and 15.5dpc, but not at 17.5 dpc in PEm. Although the amount of Atg9b protein did not change during gestation in both PEm and WTm, but was significantly higher in PEm than WTm. LC3-II was significantly higher in PEm than WTm. These suggested that *Atg9b* might have a role in maintaining the pregnancy and might have inhibited *Nos3* as *Nos3as* in PEm. The elevated LC3-II suggested that autophagy was activated in PEm placenta. Autophagy was possible to be induced by starvation of PE. Increased Atg9b might have contributed the activation of autophagy in PEm placenta.

Phenotype-Specific Adverse Effects of *XPD* Gene Abnormalities on Human Fetal and Placental Development: Trichothiodystrophy Versus Xeroderma Pigmentosum Paradox. *A. Dzutsev[1], A. Kumar[2], R. Moslehi[2].* 1) NCI, NIH, Bethesda, MD; 2) Ctr Cancer Genomics, SUNY at Albany, Rensselaer, NY.

Background: Effects of abnormalities in DNA repair and transcription genes in human prenatal life have never been studied. Mutations in *XPD*(*ERCC2*), a gene involved in the nucleotide excision repair(NER) pathway and in transcription, can lead to several different phenotypes such as trichothiodystrophy(TTD), xeroderma pigmentosum(XP) or combination of XP/TTD. Our recent genetic epidemiologic investigation revealed 4.0-fold increased risk of preeclampsia(P=0.0018) and 35-fold increased risk of a severe form of preeclampsia, namely hemolysis, elevated liver enzymes, and low platelets(HELLP) syndrome(P=0.0002) associated with TTD-affected pregnancies (where infant had two mutations) but not in unaffected pregnancies (where the infant was heterozygote or noncarrier). Pregnancies resulting in XP/TTD, also caused by mutations in *XPD*, were not associated with gestational complications. Abnormal placental development may explain the constellation of observed abnormalities; thus we hypothesize that NER/transcription genes play an important role in normal placental development and that besides the fetal genotype, the exact genetic abnormality is also relevant to the postulated mechanism. **Methods**: To test this hypothesis, we conducted a comparison of *XPD*-associated XP(n=48) and TTD(n=42) cases with respect to gestational complications and global gene expression profiles in fibroblasts in a microarray dataset. **Results**: Compared to XP-affected pregnancies, TTD-affected pregnancies were associated with significantly higher incidence of preeclmapsia, preterm delivery, low birth weight(<2500 grams), SGA<10th and <3rd percentile, and NICU hospitalization (P<0.0001 for all comparisons). Furthermore, HELLP syndrome, decreased fetal movement and elevated midtrimester maternal serum hCG levels were only reported among TTD-affected pregnancies with frequencies of 4.2%, 50% and 40%, respectively. Global gene expression profiling of TTD versus normal fibroblasts suggested differential expression of a number of genes affected by mutations in *XPD* with little overlap between XP and TTD. Downregulated pathways in TTD included NRF2-mediated oxidative stress response and progesterone metabolism. **Conclusion**: Our results indicate an important role for XPD during normal human placental and fetal development and highlight the relevance of the exact genetic abnormality to the postulated mechanism which may involve affected oxidative stress response and progesterone metabolism pathways.

Replication of a Genome-Wide Association Study of Birth Weight in Preterm Neonates. *K.K. Ryckman[1], E.N.A. Bream[1], J.R. Shaffer[2], E. Feingold[2], S.K. Berends[1], E. Gadow[3], C. Saleme[4], H.N. Simhan[5], D. Merrill[6], C.T. Fong[7], T. Busch[1], B. Feenstra[8], F. Geller[8], M. Melbye[8], M.L. Marazita[2], J.M. Dagle[1], J.C. Murray[1].* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) Centro de Educación Médica E Inverstigaciones Clínicas, Buenos Aires, Capital Federal, Argentina; 4) Instituto de Maternidad y Ginecología Nuestra Señora de las Mercedes, San Miguel de Tucumán, Tucumán, Argentina; 5) Obstetrics, Gynecology, and Reproductive Sciences, University of Pittsburgh School of Medicine, Magee-Womens Research Institute, Pittsburgh, PA; 6) Wake Forest University Baptist Medical Center, Wake Forest University School of Medicine, Winston-Salem, NC; 7) Strong Children's Research Center, University of Rochester School of Medicine, Rochester, NY; 8) Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark.

BACKGROUND: A recent genome-wide association study of birth weight by Freathy et al, which included 10,623 European term gestations, showed that the infant CC genotype of rs900400 ($p=2x10^{-35}$) near LEKR1 and CCNL1 and rs9883204 ($p=7x10^{-15}$) in ADCY5 was associated with lower birth weight. However, it is unclear whether these findings are limited to term gestations only or if the same associations are present in preterm infants. OBJECTIVE: To examine associations of maternal and infant genotype with birth weight for rs9883204 and rs900400 in a preterm population. DESIGN/METHODS: TaqMan genotyping was performed on 719 parent-infant trios from two distinct populations. A total of 441 Caucasian trios were recruited from four U.S. sites including Iowa City, Pittsburgh, Rochester and Wake Forest; the other 278 trios were recruited from Argentina. Preterm (delivery at 23-36 weeks gestation) singleton births occurring from spontaneous labor were included. Pregnancies complicated by congenital anomalies, twins, IUGR, artificial reproductive technology, preeclampsia and placenta previa were excluded. Quantitative transmission disequilibrium tests (QTDT) adjusting for infant gender and gestational age were performed in the U.S. and Argentina populations, combined as well as in each population separately. Additionally, linear regression analyses adjusting for infant gender and gestational age were performed with maternal and infant genotypes separately. RESULTS: QTDT in the combined sample revealed that the C allele of rs900400 (LEKR1/CCNL1) was associated with lower birth weight (p=0.005). Separately, rs900400 was associated in the U.S. (p=0.02) but not in Argentina (p=0.24). Linear regression also showed decreased birth weight was associated with the CC genotype of rs900400 in infants but not mothers in the U.S. (p=0.06), Argentina (p=0.04) and combined populations ($p=1.1x10^{-5}$). This result remained significant in the combined population after adjusting for smoking ($p=6.3x10^{-5}$). There were no associations with rs9883204 for the QTDT or linear regression analyses in the combined sample. CONCLUSIONS: We found that rs900400 near LEKR1 and CCNL1, previously associated with birth weight in a term population, is also associated with birth weight in a preterm population. These results indicate the potential importance of this SNP on birth weight irrespective of gestational age. This work is supported by NIH grants: R01 HD-52953 and R01 HD-57192.

Population-based screening of heterozygous SMN1 deletions in Chinese Han people with Taqman probe based real-time PCR and multiplex ligation-dependent probe amplification. *Y. Chen, MJ. Liu, HB. Cheng, HB. Li, J. Sun, J. Mao, J. Ding, H. Li.* Center for Reproduction and Genetics, Nanjing Medical University Affiliated Suzhou Hospital, Suzhou, China.

Objective: To determine SMN1 gene copy number by an efficient TagMan real-time PCR assay. Methods: 397 subjects were involved in this study: (1) 284 whole blood samples were from randomly selected pregnant women participating in prenatal care in our hospital and three husbands of them; (2) 83 amniotic fluid samples were from pregnant women with high risk of trisomy 21; (3) 30 DNA samples were kindly provided by Peking Union Medical College Hospital in China and Children's Hospital Boston in USA and used for both blinded test and validating this technique platform. The genome DNA of samples were extracted by Qiagen's QIAamp® DNA Mini Kit, and ABI's 7500 real-time fluorescence quantitative PCR system and analysis software were applied in this assay. The reagents involved in this assay, such as probes and primers, were purchased from ABI Company. The SMN1 gene copy number of all samples with ALB using as an internal reference gene was detected according to the standard operating procedures of our lab. Results: Among the first group of subjects, individuals with two copies were 95.07%(270/284), with one copy of SMN1 gene, namely SMA carrier, were 3.17%(9/284), and with three copies were 1.76%(5/284). The corresponding data in the second group were 91.57% (76/83), 7.23% (6/83) and 1.20% (1/83), respectively. The blinded test results were exactly consistent with those provided by the other laboratorys. Conclusion: (1) Established TagMan Real-Time PCR assay to determine SMN1 gene copy number is a simple, economical and efficient technique and has clinical application value; (2) This assay aim to detect SMN1 gene copy number can also apply in prenatal diagnosis or screening; (3) It needs strict quality control for clinical application of this assay.

Association between AGTR2 genetic variants and increased risk for congenital abnormalities of the kidney and urinary tract. *H.C. Sarubi[1], L. Bastos-Rodrigues[1], D.M. Debora[2], A.C. Simoes e Silva[2], E. Oliveira[2], L. De Marco[1].* 1) Surgery, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 2) Pediatrics, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil.

The Renin-Angiotensin System (RAS) plays a critical role in normal nephrogenesis. It has been suggested that, in humans, polymorphisms in genes encoding components of the RAS could cause a spectrum of congenital abnormalities of the kidney and urinary tract (CAKUT), including congenital hydronephrosis. The gene encoding the angiotensin receptor type 2 (AGTR2) is one of the candidate genes proposed for genetic association with CAKUT. During kidney development, angiotensin II functions through its two major receptors, AGTR1 and AGTR2. These receptors belong to the large family of G protein-coupled receptors with seven transmembrane domains and are both highly expressed in the fetal kidney but poorly expressed in most adult tissues. This study was undertaken to explore the role of single-nucleotide-polymorphisms (SNPs) concerning the AGTR2 gene in the development of congenital abnormalities of the kidney and urinary tract. Sixty seven infants with the diagnosis of CAKUT were recruited from a Brazilian reference center. The control population consisted of 89 healthy individuals from the same geographic area. We analyzed three Tag SNPs from the AGTR2 gene (rs1403543, rs3736556 and rs5193) which were genotyped using TaqMan® SNP Genotyping Assays. To account for ethnicity, individual DNA was independently genotyped for a set of 40 biallelic short insertion/deletion polymorphisms (indels) for genomic ancestry analysis. The difference in the proportion of genomic ancestry between the two groups was not significant. After adjustment by the permutation procedure, we found a significant association with the rs1403543 marker [P = 0.0031; OR = 1.98 (1.26 a 3.12)]. In summary, our data suggest that AGTR2 polymorphisms are associated with increased risk for congenital abnormalities of the kidney and urinary tract and are not associated with ethnicity in the Brazilian population.

The effect of various antiretroviral therapies on maternal serum aneuploidy screening in HIV positive pregnant women. *S.T. Holmes[1], K. Bajaj[2], L. Reimers[1], S. Klugman[2], P.S. Bernstein[2], R. Wright[2].* 1) Albert Einstein College of Medicine, New York, NY; 2) Department of OB/GYN, Montefiore Medical Center, New York, NY.

Objective: To evaluate differences in maternal serum markers for prenatal aneuploidy/neural tube defect screening in HIV positive women undergoing boosted and non-boosted protease inhibitor therapy. Methods: A retrospective case control study of 64 HIV positive women was conducted stratifying subjects by drug therapies (boosted protease inhibitors (BPI) vs. non-boosted protease inhibitors (NBPI)). Controls were randomly selected, matched for maternal and gestational age, HIV negative women who underwent aneuploidy screen the same month as each case. Women had either 1) first trimester combined screens (FTS) with second trimester alpha fetoprotein levels or 2) second trimester quadruple screen (STS). Results: The sample of HIV positive women receiving boosted protease inhibitor therapy during any portion of their aneuploidy screening (n=17) included 3 subject having FTS, 6 subjects having STS only, and 4 subjects having FTS and second trimester AFP and 4 patients who were on NBPI during the first trimester but were changed to BPI prior to the second trimester AFP. One patient on BPI had a positive FTS, compared to one patient on NBPI. Three of the subjects receiving non-boosted therapy had positive second trimester screens. Among the HIV negative controls, 3 had second trimester screen positive results. Seven HIV positive subjects had amniocentesis, 5 for positive screens (2 for positive first trimester combined screening and 3 for quadruple screening), compared to 1 HIV negative control for positive quadruple screen; the HIV negative control amniocentesis was positive for Down's Syndrome. Conclusion: HIV positive women undergoing boosted protease inhibitor therapy do not appear to have an increased rate of false positive prenatal screenings when compared to women on non-boosted therapy. The overall screen positive rate for HIV positive women, regardless of therapy, seems to be increased when compared to matched controls.

2466/F

ADAM12 in maternal serum prenatal aneuploidy screening: assessment of its screening efficacy in the first and second trimester of pregnancy. *M. Macek Jr[1], D. Springer[2], H. Kluckova[1], R. Vlk[3], I. Spalova[3], P. Calda[4], A. Lashkevich[1], D. Chudoba[1], D. Novotna[1], L. Dvorakova[1], H. Kuzelova[1], S. Vilimova[1,5], M. Simandlova[1], M. Turnovec[1], M. Hladikova[1], M. Macek Sr[1].* 1) Department of Biology and Medical Genetics, 2nd Faculty of Medicine, Charles Univ. Prague, Czech Republic; 2) Department of Biochemistry and Clinical Diagnostics, 1st Faculty of Medicine, Charles Univ. Prague, Czech Republic; 3) Department of Obstetrics and Gynecology, 2nd Faculty of Medicine, Charles Univ. Prague, Czech Republic; 4) Department of Obstetrics and Gynecology, 1st Faculty of Medicine, Charles Univ. Prague, Czech Republic; 5) Sanatorium Pronatal, Prague, Czech Republic.

The aim of the study was to assess the efficacy of ADAM12 prenatal maternal serum aneuploidy screening in the first (1T) and second trimester (2T), i.e. within 9-19 weeks of gestation. ADAM12 levels were measured by DELFIA ADAM12 Research Kit (Perkin Elmer, U.S.A) in frozen sera from controls and from cases with fetal aneuploidies. On average for each day, 30 samples were used for control percentile (P) calculations. A total of 85 sera from pregnancies with autosomal and heterochromosomal aneuploidies were tested in 1T and 2T in order to ascertain the decrease of ADAM12 levels under P25. P50 levels within week 9-19 rose from 235.7 to 1337.8 ng/ml, with an average daily increase of 15.7 ng/ml. Overall, the efficacy of screening by using this marker was not significantly different between 1T and 2T of pregnancy. Positive screening outcome (less than P25), within week 9-19, was for trisomy 21 - 48% (15/35), for trisomy 18 - 57% (4/7), for trisomy 13 -100% (4/4), for triploidy - 89% (8/9), for 47,XXX - 88% (7/8) and for 45,X - 12% (1/8) of cases. The highest decrease from P25 was for trisomy 21, within range P10-25 (22%). In other trisomies the highest degree of positivity was within P1-P5: for trisomy 18 - 29%, for trisomy 13 - 50%, for triploidy - 78% and for 47,XXX - 63%. Marker ADAM12 was not detected in 47,XXY, 47,XYY, including mosaic forms of 45,X pregnancies. Our results indicate an inverse relationship between the degree of phenotypic alteration in autosomal aneuploidies and decrease of ADAM12, i.e. under the P25. It is noteworthy, that the same is true for 47,XXX which is associated with mild phenotypic affection. Our results suggest, that ADAM12 is an important marker for the detection of severe autosomal aneuploidies, including triploidy and 47,XXX in the 1T and 2T of pregnancy. Supported by MZ0FNM2005.

The reliability of maternal serum triple screening for the prenatal diagnosis of fetal chromosomal abnormalities in Turkish women. *A. Pazarbasi[1], O. Demirhan[1], A.I. Guzel[1,3], D. Tastemir[1,4], M. Kasap[1], F.T. Ozgunen[2], C. Evruke[2], C. Demir[2], E. Tunc[1], B. Yilmaz[1], S. Kocaturk-Sel[1], D. Onatoglu[1], D. Alptekin[1], S. Koc[1], N. Inandiklioglu[1], O. Ozer[1].* 1) Dept Medical Biol & Genetics, Univ Cukurova, Adana, Turkey; 2) Dept. of Obstetrics and Gynecology, Univ Cukurova, Adana, Turkey; 3) Dept Medical Biol, Univ Rize, Rize, Turkey; 4) Univ Adiyaman, Adiyaman, Turkey.

The purpose of this article is to ascertain the reliability of maternal serum triple marker screening of alpha-fetoprotein, human chorionic gonadotropin and unconjugated estriol for the prenatal diagnosis of fetal chromosomal abnormalities in Turkish women. This screening was preferentially reserved to young patients. Medical records were used to analyze indications of amniocentesis and QF-PCR. Anomaly screening was performed to all patients between 13 and 22 weeks of pregnancy. 1725 pregnancies resulted screen positive to triple test and accepted fetal chromosomal analysis. Chromosomal aberrations observed in 56(3.2%) cases. The 44.6% and 55.3% of the abnormalities were numerical and structural aberrations, respectively. These included twenty cases of inv(9), fourteen cases of trisomy 21, one case of 46,XX/47,XX,+21, two cases of trisomy 18, one case of trisomy 13, one case of 47,XXY, one case 45,X, twelve cases of structural abnormalities and six cases of mosaic or tetraploidy. At a cutoff of between 1:200 and 1:270 the false positive rate increased to 21%, and spesitivity rate of 72%; and sensitivity rate of 44%; without any gains in detecting Down's syndrome. Second trimester triple marker testing is an effective screening tool for detecting fetal Down's syndrome in Turkish women.

Characterization of a de novo chromosome abnormality, der(14)(p11.2-;qter), found in the fetus with Dandy-Walker malformation, using oligonucleotide array CGH. *D. Cha[1, 2], S. Shim[2], S. Park[2], J. Park[2], S. Chung[3].* 1) Dept OB/GYN, Kangnam CHA Hosp, CHA Univerity, Seoul, Korea; 2) Genetic Research Laboratory, CHA University; 3) Dept OB/GYN, Bundang CHA Hosp, CHA Univerity, Sungnam, Korea.

A 32-year-old pregnant woman came to hospital for routine 2nd trimester checkup at 21 gestational weeks. Ultrasound examination showed abnormal findings in cerebellum. The fetus was suspected as having Dandy-Walker malformation. Amniocentesis was carried out for fetal chromosome analysis. Fetal karyotype showed that an additional material of unknown origin was identified at the short arm of chromosome 14, 46,XY,der(14)(p11.2;qter). To characterize the unknown material, oligonucleotide array CGH was carried out using the Agilent 44K human genome CGH microarray chip and a gain of 3q25.3-3qter was detected. FISH analysis confirmed the unknown material was originated from chromosome 3q. Both parents showed normal karyotypes. 3q partial trisomy related to Dandy-Walker malformation was presented in previous reports. In this report, we precisely characterized the abnormal chromosome 3 using oligonucleotide array CGH technique and this will be helpful to elucidate the molecular mechanism of Dandy-Walker malformation related to partial trisomy 3q.

2469/F

Prenatal presentations of CHARGE syndrome. *L. Demmer, T. Marino, S. Craigo.* Tufts Medical Center, Boston, MA.

CHARGE syndrome is a multiple anomaly condition characterized by coloboma, heart defects, choanal atresia, retarded growth/development, genital hypoplasia, ear anomalies and deafness. Heterozygous mutations of the CHD7 gene are responsible for most cases. Most previous studies have focused on postnatal diagnosis of CHARGE. We describe two cases, one familial and one sporadic, where anomalies were seen prenatally but the diagnosis not recognized until birth. Case 1: Imaging in the first pregnancy revealed micrognathia, complex cardiac defect, hemivertebra, club foot, Dandy-Walker variant; pregnancy was terminated. Imaging in the next pregnancy revealed micrognathia, complex cardiac defect, hemivertebra, agenesis of corpus callosum, Dandy-Walker variant, and hydrocephalus. Chromosomes and array: normal. Pregnancy was terminated; examination of the fetus revealed prominent forehead and maxilla, large nose and low set ears. Imaging in the third pregnancy revealed an AV canal defect; 3D ultrasound of face and brain MRI were unremarkable. Prenatal karyotype and array:normal. Postnatal exam revealed microphthalmia, hypoplastic semicircular canals and cupped, low set ears. CHD7 Q217X mutation confirmed CHARGE syndrome. Subsequently amniocytes from the 2nd pregnancy revealed the same mutation suggesting gonadal mosaicism. Case 2: Second trimester ultrasound revealed bilateral single lower leg bones, club feet and bowed right forearm bones with a single digit. Prenatal karyotype:normal. Postnatally choanal atresia, microphthalmia, coloboma and deafness were identified. CHD7 c.2999delC mutation confirmed CHARGE. CHARGE syndrome can be variable and complex. While minor limb defects are common, major limb anomalies have only rarely been reported. Apparently isolated major limb defects or isolated cardiac defects, while common to many syndromes, can be the only U/S finding. The classic pattern is difficult to identify prenatally; more focused imaging to detect specific anomalies in the brain, ear, choanae and semicircular canals may be warranted. Prenatal recognition of CHARGE is a worthwhile goal given the seriousness of this condition which includes significant mental, visual and hearing impairment. Increased awareness of the patterns of anomalies seen in CHARGE would allow for CHD7 testing and timely decision-making regarding pregnancy management. In addition, our report underscores the need for counseling regarding the potential for gonadal mosaicism.

Evidence review: Fetal gender identification using cell free fetal DNA (cffDNA) in maternal blood. *S.A. Devaney[1], G. Palomaki[2], J.A. Scott[1], D.W. Bianchi[3].* 1) The Genetics & Public Policy Center, Johns Hopkins University, Washington , DC; 2) Women & Infants Hospital, Alpert Medical School of Brown University, Providence, RI; 3) Floating Hospital for Children @Tufts Medical Center, Tufts University School of Medicine, Boston, MA.

Background: Non-invasive prenatal diagnosis, including fetal gender determination, can be an alternative to invasive techniques. In 1997, Lo et al identified circulating cffDNA in maternal blood. Since then a number of cffDNA gender prediction studies have been published. To determine test sensitivity/specificity and identify factors associated with performance, we reviewed the published literature. Methods: Two reviewers (SD, DB) performed independent structured PubMed literature searches with variations of the terms: DNA, cell-free, fetal, gender, prenatal, non-invasive, diagnosis. We excluded reviews and articles not in English. Reviewers extracted data on test performance and methodology. Discrepancies were resolved by discussion. Meta-DiSc, software designed to analyze diagnostic tests, was used. Given the relationship between sensitivity and specificity introduced by the threshold effect, diagnostic odds ratio (dOR) was included. Potential covariates examined were: methodology (conventional PCR, RT-PCR), sample type (plasma, serum, whole blood), publication date (<=2003, >2003), Y chromosome sequence (SRY, DYS14, DYS1) and gestational age (GA) in weeks (<7, 7-12, 13-20, >20). Results: The search yielded 855 publications, 735 were excluded on abstract content, 134 were fully reviewed, and 65 contained primary data suitable for analysis. Nineteen that did not contain >=10 male and 10 female samples were excluded, leaving 46 publications containing 60 data sets representing 3352 male and 2825 female fetuses. For the analysis of GA by week, 29 publications were included due to broad GA ranges in 17. The overall sensitivity was 95.3% (CI 94.5-96.0%), specificity was 98.5% (CI 98.0-99.0%) and dOR was 730 (CI 440-1200). RT-PCR (dOR 1070) was significantly better than conventional PCR (dOR 348) for predicting gender (p=0.03). There were no important differences found for sample type or Y sequence used. In the late first (7-12 wks) and early second (13-20 wks) trimesters, the tests performed equally well (dOR 960 and 710, respectively). Tests performed less well before 7 wks (dOR 91). After 20 wks the sensitivity and specificity of the test was 100% (dOR 4307), but this was based on only 6 data sets. Conclusion: Fetal gender prediction before 7 wks gestation is not reliable. From 7-20 wks, tests utilizing RT-PCR perform better. Multivariate analysis will be done to further clarify the combination of test characteristics that have the highest performance.

Unexpected chromosomal rearrangement detected by prenatal CGH array in a fetus with a *de novo* apparently balanced pericentric inversion. *V. Haddad[1,2], B. Benzacken[1], M. Gérard[1], S. Magnier[3], A. Verloes[1], A. Aboura[1].* 1) Department of Medical Genetics, AP-HP-Robert DEBRE University Hospital, Paris, France; 2) Department of Cytogenetics, AP-HP-Antoine BECLERE University Hospital, Clamart, France; 3) Department of Cardiology, AP-HP-Robert DEBRE University Hospital, Paris, France.

Growth retardation, conotruncal heart defect and right renal agenesis were detected in a female fetus by US scan at 24 WG. Amniocentesis performed at 28 WG revealed a *de novo* pericentric inversion 46,XX,inv(3)(p12q26). As a recent study (C.Schult-Bolard and al, 2009) showed that more than 50% of *de novo* inversions are unbalanced, we performed a 180k CGH array (Agilent), which showed no chromosome 3 rearrangement but, surprisingly, disclosed an interstitial 13 Mb deletion at 1q23-25 from 159,917,038 to 173,193,165. The deletion was confirmed by FISH. It occured *de novo*. Interstitial 1q23q25 deletion is characterized by intra uterine growth retardation, short hands/feet.The parents declined termination of pregnancy. The child died at day 3 of cardiac insufficiency. This report illustrates the fact that *de novo* rearrangements may be associated with imbalances located at distance of the breakpoints or even in another chromosome. We suggest that in prenatal diagnosis, array CGH should be used systematically to investigate fetuses witn abnormal phenotype and apparently balanced *de novo* chromosomal rearrangements.

2472/F

Identification and characterization of differential DNA methylation for potential use in non invasive prenatal diagnosis of Trisomy 21. *T.J. Jensen[1], T. Zwiefelhofer[1], M. Tang[1], C. Gebhard[3], M. Rehli[3], D. van den Boom[2], M. Ehrich[2].* 1) Research and Development, Sequenom Center for Molecular Medicine, San Diego, CA; 2) Sequenom Inc., San Diego, CA; 3) University Hospital Regensburg, Regensburg, Germany.

Prenatal diagnosis of fetal aneuploidies, including Trisomy 21, is an area of great interest in fetal maternal medicine. Current diagnostic assays use a combination of serum protein markers and ultrasound to identify a high risk group, which require additional confirmatory tests including invasive procedures. These invasive methods have risk since 0.5-2% lead to spontaneous miscarriage. To help reduce this risk, new diagnostic methods are targeting the fetal DNA itself. Fetal DNA is present in the maternal plasma in the form of circulating cell free (ccf) fetal nucleic acids. The fetal fraction comprises only 5-20% of all ccf DNA, thereby presenting a challenge in the analysis. To simplify these methods and increase the ability to utilize ccf DNA for diagnostic purposes, a discriminating factor should be employed that segregates the maternal and fetal ccf nucleic acids, thus allowing analysis of only the fetal component. A potential factor which may allow this segregation is DNA methylation. Maternal buffy coat and matched placenta tissue were used as a surrogate to determine the potential differences in DNA methylation between a woman and her developing fetus. To identify differentially methylated regions (DMRs) in the genome with a focus on chromosome 21, we employed two methodologies: methylcytosine immunoprecipitation (MCIP) coupled with microarray analysis and quantitative methylation analysis of target regions using SEQUENOM's EpiTYPER platform. For the microarray analysis we used two designs: a genome-wide CpG island microarray and a microarray tiling chromosome 21. We also performed targeted methylation analysis of all annotated CpG Islands (356) located on chr 21 using EpiTYPER. In addition, we validated genomic regions that were found to be differentially methylated by the microarrays analysis with EpiTYPER. In summary, we found 4566 regions to be differentially methylated throughout the genome between maternal and fetal DNA. A subset of 316 of these regions is located on chromosome 21. The confirmation of microarray results with quantitative mass spectrometry reveals that 94% of the regions assessed with EpiTYPER were confirmed in a set of 8 paired samples and each of these were also confirmed in a larger set of 65 paired samples. Interestingly we find that the largest methylation differences are found outside of classically defined CpG islands, indicating that those areas deserve special attention when screening for DMRs.

2473/F

An extensive genetic investigation of a translocation Y;11 observed in the antenatal period. *K. Krabchi[1], S. Mai[2], R. Vallente[2], D. Lichtenzstejn[2], O. Samassekou[1], J. Lamoureux[1], M. Bronsard[1], M. Langlois[3], I. Mongrain[3], M.S. Phillips[3], S. Malenfant[4], A. Broussin Ducos[1], C. Bouffard[1], R. Drouin[1].* 1) Division of Genetics, Department of Pediatrics, Faculty of Medicine and Health Sciences, Universite de Sherbrooke, Sherbrooke, QC, Canada; 2) Genomic centre for Cancer Research and Diagnosis, University of Manitoba, Manitoba Institute of Cell Biology, Winnipeg, MB, Canada; 3) Centre de Pharmacogénomique, Institut de Cardiologie de Montréal, Université de Montréal, Montréal, QC, Canada; 4) Centre hospitalier régional de Trois-Rivières, Pavillon Sainte-Marie, Trois-Rivières, QC, Canada.

Turner Syndrome (TS) is a genetic condition defined by the complete or partial absence of X chromosome and the total absence of a Y chromosome. A 35-year-old pregnant woman showed a 1/60 risk after prenatal screening. At 176 weeks, a cytogenetic analysis of amniocytes showed homogeneous monosomy X and the couple decided to continue the pregnancy. Subsequent morphological echography showed the presence of a male foetus. Consequently, other foetal investigations were performed to look for specific male markers. Methodology: Prenatal analysis on amniocytes: express FISH, GTW-banding karyotype and PCR amplification of foetal DNA with SRY specific primers were made. Per-partum analysis on cord blood: conventional and molecular cytogenetic techniques were used to characterize this chromosome rearrangement. Finally, microsatellite markers STS in search of microdeletions of Y (AZFa, AZFb, AZFc) and analysis by microarrays completed the investigation. 3D image analysis of nuclear organization of chromosomes 11 and Y and of telomeres in blood, buccal smears and fibroblasts were performed. Results: A phenotypically normal male child was born at full term with a translocation 45,X,der(11),t(Y;11)(pter®p11.2::q-25®pter). The long arm of the chromosome 11 showed no loss or gain of material up to the subtelomeric area. Analysis by microarrays revealed that the distal 5 Mbp fragment of Yp was translocated to the end of the chromosome 11q. The telomere organization appears regular, chromosome 11 is consistently found at the nuclear edge when it carries the Y translocation. The other chromosome 11 is located more internally. The remainder of chr Y is found in variable nuclear positions. Discussion: Prenatal diagnosis of TS should always be followed by research for SRY sequences. The presence of the arm or of a part of the Yp chromosome translocated to another chromosome gives rise to a relatively normal infertile male phenotype. The segment of the Y translocated to the distal part of the 11q25 represents a Y without centromere and the entire long arm that plays a major role in spermatogenesis. Conclusion: It is important to verify in all monosomic X conceptus for the presence of specific genetic material of the Y chromosome. Systematic complementary genetic investigations and genetic counselling performed by a qualified specialist would efficiently reduce ethical and clinical risk associated with medical pregnancy termination of incorrect TS prenatal diagnosis.

2474/F

Early prediction of preeclampsia using second trimester maternal serum markers including inhibin A. *K. Lee[1], H. Park[2], W. Hahn[2], J. Kang[1], D. Cha[1].* 1) Dept OB/GYN, Kangnam-Gu, Kangnam CHA General Hosp, CHA University, Seoul, Korea; 2) Dept OB/GYN, Bundang-Gu, Bundang CHA General Hosp, CHA University, Seoul, Korea.

The purpose of this study was to determine whether inhibin A and other second trimester serum markers are useful for early identification of pregnant women at risk for preeclampsia. Between January 2005 and March 2009, we analyzed the data of 4764 subjects who underwent second trimester multiple-marker screening for Down syndrome. Serum samples were assayed at 15+0 to 20+6 weeks for maternal serum alpha-fetoprotein (MSAFP), human chorionic gonadotrophin (hCG), unconjugated estriol (uE3) and inhibinA. We reviewed all medical records retrospectively, and assessed the relationships of several markers with preeclampsia using logistic regression analysis. The study sample included 41 patients who developed preeclampsia and a control group consisting of the other 4723 healthy subjects treated between January 2005 and March 2009. There were no significant differences in gestational ages at blood sampling, maternal weights, gravidity and parity between the two groups. However, the mean ages, Apgar scores, gestational age at delivery and neonatal weights were significantly different between the study group and the control group. In the study group, median multiples of median (MoM) values of inhibin A and human chorionic gonadotrophins (hCG), maternal serum alpha-fetoprotein (MSAFP) were elevated significantly, but unconjugated ertriol (uE3) did not differ significantly between the two groups. Inhibin A was among four markers significantly correlated with preeclampsia. Inhibin A and other second trimester serum markers may be useful for early detection of preeclampsia. Inhibin A was in fact the most important predictable marker among the markers we surveyed. The results of this study support those of previous studies, and provide quantified data elucidating the occurrence of preeclampsia. Studies adding maternal history and uterine artery Doppler data at the second trimester may further increase detection rates of preeclampsia.

2475/F

Prenatal imaging of Harlequin ichthyosis. *M. Lefebvre[1], J. Dubois[2], N. Patey[3], F. Audibert[4], V.A. Désilets[1].* 1) Department of Pediatrics, CHU Sainte-Justine, Montreal, Quebec, Canada; 2) Department of Radiology, CHU Sainte-Justine, Montreal, Quebec, Canada; 3) Department of Pathology, CHU Sainte-Justine, Montreal, Quebec, Canada; 4) Department of Obstetrics-Gynecology, CHU Sainte-Justine, Montreal, Quebec, Canada.

Introduction: Harlequin ichthyosis is a life-threatening disorder that is characterised by a thick skin that severely restricts movements and deforms facial features and distal extremities. Numerous complications are associated, particularly neonatal death from respiratory distress, dehydration and susceptibility to infections. It is an autosomal recessive condition, caused by mutations on the ABCA12 gene, on chromosome 2q34. Mutations on this gene prevent the production of a cellular lipid transport protein, explaining the phenotype. Case report: We describe a 28 years old woman, G1, referred for moderate oligohydramnios at 20 weeks of gestation. She had severe persistent oligohydramnios with normal fetal morphology at 24 weeks. Rupture of the membranes was confirmed through intramniotic infusion of indigo carmine. At 31 weeks, a fetal MRI was performed for suspicion of an amniotic bands syndrome on ultrasound. Complex facial malformations with agenesis of the upper lip, absent nasal bridge, retractile pad in front of the eye, supra orbital cutaneous prominence without cerebral malformation, were described. Important physiological, social and esthetical impairments, along with the need for reconstruction surgeries, were expected. Given the severity of the malformations, the couple asked for a pregnancy termination, which was approved by our Ethics Committee. Autopsy showed an 1800 g female foetus with generalized large diamond-shaped plaques of thick, pale and crusted skin, with large fissures and zones of separation. The face showed severe ectropion with bilateral exophthalmia and eclabion with “O-shaped” mouth, without anomalies of the nose and mouth. There were severe contractures of the small articulations bilaterally (wrists, fingers, ankles, toes) along with distal hypoplasia of fingers and toes. All internal organs were normal. Massive hyperkeratosis was seen on skin biopsy. The granulous layer was thin and the epithelium showed a papillomatous aspect. Electronic microscopy is pending. Molecular analysis of the ABCA12 gene on placental tissue reveals a disease-causing mutation (R287X) and two sequence variants (D844G and I1409V), which have not been published yet. Parental studies are pending. The former is a strong candidate for a disease mutation, since it is a non-conservative amino acid change in a position highly conserved. Conclusion: This is the first report of magnetic resonance imaging of a third trimester fetus with harlequin syndrome.

2476/F

Can syndromic macrocephaly be diagnosed in utero? *D. Lev[1,2,8], L. Ben-Sira[5,8], C. Hoffmann[6,8], M. Herrera[9], F. Vinals[10], C. Vinkler[1,2], S. Ginat[4,8], D. Kidron[7,8], T. Lerman-Sagie[2,3,8], G. Malinger[2,4,8].* 1) Inst Medical Genetics, Wolfson Medical Center, Holon, Israel; 2) Fetal Neurology Clinic,Wolfson Medical Ctr, Holon, Israel; 3) Pediatric Neurology Division; Wolfson Medical Center, Holon; 4) Department of Obstetrics and Gynecology Wolfson Medical Center, Holon; 5) Pediatric Radiology Division, Tel-Aviv Medical Center; 6) Neuroradiology Division, Haim Sheba Medical Center, Ramat Gan; 7) Depatment of Pathology, Pinhas Sapir Medical Center, Kfar Saba; 8) Sackler School of Medicine, Tel-Aviv University, Tel-Aviv; 9) Departamento de Ultrasonido, Clínica Sanatorio Alemán, Concepción, Chile; 10) Departamento de Medicina Fetal, Clínica Reina Sofía, Universidad Colsánitas, Bogotá, Colombia.

Objectives To compare between the outcomes of fetuses with apparently isolated macrocephaly and syndromic ones. To present the prenatal findings and postnatal diagnoses in children with syndromic macrocephaly. Methods We reviewed the files of all patients with fetal macrocephaly defined as a HC > 2 SD. All the patients were contacted and their development was evaluated. Results Adequate data was available for 97 patients, in 82 fetuses the macrocephaly was considered isolated (Group A), and in 15 fetuses associated anomalies were identified (Group B). Macrocephaly was diagnosed earlier in Group B patients (28.7 vs. 31.4 weeks , p = 0.028); the head circumference in Group B patients was larger (Z score 3.0 vs. 2.4, p<0.001). Group B CNS associated findings, as demonstrated by US and MRI, included mild ventriculomegaly (7), malformations of cortical development (7), callosal abnormalities (6), overdeveloped sulcation (3), large CSP (3), large subarachnoid space (2), mega cisterna magna (2), large 3rd ventricle (2); and periventricular pseudocyst, open operculum , and vermian dysgenesis (1 each). Syndromic diagnosis was reached in utero in 5 fetuses and after birth in 2. In 8 patients associated malformations were confirmed after birth but a specific diagnosis was not made. In Group A one child was diagnosed as having infantile autism. Conclusions: when fetal macrocephaly is associated with other brain or systemic anomalies the diagnosis of syndromic macrocephaly can be made in utero. Most fetuses with syndromic macrocephaly have a HC more than 2.5 SD above the mean.

2477/F

Pan-Ethnic Diagnosis of Trisomy 21 from Chorionic Villi mRNA Using High Frequency Coding-Single Nucleotide Polymorphism (cSNP) Allele Ratios. *J.A. Tynan[1], C. Deciu[1], L. Cagasan[1], M. Roy[1], J. Clemens[1], D. van den Boom[2], P. Oeth[2].* 1) Sequenom Center for Molecular Medicine, San Diego, CA; 2) Sequenom, Inc., San Diego, CA.

The measurement of allele ratios in coding SNPs (cSNPs) is useful for elucidating differential allele and tissue specific gene expression as it applies to molecular pathologies associated with loss of heterozygosity, gene amplification or loss, tissue transplantation and genetic imprinting. Prior research in prenatal diagnostics used the PLAC4 rs8130833 cSNP allele ratio measurement to detect fetal aneuploidy in mRNA isolated from maternal plasma (Lo et. al., Nat Med 13,218-223, 2007). To explore the expanded clinical viability of this methodology further, we screened a set of cSNPs from placentally expressed transcripts for their ability to detect chromosome 21 trisomy. Transcripts with increased expression in placenta versus maternal peripheral blood mononuclear cells were identified using an Affymetrix Human Exon 1.0 ST Array. SNPs within coding regions of these transcripts and with HapMap minor allele frequency greater than 5% in all populations were then selected. 155 cSNPs were screened, and four multiplexes, each consisting of 17 cSNPs, were developed after filtering assays based on multiple performance metrics. These 4 multiplexes were assessed using chorionic villi mRNA derived from 114 euploid and 11 trisomy 21 placental tissue samples. Heterozygous cSNP allele ratios were calculated from the peak area of single base primer extension products measured by MALDI-TOF mass spectrometry (MassARRAY®). A 10-fold cross-validated Mixture Discriminant Analysis classification algorithm was used to differentiate trisomy 21 positive samples from euploid samples. Two of the 17-plexes independently classified all trisomy 21 and normal samples correctly with complete population coverage; the remaining two multiplexes did not confer complete population coverage. These results demonstrate the ability to use multiplexed cSNP allele ratios in differentially expressed transcripts to distinguish copy number variations between affected and normal individuals for aneuploidy diagnosis from chorionic villi. The use of this strategy may be beneficial to monitor other allele specific gene expression or loci alterations in diverse biological events, for example, as seen with genes in the HER-2 amplification region on chromosome 17 associated with breast cancer.

2478/F

Inherited, presumably non pathogenic, genomic deletion unmasks a rare severe autosomal recessive disorder in a fetus. *H. Yonath[1, 2], H. Reznik-Wolf[1], N. Goldstein[1], Y. Bar-Joseph[1], M. Dushnitzki[1], D. Yagel[2], M. Berkenstadt[1], L. Peleg[1], M. Frydman[1,2], E. Pras[1,2].* 1) Inst Human Gen, Sheba Med Ctr, Ramat Gan, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Israel.

Prenatal Chromosomal Microarray was sent due to parental anxiety and increased beta HCG (3.03 MOM). The fetus and father were both found to carry a 224 Kb deletion on 5q21.1. The region includes two genes: *ERCC8* and *NDUFAF2*, the first known to cause Cockayne Syndrome. Concerned by the possible existence of intra-genic mutation on the maternal allele we sequenced both genes in the fetus and detected a homozygous deletion of exon 3 in *ERCC8*. For verification, we performed the following analysis: 1. Amplification of the segment between intron 2 and 4. The normal segment is about 11 Kb long. In the father and controls we could not amplify this segment, while in the mother and fetus a 3Kb fragment appeared. 2. cDNA was extracted from the mother’s peripheral lymphocytes. She was found to have multiple transcripts, as previously described in deletion carriers in *ERCC8* . 3. MLPA of *ERCC8* in the mother disclosed only one copy of exon 3. Although detailed ultrasound studies did not reveal any abnormalities in the fetus, the pregnancy was terminated at 30 weeks. Fibrobalsts and amniocytes from the fetus revealed impaired DNA recovery after 17 hr of UV exposure, thus confirming the diagnosis of Cockayne Syndrome. This is the first diagnosis of Cockayne Syndrome in such a manner. While *denovo* deletions in a prenatal setting strongly suggest a significant medical problem in the fetus, deletions inherited from a healthy parent impose a much greater diagnostic challenge. This case highlights the risk of a deleterious mutation on the second allele in a fetus with an inherited abnormality that includes genes associated with autosomal recessive disorders, and emphasizes the need for genetic counseling and possible evaluation when a deletion or duplication is inherited from a normal parent.

2479/F

Assessing the Combined Significance of SNPs in Candidate Genes for Preterm Birth. *B. Feenstra[1], F. Geller[1], H. Zhang[1], H.A. Boyd[1], K.K. Ryckman[2], J.R. Shaffer[3], J.M. Dagle[2], D.E. Weeks[2], M.L. Marazita[3], E. Feingold[3], J.C. Murray[2], M. Melbye[1].* 1) Department of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 2) Department of Pediatrics, University of Iowa, Iowa City, IA; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Background: Genome-wide association studies (GWAS) provide a vast body of genetic data and often the initial analysis results in single SNPs reaching genome-wide significance and these results can be replicated swiftly. Some of these SNPs are located near candidate genes, some are in regions where no known gene is close by. It is often the case, though, that GWAS cast doubt on earlier candidate gene studies, which claimed significance observing high risks with moderate sample sizes. Currently, candidacy of genetic regions is usually not in the focus of initial analyses, although sometimes a less stringent significance threshold for SNPs in candidate genes is chosen to prioritize these at the replication stage. With our recent GWAS of preterm birth not resulting in an immediate genome-wide significant finding, we decided to take a closer look at the gene level. Aim: We investigated a broad list of more than 200 genes putatively related to preterm birth in 713 children born at gestational age of less than 37 weeks and 982 control children born at a gestational age from 39 to 42 weeks. These genes are involved in detoxification, infection/inflammation, hormonal regulation, membrane integrity, and hemostasis - all pathways proposed as playing a role in initiating or modifying labor. Results: Set Level Association Testing, a method suggested by de la Cruz et al., was applied, which assesses the significance of SNP sets taking into account the linkage disequilibrium structure between the SNPs. Our sets are based on gene positions +/-50 kb. None of the genes reached the Bonferroni-adjusted significance threshold. However, the order of the genes differs from an order based on minimum p-value in the set of SNPs, warranting further investigation. Conclusions: Several GWAS have identified multiple independent signals in one genetic region, e.g., chromosome 8q24. Set-based approaches provide an interesting method to judge the significance of genetic regions, and SNP sets in candidate genes are an obvious starting point.

Methotrexate and Misoprostol Teratogenicity: Further Expansion of the Clinical Manifestations. *C. Kozma, J. Ramasethu.* Department of Pediatrics, Georgetown University Hospital, Washington, DC.

We describe a baby boy who was exposed to Misoprostol and Methotrexate in the first trimester of gestation as a result of a failed medical abortion. He presented with severe growth retardation, skull defects, proptotic eyes, cleft palate, and severe micrognathia. There were bilateral reduction deformities of the upper and lower extremities, missing and hypoplastic ribs, and undescended testicles. He had clinical features of pulmonary hypoplasia with severe persistent pulmonary hypertension and remained ventilator dependent until he expired. An autopsy revealed brain anomalies consistent with arrhinencephaly. Methotrexate is frequently used in conjunction with misoprostol to induce medical abortion, an off-label use as abortifacient. Both of these medications are well-established teratogens and have an X classification during pregnancy. Data from five patients who were exposed to both medications in the first trimester indicate a significant teratogenic risk to the developing fetus. Reported anomalies include growth retardation, absence or hypoplasia of the frontal bones, craniosynostosis, large fontanelle, ocular hypertelorism, short palpebral fissures, wide nasal bridge, malformed and low set ears, and micrognathia. Skeletal anomalies are frequent consisting of syndactyly, mesomelic shortening of the forearms, missing ribs, dislocated hips, and talipes equinovarus. The findings in our case are consistent with the pattern of abnormalities that have been reported in the literature. In addition, our patient had severe pulmonary hypoplasia and brain malformations, anomalies that have not been described previously. This case adds to the further documentation of the teratogenic effects of methotrexate and misoprostol on the developing fetus.

New autosomal dominant ataxia loci in Norwegian families. *J. Koht[1,2,5], G. Stevanin[2,3,4], A. Durr[2,3,4], E. Mundwiller[2,3], A. Brice[2,3,4], K.K Selmer[7], W. Carpentier[6], C.M.E. Tallaksen[1,5].* 1) Department of Neurology, Oslo University Hospital, Ullevål, Oslo, Norway; 2) INSERM U975, Groupe Hospitalier Pitié Salpêtrière, Paris, France; 3) 4UPMC Univ. Paris 6, UMR_S975, Centre de Recherche de l'Institut du Cerveau et de la Moelle épinière, CNRS 7225, Groupe Hospitalier Pitié- Salpêtrière, Paris, France; 4) APHP, Groupe Hospitalier Pitié Salpêtrière, Département de Génétique et Cytogénétique, Paris, France; 5) Faculty of Medicine, University of Oslo, Oslo, Norway; 6) P3S platform, Pitié-Salpêtrière Hospital, Paris France; 7) Department of clinical Genetics, Oslo University Hospital, Ullevål, Oslo, Norway.

Introduction: Autosomal dominant cerebellar ataxias are a clinically and genetically heterogeneous group of neurodegenerative disorders primarily characterized by unsteadiness, progressive gait and limb ataxia and dysarthria. Over 30 dominant spinocerebellar ataxias (SCA) are described, of these 16 with known genes. The number of SCA is increasing with SCA1,2,3,6 and 7 as the most common variants. The prevalence of dominant ataxias has been estimated to 4.3 in 100 000 in the Norwegian population. We recently demonstrated that only 8% of the Norwegian families are associated with SCA1,2,3,6 and 7, with many families presenting a mild progressive ataxia. Method: We selected two large 4 generation families (NOR-JON and NOR-THO) from our dominant ataxia cohort and excluded mutations in the SCA1,2,3,6, 7 and 14 genes. Whole genome linkage analysis was performed using the Illumina Linkage Panel of 6090 SNPs and additional microsatellite markers in regions with positive LOD scores. Results: The NOR-JON family displayed a very late-onset, slowly progressive, autosomal dominant cerebellar ataxia. The mean age at onset was 62 years and the first symptoms were unsteadiness and dizziness. All revealed saccadic pursuit and 5 of 7 affected subjects had pyramidal signs. MRI of the cerebrum revealed slight atrophy of the cerebellum. The genome-wide screening analysis identified significant linkage with chromosome 10 markers with a maximum multipoint LOD score of 3.1. Haplotype analysis defined a critical region of 10 cM distinct from other reported SCA loci. The NOR-THO family displayed an early onset, very slowly progressive, autosomal dominant ceebellar ataxia. The mean age of onset was 6 years. All had saccadic pursuit and pyramidal signs. MRI of the cerebrum revealed cerebellar atrophy. This family was linked to markers on chromosome 3 with a maximum bi-point LOD score of 4.02 in a critical region of 23 cM. Conclusion: We describe two Norwegian families with autosomal dominant ataxia with linkage to new loci on chromosome 3 and 10 distinct from other SCA loci. Candidate genes within the critical interval are currently screened for mutations.

2482/W

Variation in GRM7 is associated with multiple features of presbycusis. *D.L. Newman[1,2], R. Parody[3], J. Ohmen[4], L. Fisher[4], D.R. Frisina[2], R.D. Frisina[2,5], R.A. Friedman[4].* 1) School of Biological & Medical Sciences, Rochester Institute Technology, Rochester, NY; 2) International Center for Hearing and Speech Research, National Technical Institute for the Deaf, Rochester Institute of Technology, Rochester, NY; 3) John D. Hromi Center for Quality & Applied Statistics, Rochester Institute of Technology, Rochester, NY; 4) House Ear Institute, Los Angeles, CA; 5) Depts of Otolaryngology, Biomedical Engineering, Neurobiology and Anatomy, University of Rochester School of Medicine and Dentistry, Rochester, NY.

Age-related hearing loss, or presbycusis, is a common condition of the elderly that results in significant difficulties in daily life. Presbycusis is typified by a progressive loss of sensitivity to tones, starting at the highest frequencies, inability to discern between speech sounds, lengthening of the minimum discernable temporal gap in sounds, and a decrease in the ability to filter out background noise. The cause of presbycusis is well established as a combination of environmental and genetic factors. All previous research into the genetics of presbycusis has focused solely on pure tone thresholds. A few loci have been identified based on pure tones as having a likely role in susceptibility to this type of hearing loss; GRM7 is the only gene that has achieved genome-wide significance in a GWAS of age-related hearing loss susceptibility. We examined the association of GRM7 variants identified from the previous study, which was done in a European cohort with Z-scores based on pure-tone thresholds, in our European-American population from Rochester, NY (N=725), using a variety of phenotypes related to presbycusis. Principle Components Analysis was used to define factors to test against genotypes using MANOVA. We found that GRM7 was associated not only with the component related to pure tone thresholds, but also with the independent components of gap detection and hearing in noise.

Clinical and genetic characterization of a new childhood leukodystrophy: Tremor-Ataxia with Central Hypomyelination (TACH). *G. Bernard[1], I. Thiffault[2], T. Martine[1], M.L. Putorti[1], I. Bouchard[3], M. Sylvain[3], S. Melançon[4], R. Laframboise[3], P. Langevin[3], J.-P. Bouchard[5], M. Vanasse[6], A. Vanderver[7], G. Sébire[8], B. Brais[1].* 1) Research Center CHUM-Notre-Dame, Montreal, Quebec, Canada; 2) Montreal Neurological Institute, Montreal, Quebec, Canada; 3) CHUL, Centre Mère-Enfant, Quebec, Quebec, Canada; 4) Montreal Children's Hospital, Montreal, Quebec, Canada; 5) CHA, Enfant-Jésus Hospital, Québec, Québec, Canada; 6) Ste-Justine Hospital, Montreal, Quebec, Canada; 7) Children's National Medical Center, Washington DC, USA; 8) CHUS, Sherbrooke, Quebec, Canada.

PURPOSE: Leukodystrophies are a heterogeneous group of degenerative disorders characterized abnormal white matter on brain imaging. The clinical manifestations include upper motor neuron signs, developmental and/or cognitive regression with or without other neurological signs. It is estimated that up to 40 percent of patients with leukodystrophy are left without a precise diagnosis despite extensive investigations. Here, we present the clinical features and the locus of a new form of childhood-onset leukodystrophy: Tremor-Ataxia with Central Hypomyelination (TACH). METHOD: We have recruited a group of eight (1 deceased) French-Canadian children affected by a childhood-onset leukodystrophy of unknown cause. All cases have ancestors originating from the same regions of Quebec province known for genetic founder effects. We completed a detailed clinical evaluation of each patient and performed a genome scan with the Illumina Hap310 or Hap610 SNP chip on seven affected individuals and at least one non-affected family member. RESULTS: All cases presented with motor regression and were found to have upper motor neuron signs, as well as cerebellar ataxia, tremor, dysarthria, and dysmetria. Cognition seemed to be relatively preserved. Homozygosity mapping uncovered a shared chromosomal region of 3.98 Mb not previously associated with a leukodystrophy. CONCLUSION: This study presents the clinical description of a new childhood-onset leukodystrophy and the mapping of its original chromosomal locus. Identification of the mutated gene will allow physician to provide a precise diagnosis and genetic counseling to the patients and their families. It will also improve our understanding of neurodegeneration in leukodystrophies and hopefully, provide potential therapeutic targets.

Homozygosity in 1q44 presenting with microcephaly and corpus callosum abnormalities. *H. Carlson-Donohoe[1], T. Markello[2,3], C. Tifft[2,3], G. Golas[2,3], D. Adams[1,3], K. Fuentes-Fajardo[3], W.A. Gahl[1,2,3].* 1) Medical Genetics Branch, National Human Genome Research Institute, Bethesda, MD; 2) Office of the Clinical Director, National Human Genome Research Institute, Bethesda, MD; 3) Undiagnosed Diseases Program, National Institutes of Health, Bethesda, MD.

Single copy deletions in 1q44 are associated with agenesis of the corpus callosum and microcephaly. Despite extensive mapping and sequencing in the critical deletion region no gene has been validated as the cause of this phenotype in humans, although a similar phenotype in mice is caused by a recessive deletion of the *AKT3* gene. We analyzed this region as part of a genome-wide SNP array survey in a family with a single affected 6 year old male. The proband was admitted to the NIH Clinical Center through the Undiagnosed Diseases Program presenting with progressive global brain volume loss, agenesis of the corpus callosum, and developmental regression. Illumina Omni1-Quad SNP chip results revealed a single 4.7 Mb region of anomalous continuous homozygosity in 1q44 beginning with rs4658571. This region of homozygosity was not seen in any other family member, including two unaffected siblings who were determined to have the opposite parental haplotypes in the 1q44 region on both copies of chromosome 1. The total fluorescent hybridization intensity was normal throughout the region, excluding any deletion greater than a few kilobases. Analysis of the rest of chromosome 1 demonstrated no segmental uniparental disomy. Capillary sequencing of the exons of *AKT3* and the ultra conserved sequences uc.45 and uc.46 were normal on both chromosomes. We plan to sequence the remaining 4.7 Mb using regional capture technology and Next-Gen Sequencing to detect all coding and non-coding mutations. Finding a homozygous mutation in this patient may provide insight into the mechanism of the microcephaly and corpus callosum phenotype seen in the 1q44 deletion syndrome.

2485/W

Combination of "benign" CNVs predisposing to Autism Disorder in two affected brothers. *C. Castronovo[1], D. Rusconi[1], L. Larizza[1,2], M.T. Bonati[3], P. Finelli[1,4].* 1) Laboratorio di Citogenetica Medica e Genetica Molecolare, Istituto Auxologico Italiano, Milano, Italy; 2) Divisione di Genetica Medica, Dipartimento di Medicina, Chirurgia e Odontoiatria, Facoltà di Medicina e Chirurgia, Ospedale San Paolo, Università degli Studi di Milano, Milano, Italy; 3) Ambulatorio di Genetica Clinica, Istituto Auxologico Italiano, Milano, Italy; 4) Dipartimento di Biologia e Genetica per le Scienze Mediche, Università degli Studi di Milano, Milano, Italy.

Autism Disorder (AD) is a complex neurodevelopmental disorder characterized by impairment of social interaction, communication and repetitive behavior. De novo and inherited submicroscopic Copy Number Variations (CNVs) are emerging as major category of genetic risk for AD, accounting for about 10-20% of cases. We report on two brothers - 12 and 5 years of age - affected from AD and classified as high-functioning and fully autistic, respectively, by using ADI/ADOS scales. High resolution array-CGH analysis identified a few heterozygous inherited microrearrangements, shared by the siblings and reported as polymorphic CNVs in healthy people: a 252 kb deletion at 16p11.2 and two duplications at 17q21.31, 31 and 129 kb in size, which target the same sequence, one on each allele. The 16p11.2 deletion was inherited from the mother - suspected to bear it in a mosaic condition - as well as the largest duplication at 17q21.31, whereas the smallest derived from the father. We suggest that the shared CNVs, singly or combined, may be good candidate loci for AD. Both the microduplications in 17q21.31 interrupt the KIAA1267 gene, encoding for a hypothetical protein specifically expressed in the brain. CNVs affecting the same locus have been already described in autistic patients but in a heterozygous state. In our two siblings we found both alleles affected in a compound heterozygous state, likely resulting in the lack of protein expression. The CNV at 16p11.2 targets the same region disrupted by a de novo t(7;16)(p22.1;p11.2) carried by an autistic patient. This deletion is located proximally to SLC6A10 gene, paralogous to SLC6A8 on Xq 28 which has been found mutated in individuals with mental retardation, with or without autism. SLC6A10, a member of transporter protein family responsible for the uptake of neurotransmitters, is expressed in brain with a possible function in neurodevelopment. In order to understand the pathogenic role in AD of the identified CNVs, we are planning further investigations to: i) confirm the disruption of KIAA126 alleles through the two different intragenic duplications; ii) verify by BAC i-FISH the mosaicism of 16p11.2 deletion in the mother which may almost in part explain the contrasting phenotypes; iii) study the possible creatine transport perturbation by biochemical screening (creatine/creatinine dosage) as well as further SLC6A8 anomalies on Xq28, which may contribute to the phenotype onset.

Association of myocardial infarction-associated SNPs with ischemic stroke: a meta-analysis of three European Caucasian populations. *Y. Cheng[1], C.D. Anderson[2,3,4], M. Nalls[5], A. Biffi[2,3,4], L. Cortellini[2,3,4], N.S. Rost[2,3,4], K.L. Furie[2,3], T.G. Brott[6], R.D. Brown, Jr.[7], D. Hernandez[5], M. Matarin[5], J.W. Cole[8], O.C. Stine[1], J.R. O'Connell[1], S.J. Kittner[8], J. Rosand[2,3,4], J.F. Meschia[6], B.D. Mitchell[1].* 1) Department of Medicine, University of Maryland, Baltimore, MD; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 3) Department of Neurology, Massachusetts General Hospital, Boston, MA; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 5) National Institute of Aging, Bethesda, MD; 6) Department of Neurology, Mayo Clinic, Jacksonville, FL; 7) Department of Neurology, Mayo Clinic, Rochester, MN; 8) Department of Neurology, University of Maryland, Baltimore, MD.

Background — Stroke is the third leading cause of death in the United States. Ischemic stroke, which is caused by the blockage of blood flow to the brain, shares many common risk factors with coronary artery disease. We hypothesized that genetic variants associated with myocardial infarction (MI) are also associated with the risk of ischemic stroke.

Methods — Eleven previous identified MI-associated SNPs were evaluated for their associations with ischemic stroke in 2,441 cases and 3,189 controls from three European Caucasian case-control studies, including the Genetics of Early Onset Stroke (GEOS) study, Ischemic Stroke Genetics Study (ISGS) and the Massachusetts General Hospital (MGH) study. The previously identified MI-associated SNP, or a surrogate SNP in high LD ($r^2 > 0.8$) with it, was genotyped by the Illumina or Affymetrix GWAS platform used in the respective studies. Imputed genotypes were used in the ISGS study. A genotype risk score was also computed for each individual by summing the number of MI-risk alleles across each of the 11 loci. Logistic regression, adjusted for age, sex, study-specific covariates, was performed within each study to obtain study-specific betas and p-values under an additive model. Meta-analysis of the three studies was conducted using both a sample-size weighted and an inverse variance weighted approach as implemented in the METAL software program.

Results — Despite having 80% power to detect odds ratios of 1.12 - 1.19 (at allele frequencies = 0.10 - 0.50) in the combined sample, none of the 11 MI-associated SNPs were significantly associated with ischemic stroke in any of the studies individually or in the meta-analysis. However, the genotype risk score was significantly associated with risk of ischemic stroke, with each additional MI-risk allele associated with a 1.04-fold increase in the odds of stroke (95% CI: 1.01-1.07; meta-analysis P =0.006).

Conclusions — None of the individual MI-associated SNP was significantly associated with ischemic stroke in this study of European Caucasians. However, these previously identified MI risk alleles increased stroke risk on average by 4% per allele.

2487/W

P53 gene Arg72Pro polymorphism and Sporadic Amyotrophic Lateral Sclerosis. *E. Ergul[1], M.D. Sozuguzel Ozel[1], A. Sazci[1], H.A. Idrisoglu[2].* 1) Medical Biology and Genetics, Faculty of Medicine, University of Kocaeli,Umuttepe, 41380, Kocaeli, Turkey; 2) Department of Neurology, Faculty of Medicine, University of Istanbul, Capa, 34280,Istanbul, Turkey.

Amyotrophic lateral sclerosis (ALS) is a devestingly progressive and eventually fatal neurodegenerative disorder affecting motor neuron cortex, brain stem and spinal cord, and leading to muscle wasting, weakness and profound paralysis.To examine an association between p53 gene Arg72Pro (rs1042522) polymorphism and sporadic amyotrophic lateral sclerosis (SALS), we genotyped 394 Turkish SALS patients and 439 matched healthy controls by a PCR-RFLP technique. We obtained a statistically significant association between female SALS patients with 72AP genotype and female healthy controls (X2=4.102; P=0.043). Consequently it appears that p53 Arg72Pro polymorphism is associated with SALS in a gender specific manner.

2488/W

Vascular endothelial growth factor -2578C/A polymorphism and amyotrophic lateral sclerosis. *Y.T. Esengul[1], E. Ergul[1], M.D. Sozuguzel Ozel[1], A. Sazci[1], H.A. Idrisoglu[2].* 1) Medical Biology and Genetics, Faculty of Medicine, University of Kocaeli,Umuttepe, 41380, Kocaeli, Turkey; 2) Department of Neurology, Faculty of Medicine, University of Istanbul, Capa, 34280,Istanbul.

Amyotrophic lateral sclerosis(ALS) is a exceptionaly progressive and eventually fatal neurodegenerative disorder. Motor neurons of the motor cortex, brainstem, and spinal cord are affected, leading to muscle wasting, weakness and profound paralysis. The incidence and prevalence of ALS are 1-2 and 4-6 per 100 000 people each year in the world. Vascular endothelial growth factor (VEGF) plays a critical role in the induction of angiogenesis.- Mice with a subtle deletion of the hypoxia response element in the VEGF promoter, causing reduced VEGF expression, leading to adult-onset motor neuron degeneration, reminiscent of ALS. Studies in human gave conflicting results. We genotyped 385 SALS patients and 312 healthy controls to show whether VEGF -2578C/A(rs699947) polymorphism was implicated in SALS by using a PCR-RFLP method. In conclusion, There was no association between VEGF -2578C/A polymorphism and SALS(X2=0.533; P=0.766).

Very High-Density Linkage Survey of Schizophrenia and Bipolar Disorder Families Reveals Genetic Overlap and Implicates Novel Regions and Genes. *A. Fanous[1,2,3], F. Middleton[4], R. Amdur[1,2], B. Maher[3], H. Medeiros[5], K. Gentile[4], J. Knowles[5], M. Azevedo[6], M. Pato[5], C. Pato[5].* 1) Washington VA Medical Center, Washington, DC; 2) Georgetown University School of Medicine, Washington, DC; 3) Virginia Commonwealth University School of Medicine; 4) Upstate Medical University, Syracuse, New York; 5) University of Southern California, Los Angeles, California; 6) Psychiatry Service, Ponta Delgada, Azores, Portugal.

Background: Recent family and GWAS studies strongly suggest shared genetic risk factors for schizophrenia (SZ) and bipolar disorder (BP). Linkage studies have not been rigorously used to test this hypothesis. Methods: Fifty-one families with at least one sibpair concordant for either SZ or psychosis (PSY, which includes either SZ or psychotic BP) were genotyped using the Affymetrix 50K Xba SNP array. NPL and LOD scores for SZ, BP, and PSY were calculated in Merlin. Empirical significance was calculated using 1000 gene-dropping simulations. Chromosomes with loci linked to BOTH SZ and BP were counted. Empirical significance of joint linkage was determined by a) the number of simulated BP scans having the same number of loci jointly linked with the real SZ scan, and b) the number of simulated SZ scans having the same number of loci jointly linked with the real BP scan. Results: For SZ and PSY, several regions previously linked in this and other samples were suggestively linked. For BP, chromosome 1p36 (11.54-15.71 MB) achieved significance with a LOD of 3.51; as did chromosome 11p (89.32-90.15 MB) with an NPL of 4.15. The 95% CI of the latter corresponded extremely closely to the physical coordinates of DLG2, which encodes postsynaptic density protein PSD-93. Four chromosomes had loci at which both SZ and BP had NPL≥1.98 (empirical P=.01 using simulated SZ scans; .07 using simulated BP scans). Conclusions: Using higher-density marker maps than used in any previous SZ and BP linkage study, we observed a) significant linkage to 1p36, which was not observed using sparser maps; b) for the first time we know of, significant linkage of any psychiatric disorder (BP) implicating only one gene (DLG2); and c) confirmation of genetic overlap between SZ and BP.

2490/W

Association study of TCI scale and genetic variants of DRD4, DAT1 and 5HTT with bipolar disorder in the Japanese. *L. Gotoh, N. Oribe, A. Takata, H. Mitsuyasu, H. Kawasaki, S. Kanba.* Dept Neuropsychiatry, Kyushu Univ, Fukuoka, Japan.

Bipolar disorder (BD) is a common, severe, chronic, and life-threatening psychiatric illness where patients alternate between episodes of depression and mania. Detailed pathophysiology of BD is still unclear, but family, twin and adoption studies consistently indicate a strong genetic component. Therefore, a number of genetic studies of BD have been conducted. In particular, genes related to the serotonin and dopamine neurotransmissions were regarded good candidate genes for BD. Furthermore, some reports suggested that several dimensions of temperament and character inventory (TCI) scale correlated with BD. TCI scale is constructed with 7 dimensions including 4 temperaments which was involved in several monoaminergic neurotransmissions in the CNS and 3 characters. It was reported that BD patients showed the low self-directedness (SD) score and high harm-avoidance (HA) and self-transcendence (ST) scores of TCI and that the genetic variants affected the scores of TCI. Therefore, we performed an association study of BD or TCI score and some genetic variants (serotonin transporter (5HTT); 44-bp insertion/deletion polymorphism in the promoter region (SERTPR) and variable number of tandem repeats (VNTR) in second intron (SERT-in2), dopamine D4 receptor (DRD4); 48-bp VNTR in exon3 and dopamine transporter (DAT1); 40-bp VNTR in 3' UTR). Fifty Japanese BD patients diagnosed using the Structured Clinical Interview for DSM-IV (SCID) and 50 Japanese normal controls (NC) were included in this study. All subjects were given informed consent before blood collection strictly based on the ethical regulations of Kyushu University. These genetic variants were genotyped by electrophoresis after PCR amplification and association analyses were performed. As a result, comparing of genetic variants and disease, SERTPR indicated statistically significant difference between BD and NC, whereas other genetic variants showed no differences. In comparison of genetic variants and TCI scores, only DAT1-VNTR showed significances in Extravagance score (NS3; a subscale of novelty-seeking (NS)) and in analysis of disease and TCI scores, the HA and SD scores indicated significant differences. Thus, it was able to hypothesize that the genetic variants which were analyzed in this study, affected TCI scores and pathophysiology of BD respectively but not concurrently. Further analysis with more samples and genetic variants is now in progress.

2491/W

The role of *Chrna6* and *Chrnb3* genes in alcohol behaviors using mouse models. *N. Hoft[1], H. Kamens[1], J. Miyamoto[1], M. Ehringer[1,2].* 1) Inst Behavioral Genetics, Univ Colorado, Boulder, CO; 2) Department of Integrative Physiology, Univ Colorado, Boulder, CO.

Genes encoding the α6 and β3 nicotinic acetylcholine receptor subunits (*CHRNA6* and *CHRNB3*) have been associated with early subjective response to nicotine (Zeiger et al, 2008; Ehringer et al, 2010) and nicotine dependence (Bierut et al, 2007; Saccone et al, 2007; Hoft et al, 2009). It is well-known that tobacco and alcohol use behaviors are highly co-morbid (Kendler et al, 2007), and functional evidence from pharmacology and animal models (Cardoso et al, 1999; Zuo et al, 2004; Butt et al, 2004) supports the hypothesis that nicotinic receptors may be a common site of action for these two drugs in the dopaminergic system. We recently found evidence for association between the *CHRNB3/A6* gene cluster and alcohol behaviors in humans (Hoft et al, 2009). Furthermore, we have performed in vitro assays showing that variations (SNPs) in the promoter region of the human *CHRNB3* gene may lead to differences in gene expression (Ehringer et al, 2010). We are now engaged in testing knock-out (KO) mice, which lack either the *Chrna6* or *Chrnb3* gene. Specifically, we are examining whether the KO animals show differences in voluntary alcohol consumption (two-bottle preference), sensitivity to alcohol (loss of righting reflex and acute functional tolerance), or alcohol induced ataxia (a balance test). Preliminary data suggest that the *Chrnb3* KO mice may drink less alcohol than their wild-type littermates, while differences in animals lacking *Chrna6* are less clear. For the sensitivity measures, preliminary data suggest that female mice lacking the *Chrna6* gene take significantly longer to recover righting reflex ($p<0.03$) indicating greater sensitivity than their wild-type littermates. Similarly the *Chrnb3* KO animals show a trend toward being slightly more sensitive to alcohol in that it took longer for them to recover from loss of righting (return of righting reflex) than their wild-type littermates. These results complement the human genetic studies, providing support for the *CHRNB3/A6* genes as potential contributors to the co-morbidity of alcohol and tobacco behaviors. This work was supported by NIH grants AA015336 (ME), DA017637 (NH), and AA017889 (NH, JM, HK).

Genome-wide gene expression and DNA methylation analyses of significantly discordant monozygotic twins for cognitive ability. *K. Kobayashi[1], M. Furukawa[1], C. Yu[1], C. Shikishima[2], J. Sese[3], H. Sugawara[4], K. Iwamoto[5], T. Kato[4], J. Ando[6], T. Toda[1].* 1) Div Mol Brain Sci & Neurol, Kobe Univ Grad Sch Med, Kobe, Japan; 2) Keio Adv Res Ctr, Keio Univ, Tokyo, Japan; 3) Dept Comput Sci, Ochanomizu Univ, Tokyo, Japan; 4) Lab Mol Dynam Mental Disord, RIKEN BSI, Saitama, Japan; 5) Dept Mol Psychiatry, Grad Scl Med, Univ Tokyo, Tokyo, Japan; 6) Fac Letters, Keio Univ, Tokyo, Japan.

It has been suggested that intelligence is a multifactorial trait and is influenced by not only environmental but also genetic factors. Although the concordance rate in monozygotic (MZ) twins is much higher than in dizygotic twins, some MZ twins exhibit significant discordance in intellectual levels. The discordance could be caused by epigenetic differences between twins or de novo genomic mutations that occurred in either sib. Epigenetic differences are not accompanied with the changes of genomic sequence, so that gene expression analysis is a promising predictor of discordance-associated genes that are influenced by the epigenome. To investigate the genetic factors for intelligence, we extracted total RNA from lymphoblastoid cell lines of six pairs of MZ twins with significantly discordant intelligence quotient (IQ) and performed gene expression analysis by using Affymetrix gene expression microarrays. The expression data were normalized for each pair with Robust Multichip Average method and analyzed with Gene Set Enrichment Analysis method to identify differentially expressed gene sets between the sibs. As a result, we found that some gene sets related to immunological response tend to be up-regulated in the sibs with lower IQ. Next, we also conducted the DNA methylation analysis of the same twin pairs using the genome DNA derived from lymphocytes with Affymetrix human promoter array and Tiling Analysis Software. Quantile normalization and wilcoxon signed-rank test were performed for each pair to detect significantly methylated regions in one side of the sibs. On the candidate methylated regions identified by TAS, we could not find remarkable differences in methylation status between the sibs by bisulfite genomic sequencing. Further studies will be required to identify genes associated with intelligence.

2493/W

Evidence for an association of the *NOS1* and *NOS3* genes with stroke susceptibility. *H. Manso[1,2,3], T. Krug[1,4], J. Sobral[1,2,3], I. Albergaria[2], G. Gaspar[2], M. Correia[5], R. Taipa[5], M.R. Silva[6], J.P. Gabriel[6], G. Lopes[5], I. Matos[7], J. Jiménez-Conde[8], R. Rabionet[9], J.M. Ferro[10], S.A. Oliveira[1,4], A.M. Vicente[1,2,3].* 1) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 2) Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisbon, Portugal; 3) Center for Biodiversity, Functional & Integrative Genomics; 4) Instituto de Medicina Molecular, Lisbon, Portugal; 5) Serviço de Neurologia, Hospital Geral de Santo António, Porto, Portugal; 6) Serviço de Neurologia, Hospital de São Pedro, Vila Real, Portugal; 7) Serviço de Neurologia, Hospital Distrital de Mirandela, Mirandela, Portugal; 8) Neurology Unit, IMIM-Hospital del Mar, Barcelona, Spain; 9) Center for Genomic Regulation (CRG-UPF) and CIBERESP, Barcelona, Spain; 10) Serviço de Neurologia, Hospital de Santa Maria, Lisbon, Portugal.

Stroke is a leading cause of death and significant disability in western countries. It is a complex disease thought to result from the interplay between well-established environmental/life-style risk factors and genetic risk factors, still unknown for the most common forms of stroke. Clinical conditions, such as hypertension and atherosclerosis, also increase the risk of stroke. Several lines of evidence suggest that nitric oxide (NO) plays a role in hypertension and can have anti-atherosclerotic actions by regulating platelet function, leukocyte adhesion and diapedesis, by preventing vascular smooth muscle cells proliferation and by inhibiting LDL oxidation. The synthesis of NO is catalyzed by nitric oxide synthases (NOS) expressed in various tissues, encoded by the *NOS* genes. In the present study we investigated the role of *NOS1* and *NOS3*, which encode the neuronal and endothelial NOS, respectively, in stroke risk. 37 *tag* SNPs in *NOS1* (12q24.2-q24.31) and 5 *tag* SNPs in *NOS3* (7q36), were genotyped and tested for association with stroke risk in a population sample of 551 ischemic stroke patients and 530 control subjects. Logistic regression analysis was carried out to adjust for significant stroke risk factors: age, gender, hypertension, diabetes and ever smoking. 13 SNPs and 8 haplotypes in *NOS1* and 2 SNPs in *NOS3* were associated with stroke risk ($0.0002<P<0.0464$ and $0.0117<P<0.0379$, respectively); 4 SNPs and 1 haplotype in *NOS1* and 1 SNP in *NOS3* remained significant after correction for multiple testing. SNP imputation in and around the *NOS1* gene identified 7 additional SNPs associated with stroke risk ($P<0.01$). Preliminary *NOS1* sequencing results, for 7 exons including regions with the most significant associations, revealed one exonic synonymous alteration and two intronic base changes affecting donor and acceptor splice sequences. The significance of these sequence changes is under assessment. We further investigated the occurrence of epistasis (non-additive genetic interaction) between *NOS1* and *NOS3* variants, as it is expected to occur in complex disorders like stroke where genotype/phenotype correlations are non-linear. Using the multifactor dimensionality reduction method, we found no evidence for epistasis between *NOS1* and *NOS3*, indicating an independent effect of both genes. The present findings confirm the previous stroke association of *NOS3* and show novel evidence implicating *NOS1* gene variants in the susceptibility to ischemic stroke.

Mental retardation affects 2-3% of the population and shows a high heritability. Neurodevelopmental disorders that include pronounced impairment in language and speech skills occur less frequently. For most cases, the molecular basis of mental retardation with or without speech and language disorder is unknown due to the heterogeneity of underlying genetic factors. We have used molecular karyotyping on 1523 patients with mental retardation to detect copy number variations (CNVs) including deletions or duplications. These studies revealed three heterozygous overlapping deletions solely affecting the *forkhead box P1 (FOXP1)* gene. All three patients had moderate mental retardation and significant language and speech deficits. Since our results are consistent with a *de novo* occurrence of these deletions, we considered them as causal although we detected a single large deletion including *FOXP1* and additional genes in 4104 ancestrally matched controls. These findings are of interest with regard to the structural and functional relationship between FOXP1 and FOXP2. Mutations in *FOXP2* have been previously related to monogenic cases of developmental verbal dyspraxia. Both *FOXP1* and FOXP2 are expressed in songbird and human brain regions that are important for the developmental processes that culminate in speech and language.

The Gabbr1 and Gabbr2 genes are involved with addictive behavior: a study in different phenotypes of ethanol consumers. *A.F. Ribeiro[1], D. Correia[2], S. Chiavegatto[3], R. Boerngen-Lacerda[2], A.L. Brunialti-Godard[1].* 1) Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil; 2) Universidade Federal do Paraná, Curitiba, Paraná, Brazil; 3) Instituto do Coração, São Paulo, São Paulo, Brazil.

Studies involving humans and animals have shown the modulation of ethanol intake behavior mediated by GABAB receptor agonist (baclofen). The Gabbr1 and Gabbr2 genes codify two proteic subunits, GB1 and GB2, that compose the GABAB receptor. Presynaptically, the GABAB receptor inhibits dopaminergic, GABAergic, and glutamatergic systems, and alterations in these systems are well known to be associated with addictive behavior. In an attempt to understand the participation of GABAB in alcoholism, we used non-inbred, Swiss mice exposed to an addiction model based on a three-bottle free-choice paradigm (water, 5% v/v ethanol, and 10% v/v ethanol) consisting of four phases: acquisition (AC), withdrawal (W; first aversive stimulus), reexposure (RE), and quinine-adulteration (AD; second aversive stimulus). Based on their individual ethanol intakes, mice were divided into three groups: addicted (A; preference for ethanol during AC and no reduction in consumption in AD), non-addicted heavy-drinker (HD; preference for ethanol during AC and reduction after AD), and non-addicted light-drinker (LD; preference for water during all phases). For the molecular analysis, mRNA was quantified using real-time polymerase chain reaction in four dissected brain regions: prefrontal cortex, hypothalamus, hippocampus, and striatum. In the prefrontal cortex of animals in Group A, we found high Gabbr1 and Gabbr2 transcript levels, with significant Gabbr1 transcript levels compared with Groups C (control), LD, and HD. In the hippocampus of animals in Group A, Gabbr2 mRNA levels were significantly lower compared with Groups C, LD, and HD. In the striatum, we found a significant increase in Gabbr1 transcription compared with Groups C, LD, and HD. No differences in Gabbr1 or Gabbr2 transcript levels in the hypothalamus were observed among groups. We found molecular differences on transcript levels of the Gabbr1 and Gabbr2 genes in cerebral areas related to drug taking only mice behaviorally classified as addicted, suggesting that these genes contribute to ethanol addiction. Moreover, it was possible to visualize the dynamic of the answers of the Gabbr1 and Gabbr2 genes within different brain areas that are important for maintaining addictive behavior.

The impact of cytochrome P450 polymorphisms on verbal memory in HIV infected and at risk women. *E.E. Sundermann[1], L.H. Rubin[2], J.R. Bishop[3], K.M. Weber[4], M.H. Cohen[4], H. Crystal[5], V. Valcour[6], E.T. Golub[7], R. Karim[8], K. Anastos[9], C. Liu[10], P.M. Maki[1, 2].* 1) Psychology, University of Illinois, Chicago, Chicago, IL; 2) Psychiatry, University of Illinois, Chicago, Chicago, IL; 3) Pharmacy Practice, University of Illinois, Chicago, Chicago, IL; 4) The Core Center at Stroger Hospital of Cook County, Chicago, IL; 5) State University of New York Downstate Medical Center, Brooklyn, NY; 6) WIHS Center at the University of California, San Francisco, San Francisco, CA; 7) Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 8) WIHS Center at the University of Southern California, Los Angelos, CA; 9) Medicine, Montefiore Medical Center and Albert Einstein College of Medicine, Bronx, NY; 10) District of Columbia WIHS Center, Washington D.C.

Objective: Polymorphisms on genes encoding the cytochrome 450 enzyme (CYP1A1 and CYP1B1) influence estrogen catabolism and have been associated with mood and menopause symptoms. Estrogen impacts certain cognitive abilities, including verbal memory. Although verbal memory can vary in relation to estrogen polymorphisms, particularly in African-American women, the relationship between certain CYP genes and verbal memory is unknown. We examined CYP genes in relation to verbal memory among a sample of women enrolled in the Women's Interagency HIV Study (WIHS). Methods: Participants included primarily African American, premenopausal and perimenopausal women from the WIHS who consented to genetic testing and completed the Hopkins Verbal Learning Test (HVLT). Functional SNPs on the CYP1A1 (rs2606345) and CYP1B1 (rs1056836) genes were examined due to their previous association with estrogen-related clinical outcomes in a healthy population. Linear regression was used to test the association between CYP SNPs and verbal memory scores (HVLT immediate and delayed recall trials) after adjusting for relevant covariates under an additive model. Results: The sample included 412 HIV-infected and 198 HIV-uninfected women (age range 23-57, 71% African-American). In unadjusted analyses, the CYP1A1 SNP was associated with both immediate ($p<0.05$) and delayed ($p<0.001$) recall scores, and the CYP1B1 was associated with delayed recall scores ($p<0.05$). In analyses adjusted for age, depression, HCV, race, menopause status, educational attainment and illicit drug use, only the CYP1A1 SNP was associated with verbal memory; the CC genotype was associated with lower delayed recall compared to the AA genotype ($\beta=0.09$, $p<0.05$). When analyses were restricted to African American women only, the relationship between the CYP1A1 CC genotype and poorer verbal memory became stronger ($\beta= 0.11$, $p<0.001$). No significant interactions were observed between HIV serostatus and genotype group. HIV serostatus independently predicted verbal memory; HIV+ women performed significantly worse than HIV- women on immediate recall trials. Conclusion: Both HIV and CYP1A1 CC genotype are independent risk factors for poorer verbal memory performance. The effect of the CYP1A1 SNP on verbal memory was most pronounced among African American women. Findings suggest that changes in estrogen signaling, by way of a CYP1A1 polymorphism, impacts verbal memory, in addition to mood and menopause symptoms.

2497/W

Characterization of the Neuroglobin promoter and its response to amyloid beta in vitro. *M. Szymanski[1], R. Wang[2], S. Bassett[2], D. Avramopoulos[1,2].* 1) Inst Gen Med, Johns Hopkins Univ, Baltimore, MD; 2) Psychiatry, Johns Hopkins Univ, Baltimore, MD.

Alzheimer's disease (AD) is a late onset dementia with significant heritability. Brain pathology findings include plaques containing amyloid beta (A-beta) aggregates, a peptide suspected to be directly involved in the observed neuronal cell death. We previously reported strong linkage on chromosome 14q to AD using the presence or absence of co-morbid hallucinations as a covariate. Upon follow-up we reported that the gene encoding neuroglobin (NGB) contains SNPs with significant associations to AD and an expression profile in the temporal lobe that is consistent with a role in the disease risk. NGB is a vertebrate globin mainly expressed in neurons, and is shown by many studies to play a neuroprotective role. NGB expression is induced by hypoxia and ischemia in vitro and overexpression protects cells against hypoxia, ischemia, oxidative stress and from the toxic effects of A-beta in vitro and in vivo. Previously we showed that NGB RNA levels in the temporal lobe are reduced with advancing age and in females, both risk factors for AD. We also found that NGB expression is higher in AD affected brains, consistent with upregulation in response to the disease process. We have explored the NGB promoter region through constructs driving a luciferase reporter gene transfected into neuronal-like cells. We identified potential enhancer elements between -306 and -1142 and potential repressor elements between -1124 and -1568 from the transcription start site. Based on our results and the literature we hypothesized that A-beta likely upregulates NGB expression, perhaps through promoter elements present in our constructs. We tested our hypothesis on our longest reporter construct, treating transfected cells with a toxic fragment of A-beta, including amino acids 25 to 35. We found significant upregulation of the reported expression upon A-beta exposure, increasing with concentration and with time. Our results support previous observations on postmortem tissue and the hypothesis that Aβ induces NGB expression. We speculate that this is a defense mechanism and might be inadequate in AD patients. Further exploration of the mechanisms underlying the response to A-beta and the regulation of NGB might lead to targets for pharmacological intervention enhancing the NGB mediated neuroprotection against AD and stroke.

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease, is a fatal neurodegenerative disorder characterized by progressive wasting and weakness of limb, bulbar, and respiratory muscles. A candidate gene study suggested that mutations in angiogenin (*ANG*) are associated with ALS. However, subsequent studies have produced conflicting results. In this study we sought to elucidate the role of *ANG* in ALS by performing large sequencing experiments and incorporating data from previous studies into the analysis. We demonstrate an excess of rare mutations in ALS patients with $P = 1.62 \times 10^{-8}$ and OR = 27.37. Several patients carrying *ANG* mutations also demonstrated signs of Parkinson's disease (PD). Epidemiologic studies have also that relatives of ALS patients are at an increased risk for PD (RR = 3.0). We therefore explored the possibility that *ANG* may also predispose to PD. Statistical analysis showed an excess of rare mutations in PD with $P = 3.67 \times 10^{-4}$ with OR = 13.45. This study firmly establishes that *ANG* is involved in ALS and highlights the discovery of a novel risk gene for PD.

Inactivation of fibroblast growth factor binding protein 3 causes anxiety-related behaviors associated with attenuated phosphorylation of extracellular signal-regulated kinase in the orbitofrontal cortex. *Y. Yamanaka[1], A. Kitano[1], K. Takao[2], A. Prasansuklab[3], T. Mushiroda[3], K. Yamazaki[4], T. Abe[5], N. Iwata[6], T. Miyakawa[2], Y. Nakamura[7], T. Nakahata[1], T. Heike[1].* 1) Graduate School of Medicine, Kyoto University, Kyoto, Japan; 2) Genetic Engineering and Functional Genomics Unit, Kyoto University, Kyoto, Japan; 3) Laboratory for International Alliance, RIKEN Center for Genomic Medicine, Yokohama, Japan; 4) Laboratory for Genotyping Development, RIKEN Center for Genomic Medicine, Yokohama, Japan; 5) Laboratory for Animal Resources and Genetic Engineering, RIKEN Center for Developmental Biology, Kobe, Japan; 6) Department of Psychiatry, Fujita Health University, Toyoake, Japan; 7) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

The neurobiological mechanisms of emotional modulation and the molecular pathophysiology of anxiety disorders are largely unknown. The fibroblast growth factor (FGF) family has been implicated in the regulation of many physiological and pathological processes, which include the control of emotional behaviors. The present study examined mice with a targeted deletion of the fgf-bp3 gene, which encodes a novel FGF-binding protein, in animal models relevant to anxiety. To define the behavioral consequences of FGF-BP3 deficiency, we evaluated fgf-bp3-deficient mice using a number of anxiety-related behavioral paradigms that provide a conflict between the desire to explore an unknown area or objects and the aversion to a brightly lit open space. The fgf-bp3-deficient mice exhibited alterations in time spent in the central area of the open-field arena, were less active in the lit areas of a light/dark transition test, and had a prolonged latency to feed during a novelty-induced hypophagia test. These changes were associated with alterations in light-induced orbitofrontal cortex (OFC) activation in an extracellular signal-regulated kinase (ERK) pathway-dependent manner. These results demonstrate that FGF-BP3 is a potent mediator of anxiety-related behaviors in mice and suggest that distinct pathways regulate emotional behaviors. Therefore, FGF-BP3 plays a critical role in the regulation of emotional states and in the development of anxiety disorders and should be investigated as a therapeutic target for anxiety disease in humans.

Clinical Case Report of KIF1A Duplication in Idiopathic Autism. *F. Bartel[1], A. Dwivedi[1], S. Cathey[2], B. DuPont[1].* 1) Dept Cytogenetics, Greenwood Gen Ctr, Greenwood, SC; 2) Charleston Clinical Office, Greenwood Gen Ctr, N. Charleston, SC.

A 3 yr old male with idiopathic autism, tall forehead and mildly hyperextensible elbows was referred for genetic testing. Molecular testing for Fragile X syndrome was normal. Subsequent high resolution microarray analysis using the Affymetrix Genome-Wide SNP 6.0 array identified a 47 kb duplication within the KIF1A (kinesin family member 1A) gene. Quantitative PCR data for confirmation of the duplication, family study, and transcript expression will be presented. To our knowledge this is the first report implicating KIF1A in idiopathic autism. These results also suggest a possible contribution of KIF1A to the autistic behaviors observed in some patients with monosomy 2q37.

2501/W

Replication study of association of the DPP6 gene with Primary Progressive Multiple Sclerosis (PPMS). *P. Brambilla[1], F. Esposito[1,2], G. Giacalone[1,2], M. Sorosina[1], M. Rodegher[2], R. Capra[3], A. Ghezzi[4], D. Galimberti[5], E. Scarpini[5], H. Westerlind[6], V. Martinelli[2], J. Hillert[6], G. Comi[1,2], F. Martinelli Boneschi[1,2].* 1) Institute of Experimental Neurology (INSPE), San Raffaele Scientific Institute, Milan, MI, Italy; 2) Department of Neurology, San Raffaele Scientific Institute, Milan, MI, Italy; 3) Department of Neurology, Spedali Civili, University of Brescia, Brescia, Italy; 4) Multiple Sclerosis Study Center, Hospital of Gallarate, Gallarate (VA), Italy; 5) Department of Neurological Sciences, “Dino Ferrari” Center, University of Milan, IRCCS Ospedale Maggiore Policlinico, Milan, Italy; 6) Department of Neurology, Karolinska University Hospital, Huddinge, Stockholm, Sweden.

Objectives: It is still unclear whether the clinical course and severity of MS is driven by genetic factors. A whole-genome association study (WGA) has been performed on 200 Italian patients affected with PPMS, which represents a rare clinical course affecting about 10-15% of MS patients and it is characterized by a progressive accumulation of irreversible neurological symptoms from the onset of the disease. Results of WGA study identified a novel locus, the dypeptidil-peptidase 6 (DPP6) gene. Methods: We carried out a case-control association study on 244 Italian PPMS cases and 225 age- and sex-matched controls (discovery sample) to better explore the locus by genotyping 19 single nucleotide polymorphisms (SNPs) on DPP6 gene using the TaqMan technology (Applied Biosystems®). 13 SNPs have been selected using a tagging approach to cover the region around two SNPs (rs6956703 and rs11767658), originally associated to PPMS in the WGA study. 5 SNPs have been selected as coding SNPs and as present in the 5’region, and one SNP because found to be associated with amyotrophic lateral sclerosis. The same genotyping technology was used to explore the association of the locus in 179 PPMS and 198 controls from Northern Europe (replication sample). PLINK and Haploview softwares were used for the data analyses. Results: 6/19 SNPs (rs2046748, rs4960555, rs11976061, rs10244476, rs1532090 and rs11767658) showed a significant difference in allelic frequencies ($p<0.05$ after Bonferroni correction) between cases and controls in the discovery sample. None of them have been confirmed to be associated in the replication sample. An haplotype association analysis has been performed in the discovery sample confirming the results on individual SNPs. Additional analyses on haplotype distribution in replication sample and approaches of meta-analyses are ongoing. Conclusions: 6/19 SNPs were found to be associated with Italian PPMS, confirming the original results of WGAS, but none of them was confirmed in the replication sample of North Europe origin, suggesting that the original association was a false positive signal or a phenomenon restricted to South European populations. Additional experiments are ongoing to make a final statement on the relationship between DPP6 and PPMS and MS in general.

2502/W

Next-generation pooled sequencing identifies new rare variants implicated in late-onset familial AD. *C. Cruchaga[1], G. Haller[1], S. Chakraverty[1], K. Mayo[1], FL. Vallania[2], RD. Mitra[2], A. Goate[1], NIA-LOAD/NCRAD Family Study Consortium.* 1) Department of Psychiatry, Washington University, St. Louis, MO, USA; 2) Department of Genetics, Washington University, St. Louis, MO, USA.

Familial Alzheimer disease (FAD) is characterized by an early onset (<60 years) and is inherited as an autosomal dominant trait with high penetrance. Mutations in three genes, APP, presenilin 1 (PSEN1), and presenilin 2 (PSEN2), have been reported to cause FAD. To date 173 mutations in PSEN1, 26 in APP and 14 in PSEN2 have been identified in FAD cases. In addition, mutations in progranulin (GRN), and microtubule-associated protein tau (MAPT) which cause frontotemporal dementia, can have a clinical presentation indistinguishable from AD. The frequency of mutation in these genes in late-onset AD (LOAD) families has been less well studied. We have used second generation sequencing technology to screening APP, PSEN1, PSEN2, MAPT and GRN for pathogenic mutations in 450 LOAD families with 4 or more affected members, recruited by the NIA Late Onset Alzheimer's Diseases Genetics Initiative. We have found 2 known pathogenic mutations in PSEN1 affecting 8 families, 2 mutations in PSEN2 affecting 13 families, 1 mutation in MAPT affecting 1 family and 3 mutations in GRN affecting 5 families. In total 6% of the families carried a known pathogenic mutation. We have also found 22 new non-synonymous and splice variants in an additional 35 families (7.8% of the total families). Preliminary results indicate that some of the new mutations, such as N660Y in PSEN1, A556T in MAPT and a splice variant (c.1181-1G>T) in GRN, segregate with disease status. On the other hand, we found that the non-synonymous change R62H in PSEN2, previously reported but with unclear pathogencity, does not segregate with disease status but modifies age at onset (P = 1.2 ×10-3, n=21) and shows epistasis with APOE ε4 (P-value for the epistasis (APOE*SNP) = 0.01. These results demonstrate that approximately 10% of LOAD families with 4 or more affected individuals carry pathogenic variation in known dementia causing genes. Furthermore, mutations in MAPT and GRN were just as common in these families as mutations in PSEN1, APP and PSEN2, highlighting the need to screen these genes in clinically diagnosed family cohorts in addition to the FAD genes. Lastly, most of these densely affected families do not carry mutations in the known genes strongly suggesting that novel LOAD genes with high penetrance remain to be identified.

2503/W

EPISTASIS IN ADRENERGIC GENES CONFERRING RISK FOR SUICIDAL BEHAVIOUR AND SCHIZOPHRENIA. *V. De Luca, R.P. Souza, J. Strauss, J.L. Kennedy.* Dept Neurogenetics, Univ Toronto, Toronto, ON, Canada.

A large body of evidence suggests that suicidal behaviour is associated with altered noradrenergic neurotransmission. There are nine adrenergic receptor genes (α1A, α1B, α1D, α2A, α2B, α2C, β1, β2, β3). Our hypothesis is that the gene encoding for the adrenergic receptor genes might contain genetic variants conferring increased risk for suicidal behaviour in schizophrenia. In order to test this hypothesis, we genotyped two adrenergic receptors α2B and α2C in a cohort of 600 schizophrenics in which 21% attempted suicide. No association between suicide attempt and the Ins/del polymorphisms in ADRA2C and ADRA2B genes was found, however these two genes have a significant homology in the polymorphic regions suggesting that epistasis can be present between these two genes. Haplotype analysis for the two genes, revealed no association between suicide attempts and haplotype distribution. As we tested for epistasis between ADRA2C and ADRA2B genes, we found no significant interaction in conferring risk for suicide attempts. These results suggest that α2 adrenergic receptors may not influence suicidal behaviour in patients with schizophrenia.

2504/W

Identification and functional characterization of three novel alleles for the serotonin transporter-linked polymorphic region. *E.A. Ehli[1,4], Y. Hu[2], T. Lengyel-Nelson[1], J.J. Hudziak[3], G.E. Davies[1,2,4].* 1) Avera Institute for Human Behavioral Genetics, Sioux Falls, SD; 2) South Dakota State University, College of Pharmacy, Brookings, SD; 3) University of Vermont, College of Medicine, Burlington, VT; 4) University of South Dakota, Sanford School of Medicine, Department of Psychiatry, Sioux Falls, SD.

A promoter polymorphism in the serotonin transporter gene (5-HTTLPR) has been reported to confer relative risk for phenotypes (depression/anxiety) and endophenotypes (amygdala reactivity). In this report, we identify and characterize three rare 5-HTTLPR alleles not previously described in the human literature. The three novel alleles were identified while genotyping 5-HTTLPR in an ADHD clinical population. Two of the novel alleles are longer than the common 16-repeat long (L) allele (17 and 18 repeats) and the third is significantly smaller than the 14-repeat short (S) allele (11 repeats). The sequence and genetic architecture of each novel allele is described in detail. We report a significant decrease in the expression between the XL17 (17r) allele and the LA (16r) allele. The XS11 (11r) allele showed similar expression with the S (14r) allele. A 1.8 fold increase in expression was observed with the LA(16r) allele compared to the LG (16r) allele which replicates results from earlier 5-HTTLPR expression experiments. In addition, transcription factor binding site (TFBS) analysis was performed using MatInspector which showed the presence of different putative TFBSs between the novel alleles and the common L (16r) and S (14r) alleles. Our findings argue for at least four functionally different SERT promoters.

2505/W

Mutations in the TSGA14 gene in families with autism spectrum disorders. *E. Korvatska[1], A. Estes[2], J. Munson[3], G. Dawson[4], L. Bekris[5], R. Kohen[3], C.-E. Yu[5], G. Schellenberg[6], W.H. Raskind[1,3].* 1) University of Washington, Medicine, Division of Medical Genetics, Seattle, WA; 2) University of Washington, Speech and Hearing Sciences, Seattle, WA; 3) University of Washington, Psychiatry and Behavioral Sciences, Seattle, WA; 4) Autism Speaks Foundation; University of North Carolina, Department of Psychiatry, NC; 5) University of Washington, Medicine, Division of Gerontology and Geriatric Medicine, Seattle, WA; 6) University of Pennsylvania, Department of Pathology and Laboratory Medicine, Philadelphia, PA.

Linkage to 7q has been robust genetic finding in familial autism. A previous scan of multiplex families with autism spectrum disorders found a linkage signal of genome-wide significance at D7S530 on 7q32. We searched a candidate imprinted region at this location for genetic variants in families with positive linkage scores. Using exon resequencing, we identified three rare potentially pathogenic variants in the TSGA14 gene, which encodes for a centrosomal protein. Two of the variants were missense mutations (c.664C>G; p.P206A and c.766T>G; p.C240G) that changed conserved residues in the same protein domain; the third variant (c.192+5G>A) altered splicing, which resulted in a protein with an internal deletion of 16 residues and a G33D substitution. These rare TSGA14 variants are enriched in the affected subjects (6/348 patients versus 2/670 controls, Fisher's exact two tailed p= 0.022). This is the first report of a possible link of a gene with a centrosomal function with familial autism.

2506/W

Acute to Chronic Pain Transitions (ACPT) After Peripheral Nerve Injury: Genomic Insights. *R.C Levitt[1,2,3], Q. Li[1], Y. Zhang[1], R.W Morris[1,2], E.S. Fu[1].* 1) Anesthesiology, Miller School of Medicine, University of Miami, Miami, FL; 2) Hussman Institute of Genomics, Miller School of Medicine, University of Miami, Miami, FL; 3) Miami Veterans Healthcare System, Miami, FL.

Background: Acute postoperative pain is followed by persistent pain in up to 50% of patients undergoing surgical procedures. It is now generally accepted that the development of chronic pain depends on nerve injury and is a complex heritable trait influenced by multiple genes, gene-environment, and gene-gene interactions. We hypothesize that susceptibility to ACPT after peripheral nerve injury, along with the resistance to therapy and rehabilitation, are causally associated with polymorphic genes, and that these genes and the pathways can be identified using functional genomics. In this study, using mechanical pain responses after peripheral nerve injury in mice, we have identified genetic loci associated with the ACPT over time. **Methods:** The chronic constriction injury of the sciatic nerve (CCI) model in mice was used to evaluate the ACPT (C57BL6/J, DBA2/J, A/J, NZW/LacJ, SJL/J, AKR/J, 129S1/SvLmJ, CAST/EiJ, FVB/NJ, BALB/cJ, CBA/J, C3H/HeJ, n= 5-8 males each). Withdrawal thresholds to mechanical pain (von Frey filaments to affected hindpaw) were measured on Days 1, 7, 14 and 21 after CCI. Haplotype association mapping (HAM) was conducted using snpBrowser (http://compgen.unc.edu/?page_id=17.) This method depends on the dataset of 7.8M single nucleotide polymorphisms (SNP) in these stains. HAM uses ANOVA to analyze association with the phenotype, using contiguous 3 SNP windows. In this exploratory study, a significant level of P<0.0001 (-logP=LOD 4.0) was used to select SNP associated with mechanical responses. **Results:** Baseline mechanical responses differed between inbred strains. Thresholds after CCI as compared with Baseline indicate A/J and NZW/LacJ had the least change in mechanical threshold after CCI; AKR/J, BALB/cJ, and DBA/2J showed the greatest ACPT. Heritability estimates averaged about 50%, with an estimated 3.5 genes underlying the ACPT. HAM results identify four separate chromosomal loci associated with differences in mechanical response on Day 1 and 7 after CCI. **Discussion:** Highly reproducible differences between strains for the ACPT demonstrate that this neurobehavioral phenotype is heritable. Preliminary HAM mapping of quantitative trait loci (QTL) contributing to the ACPT through Day 7 suggest the ACPT is likely to be oligogenic. Our continuing studies may help identify gene candidates underlying susceptibility to neuropathic pain and explain resistant to treatment and rehabilitation, and lead to new therapeutic approaches.

2507/W

Haplotype-Based Study of the Association of Alcohol Metabolizing Genes with Alcohol Dependence in Four Ethnically Diverse Populations. *J. LIU[1], Z. Zhou[1], C. Hodgkinson[1], Q. Yuan[1], P. Shen[1], C. Mulligan[2], A. Wang[1,2], R. Gray[2], A. Roy[3], M. Virkkunen[4,5], D. Goldman[1], M. Enoch[1].* 1) National Institute on Alcohol Abuse and Alcoholism, Rockville, MD; 2) Department of Anthropology, University of Florida,Gainesville, FL 32610; 3) Mental Health and Behavioral Science, Department of Veterans Affairs New Jersey Health Care System, East Orange; 4) Institute of Clinical Medicine, Department of Psychiatry, University of Helsinki, Finland (MV); 5) Kellokoski Hosapital, Kellokoski, Finland (MV).

Background: Ethanol is metabolized by two rate limiting reactions: alcohol dehydrogenases (ADH) convert ethanol to acetaldehyde, subsequently metabolized to acetate by aldehyde dehydrogenases (ALDH). Approximately 50% of East Asians have genetic variants that significantly impair this pathway and influence alcohol dependence (AD) vulnerability. We investigated whether variation in alcohol metabolism genes might alter the AD risk in four non-East Asian populations by performing systematic haplotype association analyses in order to maximize the chances of capturing functional variation. Methods: Haplotype-tagging SNPs were genotyped using the Illumina GoldenGate platform. Genotypes were available for 40 SNPs across the ADH genes cluster and 24 SNPs across the two ALDH genes in four diverse samples that included cases (lifetime AD) and controls (no Axis 1 disorders). The case, control sample sizes were: Finnish Caucasians: 232, 194; African Americans: 267, 422; Plains American Indians: 226, 110; Southwestern American (SW) Indians: 317, 72. Results: In all four populations, as well as HapMap populations, five haplotype blocks were identified across the ADH gene cluster: (1) ADH5-ADH4; (2) ADH6-ADH1A-ADH1B; (3) ADH1C; (4) intergenic; (5) ADH7. The ALDH1A1 gene was defined by four blocks and ALDH2 by one block. No haplotype or SNP association results were significant after correction for multiple comparisons; however several results, particularly for ALDH1A1 and ADH4, replicated earlier findings. There was an ALDH1A1 block 1 and 2 (extending from intron 5 to the 3' UTR) yin yang haplotype (haplotypes that have opposite allelic configuration) association with AD in the Finns driven by SNPs rs3764435 and rs2303317 respectively, and an ALDH1A1 block 3 (including the promoter region) yin yang haplotype association in SW Indians driven by 5 SNPs, all in allelic identity. The ADH4 SNP rs3762894 was associated with AD in Plains Indians. Conclusions: The systematic evaluation of alcohol metabolizing genes in four non-East Asian populations has shown only modest associations with AD, largely for ALDH1A1 and ADH4. A concentration of signals for AD with ALDH1A1 yin yang haplotypes in several populations warrants further study.

2508/W

Synaptic vesicles related genes and migraine predisposition. *J.L. Neto[1], C. Lemos[1], J. Pereira-Monteiro[1,2,3], J. Sequeiros[1,3], A. Sousa[1,3], I. Alonso[1].* 1) UnIGENe, Institute for Molecular and Cell Biology (IBMC), Porto, Portugal; 2) Neurology Service, Hospital Santo António (HSA), Porto, Portugal; 3) Instituto de Ciências Biomédicas Abel Salazar (ICBAS), Porto, Portugal.

Migraine is a neurological disorder clinically characterized by recurrent headache episodes associated with other symptoms such as sensorial hypersensitivity or nausea. This disorder affects approximately 15% of the general population and has a significant genetic component, although the genes responsible for common migraine susceptibility have not yet been identified. There is evidence that the neurotransmitter systems play a pivotal role in common migraine pathophysiology. Recently, in Portuguese and Catalonian populations an association between *STX1A* and increased migraine predisposition was found. *STX1A* encodes Syntaxin 1A, a component of the SNARE complex, involved in the synaptic vesicles' membrane fusion and subsequent neurotransmitter release. A case-control association study is being conducted, using the Portuguese sample where association with *STX1A* was previously ascertained, composed of 188 unrelated migraineurs and 287 migraine-free controls, age and ethnically-matched with cases. 110 tagging SNPs are being studied with total coverage of common variation (MAF>10%) in genes encoding proteins related with the synaptic vesicles' machinery. The SNPs' frequencies in the European population were obtained resorting to the Hapmap , and Haploview v4.1 was used to plot LD patterns and select the tagging SNPs. The SNPs in study were divided in sets, and are being genotyped in five 22-plex multiplex SNaPshot assays. SNaPshot is a powerful, consistent, easy to use, high throughput technique specifically used to genotype SNPs. Results are being analyzed with Genemapper v4.0 software. Genotyping of all 475 individuals for 22 of the 110 SNPs is currently in its final stage; a preliminary association analysis is expected very soon. When all SNPs from a gene are genotyped, haplotypic association is also going to be analyzed in order to assess the possible existence of a susceptibility haplotype. Epistasis, often neglected in complex traits' studies, will be taken in consideration and the presence of genetic interactions, based on functional relationships, will be analyzed to assess their role in migraine predisposition. The acquirement of knowledge about association between genetic polymorphisms and migraine susceptibility is crucial because it can be useful as a starting point for more in depth studies, and the determination of genetic risk factors for migraine can bring dazzling advantages in migraine diagnosis and treatment.

Dopamine Transporter Genotype Predicts Cognitive Flexibility in Healthy Control and Methamphetamine-Dependent Subjects. *E.L. Nurmi[1], D. Ghahremani[1], S.A. Wilson[1], J.T. McCracken[1, 3], E.D. London[1, 2, 3].* 1) Department of Psychiatry and Biobehavioral Sciences, University of California Los Angeles, Los Angeles, CA; 2) Department of Molecular and Medical Pharmacology, University of California Los Angeles, Los Angeles, CA; 3) The Brain Research Institute, University of California Los Angeles, Los Angeles, CA.

Cognitive flexibility is crucial for adaptive responding to environmental stimuli. Deficits in cognitive flexibility may be seen as behavioral rigidity, indexed by perseverative responding on "reversal learning" tasks that require response adjustment when contingencies of the task change. Studies in animal models and human subjects have shown that dopamine (DA) neurotransmission in the striatum and prefrontal cortex mediates reinforcement learning and the integration of negative feedback during reversal learning. In addition, serotonin in the orbitofrontal cortex may contribute to cognitive flexibility, possibly by reducing interference from salient stimuli. As an initial assessment of the contribution of genetic variation to cognitive flexibility, we employed a deterministic reversal learning task (Ghahremani et al, Cerebral Cortex, in press) and compared performance (reversal errors) among carriers and non-carriers of the dopamine transporter (DAT1 or SLC6A3) 9-repeat allele as well as the long promoter allele of the serotonin transporter (HTT or SLC6A4). Because of the purported association of cognitive control deficits with substance abuse disorders, we included a group of methamphetamine-dependent (MA) subjects (n=36) in addition to a healthy control (HC) group (n=35) and tested for an effect of MA abuse and interactions of MA abuse with genotype. The findings to date indicate that 9R carriers (n = 35) of DAT 1 exhibit poorer reversal learning than those without (n = 34) the 9R allele (mean errors ± SD in HC and MA groups: 1.66 ±1.16 and 1.86 ±.610 for 9R+; 1.28 ± 0.562 and 1.55± 0.971 for 9R-). The effect of DAT1 genotype was statistically significant (p=.042) whereas the main effect MA and the interaction of MA with genotype were not, nor were comparisons on the basis of HTT-LPR genotype (p=.123). Expression of DAT1 is modulated by the number of repeats in the 3'UTR VNTR, with the 9 repeat allele reducing transporter expression. These findings are consistent with a central role for intrasynaptic DA and its transporter modulated reuptake in cognitive flexibility in humans. Ongoing investigations will comprehensively screen candidates and correlate genotypes, in vivo dopamine binding, and behavior to further explore these mechanisms. Supported by NIH grants P20 DA022539 and R01 DA020726 (EDL), M01 RR00865 (UCLA GCRC) and endowments from the Thomas P. And Katherine K. Pike Chair in Addiction Studies and Marjorie M. Greene Family Trust (EDL).

Vitamin D metabolic pathway genes and risk of multiple sclerosis in Canadians. *S. Orton[1], S.V. Ramagopalan[1], L. Handunnetthi[1], M. Chao[1], M.R. Lincoln[1], F. Moultrie[1], N. Perrier[1], A. Para[1], A.D. Sadovnick[2], G.C. Ebers[1], Canadian Collaborative Study Group.* 1) Wellcome Trust Centre for Human Genetics and Dept Clinical Neurology, University of Oxford, Oxford, United Kingdom; 2) Department of Medical Genetics and Faculty of Medicine, Division of Neurology, University of British Columbia; Vancouver, Canada (ADS).

Background. Multiple sclerosis (MS) is determined by interactions between genes and environment and the influence of vitamin D adequacy has been proposed. Previous studies have shown that serum 25-hydroxyvitaminD (25(OH)D) levels are genetically influenced. Polymorphisms in vitamin D pathway genes are candidates for association with MS susceptibility. Methods. MS patients (N=1364) and their unaffected first-degree relatives (N= 1661) were ascertained through the Canadian Collaborative study. Seventy-one SNPs, across four genes [vitamin D receptor (VDR), 1-alpha-hydroxylase (CYP27B1) enzyme, vitamin D binding protein (DBP), 24-hydroxylase (CYP24)], were genotyped and tested for association with MS susceptibility using TDT. Secondary analyses included stratification for HLADRB*15, differences in parental allele frequencies and parent of origin analysis. Results. We found no significant association of vitamin D pathway genes with MS susceptibility after correction for multiple comparisons. However, SNPs selected for previously positive associations with MS and/or 25(OH)D levels showed marginally significant results, including distorted transmission of the VDR Fok1 variant (rs2228570, p=0.03) in DRB15-negative patients and differences in maternal versus paternal allele frequency of DBP SNPs (rs4588, p=0.02 and rs7041, p=0.03). Interpretation. The findings do not directly connect vitamin D metabolism genes to MS susceptibility, despite a large sample size. We cannot exclude small effects and the results are consistent with the involvement of previously reported SNPs in VDR and DBP genes.

Whole Genome aCGH Analysis for CMT and Related Peripheral Neuropathies. *D. Pehlivan[1], C. Gonzaga-Jauregui[1], F. Zhang[1], J.R. Lupski[1,2,3].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Charcot-Marie-Tooth (CMT) and related peripheral neuropathies represent a heterogeneous group of genetic disorders of the peripheral nervous system with an estimated frequency of 1 in 2500 individuals. Over the last two decades, about 30 genes and 10 linkage regions have been identified in which mutations cause CMT. Still for ~10% of cases the causative genes and mechanism remain unknown. Copy number variations (CNVs) are an important cause of CMT cases as duplication of PMP22 gene region represents 70% of CMT1 cases. Therefore, we hypothesized that copy number changes involving other CMT genes might be found amongst CMT patients in which the molecular genetic etiology is unknown. We designed Agilent Custom 8x60K comparative genomic hybridization (CGH) array to detect copy number variations in all CMT genes, CMT linkage regions and neuropathy related genes. We selected probes spanning 47 genes including 10 kb of flanking regions and 13 CMT candidate regions to be interrogated. Thus far, 96 patients with CMT with unknown molecular cause were already analysed. In total, 39 CNVs were detected. 31 out of 39 were unlikely to be the cause of the disease as they overlap with variants found among the normal population. Eight CNVs varying in size were selected as potential disease-associated candidate rearrangements. Breakpoints of those candidate CNVs were further refined using long-range PCR and sequencing; Chromosomal aberrations were in linkage regions for 6 patients and in one of the CMT gene regions for 2 patients. For cases with rearrangements in linkage regions, function of the gene is not associated with CMT phenotype in 4 cases. For the remaining 2 cases, both were Alu mediated deletion and the function of the gene may be associated with the CMT phenotype. For aberrations in CMT gene regions, one patient had a duplication in the MPZ gene and the other patient had a deletion in PMP22 region. These results indicate that CNVs might be a relevant cause of CMT in patients with unknown molecular genetic etiology.

2512/W

Serotonin transporter gene variants (5HTTLPR and STin2) and susceptibility to depressive and anxiety symptoms in undergraduate students in Bogotá Colombia. *C.S. Perea[1], A. Castañeda[2], R. Sebastian[1], K. Peña[1], B.A. Otalora[1], H. Groot[1], Y. Gomez[2], M.C. Lattig[1].* 1) Laboratorio de Genetica Humana Departamento de Ciencias Basicas Universidad de los Andes Bogota - Colombia; 2) Departamento de Psicologia Universidad de los Andes Bogota - Colombia.

The functional 5HTTLPR and the STin2 variations located in the serotonin transporter gene (SERT, SLC6A4, 5HTT) have been associated with hyper reactivity to stress and therefore with vulnerability to develop higher than normal anxiety and depression symptoms in young adults in several populations. We thought to examine the influence of the short/long (s/l) 5HTTLPR variant and the (12/10/9) STin2 variants on susceptibility to develop depression and/or anxiety symptoms in undergraduate freshman and sophomore students from the Universidad de los Andes, Bogota - Colombia. Psychological tests (BDI-II, IDER, STAI) were used to evaluate depression and anxiety traits and genotype analysis of the s/l 5HTTLPR variants and the 12/10/9 STin2 variants were performed. A total of 348 students participated in the study (female 177, male 171). We classified the individuals in five different groups according to the psychological tests; controls for depressive traits (n=277, 82.9%), controls for anxiety traits (n=241, 76.7%), individuals with depressive traits (n=57,17.1%), individuals with anxiety traits (n=73, 23.3%), and individuals with both depressive and anxiety traits (n=38). Regarding the allele frequencies, the individuals were categorized in the following groups; individuals with the 5HTTLPR short allele (52.3%), 5HTTLPR long allele (47.7%), STin2.12 allele (67.3%), STin2.10 allele (32.2%), and STin2.9 allele (0.54%). Genotype frequencies are as follows: 5HTTLPR s/s (26.4%), 5HTTLPR s/l (51.9%), 5HTTLPR l/l (21.7%), STin2 12/12 (46.8%), STin2 12/10 (39.9%), STin2 10/10 (12.2%), and STin2 12/9 (1.1%). In order to determine the effect the 5HTTLPR and STin2 variants on the susceptibility to develop depressive or anxiety traits we performed non parametric multivariate analysis (SSPS 18). Our results indicate that neither 5HTTLPR and STin2 alleles, either acting alone or together, are strong determinant factors in the vulnerability to develop depressive and/or anxiety symptomatology in our population of study; suggesting that additional gene variants and environmental factors are influencing these behavioral traits as has been shown in several studies. Although we did not find any association, it is important to note that this is the first report of the STin2 genetic frequencies in the Colombian population.

2513/W

The Association Analysis of COMT, GABA, and SCL6A4 Genes With Autism Spectrum Disorders in the CHARGE Study. *L. Qi[1], Y.H. Lo[2], L. Schmidt[3], R.J. Schmidt[1,4], I.N. Pessah[4,5], I. Hertz-Picciot[1,4], F. Tassone[3,4].* 1) Dept. Public Health Sciences, Univ California, Davis, Davis, CA; 2) Dept. Biostatistics, Univ. Michigan, Ann Arbor, MI; 3) Dept. Biochemistry and Molecular Medicine, Univ California, Davis, Davis, CA; 4) MIND Institute, Univ California Davis Medical Center, Sacramento, CA; 5) Dept. Molecular Biosciences, School of Veterinary Medicine, Univ California, Davis, Davis, CA.

We have studied three genes, catechol-O-methyl transferase (COMT), gamma-aminobutyric acid (GABA) A receptor, and SCL6A4 (serotonin transporter) in children participating in the CHARGE (Childhood Autism Risks from Genetics and the Environment) Study. The CHARGE study is a large, ongoing case-control investigation of Northern California children aged 2-5 years with clinically confirmed diagnoses of: autism (AU), autism spectrum disorders (ASD), developmental delays, or typical development (TD). In this study, we genotyped 15, 16, and 7 single nucleotide polymorphisms (SNPs) located within the COMT, GABA, and SCL6A4 genes, respectively, in 104 children with AU and 130 TD controls. Significant genetic associations were observed for 5 COMT, 3 GABA, and 1 SCL6A4 SNPs. Haplotype-specific association analysis revealed that the SNP3/SNP4/SNP5/SNP6 and SNP10/SNP11/SNP12 haplotypes within the COMT gene, and the SNP3/SNP4/SNP5/SNP6 and SNP6/SNP7/SNP8/SNP9 haplotypes within the GABA gene were significantly associated with autism (p-values were 0.021 and 0.048 for the COMT haplotypes, and 0.004 and 0.014 for the GABA haplotypes, respectively). Our study suggests the possible involvement of the COMT and GABA genes in the susceptibility to autism. Future replications are warranted before definitive conclusions can be drawn.

Fine-scale mapping of a schizophrenia susceptibility locus on chromosome 13q32-34. *L. Rodriguez-Murillo[1], B. Xu[1], J.L. Roos[4], G.R. Abecasis[5], J.A. Gogos[2, 3], M. Karayiorgou[1].* 1) Department of Psychiatry, Columbia Univ, New York, NY; 2) Department of Physiology and Cellular Biophysics, Columbia Univ, New York, NY; 3) Department of Neuroscience, Columbia Univ, New York, NY; 4) Department of Psychiatry, University of Pretoria, Pretoria, RSA; 5) Department of Biostatistics, Michigan University, Ann Arbor, MI.

Schizophrenia is a chronic psychiatric disease characterized by psychotic symptoms as delusions and hallucinations, apathy, altered emotional reactivity, and cognitive deficits as impairments in executive function, attention and working memory. Heritability is estimated to be up to 80% for first degree relatives. Schizophrenia, like other common diseases, is multifactorial in nature with complex genetic etiologies. It is likely that both common and rare alleles contribute to the risk of schizophrenia, although the relative impact of each remains unknown. Previously, we performed a genome-wide linkage scan in South Africa Afrikaners (a founder population of European descent) with microsatellites spaced 2 cM on average across the genome and obtained strong evidence for linkage on chromosome 13q32-34. We could not find any rare or common CNV that accounts for the linkage signal within this region. The goal of the present study was to look for common variants associated with schizophrenia located within the linkage region. To this end, we genotyped 415 Afikaner families with at least one member with schizophrenia for ~700 SNPs localized within the 13q32-34 linkage region, and performed a family-based association analysis. A few SNPs showed nominally significant association and were followed up in a US family sample. Replication and meta-analysis identified one SNP within 13q33.3 as associated with schizophrenia. However, further analyses will be necessary to understand the contribution of this genetic variant to schizophrenia.

Amyloid pathway-based candidate gene analysis of [^{11}C]PiB-PET in the Alzheimer's Disease Neuroimaging Initiative (ADNI) cohort. *S. Swaminathan[1,2], L. Shen[2,3], S.L. Risacher[2], S. Kim[2,3], K. Nho[2,3], J.D. West[2], T. Foroud[1], K.K. Yoder[2], S.G. Potkin[4], M.J. Huentelman[5], D.W. Craig[5], W.J. Jagust[6,7], C.A. Mathis[8], M.W. Weiner[9,10], A.J. Saykin[1,2], Alzheimer's Disease Neuroimaging Initiative (ADNI).* 1) Department of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 2) Center for Neuroimaging, Department of Radiology and Imaging Sciences, Indiana University School of Medicine, IN; 3) Center for Computational Biology and Bioinformatics, Indiana University School of Medicine, Indianapolis, IN; 4) Department of Psychiatry and Human Behavior, University of California, Irvine, CA; 5) Neurogenomics Division, The Translational Genomics Research Institute, Phoenix, AZ; 6) Helen Wills Neuroscience Institute, University of California Berkeley, Berkeley, CA; 7) Lawrence Berkeley National Laboratory, Berkeley, CA; 8) Department of Radiology, University of Pittsburgh, Pittsburgh, PA; 9) Departments of Radiology, Medicine and Psychiatry, University of California, San Francisco, CA; 10) Department of Veterans Affairs Medical Center, San Francisco, CA.

Amyloid neuroimaging provides *in vivo* data on plaque formation in those with or at risk for Alzheimer's disease (AD). This method provides an opportunity to examine the influence of genetic variation within the amyloid pathway in plaque deposition during early stages of AD. We studied 103 participants from the Alzheimer's Disease Neuroimaging Initiative (ADNI) cohort with available [^{11}C]PiB, which binds with high affinity to Aβ, and genotype data (Illumina Human610-Quad BeadChip). Standardized uptake value ratio (SUVR) measures of PiB binding in anterior cingulate, frontal cortex, parietal cortex and precuneus, have been shown to be good indicators of amyloid deposition and we used the average baseline SUVR across the four regions as a quantitative phenotype. Candidate genes identified from a search for "amyloid" on Gene Ontology and present in the AlzGene database (a collection of previously studied AD genes), were included in the analysis. SNPs in the untranslated regions, exons and introns of these genes with a minor allele frequency ≥ 0.20 were chosen. 275 SNPs in 16 genes remained after filtering and were subjected to a set-based test in PLINK software with age as a covariate, and without and with *APOE* ε4 status as a covariate. The set method takes into account linkage disequilibrium between SNPs and calculates an empirical p-value for each gene correcting for number of SNPs within each gene tested. Two candidate risk genes were identified: the known risk factor SNP (rs429358) in the *APOE* (Apolipoprotein E) gene and a SNP (rs7551288) in *DHCR24* (24-dehydrocholesterol reductase or seladin-1) gene (empirical p = 0.022 and 0.052 without and with *APOE* ε4 status as a covariate, respectively). *DHCR24* is thought to confer resistance against Aβ- and oxidative stress-induced apoptosis, and effectively inhibits the activation of caspase-3, a key mediator of the apoptotic process. The identified SNP appears to have an additive effect: higher number of minor alleles correlate with lower average SUVR values, supporting the hypothesis that this gene may play a neuroprotective role against Aβ deposition. Our initial results suggest that further investigation of the role of *DHCR24* in AD is warranted.

2516/W

Is there a common evolutionary background for music and language faculties? - Analysis of dyslexia candidate genes in Finnish families tested for musical aptitude. *L. Ukkola[1], K. Salo[1], P. Onkamo[2], P. Raijas[3], K. Karma[4], I. Järvelä[1,5].* 1) Dep Med Gen, Univ Helsinki, Helsinki, Finland; 2) Dep Biological and Environmental Sciences, University of Helsinki, Helsinki, Finland; 3) Sibelius Academy, DocMus Department, Helsinki, Finland; 4) Sibelius Academy, Department of Music Education, Helsinki, Finland; 5) Laboratory of Molecular Genetics, Helsinki University Central Hospital, Helsinki, Finland.

Musical aptitude is a cognitive function of the human brain. Common evolutionary background of music and language recognition has been long speculated, based for example on partially overlapping brain regions in PET studies. Moreover, low scores in a test for musical aptitude, Karma Music test (KMT), have been shown to reliably predict dyslexia. Here phonological awareness, a basic natural property not dependent on learning and defective in dyslexia could be understood as poor auditory structuring ability measured by KMT. Previously, we have carried out a genome-wide linkage analysis for musical aptitude in multigenerational families tested for musical aptitude using auditory structuring ability test (KMT) and Carl Seashores test for pitch (SP) and for time (ST). Evidence for linkage was obtained for several loci, including DYX6, a candidate locus for dyslexia, on chr. 18q.

In order to understand the neurobiological basis of music in human evolution and communication we analyzed previously reported risk alleles of a set of dyslexia susceptibility genes: *KIAA0319, DCDC2, DYX1C1, and C2ORF3*. Several SNPs were chosen in these loci and genotyped in multigenerational families (N=395). Family-based association analyses (FBAT and QTDT) were used for analyzing the data. Preliminary results point to SNPs in *KIAA0319* and *DCDC2*, which are located next to each other on chr. 6 with the Seashore Pitch test, with p-value 0.02. Currently, more families (total N=600) are being genotyped, thus, refined results will be presented in the meeting.

2517/W

Autism and/or Intellectual Disability in Children with 16p13.11 Microduplication: report on 4 New Cases. *A. Battaglia[1,2], A. Novelli[3], L. Bernardini[3], R. Tancredi[1], R. Igliozzi[1], E. Santocchi[1], A. Capalbo[3], M.C. Digilio[4].* 1) Dev Neurosciences, Stella Maris nst/Univ Pisa, Pisa, Italy; 2) Division of Medical Genetics, Dept. Pediatrics, University of Utah, Salt Lake City, UT, USA;; 3) Ospedale CSS-IRCCS, San Giovanni Rotondo e Istituto CSS Mendel, Roma, Italy; 4) Ospedale Bambino Gesù-IRCCS, Roma, Italy.

Autism and intellectual disability (ID) are often associated, suggesting that these conditions are etiologically related. Recently, array-based comparative genomic hybridization (array-CGH) has identified submicroscopic deletions and duplications as a common cause of ID, and as risk factors for autism spectrum disorders (ASDs). Here we describe 4 patients (3 females, 1 male) from four unrelated families, with autism or ID in whom array-CGH disclosed a dup 16p13.11. The smallest overlapping duplicated region started to14,956,252 and ended at 16,157,108, including 11 RefSeq genes (PDXDC1, NTAN1, RRN3, MPV17L, C16orf45, KIAA0430, NDE1, MYH11, C16orf63, ABCC1, ABCC6). The duplication was confirmed in all cases by RT-PCR on MYH11 gene. The same analysis extended to parents demonstrated in 3 cases the maternal and in 1 case the paternal segregation of the CNV. One female patient had autism (through ADOS, ADI) and the other 3 had ID. Dup16p13.11 was associated with FMR1 premutation in the autistic female; and with an expansion of the promoter region of FMR2 and with a del 12p11.23 in two of the other three ID patients. Minor dysmorphic features were present in all. Our report suggests that dup16p13.11 represent recurrent genomic imbalances which predispose to autism and/or ID.

2518/W

Autism, Mental Retardation, and Cognitive-Behavioral Features of Children with Subtelomeric Deletions. *G. Fisch[1], P.D. Grossfeld[2], R. Falk[3], J. Youngblom[4], R. Simensen[5], A. Battaglia[6].* 1) NYU Colleges of Dentistry & Nursing, New York, NY; 2) School of Medicine, University of California, San Diego; 3) Cedars Sinai Hospital, Los Angeles, CA; 4) Dept of Biology, California State University, Turlock, CA; 5) Greenwood Genetics Center, Greenwood, SC; 6) Dept. of Neurology, University of Pisa, Pisa, Italy.

Until recently, cognitive-behavioral features of children with subtelomeric deletions have not been systematically evaluated. The aim of our study was to provide an update of our assessment cognitive-behavioral features of children with 4 different subtelomeric deletions, using a comprehensive neuropsychological assessment battery. Our assessment battery consisted of 5 standardized measures of cognitive ability [Stanford-Binet 4th Ed: SBFE], adaptive behavior [Vineland Adaptive Behavior Scale: VABS], emotionality and temperament [Child Behavior Checklist: CBCL], attentiveness/hyperactivity [Conners Parent Rating Scale: CPRS], and autism [Child Autism Rating Scale: CARS]. We examined 43 children, ages 4-20 years, with deletion 2q37 [n=8], invdupdel(8p23) [n=7], deletion 11q25 [Jacobsen syndrome: JBS; n=11], or 4p16 [Wolf-Hirschhorn syndrome: WHS; n=19], from 9 sites in the US, the UK and Europe. We found 13/43 (30%) of our sample with CARS scores ≥ 30 who could be diagnosed as autistic. Attention deficits and hyperactivity [ADHD] were also noted in 25/43 [58%] of the sample of children assessed. Cognitive ability ranged from low-normal to severe ID. Children with JBS had significantly higher cognitive abilities, while those with WHS were significantly lower. Adaptive behavior was also significantly higher among children with JBS. Cognitive ability and adaptive behavior profiles were statistically significantly different among the groups. We conclude that cognitive-behavioral profiles and the risk of developing autism differ among children with dissimilar subtelomeric deletions. Moreover, differences in cognitive-behavioral profiles support a model of different gene-brain-behavior pathways producing ID.

2519/W

The association of brain-derived neurotrophic factor haploinsufficiency and autism symptoms in WAGR syndrome. *S.R. Fuhr[1], C. Golden Williams[2], A. Thurm[2], S.M. Brady[1], M.D. Lee[1], Y.C. Zheng[1], S.E. Swedo[2], J.C. Han[1].* 1) NICHD, National Institutes of Health, Bethesda, MD; 2) NIMH, National Institutes of Health, Bethesda, MD.

Purpose: WAGR syndrome (Wilms tumor, aniridia, genitourinary anomalies, mental retardation) is a rare genetic disorder caused by heterozygous chromosome 11p13 deletions of variable size. Due to its role in brain development and function, we hypothesized that haploinsufficiency of brain-derived neurotrophic factor (BDNF), a gene that is often deleted in patients with WAGR syndrome, may play a role for autism spectrum disorder (ASD) development in this population. **Methods:** Twenty patients with WAGR syndrome (10F/10M, age 6-37y) were recruited to the NIH through the International WAGR Syndrome Association. ASD symptoms were assessed using Autism Diagnostic Interview-Revised (ADI-R, parent interview, N=20), Autism Diagnostic Observation Schedule (ADOS, direct behavioral observation, N=15), and clinical judgment of doctoral level psychologists. Deletion boundaries were determined by array comparative genomic hybridization. Prevalence of ASD was compared by Fisher's exact test. **Results:** The deletion sizes ranged from 2.9 to 15.1 Mb. Thirteen subjects had heterozygous *BDNF* deletion (+/-) while 7 had intact *BDNF* (+/+). All but one subject met criteria for mental retardation, ranging from mild to severe. Visual impairment ranged from legal blindness to complete lack of vision. Using ADI-R, 7 out of 13 *BDNF*+/- subjects met "ever" ASD criteria compared to none out of 7 *BDNF*+/+ subjects [54% (95% CI: 25-80%) vs. 0% (95% CI: 0-41%), p=0.04]. However, using ADI current codes, ADOS, and clinical judgment, only 1 out of 9 *BDNF*+/- subjects met ASD criteria (with 1 other also meeting criteria only on the ADI-R) compared to none out of 6 *BDNF*+/+ subjects [11% (95% CI: 0-48%) vs. 0% (95% CI: 0-45%), p=1.00). **Conclusion:** Because WAGR syndrome includes visual impairment, mental retardation, and serious medical illness in early childhood, current functioning may be more reliable than ADI-R "ever" codes in assessing autism symptoms in this population. Further exploration of cognitive and/or visual impairments is needed to validate the observation of an association between *BDNF* haploinsufficiency and a history of autism symptoms. (This research was supported by the Intramural Research Program of the NICHD and NIMH, NIH.).

2520/W

High frequency of abnormalities in genetic copy number analysis in 245 cases of combined schizophrenia and epilepsy. *L. Stewart, A. Hall, S. Kang, C. Shaw, A. Beaudet.* Baylor College of Medicine, Houston, TX.

Recent studies have identified copy number variants (CNVs) in many neuropsychiatric disorders, including intellectual disability, autism, epilepsy, schizophrenia, and bipolar disorder. Remarkably, certain deletions can be associated with any combination of these phenotypes. We hypothesized that individuals with more than one of these phenotypes might be more likely to have a CNV as a cause of their disabilities. We selected 245 individuals with both schizophrenia and epilepsy from the NIMH Human Genetic Initiative collection. Specifically excluded from the study cases were individuals with seizures from: antipsychotic drugs, electrolyte imbalances, infection/fever, and trauma. DNAs were analyzed using array comparative genomic hybridization (CGH). Clinical arrays, used once previously in a CLIA laboratory, were stripped and re-used to screen these samples. The array used is a 180K Agilent oligonucleotide array designed to detect common clinical abnormalities, including exon-by-exon coverage for over 1700 genes known to be relevant or potentially relevant to various phenotypic disabilities. All potentially clinically significant abnormalities were confirmed by an independent array or other method. We identified the following changes: 3 del 22q11.2, 3 del 1q21.1, 2 dup CHRNA7, 2 dup 15q11-q13, 1 del NRXN1, 1 del15q13.3, 1 del 9p24.3, 1 dup7q11.23 and 1 del 16p13. A similar number of NIMH control DNA samples were analyzed using the same array platform. We eliminated controls who reported by questionnaire a history suggestive of major depressive episode, generalized anxiety disorder, alcohol and/or drug dependence, or obsessive compulsive disorder. Only one abnormality potentially known to be associated with phenotypic effects (dup 22q11.2) was detected in the control population. We identified 13 abnormalities of highly likely clinical significance not counting the two dup CHRNA7 in the 245 cases with combined schizophrenia and epilepsy for a frequency of 5.3 percent. Many variants of uncertain significance were observed in cases and controls, and further validation and characterization are in progress. These data support the hypothesis that the frequency of identifiable genetic abnormalities in cases with combined schizophrenia and epilepsy is greater than for either phenotype alone. These samples should also be enriched for other genetic abnormalities, including point mutations that would lead to the combined phenotype of schizophrenia and epilepsy.

2521/W

Exon-Focused CGH Array for X-Linked Mental Retardation. *P. Bayrak-Toydemir, M. Priest, T. Lewis.* ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT.

BACKGROUND: Mental retardation (MR) is estimated to effect 1-3% of the population. Given the excess of males observed in large cohorts of patients, defects of genes on the X chromosome are believed to account for greater than 25% of moderate and severe forms and almost 50% of mild forms of mental retardation. There are more than 90 genes on the X chromosome which have been related to MR. However, in other genes copy number changes of variable sizes ranging from single exon of a gene to deletions/duplications of many genes might also cause X-linked MR (XLMR). METHODS: To explore the role of X-chromosome gene deletions and duplications XLMR, a custom 720K NimbleGen CGH array was designed. 1737 transcripts were identified in the USCS Genome Browser and compiled into 954 composite transcripts to account for genes with multiple transcripts. The array contains probes spanning the length of the chromosome, covering the 7722 exons of the 954 transcripts with tiled 60mer probes at 15 bp spacing. Exons represent 2.6Mb, or just 1.7%, of the X chromosome yet 24% of the probes are concentrated in these regions. Probes are placed at a mean interval of 140 bp in introns and 1kb 5' and 3' of each transcript, accounting for 49% of the probes. Probe density in intergenic regions is at a mean spacing of 525 bp. Genomic DNA of nine individuals with known variations were hybridized against sex-matched controls and results compared against the known variations. RESULTS: Nine patient samples harboring deletions or duplications ranging in size from 1.6 Mb to 1186 bp were analyzed. Three samples with contiguous multiple gene deletions were identified using a 10X averaging window in the SignalMap2.5 software. Deletions and duplications in the four exon and two single gene samples were identified using a 1X-averaging window. Results were concordant with previous studies. CONCLUSIONS: A high-density custom X-chromosome array has been designed for detecting copy number changes ranging from large genomic regions to variations within a single gene. Currently 215 (22%) of the genes on the X chromosome are known to be involved in XLMR, however roughly 40% of the protein coding genes on the X chromosome are expressed in the brain; in principal XLMR could result from copy number changes in any of these genes. Our custom designed exon-focused X chromosome array includes coverage of all known XLMR genes and potential XLMR genes with high sensitivity and specificity.

High Resolution aCGH Reveals Rare Structural Variation in Autism Candidates. *D.J. Hedges[1], P.L. Whitehead[1], B. Butler[1], H.N. Cukier[1], K. Hamilton[1], J.M. Jaworski[1], L. Nathanson[1], R. Martinez[1], S.L. Hauser[2], J. Oksenberg[3], J. Lee[1], M.L. Cuccaro[1], J.R. Gilbert[1], M.A. Pericak-Vance[1].* 1) Dr. John P. Hussman Institute fro Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Neurology, School of Medicine, University of California, San Francisco, CA; 3) Institute for Human Genetics, School of Medicine, University of California, San Francisco, CA.

In order to detect copy number variation (CNV) events in autistic and control individuals at sub-10kb resolutions typically not achievable with SNP-based arrays, we employed a candidate gene strategy using array-based comparative genomic hybridization (aCGH). Candidate loci were chosen based on their relationship to biological pathways implicated in autism. We placed particular emphasis on genes involved in Gamma-aminobutyric acid (GABA) processing and signalling. GABA is the major inhibitory neurotransmitter in the brain, acting primarily via the GABA receptors (GABR). Multiple lines of evidence, including alterations in levels of GABA and GABA receptors in autistic patients, indicate that the GABAergic system may be involved in autism etiology. Thus, we examined GABA-related pathways, along with genes from additional biological pathways implicated in autism, for structural variants. All autism cases were idiopathic with a minimum of comorbid conditions and dysmorphic features. Our initial high resolution (custom targeted Agilent 244k) screen of 66 loci (43 GABA-related and 23 additional autism candidate loci) within 150 idiopathic autism cases and 150 age and race-matched controls identified several hundred potential structural variations. A subset of these variants were exclusive to (or over-represented within) autism cases compared to control individuals. CNV loci were prioritized for confirmation and additional analyses based on frequency distribution among cases and controls, as well as predicted impact on gene structure, expression, and/or regulation. Validation assays were performed on 29 priority loci using TaqMan CNV assays (Applied Biosystems). The specific individuals harboring the variants were tested, along with 170 case and 170 matched control individuals that were not part of the initial aCGH screen. Insertions and deletion events were confirmed to be present at 14 loci, including GABBR2, JAKMIP1, SLC38A3, Neuroligin 4Y, Neuroligin 2, and ABAT. Four events below 10kb in size were detected via aCGH and independently confirmed. These results provide further evidence that biologically important structural variation exists below the effective resolution typically provided by standard SNP-based arrays. Our data highlight that the continued heavy reliance on GWAS array data for CNV discovery will fail to provide a complete picture of biologically relevant structural variation.

MAGI1 copy-number variation in bipolar affective disorder and schizophrenia. *R. Karlsson[1,2], L. Graae[1], M. Lekman[1,3], D. Wang[4], R. Favis[4], T. Axelsson[5], D. Galter[1], A. Carmine Belin[1], S. Paddock[1].* 1) Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden; 2) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 3) Department of Clinical Neuroscience, Karolinska Institutet, Stockholm, Sweden; 4) Johnson & Johnson Pharmaceutical Research and Development LLC, Raritan, NJ; 5) Department of Medical Sciences, Molecular Medicine, Uppsala University, Uppsala, Sweden.

Bipolar affective disorder (BPAD) and schizophrenia (SZ) are common and devastating diseases of the human brain that have consistently been shown to be highly heritable. After many years of ambiguous genetic research results, recent large-scale genetic studies have been very encouraging and revealed common variants that contribute to disease risk, as well as several rare disease-associated copy-number variants (CNVs). It is, however, remarkable that to date no variation has been identified that shows segregation with disease in larger pedigrees, which is to be expected for rare yet highly penetrant disease loci.

We identified a ca. 200kb deletion in the first intron of the MAGI1 gene that showed complete segregation with disease in a BPAD pedigree, with six of six affected individuals carrying the mutation. Additional support for involvement of the MAGI1 gene in psychiatric disease was derived from further analysis of 47 BPAD pedigrees (N=270), sporadic cases from clinical trials (1,123 BPAD, 3,192 SZ and 377 schizoaffective [SA]) and publicly available datasets (2,698 BPAD, 4,095 SZ). Seven additional CNVs over 100kb were identified in MAGI1 in these materials, while just two CNVs over 100kb were identified in the same gene in 14,907 control samples (association p-value = 0.05; Fisher's exact test, two-sided alternative hypothesis).

The MAGI1 gene encodes a post-synaptic scaffolding protein that interacts with a multitude of molecules that have been identified in the molecular pathology of BPAD and SZ, such as neuroligin, beta-catenin, the neuregulin receptor ERBB4 and glutamate receptors. In addition, we found further supporting evidence for a role of MAGI1's close relative MAGI2 in psychiatric disease. Our findings together with previous studies suggest involvement of MAGI1 in BPAD and SZ etiology, support the notion of a genetic overlap between the disorders, and may contribute to our understanding of underlying molecular mechanisms.

***CHRNA7* duplication - Could this common copy number variant represent a risk factor for neurodevelopmental and neuropsychiatric phenotypes?** *C.P. Schaaf, S. Mahadevan, R. Person, P. Szafranski, P. Stankiewicz, A.L. Beaudet.* Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Copy number variants of 15q13.3 have been associated with a wide variety of neurodevelopmental and neuropsychiatric phenotypes, including intellectual disability, autism spectrum disorder, schizophrenia and epilepsy. *CHRNA7*, encoding for the alpha7 subunit of the neuronal nicotinic acetylcholine receptor, which is highly expressed in brain, has been proposed as the causative gene for the majority of neurodevelopmental phenotypes in the 15q13.3 microdeletion and microduplication syndromes. Four main classes of copy number variants at the 15q13.3 locus have been reported: Large (1.5-1.6 Mb) deletions encompassing six genes, including *CHRNA7*; the reciprocal large (1.5-1.6 Mb) duplications; and the smaller (430-680 kb) *CHRNA7* deletions and duplications. While the respective deletion syndromes have variable expressivity of phenotypes, penetrance of all reported cases to date is >80%. The respective microduplications and their associated potential for increased dosage of alpha7 subunit of nicotinic acetylcholine receptors are of uncertain clinical significance at present. We ascertained individuals with *CHRNA7* duplications that were referred to the Baylor Genetics Laboratories for high-resolution array-CGH. We present detailed clinical data of 13 probands (ages 2-12 years) and extensive pedigree analyses thereof. All probands display developmental delay/intellectual disability of variable severity. Other common clinical findings include muscular hypotonia (8/13) and neuropsychiatric phenotypes such as autism spectrum disorder (6/13), anxiety disorder, disruptive behavior disorder and bipolar disorder (each 1/13 among probands). The study of 735 parents of patients with autism spectrum disorder from the Simons Simplex Collection reveals a frequency of 7/735 (1/105) for the *CHRNA7* duplication, which is higher than the frequency reported for the general population (1/170). Transmission Disequilibrium Testing reveals an increased inheritance of the duplicated allele to affected children (5 vs. 3) as compared to unaffected children (2 vs. 5).Preliminary findings might suggest some pathological significance of *CHRNA7* duplications with modest penetrance, but until larger numbers of samples are analyzed, the *CHRNA7* duplication remains of unknown significance.

2525/W

Analysis of Neuropsychiatric Copy Number Variants in 22q11.2 Deletion Syndrome. *M.B. Sheridan[1], P. Goldenberg[1], M. Xie[2], X. Gai[2], J.C. Perin[2], M. Bowser[1], A. Hacker[1], D. McDonald-McGinn[1], E.H. Zackai[1,3], R. Gur[4], T.H. Shaikh[5], B. Morrow[6], B.S. Emanuel[1,3].* 1) Division of Human Genetics; 2) Bioinformatics Core, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics; 4) Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA; 5) Department of Pediatrics, University of Colorado, Denver, CO; 6) Department of Genetics, Albert Einstein College of Medicine, Bronx, NY.

22q11.2 deletion syndrome (22q11DS) is the most common microdeletion syndrome, occurring in ~1:4,000 births. It is associated with a spectrum of neuropsychiatric disorders, including schizophrenia (SCZ) which is present in 23-30% of adults with 22q11DS. This is significantly increased over the 1% population prevalence of SCZ. We hypothesize that 22q11DS patients who develop SCZ have copy number variants (CNVs), other than the 22q11 deletion, that affect genes critical to neurobiological and neurodevelopmental pathways. The Affymetrix SNP 6.0 platform was used to identify CNVs in 208 22q11DS patients. CNV analysis was performed with Partek Genomics Suite, as well as in-house software. We focused primarily on larger CNVs that were detected by both approaches and represented by more than 50 probes, as they are less likely to be false positives. Validations are ongoing using FISH and/or real-time quantitative PCR. Not surprisingly, the 22q11 deletion is the largest CNV detected in each patient with an average length of 2,617,625 bp. 1,784 additional CNVs were detected in the 208 patients studied. The majority of these (87.3%) were either common CNVs or did not contain genes. Nevertheless, several of the large CNVs were rare, contained genes that have been previously associated with neuropsychiatric phenotypes, and were not detected in healthy controls in available CNV databases. These included an 870kb duplication involving *GRM3* in a 9 year-old patient who has deficits in emotion recognition, typical of SCZ patients. *GRM3* encodes a metabotropic glutamate receptor and is a candidate SCZ gene that may have epistatic interactions with catechol-O-methyltransferase (*COMT*), a gene in the 22q11 deleted region. Another 22q11DS patient was found to carry a ~1.5Mb deletion at 16p13.11. Deletions and reciprocal duplications in this region have been associated with SCZ and mental retardation. The behavioral phenotype of this individual is currently not known, as evaluation of this group of patients through brain-behavior studies is ongoing. Thus, although the entire cohort of patients has not been extensively screened for neuropsychiatric disorders, CNVs were detected in some that affect genes or chromosomal regions that have been implicated in neuropsychiatric diseases. These preliminary observations support our hypothesis that there may be other CNVs or alterations within the genomes of 22q11DS patients that predispose to neuropsychiatric phenotypes.

2526/W

Analysis of phenotype and microarray detected genome dosage changes in autism. *M. Smith[1], P.L. Flodman[1], K. Osann[1], M.C. Moore[1], J.J. Gargus[1], M. Simon[2], D. Wallace[2].* 1) Dept Pediatrics, Univ California, Irvine, Irvine, CA; 2) MAMMAG, Dept. of Biological Chemistry, Univ California, Irvine, Irvine, CA.

In our study of autistic probands recruited locally we carried out autism diagnosis using ADOS and ADI instruments. Probands underwent dysmorphology and neurological examinations and cognitive and language evaluations. We undertook microarray analyses using AFFYMETRIX 6.0 SNP arrays in 51 probands. We identified 3 groups: probands with CNVs >1mb in size (10 individuals), those with CNVs >100kb but less than 1mb (12 individuals); 29 with no copy number changes found using defined search parameters (20 markers, 100kb segments no more than 60 percent overlap with known variants). We determined that the gender ratio of subjects in each of these three groups was significantly different (Chi square p=0.03). In the group with copy number variants greater than 1mb the male:female ratio was 1:1.In the group with copy number variants greater than 100k but less than 1mb, the male:female ratio was 3:1. In the group with no copy number variants the male:female ratio was 8.7:1. Among those with no CNVs or CNVs >100kb, but less than 1mb lower IQ was associated with more severe autism as evidenced by higher CS scores (r=-0.34, p=0.03). In the group with large CNV >1Mb, IQ scores were significantly lower and were not correlated with CS scores, suggesting this group constitutes a separate category. In 2 siblings with autism we identified an unbalanced chromosome translocation that led to duplication of 2pter-p25.2 and deletion of CACNA1C and other genes in 12pter-12p13. The siblings differed in the degree of severity of impairment and SNP genotyping combined with copy number analysis (Birdsuite algorithm) revealed that they had each inherited different homologs of chromosomes 12 and 2 from the non-translocation carrying parent. We identified a number of large rare chromosome abnormalities in regions of the genome reported to be associated with autism, other neurobehavioral abnormalities and epilepsy by other investigators, these included CNVs greater than 1 Mb in size in 15q11-q13.3, 15q13-q14 and 15q24. In addition we found rare copy number variants around or >100kb that impacted specific genes previously noted in other studies to be altered in autism, e.g. NRXN1,and Xp11.2 genes ASMTL, ASMT, and ZNF57 gene on Xp11.3. We identified CNVs in THSD7A and THSD7B that encode subunits of thrombospondin 1 that interacts with neuroligin 1. In two subjects we identified deletions in KCNH8 that encodes a potassium channel gene involved in ion and neurotransmitter conductance.

Genetic and epigenetic analyses of monozygotic twins discordant for bipolar disorder. *H. Sugawara[1,2], K. Iwamoto[3], M. Bundo[3], N. Adati[4], J. Ueda[1], I. Kusumi[5], Y. Okazaki[6], J. Ishigooka[2], T. Kojima[4], T. Kato[1].* 1) RIKEN Brain Science Institute, Wako, Japan; 2) Department of Psychiatry, Tokyo Women's Medical University, Tokyo, Japan; 3) Department of Molecular Psychiatry, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 4) Computational Systems Biology Research Group, Advanced Computational Sciences Department, RIKEN Advanced Science Institute, Kanagawa, Japan; 5) Department of Psychiatry, Hokkaido University, Sapporo, Japan; 6) Tokyo Metropolitan Matsuzawa Hospital, Tokyo, Japan.

Although concordance rates in monozygotic (MZ) twins in bipolar disorder and schizophrenia are very high, they are not 100%. Because MZ twins have been regarded as having identical genomes, these facts suggest the importance of environmental or epigenetic factor for the onset of mental disorders. In fact, considerable epigenetic differences between MZ twins have been reported by several groups. On the other hand, there are also reports of genetic differences between MZ twins such as point mutations and microsatellite repeat length. In addition, difference of copy number variations between MZ twins has recently been discovered. Therefore, both genetic and epigenetic factors may play a role in the discordance of the onset of diseases between MZ twins.

We have been searching for both genetic and epigenetic differences between MZ twins discordant for bipolar disorder. For genetic analysis, we performed in-depth CNV analysis of the lymphoblastoid cell lines derived from two pairs of discordant MZ twins using Agilent 244K CGH and 488K CNV arrays. We could not detect significant CNV differences between the MZ twins except for the immunoglobulin-associated regions. In addition, we are performing whole exome sequencing to explore the genetic differences between the MZ twins at a single base pair resolution. For epigenetic analysis, we used Methylcollector Ultra Kit for the enrichment of CpG methylated DNA, and compared genome-wide DNA methylation patterns of promoter regions between the MZ twins using Affymetrix Human Promoter Array. We performed bisulfite PCR sequencing analysis to confirm the differences. We found a number of regions showing DNA methylation differences between the MZ twins. Some of them were confirmed by bisulfite PCR sequencing analysis.

Possible pathophysiological role of the both genetic and epigenetic difference between the MZ twins is a matter of interest in our future study.

2528/W

Apolipoprotein E polymorphisms and sporadic amyotrophic lateral sclerosis. *M.D. Sozuguzel Ozel[1], E. Ergul[1], A. Sazci[1], H.A. Idrisoglu[2].* 1) Medical Biology and Genetics, University of Kocaeli, Faculty of Medicine, Umuttepe, Kocaeli, Turkey; 2) Department of Neurology, Faculty of Medicine, University of Istanbul, Capa, 34280, Istanbul, Turkey.

The apolipoprotein E (apoE) gene located on chromosome 19 in human plays a critical role in predisposition to late onset Alzheimer's disease and other human neurodegenerative disorders. In the present study, for the first time in the Turkish population, we carried out the analysis of genetic association of apoE gene variants in 392 (244 male (62.24%), 148 female (37.76%);)sporadic amyotrophic lateral sclerosis patients (ALS) aged from 20 to 75 years (53.56±13.780) and 366 (225 male (61.48%); 141(38.52%) female;healthy controls aged from 20 to 75 years(53.54±16.403). In order to do genotype analysis, a polymerase chain reaction- restriction fragment length polymorphism procedure was employed. The distribution of ε2, ε3, and ε4 alleles was 7.53%, 84.57% and 7.90% in SALS and 7.92%, 84.02%, and 8.06% in controls respectively. There was no allelic association between APOE gene and SALS in overall population.However individuals with ApoE2/4 genotype showed significant protection against SALS (χ2=7.062; P=0.008; OR=0.101; 95%CI= 0.013, 0.805). When we analyzed the data according to gender, there was no association between APOE gene and SALS in males(χ2=5.649; P=0.342). Whereas the ε3 allele was associated with SALS in females(χ2=5.978;P=0.014; OR=8.842; 95%CI=1.091-71.634). APOE 2/4 genotype provided protection against SALS in females(χ2=6.431;P=0.011). Consequently APOE gene shows association with SALS in Turkey on a gender specific manner.

2529/W

Recurrent disruption of *HIP1* identified in patients with epilepsy, learning difficulties, mental retardation, and neurobehavioral abnormalities. *M. Bartnik[1] *, M.B. Ramocki[2,3] *, P. Szafrański[4], Z. Xia[4], G.S. Miller[5,6], E. Szczepanik[7], J.G. Coldwell[5], C.I. Akman[2], P.I. Bader[8], S.-H.L. Kang[4], C.A. Bacino[4], A. Patel[4], E. Bocian[1], S.W. Cheung[4], T. Mazurczak[1], P. Stankiewicz[1,4].* 1) Dept of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 2) Dept of Pediatrics, Section of Pediatric Neurology and Developmental Neuroscience, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX; 4) Dept of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 5) Children's Medical Center at Hillcrest, Tulsa, OK; 6) University of Oklahoma, Tulsa, OK; 7) Dept of Neurology, Institute of Mother and Child, Warsaw, Poland; 8) Northeast Indiana Genetic Counseling Center, Fort Wayne, IN. *These authors contributed equally.

In a few patients with an unusual association of Williams-Beuren syndrome (WBS) and infantile spasms, larger sized 7q11.23 deletions extending distally have been described. *MAGI2* (*membrane-associated guanylate kinase inverted-2*), mapping ~ 3.5 Mb distal to the WBS common deletion region, has been proposed to be responsible for infantile spasms. However, not all reported patients with deletions of *MAGI2* developed infantile spasms and to date, no point mutations have been identified in *MAGI2*. Further, at least two reported WBS patients with a 7q11.23 deletion leaving *MAGI2* intact have been diagnosed with infantile spasms. We report 10 individuals from five unrelated families with epilepsy, learning difficulties, mental retardation, and neurobehavioral abnormalities, who segregated a microdeletion between the WBS region and *MAGI2*. In four families, a recurrent ~ 1.1 Mb deletion likely resulted from nonallelic homologous recombination between flanking large complex low-copy repeats. A smaller sized deletion (~ 180 kb) in the fifth family enabled us to narrow the critical region to one gene, *HIP1* encoding Huntington interacting protein 1. HIP1 regulates AMPA-type (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) glutamate receptor trafficking in the central nervous system through its function in clathrin-mediated endocytosis. Mice with targeted mutation in the *Hip1* gene (*Hip1*$^{-/-}$) develop a neurological phenotype characterized by failure to thrive, tremor, and gait ataxia by 3 months of age. Five previously described patients with HIP1 deletions manifested severe MR but not epilepsy, and a parent with *HIP1* deletion in one of our families is reportedly normal, indicating incomplete penetrance. Magnetic resonance imaging of the brain was abnormal in one affected individual. We also have identified a reciprocal ~ 1.1 Mb microduplication in a patient with neurobehavioral abnormalities, including bipolar disorder and ADHD. Our collective data suggest that haploinsufficiency of *HIP1* is responsible for both focal and generalized epilepsies, which are associated with a broad range of cognitive dysfunction (cognitively normal to mild learning difficulties to severe intellectual disability) and neurobehavioral abnormalities, including inattention, hyperactivity, impulsivity, and aggression. Supported in part by grant R13-0005-04/2008 from the Polish Ministry of Science and Higher Education.

An investigation into the causes of Landau-Kleffner Syndrome. *J. Conroy[1], J. Casey[1], N. Shah[1], R. Regan[1], M. Morgan[2], K. Collins[3], B. Parry-Fielder[3], S.A. Lynch[4], M. King[2], S. Ennis[1,4].* 1) Sch Med & Med Sci, Univeristy College Dublin, Dublin 4, Ireland; 2) Department of Neurology, Children's University Hospital Temple Street, Dublin, Ireland; 3) The Royal Children's Hospital, Melbourne, Australia; 4) National Centre for Medical genetics, Dublin, Ireland.

Landau Kleffner Syndrome (LKS) is a rare epileptic disorder of childhood of unknown aetiology (OMIM 245570). It is characterised by acquired receptive and expressive aphasia, epileptic seizures, and is associated with characteristic focal/multifocal spikes or spike and wave discharges which are continuous during sleep. Many children also exhibit behavioural disturbances that overlap those displayed by individuals with autism. Some individuals experience a complete recovery of language aphasia, but approximately 50% remain with severe residual language deficits. This study comprises 2 sets of discordant twins (one twinset has previously been reported by Feekery et al, 1993) and an additional 3 affected individuals. As the etiology of LKS remains unclear, a broad investigation was undertaken. All samples were genotyped on the Illumina 1M SNP array. CNV analysis was performed using PennCNV. *De novo* post-twinning CNV frequency could be 5% on an individual basis, and 10% per twinning event (Bruder et al, 2008). CNVs were analysed in a two step strategy. Firstly CNVs were compared in each affected twin to its unaffected twin. Then, all CNVs in the remaining individuals were compared to the "discordant CNVs" to identify if a common gene was affected. No single causative CNV was detected in all of the 5 affected individuals. Methylation differences were assessed using the Human methylation27 Illumina array. Again, the methylation analysis was performed using a two step strategy. Firstly, those methylation differences (Delta Beta values ≥ or £ 0.34, and Diff Score ≥ 32) between the discordant twin pairs were catalogued. In total there were 135 probes which were differentially methylated between affected and unaffected twin. Two overlapped (in PEG10 and CASP2). The additional 3 samples were compared to the unaffected twins and 14 control samples. The above 2 probes did not show differential methylation. When all LKS samples were compared to all controls, no significant autosomal differential methylation was detected. Using exome sequencing, possible patient specific mutations leading to the development of LKS were sought. Both discordant twin pairs, and 2 of the 3 remaining samples were sequenced (performed by GATC Biotech). Again, the analysis of variants began with identifying those mutations that are discordant between twins, and then analysis was extended to the 2 remaining affected individuals. These results will be presented at this meeting.

Array CGH detection of clinically relevant copy-number changes in epilepsy. *M.B. Ramocki[1,3], S.R. Lalani[2,3], Z. Xia[2], C. Shaw[2], S.-H.L. Kang[2], C.A. Bacino[2,3], A. Patel[2], J.R. Lupski[2,3,4], S.W. Cheung[2], A.L. Beaudet[2,3,4], P. Stankiewicz[2].* 1) Department of Pediatrics, Section of Pediatric Neurology and Developmental Neuroscience, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX; 4) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Copy-number variation (CNV) is a well-documented cause of syndromic epilepsy. Nonrecurrent CNVs disrupting *SCN1A*, *LIS1*, *MEF2C*, and *CDKL5*, or duplicating MECP2, and recurrent deletions in 15q11.2, 15q13.3 (*CHRNA7*), 16p13.11, 16p11.2, 16p12.1, and 1q21.1 cause generalized or focal epilepsy. We hypothesized that retrospective query of clinical chromosomal microarray analyses (CMA) performed on patients with epilepsy at Texas Children's Hospital would provide a rich source of information for gene identification and lend insight into the prevalence of previously identified CNVs in epilepsy. Out of ~2000 local patients referred for CMA between 2/04 and 3/10 with referring clinical indications of epilepsy, seizure, or infantile spasms, we identified 182 (9%) cases with nonpolymorphic CNVs. Upon extensive chart review, 36 cases were excluded because an epilepsy diagnosis could not be confirmed. Of the remaining 146 cases, 41 (28%) were genetically diagnostic based on previously reported CNVs associated with epilepsy including: Angelman syndrome (6), unbalanced translocations (5), 16p11.2 deletion (3), 1p36 deletion (3), 1q21.1 deletion (3), 1q21.1 duplication (2), *MECP2* duplication (2), *SCN1A* deletion (2), 15q11.2 (BP1-BP2) deletion (2), 15q13.3 duplication (2), Williams-Beuren region duplication (1), 9q34.3 deletion (1), 14q11.2 deletion (1), 15q13.3 deletion (1), 16p13.11 duplication (1), 17q21.31 deletion (1), 22q11.2 deletion (1), Xp22.31 deletion (1), *CDKL5* deletion (1), mosaic deletion of LIS1 (1), and XYY (1). We also identified 20 novel microdeletion (14) and microduplication (6) CNVs less than 1 Mb in size that harbor potential dosage-sensitive epilepsy causative or susceptibility genes. Microdeletions include chromosomes 2q34 (*ERRB4*), 3q21.2 (*PTPLB*), 7p11.2 (*GBAS*), 7p15.2 (*HOXA1*), 7q11.23 (*HIP1*), 8q24.22 (*KCNQ3*), 9q34.2 (*SLC2A6*), 11q12.2 (*MS4A* gene family), 11q22.3 (*GRIA4*), 15q26.1 (*KIF7*), 18q12.3 (*RIT2*), 19q13.12 (*ZNF* gene family), Xq21.31 (*CPXCR1*), and Xq28 (*VAMP7*); and microduplications include chromosomes 3p24.3 (*KCNH8*), 5p13.2 (*GDNF*), 8p21.2 (*NEFL*), 14q12 (*FOXG1*), 17p13.2 (*UBE2G1*), Xp22.32 (*NLGN4X*) (2 cases), and Xp11.22 (*PHF8*). Our results further confirm the pathogenic role of both recurrent and nonrecurrent submicroscopic CNVs in the etiology of epilepsy and demonstrate the usefulness of our approach to the identification of novel epilepsy genes. Accumulating data support the clinical use of CMA in the genetic diagnosis of epilepsy.

MOLECULAR ANALYSIS OF THE SCN1A GENE IN SOUTHERN ITALIAN PATIENTS WITH SEVERE MYOCLONIC EPILEPSY OF INFANCY. *F. Rocca[1], F. Annesi[1], G. Provenzano[1], E.V De Marco[1], P. Tarantino[1], V. Greco[1], D. Civitelli[1], V. Scornaienchi[1], G. Tortorella[2], G. Incorpora[3], A. Labate[4], A. Gambardella[1,4], G. Annesi[1].* 1) Inst Neurol Sci, National Res Council, Mangone, Italy; 2) Departement of Neurosciences, Psychiatry and Anaesthesiology University of Messina, Messina, Italy; 3) Pediatric Unit, Hospital " Civile - Paternò Arezzo", Ragusa, Italy; 4) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Severe myoclonic epilepsy of infancy (SMEI), or Dravet syndrome, is a severe autosomal dominant epileptic encephalopathy mainly caused by de novo mutations in the voltage-gated sodium channel gene (SCN1A). Most of these mutations are nonsense or frameshift; missense mutations are also common. Recent studies have already reported that about 12% of mutation-negative SMEI patients have microchromosomal abnormalities involving SCN1A. However, the rates of detection of SCN1A mutation in SMEI patients range widely in the different populations. To investigate the frequency of SCN1A mutations in our population, we analyzed 19 SMEI patients (10 males and 9 females) from Southern Italy, who fulfilled the strict clinical definition of SMEI.Mutation analysis was performed by direct sequencing. The genomic anomalies were screened using multiplex ligation-dependent probe amplification (MLPA) and confirmed by Gene dosage experiment.Six different heterozygous coding variants were found in 6 unrelated SMEI cases (31.5%): 4 novel mutations (Thr1289Ile, 3840insT, IVS7+4delA, Glu1021X) and 2 previously described (IVS24-2A/G, Ser1505X). Using MLPA assay we identified a deletion of exons 1-25 in one of the 13 patients without SCN1A point mutations (8%). The 3840insT and IVS24-2A/G mutations were de novo; the parents of the other patients were not available.The frequency of SCN1A mutations is lower in our SMEI patients in comparison to other populations. Our results confirm the importance of screening the coding regions with both direct sequencing and a quantitative method and suggest that further genetic studies are needed to determine the causative mutations and genes involved in the remaining SCN1A-negative patients.

Analysis of Autism Spectrum Disorder Families Reveals Association with Inflammatory Gastrointestinal Disease Loci. *S.J. Walker[1], P.S. Ramos[2], C.D. Langefeld[2].* 1) Institute for Regenerative Medicine, Wake Forest Univ, Winston Salem, NC; 2) Dept Biostatistical Sciences, Wake Forest Univ Health Sciences, Winston Salem, NC.

Autism spectrum disorders (ASDs) comprise a heterogeneous collection of affected developmental features centered on deficits in cognition, communication, social acuity, and coupled with repetitive, stereotyped patterns of behavior. In addition to the core deficits, affected children (currently estimated to be 1 in 110 in the U.S.) also display a wide range of concurrent medical conditions. One frequently cited co-morbid finding in ASD children is chronic gastrointestinal (GI) symptoms. To determine if the GI symptoms observed in these ASD children share unique genetic risk factors with known inflammatory diseases of the bowel, we performed a family-based association analysis between gene variants implicated in GI inflammatory diseases and ASD. We compiled a list with 195 SNPs reported as significant in genome-wide association studies (GWAS) of GI inflammatory diseases (inflammatory bowel disease, Crohn's disease, ulcerative colitis, and celiac disease), available either at the GWAS catalog (www.genome.gov/gwastudies) or curated manually. We used genotypic and phenotypic data available from the Autism Genetic Resource Exchange (AGRE) repository to evaluate GI loci that were associated with ASD in 1,510 trios and a subset of 269 trios where the affected child also has reported GI involvement (ASD-GI). The standard Transmission Disequilibrium Test (TDT) implemented in PLINK was performed using genotypic data from the Illumina Hap550 platform. The most significant P-value is in the Kruppel-like factor 12 (KLF12) region (rs11617463, PASD=6.95x10-04, OR [95%CI] =0.71 [0.58-0.87]), in a locus that has shown association to both Crohn's and celiac disease. An effect at the EPH receptor A7 (EPHA7) region, which has been associated with celiac disease, was observed in all ASD trios and the subset with GI symptoms (rs4446534, PASD=1.74x10-03, ORASD=0.84 [0.76-0.94], PASD-GI=5.75x10-03, ORASD-GI=0.74 [0.6-0.92]; rs4571541, PASD= 5.79x10-03, ORASD=0.85 [0.76-0.95], PASD-GI=9.51x10-03, ORASD-GI= 0.73 [0.57-0.93]). When we analyzed the subset of children with GI complications, the most significant locus was that of 6-phosphofructo-2-kinase/fructose-2, 6-biphosphatase 3 (PFKFB3, rs1064891, PASD-GI=4.99x10-04, OR=0.67 [0.53-0.84]), which has been associated with celiac disease and is near interleukin 2 receptor alpha (IL2RA). This study demonstrates that several loci associated with inflammatory GI diseases are also associated with ASD.

A migraine susceptibility locus segregating in rolandic epilepsy families maps to 17q21.33-q22. *L. Addis[1], T. Chiang[2], W. Li[2], L.J. Strug[2], D.K. Pal[1].* 1) Clinical Neurosciences, Institute of Psychiatry, King's College London, London, United Kingdom; 2) Hospital for Sick Children, Toronto, ON, Canada.

Migraine without aura is co-morbid in Rolandic Epilepsy (RE) cases, and familial aggregation studies indicate a 3-fold elevated risk of migraine in their seizure-free siblings. These results suggest a shared susceptibility that is not directly mediated by seizures. Although migraine is believed to be a complex genetic disorder in the general population, the genetic model for migraine in a homogenous sample of RE families may be less complex. On this assumption we carried out a genome-wide linkage screen to map a migraine susceptibility locus in 23, 2-4 generation RE families. The families were singly ascertained in the USA as part of an investigation into the genetic causes of RE. These families contained at least one member who also met the International Classification of Headache Disorders (ICHD-2) criteria for migraine. Using Genehunter, the maximum HLOD obtained was 4.4 between markers D17S788-D17S787 under a recessive model of inheritance, 99% penetrance. At this locus, 17 of the families provided positive LOD scores. Singlepoint linkage analysis provided a LOD of 2.1 at the same markers and under the same inheritance model. Analysis of differential male and female recombination fractions did not provide evidence for imprinting. The 9MB, 2LOD interval on chromosome 17 contains a relatively small number of genes, which we are currently investigating to elucidate functional variants. Loci on chromosomes 1q and 2q also provided linkage evidence, with LODs above 2.3 for both single- and multipoint analysis. These loci will also be further investigated given the observed heterogeneity at the 17q locus. None of these loci have been previously reported in the literature as migraine susceptibility loci, and thus it is possible that the 17q locus and others are specific to migraine without aura susceptibility in RE. Siblings of RE cases are at a 50% risk of carrying the EEG abnormality associated with RE. Thus the presence of RE in a family may represent a marker of a heritable form of cortical excitability, which along with additional genetic factors, can result in either RE, migraine, or both. Understanding the genetic etiology of migraine in RE can also provide important insight into migraine in the general population.

2535/W

Using Ingenuity Pathway Analysis to study gene relationships under linkage peaks of interest in Autism Spectrum Disorders. *A. Hare[1], M. Azaro[1], V. Vieland[2], J. Flax[1], L. Brzustowicz[1].* 1) Gen, Rutgers Univ, Piscataway, NJ; 2) The Research Institute at Nationwide Children's Hospital, Columbus, OH.

Using behavioral and genetic information from the Autism Genetic Resource Exchange (AGRE) dataset we developed behavioral phenotypes and investigated linkage and association for individuals with and without Autism Spectrum Disorder (ASD) who exhibit expressive language behaviors consistent with a motor speech disorder. Speech and language variables from Autism Diagnostic Interview-Revised (ADI-R) were used to develop two motor speech phenotypes (NVMSD:ALL and NVMSD:C). Using Affymetrix 5.0 data, the Posterior Probability of Linkage (PPL) framework was used to assess the strength of evidence for or against trait-marker linkage and linkage disequilibrium (LD) across the genome. We identified several linkage peaks based on two related expressive language phenotypes consistent with a potential motor speech disorder: Chromosomes 1q24.2, 3q25.31, 4q22.3, 5p12, 5q33.1, 17p12, 17q11.2 and 17q22 for NVMSD:ALL and 4p15.2 and 21q22.2 for NVMSD:C. While no compelling evidence of association was obtained under those peaks, we were able to identify several potential genes of interest using the core analysis of Ingenuity Pathway Analysis (IPA). IPA utilizes a Right-tailed Fisher's exact test to calculate a p-value determining the probability that each biological function and/or disease represented by the genes in our linkage regions is due to chance alone. Genes with functions related to Nervous System Development and Function, Neurological Disorders, Genetic Disorders, and Psychological Disorders were identified from the core analysis. We conducted control analyses in IPA in order to verify the reliability of the use of IPA in candidate gene identification. The results of the IPA control analyses were treated as a background subtraction tool for our linkage analyses in order to ensure that the final candidate gene list was unique to our phenotype. Each control analysis was comprised of a core analysis of 645 randomly selected genes designed to mimic the number of genes included in the core analysis of our linkage regions. Overall, 52 candidate genes were selected from a total of 645 genes for NVMSD:ALL and 51 candidate genes were selected from 388 genes for NVMSD:C. Given that autism spectrum disorders are complex with a wide range of behaviors and a large number of underlying genes, this motor speech phenotype may be one of several that should be considered when developing narrow, well-defined, phenotypes in the attempt to reduce genetic heterogeneity.

2536/W

Identification of an autosomal recessive stuttering locus on chromosome 3q13. *M. Raza[1], S. Riazuddin[2], D. Drayna[1].* 1) SSBCD, LMG, NIDCD/NATIONAL INSTITUTE OF HEALTH, 5 RESEARCH COURT, ROCKVILLE, MD; 2) ALLAMA IQBAL MEDICAL COLLEGE, LAHORE PAKISTAN.

Stuttering is a common speech disorder characterized by involuntary disruptions of verbal expression. Although its causes remain poorly understood, there is good evidence for genetic contributions to this disorder. Because of marginally significant linkage scores and difficulties reproducing linkage observations across studies, we sought to increase the power to detect linkage using highly consanguineous families. We studied families from the Pakistani populations in which inbreeding is common. We enrolled 6 consanguineous families from Pakistan, all containing multiple members who stutter. Family members were diagnosed using the Stuttering Severity Instrument-3, and we performed a genome wide linkage scan using the SNP genotyping with the Illumina 6K Chip. The program Pedcheck was used to test for proper inheritance within families. Two-point parametric linkage analysis was performed using SuperLink v1.4 from the EasyLinkage v5.08 package. The disease allele frequency was set at 0.01 and Caucasian allele frequencies provided by Illumina were used for the analysis. Due to the high degree of consanguinity in this family and in the Pakistani population, autosomal recessive inheritance was assumed. Significant evidence of linkage, with a LOD score of 3.23 under a recessive mode of inheritance, was found at SNP rs7631540 on chromosome 3q13.31 (at 115.31 Mb) in one family, designated PKST77. No markers showed significant linkage under either additive or dominant models of inheritance in this family. The surrounding interval was genotyped with additional microsatellite and SNP markers. LOD scores of 3.13, 4.23 and 3.74 were obtained with markers rs1317244 (113.53 Mb), D3S1310 (116.26 Mb) and D3S1303 (119.64 Mb), respectively. Haplotype construction narrowed the linkage interval to 3.24 Mb (extending from SNPs rs13062867 to rs714697). Based on the UCSC genome browser, some 46 known and predicted genes are found in this region of chromosome 3q. Within this interval, the exons of the candidate gene DRD3 (Dopamine Receptor D3) were sequenced in affected as well as unaffected individuals from PKST77, however no novel variation was observed. Our results demonstrate strong evidence of a novel stuttering linkage locus based on studies in a consanguineous stuttering family PKST77. In addition to the previously reported stuttering genes on chromosomes 12q and 16p (Kang, et al., 2010), an additional stuttering locus resides on chromosome 3q.

2537/W

Homozygosity Haplotype analysis of high denisty SNP genotype data link an autosomal dominant atypical movement disorder to chromosome 19p13.3-q13.12. *L. Yu[1], Y. Liu[2], M. Kan[2], A. Nicolas[3], L. Gao[4], L. He[2,4], R. Margolis[1].* 1) Dept. of Psychiatry & Behavioral Sci, Johns Hopkins University, Baltimore, MD; 2) Institutes of Biomedical Sciences, Fudan University, Shanghai, China; 3) Department of Neurology, University of Alabama at Birmingham School of Medicine,Birmingham AL; 4) Bio-X Center, Shanghai Jiaotong University, Shanghai, China.

The considerable information content of high-density single nucleotide polymorphism (SNP) genotyping makes this approach potentially quite valuable for linkage analysis. However, high-density SNP genotype data present an analytic challenge. A recently developed non-parametric method termed Homozygosity Haplotype (HH) analysis allows for a genome-wide search of the shared autosomal segments among patients using high-density SNP genotype data. We have applied this method to individuals from a family with an atypical movement disorder, segragating in an autosomal dominant pattern. The phenotype consists primarily of a late onset slowly progressive gait ataxia complicated in some individuals by abnormal tone, dystonia, and/or episodic attacks of ataxia. We performed a genome wide scan using the Illumina human1M-duo beadChip. HH analysis revealed a 33.4 Mb genomic region on chromosome 19 suggestive for linkage (-log10P is between 2.9 and 5.7). We independently validated the region on Chr19p13.3-q13.12 using microsatellite markers, with a maximum two-point LOD score of 3.64 at D19S406. In conclusion, both parametric and non-parametric analyses support linkage of the disorder to Chr19p13.3-q13.12. The defined genomic interval will facilitate identification of the causative mutation.

Nicotine Dependence: Linkage and Association Analyses Suggest a Role for ST8SIA4. *P.A. Madden[1], M. Pergadia[1], A.C. Heath[1], N.G. Martin[2], J. Kaprio[3,4,5], G.P. Montgomery[2], Nicotine Addiction Genetics Consortium.* 1) Psychiatry, Washington University, St. Louis, MO, USA; 2) Queensland Institute of Medical Research, Brisbane, Australia; 3) Department of Public Health, University of Helsinki, Helsinki, Finland; 4) Institute for Health and Welfare (THL), Helsinki, Finland; 5) Institute for Molecular Medicine Finland FIMM, University of Helsinki, Helsinki, Finland.

The Nicotine Addiction Genetics Project (NAG) is an international collaborative study between investigators from Australia, Finland and the USA to identify factors that affect risk for tobacco use and dependence. Presented will be linkage and gene-based genetic association findings for nicotine dependence (ND), defined using a quantitative measure derived from the factor analysis of survey items based on DSM-IV Nicotine Dependence and the Fagerstrom Test for Nicotine Dependence assessed during the heaviest period of cigarette smoking in Finnish and/or Australian subjects. Because no evidence suggests that dependence on nicotine is a quantitative trait, analyses using a quantitative measure should maximize our power to identify chromosomal regions that harbor risk loci for this public health problem. Linkage findings were obtained from the separate and combined analysis of 10cM microsatellite marker genome scan data on DNA obtained from 2300 Australian and Finnish subjects from 440 families ascertained for heavy lifetime cigarette use. Results indicate a linkage signal for ND on chromosomes 5 (LOD=3.9, empirical p=0.03) among Australian smokers. Subsequently, a gene-based test (VEGAS), that adjusts for both linkage disequilibrium and gene size, was applied to SNP data limited to the region under the chromsome 5 linkage peak. The top ranked gene was ST8SIA4 (p=7.0E-06; which exceeds the Bonferroni corrected threshold: p < 2.5E-04). ST8SIA4 is a polysialyltransferase which is involved in the polysialylation of the neural cell adhesion NCAM molecule, the expression of which has been reported in findings from animal research to be affected by the presence of nicotine. Our linkage findings were observed in the Australian, but not the Finnish linkage sample, suggesting that these findings might be most relevant in families with more severe levels of heavy smoking and ND.

2539/W

Using family-based association study to refine the candidate region for bipolar affective disorder on chromosome 3p22. *R. Secolin[1], C.E.M. Banzato[2], M.C.M. Oliveira[2], M.F.R. Bittar[1], P. Dalgalarrondo[2], I. Lopes-Cendes[1].* 1) Dept Med Gen, Univ Campinas - UNICAMP, Campinas, SP, SP., Brazil; 2) Dept Medical Psychology and Psychiatry, Univ Campinas - UNICAMP, Campinas, SP, SP., Brazil.

Background: BPAD is a common psychiatric illness, with a prevalence of 0.8-2.6 % in the general population. Clinical features include episodes of mania or hypomania, interspersed with periods of depression. Genetic factors are known to contribute to the etiology of BPAD. We have previously identified a candidate locus on chromosome (ch) 3p22 using a group of nuclear families segregating BPAD and a family based association strategy. **Objectives:** To refine the ch 3p22 candidate region for BPAD using additional SNPs in our group of families. **Methods:** We evaluated 97 nuclear families, with a total of 411 individuals, including 96 patients who fulfilled clinical criteria for BPAD according to DSM-IV classification. We genotyped 94 SNPs within the 3p22 candidate locus using the SNPlex® system (Applied Biosystems). Statistical power was verified using TDT POWER CALCULATOR. Genotyped data was processed by JINGLEFIX program, which also estimated minor allele frequency (MAF). Mendelian inconsistencies were evaluated by PEDCHECK software. We estimated Hardy-Weinberg equilibrium and linkage disequilibrium using HAPLOVIEW software. Family based association analysis was performed by the transmission disequilibrium test (TDT) using TDTAE software. Statistical results were adjusted for multiple comparisons using the Bonferroni correction. **Results:** Our sample showed statistical power higher than 80% to detect association. Four SNPs presented MAF < 0.05 (rs3772105, rs35107818, rs11928905 and rs35479964) and two were in Hardy-Weinberg disequilibrium (pvalue < 0.001; rs2290528, rs2685112), these were excluded from the final analysis. We found significant association signal for SNP rs166508, even after Bonferroni correction ($p_{corrected}$ = 0.0187). **Conclusions:** We demonstrated that SNP rs166508 is associated with BPAD in our family sample. This SNP is located within intron 15 of the integrin alpha 9 (*ITGA9*) gene. *ITGA9* encodes a subunit of the alpha 9 integrin, an integral membrane glycoprotein which is a receptor for a nerve growth factor, neurotrophin 3 and brain-derived neurotrophic factor. It remains to be determined whether *ITGA9* plays a role in the mechanism underlying BPAD. FAPESP, São Paulo, Brazil.

2540/W

Genome-Wide Copy Number Analysis of Schizophrenia Patients. *D. Rudd, M. Axelsen, E. Epping, T. Wassink.* Univ Iowa, Iowa City, IA.

Schizophrenia is characterized by positive and negative symptoms that include hallucinations, delusions, disorganized thought as well as flat affect and decreased speech. Previous studies have identified both common and rare copy number variants that confer risk to developing schizophrenia. Therefore, we analyzed our novel sample set of schizophrenia patients for genome-wide copy number variation in order to identify novel candidate genes. We used Affymetrix Genotyping Console 3.0 to analyze signal intensity data from Affymetrix Genome-Wide Human SNP Array 6.0 microarrays. To date we have analyzed 58 schizophrenia probands and 23 psychiatrically unaffected controls. CNVs discussed in this abstract were confirmed by qPCR and were not present in controls. First, we identified a 973kb deletion in one proband within *CNTN4* that disrupts the 5' untranslated region as well as the first 4 of exons of the long isoform. *CNTN4* is a GPI-anchored neuronal membrane protein that belongs to the super-family of neuronal cell adhesion molecules involved in axonal growth and guidance, and is involved in the fasciculation of the central nervous system. In addition, *Cntn4* knock out mice exhibit behavioral and neurological phenotypes. In humans, disruption of *CNTN4* is associated with an increased risk to develop an autism spectrum disorder (ASD) and is believed to contribute to the impaired social functioning observed in 3p deletion syndrome. Published data in two previous studies done by the same author reported no copy number variation in *CNTN4* out of 812 total controls. In two more unrelated probands we identified 435kb and 627kb deletions on chromosome 15q11.2 spanning the genes *NIPA1, NIPA2, CYFIP1* and *GCP5*. These four genes are highly conserved and located between breakpoint 1 and breakpoint 2 of the Prader-Willi/Angelman Syndrome (PW/AS) region. A previous report indicates that patients harboring an inherited or *de novo* heterozygous deletion in this region who additionally do not meet diagnostic criteria for PW/AS have severe psychiatric phenotypes such as attention deficit hyperactivity disorder, ASDs, and obsessive-compulsive behavior compared with 350 healthy, unrelated controls. Preliminary results in our genome-wide analysis of copy number variation in schizophrenia have identified promising candidates for disease etiology. Future directions include analysis and validation of CNVs in the remainder of the sample set of approximately 500 probands.

2541/W

Association of protein-coding variants in the microcephalin gene with cognition and symptoms of schizophrenia. *E.A. Epping[1], B.C. Ho[1], N.C. Andreasen[1], M. Axelsen[1], S. Mugge[1], T.H. Wassink[1,2].* 1) Department of Psychiatry, University of Iowa Carver College of Medicine, Iowa City, IA; 2) Interdisciplinary Program in Genetics, University of Iowa, Iowa City, IA.

Purpose: Schizophrenia is considered a highly heritable disorder disrupting normal brain development, but the etiologic factors responsible remain to be fully understood. The microcephalin protein encoded by the gene *MCPH1* is highly expressed early in brain development and regulates neuronal progenitor cell division. Deleterious mutations in *MCPH1* have been shown to result in primary microcephaly, and common polymorphisms have been implicated in evolution of human cortical size and cognitive functioning. In this work, it is hypothesized that protein-coding variants in *MCPH1* are associated with variation in brain morphology, cognition, and symptoms of schizophrenia. **Methods:** A sample of 313 individuals with schizophrenia or schizoaffective disorder and 175 healthy control subjects were genotyped at *MCPH1* protein coding SNPs rs930557 (His/Asp), rs1057090 (Ala/Val), and rs1057091 (Pro/Ser). The majority of these subjects have had structural brain MRIs, testing of cognitive function (27 tests grouped into 5 domains), and in patients, assessment of symptoms using scales for positive or negative symptoms of schizophrenia. Analyses of covariance using appropriate covariates for brain volumes or cognitive domains were performed to determine genotype effects. A genotype by diagnostic group interaction term was also included in the general linear models. Symptom measures were compared using t-tests. **Results**: Patients homozygous for the Pro variant at rs1057091 had significantly lower severity of hallucinations ($p < 0.02$) and delusions ($p < 0.05$) compared to Ser carriers. A significant genotype effect was also observed for the verbal memory domain with this variant ($p = 0.0001$), with poorer performance found in Pro homozygotes. A significant genotype effect was also observed for the rs1057090 SNP, with worse verbal memory performance in Ala homozygotes ($p < 0.01$). While there were no significant genotype effects on cortical brain volumes, Pro and Ala homozygotes had smaller hippocampus volumes, consistent with worse performance on tests of verbal memory. No significant effects were observed for the rs930557 SNP. **Summary:** Protein-coding variants in *MCPH1* were found to be associated with differences in verbal memory, hippocampus volumes, and positive symptoms of schizophrenia. The effect on verbal memory was found in both patient and control populations for two SNPs indicating these may contribute to variation in general cognitive functioning.

Association of HLA class I markers with Multiple Sclerosis in the Italian and UK population: evidence of two independent protective effects. *L. Bergamaschi[1], M. Ban[2], N. Barizzone[1], L. Corrado[1], M. Leone[3], M.E. Fasano[4], F.R. Guerini[5], P. Naldi[3], C. Agliardi[5], E. Dametto[4], M. Salvetti[6], A. Visconti[6], D. Galimberti[7], E. Scarpini[7], P. Cavalla[8], R. Bergamaschi[9], D. Caputo[10], S. Cordera[11], D. Vecchio[3], P. Momigliano-Richiardi[1], S. D'Alfonso[1].* 1) Department of Medical Sciences, University of Eastern Piedmont, Novara, Italy , Novara, Italy; 2) University of Cambridge, Department of Clinical Neuroscience, Addenbrooke's Hospital, Hills Road, Cambridge, CB2 0QQ, UK; 3) Department of Neurology, Ospedale Maggiore, and IRCAD, Novara, Italy; 4) Transplantation Immunology, San Giovanni Battista Hospital, Turin, Italy; 5) Laboratory of Molecular Medicine and Biotechnology, Don C. Gnocchi Foundation IRCCS, S. Maria Nascente, Milan, Italy; 6) Neurology and Center for Experimental Neurological Therapy (CENTERS), Università La Sapienza, Rome, Italy; 7) Department. of Neurological Sciences, University of Milan, Dino Ferrari Center, Fondazione Ospedale Maggiore Policlinico, Milan , Italy; 8) Department of Neurology, Ospedale San Giovanni Battista, Turin, Italy; 9) Neurological Institute C. Mondino, IRCCS, Pavia, Italy; 10) Multiple Sclerosis Unit, Don C. Gnocchi Foundation, IRCCS, S. Maria Nascente Milan, Italy; 11) Neurology Ospedale Umberto Parini, Aosta, Italy.

Background: We recently contributed to demonstrate for Multiple Sclerosis (MS) a second association signal in the class I HLA region independent of the well-established effect of the HLA-DR15 allele. In an Italian cohort we confirmed the association of HLA-A*02 and observed that the contemporary presence of HLA-Cw*05 significantly increased (3-fold) the protective effect of HLA A*02, independently of DR15. A*02-Cw*05 is carried by two HLA extended haplotypes characterized by the B*4402 and B*1801 alleles, respectively. Objectives and Methods: To better understand whether the strong protection of the A*02-Cw*05 combination was due to a haplotypic effect or a direct role of these two markers we extended the analysis in our Italian cohort (1445 MS cases and 973 controls) to the HLA-B*44 and -B*18 alleles and verified the association of the different combinations of tested HLA class I markers in an independent UK cohort (721 MS cases, 408 controls and 480 family trios). Results: The analysis of the Italian samples showed a strong protective effect of the A*02-Cw*05 combination carrying B*44 (OR=0.27 p=3.3x10-05), independently of DR15. This was confirmed in UK family trios (OR=0.33 p=5.5x10-4) and in a combined cohort of UK family trios and case/controls (OR=0.53 p=0.044). In both populations this protective effect was significantly stronger than that mediated by A*02 alone. At difference from A*02, the other HLA class I tested markers (Cw*05, B*44 and B*18) did not show individually any significant protection. Conclusions: This study identified two independent protective effects which are tagged by the A*02-Cw*05-B*44 haplotype and the A*02 allele, respectively.

Racial disparity in regulatory genetics of SLC6A3, a dopamine transporter implicated in multiple neuropsychiatric disorders. *Z. Lin, Y. Zhou.* Dept Psychiatry, MRC 114, Mclean Hosp/Harvard Med Sch, Belmont, MA.

Chromosomal DNA sequence polymorphisms may contribute to individuality, confer risk for diseases and most commonly, are used as genetic markers in association study. Current genome-wide association studies or candidate gene approaches use same genetic markers to underpin risk factors for complex diseases in various world populations and often result in inconsistent findings. To better understand ethnicity-specific genetics, we deep-sequenced the regulatory regions of SLC6A3, a gene that encodes the dopamine transporter and is implicated in many brain disorders with racial disparity, in 30 African (AA) and 30 Caucasian (CA) Americans. AA and CA carry 50.9% and 33.3% ethnicity-specific common polymorphisms including all of the most common ones in the SLC6A3 promoter. More than a half of the polymorphisms are not in the dbSNP yet. In each sample, 95% of the chromosomes carry unique regulatory haplotypes and none of the haplotypes are shared between the two ethnicities. Finally, a quarter of the haplotypes evolved in an ethnicity-specific manner and the rest co-evolved independently of ethnicity. These findings suggest that we are still at the beginning stage of understanding human genetics and that deep-sequencing will help dissect genetic variations underlying individuality, ethnicity and complex disease.

2544/W

Analysis of SNCA-LRRK2 genes interaction in Parkinson's disease and controls. *A. Parsian[1], J.H. Zhao[2], B. Patra[3].* 1) Div Neuroscience & Behavior, NIAAA/NIH, Bethesda, MD; 2) MRC Epidemiology Unit, Cambridge, UK; 3) Department of Pathology, Thomas Jefferson University, Philadelphia, PA.

Our earlier reports of eight single nucleotide polymorphisms (SNPs) in the SNCA and LRRK2 regions have indicated that they are at most have modest increase of susceptibility. In the current investigation, we focused on their interactions. The sample included 227 familial and 355 sporadic cases of Parkinson's diseases and 236 unrelated controls. As SNP-wise analysis shows no evidence of association we selected haplotype showing increased risk according to haplotype specific analysis in SNCA as covariate to those in LRRK2 in an interaction analysis both using R/haplo.stats, and vice versa. As in our earlier report, haplotype 112 of 770-int4-Rep1 in SNCA has frequency of 0.04817 (haplo.em) and shows moderate significance (haplo.score score statistic 2.53, asymptotic and simulated p values = 0.01; haplo.glm t-statistic=2.37 and p = 0.0182). In contrast, haplotypes 211212 and 212211 for rs10506151-rs10784486-rs1365763-rs1388598-rs1491938-rs1491941 in LRRK2 have score statistics -1.79 and -1.42 and t-statistic -1.79 (p = 0.0744) and -1.76 (p = 0.0794). The strongest evidence of statistical significance is the presence of SNCA haplotype 112 and haplotypes 222111 and 222221 in LRRK2 (both with t-statistic>5, p<0.0001), or presence of haplotypes 211212 and 212211 in LRRK2 with haplotype 122 in SNCA (t-statistic=1.77, p=0.078). Given the recent successes of genome-wide association studies (GWASs) which largely indicate that SNPs established accounted for a small amount of phenotypic variations, it is hopeful that study of gene-gene interactions can help to identify further genotypic contributions to the "missing heritabilities". Our results are in line with earlier reports that specific haplotypes in these two genes might contribute to increased risks of Parkinson's disease.

Lack of association between G-protein coupled receptor kinase 5 gene and Parkinson's disease. *P. Tarantino[1], E.V. De Marco[1], F.E. Rocca[1], F. Annesi[1], D. Civitelli[1], G. Provenzano[1], V. Scornaienchi[1], V. Greco[1], C. Colica[2], G. Nicoletti[3], A. Quattrone[3,4], G. Annesi[1].* 1) Inst Neurological Sci, National Research Council, Mangone, Cosenza, Italy; 2) Institute of Neurological Sciences, National Research Council, Catanzaro, Italy; 3) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 4) Neuroimaging Research Unit, National Research Council, Catanzaro, Italy.

The major component of Lewy Bodies (LB), the pathological hallmark of Parkinson's disease (PD), is α-synuclein, most prominently phosphorylated at serine 129. G-protein coupled receptor kinase 5 (GRK5) has been reported to phosphorylate α-synuclein in vitro, enhancing the α-synuclein toxicity to dopaminergic neurons in Drosophila model. Moreover, GRK5 was found in LBs from brain of PD patients. A genetic association study performed in the Japanese population revealed haplotypic association of the GRK5 gene with susceptibility to sporadic PD. We aimed at investigating whether four single-nucleotide polymorphisms (SNPs) within the GRK5 gene could represent risk factors for sporadic PD in Southern Italy. We studied 446 patients with PD and 450 controls coming from Southern Italy. Genomic DNA was extracted from peripheral venous blood using a standard phenol-chloroform method. All the subjects were genotyped for the SNPs rs871196, rs2420616, rs7069375, rs4752293 located in the GRK5 gene and selected from those previously used by other researchers. Genotyping was carried out with TaqMan assays on an ABI7900 real-time PCR instrument. A haplotype analysis was also performed.All markers were in Hardy-Weinberg equilibrium in both patients and controls. The distribution between the two groups did not show significant differences at allelic, genotypic and haplotypic level. This result was not modified either by using different models (dominant and recessive) or stratifying by sex.There is a considerable debate as to the precise role of members of the GRKs family. Besides their main role of selectively phosphorylating agonist-occupied G-protein-coupled receptors (GPCRs) for the desensitization, GRKs also phosphorylate non-GPCR substrates, such as α-synuclein. Finally, others studies report that only endogenous GRK3 or GRK6 phosphorylated α-synuclein at Ser 129 in HEK293 cells. However, they suggested that GRK2 or GRK5, when overexpressed, could expand beyond their physiological localization in the cell allowing GRK a non-physiological access to α-synuclein and, consequently, its phosphorylation. Our data do not suggest any implication of the GRK5 gene in susceptibility to PD in Southern Italy.Nevertheless, it is also possible that this gene plays a minor role in the pathogenesis of sporadic PD.Further studies in other populations could help to elucidate this debate.

Variants on chromosome 15q25 are associated with age at initiation of daily smoking. *M. Kapoor[1], J. Wang[1], S. Bertelsen[1], A. Agrawal[1], J. Budde[1], B. Porjesz[2], H. Edenberg[3], K. Bucholz[1], J. Kramer[4], S. Kuperman[5], A. Brooks[6], J. Tischfield[6], L. Bierut[1], A. Goate[1].* 1) Department of Psychiatry, Washington University, St Louis, MO; 2) Department of Psychiatry, State University of New York, Brooklyn, NY; 3) Department of Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN; 4) Department of Psychiatry, University of Iowa College of Medicine, Iowa City, IA; 5) Division of Child Psychiatry, University of Iowa Hospitals, Iowa City, IA; 6) Department of Genetics, Rutgers University, Piscataway, NJ.

Epidemiological research suggests that age at smoking initiation is related to consequent aspects of smoking behavior, such as cigarette consumption, nicotine dependence and smoking cessation. Studies have shown that the younger an individual starts smoking, the higher the subsequent cigarette consumption and risk of nicotine dependence, and the lower the likelihood of quitting. Several genome-wide association and candidate gene studies have linked chromosome 15q24-q25.1 (a region including the CHRNA5-CHRNA3-CHRNB4 gene cluster) with substance dependence and smoking-related illnesses such as lung cancer and chronic obstructive pulmonary disease. To further examine the impact of this gene cluster region on the development of substance use disorders, we tested whether variants within and flanking the CHRNA5/A3/B4 gene cluster affect age at onset of daily smoking. A total of 34 SNPS were analyzed in a European American only cross sectional sample of adolescents and young adults from the families recruited for the Collaborative Study of the Genetics of Alcoholism (COGA). A within-family quantitative transmission disequilibrium test (QTDT) was used to test for association between age at initiation of smoking and genetic markers on chromosome 15q25. Significant associations (p<0.05) were found between the age at smoking initiation and multiple SNPs in this region. There was very strong evidence of association between rs16969968 and age of onset of daily smoking. Additional SNPs in this region were also found to be moderately associated with the age of onset of regular drinking. Our results suggest that a gene or genes in this region may be involved in increased risk of nicotine dependence by influencing the age of onset of daily smoking. There may also be common genetic determinants, which govern the regular use of alcohol, tobacco and other substances of addiction.

Analysis of Autism Spectrum Disorder Families Reveals an Enrichment of Immune Loci. *C.D. Langefeld[1], P.S. Ramos[1], S.J. Walker[2].* 1) Dept Biostatistical Sciences, Wake Forest Univ , Winston-Salem, NC; 2) Institute for Regenerative Medicine, Wake Forest Univ, Winston-Salem, NC.

Autism Spectrum Disorders (ASDs) encompass a heterogeneous group of clinical descriptors whose core features include deficits in cognition, communication, and social acuity, coupled with stereotypical behaviors. The etiology of ASDs, with very few exceptions, is unknown although a growing number of clinical and basic research studies have implicated immunological abnormalities as being associated with and/or responsible, at least in part, for the cognitive and behavioral deficits seen in ASD children. In order to assess a potential enrichment of immune loci in autistic children, we used genotypic data available at the Autism Genetic Resource Exchange (AGRE) repository to perform a family-based association analysis between variants in immune loci and ASD. We used a bioinformatics database (Ingenuity Pathway Analysis) to compile a list with 2,012 genes with known immune function. We tested 27,563 SNPs genotyped on the Illumina Hap550 platform in the AGRE collection of 1,510 trios, and performed the standard Transmission Disequilibrium Test (TDT) as implemented in PLINK. We have adjusted the reported P-values by running up to 1 million permutations. We observed a significant enrichment of results with P<0.001 (53 vs. 28 expected SNPs, P=1.0x10-05), suggesting the presence of true positive associations. Two of the most significant loci map to chromosome X: a significant variant near moesin (MSN, rs5918959, P=1.00x10-06, OR [95%CI] =0.24 [0.14-0.41]), and several variants in the CD99 molecule-like 2 (CD99L2, rs11796490, P=1.20x10-05, OR=0.68 [0.58-0.80]; rs11797645, P=1.58x10-03, OR=0.75 [0.63-0.89]; rs11797944, P=1.41x10-03, OR=0.75 [0.64-0.89]). Several SNPs in the jumonji AT rich interactive domain 2 (JARID2) gene, which has been previously implicated in schizophrenia, have also shown significant association with ASD (rs13193457, P=1.80x10-05, OR=0.61 [0.49-0.75]; rs794776, P=6.48x10-04, OR=0.64 [0.51-0.80]; rs6459404, P=7.15x10-04, OR=1.21 [1.09-1.34]; rs6921502, P=8.43x10-04, OR=1.20 [1.09-1.33]). A variant in the thyroid peroxidase gene (TPO), which has been associated with hypothyroidism, is also among the most significant (rs1514687, P= 1.50x10-05, OR=1.46 [1.24-1.72]). This study demonstrates that there is an enrichment of immune-function genes in autistic children, and that several novel genes with immune functions are associated with ASD.

2548/W

Confirmation of association between Multiple Sclerosis and CYP27B1. *E. Sundqvist[1], M. Bäärnhielm[2], L. Alfredsson[2], J. Hillert[1], T. Olsson[1], I. Kockum[1].* 1) Dept. Clinical Neuroscience, Karolinska Institutet, Stockholm, Stockholm, Sweden; 2) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden.

Multiple Sclerosis, MS (OMIM #126200) is a complex inflammatory disease, characterised by lesions in the central nervous system. Both genes and environmental factors influence disease susceptibility. There is an apparent geographical pattern in MS prevalence, with increasing prevalence with increasing latitude, and the level of solar and UV radiation have been implicated in causing this difference in incidence. There is also a month-of birth effect in MS susceptibility, which could be linked to differences in climate, including sun exposure, during the year. Vitamin D levels are dependent on the level of UV radiation, and vitamin D deficiency has been implicated in MS and autoimmune disease such as type 1 diabetes, where patients have lower levels of 25-OHD3 in blood than controls. Previtamin D3 is produced in the skin, and in the liver turned into 25-OHD3. In the kidney, skin and immune cells 25-OHD3 is turned into the bioactive 1,25(OH)2D3 by the enzyme coded by CYP27B1 on chromosome 12q13.1-3. 1,25(OH)2D3 binds to the Vitamin D receptor, expressed in T cells and antigen presenting cells. 1,25(OH)2D3 has a suppressive role on the adaptive immune system, decreasing T cell and dendritic cell maturation, proliferation and differentiation, shifting the balance between Th1 and Th2 cells in favor of Th2 cells, and increasing the suppressive function of regulatory T cells. Rs703842 in the 12q13-14 region was associated to MS in a recent study by the ANZgene consortium, Nature Genetics, 41(7), 2009. We show associations to three SNPs in this region in our Swedish material (2158 cases, 1759 controls) rs4646536, rs10877012, rs10877015 (p=0.01, 0.01 and 3.5 x 10-3, respectively). We imputed rs703842 and performed a joint analysis with the ANZgene results, reaching a significant association of rs703842 with disease (p = 5.1 x 10-11 odds ratio 0.83 (0.79 - 0.88 95% confidence interval). Because of its close association with 25-OHD3 our results lend further support to the role of vitamin D in MS pathology. Lower exposure to sunlight and low expression of CYP27B1 mRNA will likely influence the amount of available active vitamin D3 in the body. In individuals with other genetic risk factor(s) and possibly exposed to other environmental factor(s), this could, through the effects of vitamin D3 on the immune system, lead to the development of MS or other autoimmune disease.

Genetic association study of the monoamine oxidase A gene polymorphism (MAO-A VNTR) with gambling behaviour. *R.P.L. Tong[1], R.P. Souza[1,2], N. Freeman[1], M. Tampakeras[1], S. Shaikh[1], D.M. Casey[3], D.C. Hodgins[3], G.J. Smith[4], R.J. Williams[5], D.P. Schopflocher[6], R.T. Wood[7], N. el-Guebaly[8], D.S.S. Lobo[1,2,9], J.L. Kennedy[1,2].* 1) Neurogenetics Section, Neuroscience Department, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 3) Psychology Department, University of Calgary, Calgary, Alberta, Canada; 4) Faculty of Extension, University of Alberta, Calgary, Alberta, Canada; 5) School of Health Sciences, University of Lethbridge, Lethbridge, Alberta, Canada; 6) Faculty of Nursing, University of Alberta, Calgary, Alberta, Canada; 7) Department of Sociology, University of Lethbridge, Lethbridge, Alberta, Canada; 8) Division of Addiction, Department of Psychiatry, university of Calgary, Calgary, Alberta, Canada; 9) Problem Gambling Service, Addictions Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.

Problem gambling (PG) is an impulse-control disorder with a life-time prevalence of 5%; in adults and its heritability has been estimated at 50-60%; in twin studies. Serotonin (5-HT) and dopamine (DA) dysregulation has been associated with PG. Thus, functional polymorphisms that affect the activity of 5-HT and DA may predispose individuals to PG. The monoamine oxidase (MAO) enzyme catabolizes 5-HT and DA in brain regions that regulate impulse control. A functional variable number tandem repeat (VNTR) polymorphism in the promoter region of the X-chromosome MAO-A gene (MAO-A VNTR) has demonstrated allele-specific enzyme expression where the 4-repeat allele has been associated with higher expression and lower impulsivity while the opposite is true for the 3-repeat allele. Here, we investigate the effect of the MAO-A VNTR polymorphism on gambling behavior. A sample of 1122 subjects (50.1% males, mean age = 39.95 ± 7.38) were stratified by ethnicity (Caucasian, African, and Asian). Each subject was assessed by the Canadian Problem Gambling Index (CPGI) or the South Oaks Gambling Screen (SOGS) and assigned to the PG or non-PG group. All participants were genotyped for the MAO-A VNTR functional polymorphism. An allelic analysis was performed on the overall sample as well as an analysis of males and females separately to analyze the association between the MAO-A VNTR and the gambling behaviour. The MAO-A VNTR polymorphism alleles were not significantly associated with gambling behaviour in the overall sample ($p>0.05$). Also, the allelic analysis of the ethnically stratified samples found that there was no significant association between the MAO-A VNTR alleles and gambling group across the different ethnic groups (all ethnicity groups: $p>0.05$). The results from our study suggest that the MAO-A VNTR polymorphism may not play a role in gambling behaviour. Further study should investigate whether other functional polymorphisms affecting 5-HT and DA activity are associated with gambling behaviour. Also, efforts should be taken to replicate the results of this study as genetic findings may have therapeutic implications and improve the treatment of PG.

2550/W

Gene x gene interaction analysis in susceptibility to bipolar spectrum disorder. *J.A. Donald[1], J.M. Fullerton[2], P.B. Mitchell[3], P.R. Schofield[2].* 1) Department of Biological Sciences, Macquarie University, Sydney, Australia; 2) Prince of Wales Medical Research Institute, Sydney, Australia; 3) School of Psychiatry, University of New South Wales, Sydney, Australia.

This study aims to identify interactions between genes of small effect that may contribute to susceptibility to bipolar spectrum disorder, a highly heritable psychiatric condition, for which few genes of large effect have been identified. A nonparametric linkage (NPL) analysis of 65 Australian extended pedigrees was conducted. Chromosome-by-chromosome correlation analysis of family-specific NPL scores was conducted to detect evidence of genetic interaction, followed by interaction-specific multipoint NPL and permutation analysis. Finally, a single nucleotide analysis of each interaction region was conducted to fine map putative gene x gene interactions using the publicly available GAIN and WTCCC genome-wide association (GWAS) datasets (2933 cases, 2534 controls), with follow-up analysis of SNP data from our Australian cohort (216 cases, 164 controls). We demonstrated four robust interchromosomal interaction clusters exceeding Bonferroni correction at α =.05 (uncorrected p < 5.38e-07) on 11q23-25-2p15-12, 4q32-35-1p36, 12q23-24-4p16-15, and 20q13-9q21-22. Using the combined GWAS dataset, we identified a suggestive SNP-based interaction on 2p14-11q23 after multiple testing correction (uncorrected p=5.761e-10, corrected p=0.06794). This interaction failed to replicate in our small Australian cohort. The 4q32-35-1p36 interaction was further investigated in the Australian cohort, examining 11 putative functional candidate genes in 1p36 with 4q35 SNPs in the FAT and MTNR1A genes, which were previously associated with bipolar disorder. We identified a nominal SNP x SNP interaction cluster (7 of the top 17 p values), spanning the promoter of the melatonin receptor MTNR1A and exons 7-22 of CAMTA1, a transcription activator known to potentiate deactivation of rhodopsin, a G-protein coupled light receptor. Expression array analysis of these genes shows a disease specific correlation in brain expression (p=0.009). This study highlights the difficulties in identifying robust genetic interactions underlying bipolar disorder susceptibility. However these results suggest an interaction between two genes that may result in increased sensitivity to circadian cues.

2551/W

Common variants in the regulative regions of GRIA1 and GRIA3 receptor genes are associated with migraine susceptibility. *D. Formicola[1], A. Aloia[1], S. Sampaolo[2], O. Farina[2], D. Diodato[2], L.R. Griffiths[3], F. Gianfrancesco[1], G. Di Iorio[2], T. Esposito[1].* 1) Inst Genetics & Biophysics, Italian Natl Research Council, Naples, Naples, Italy; 2) Headache Service - Department of Neurological Sciences, Second University of Naples, Italy; 3) Genomics Research Centre, School of Medical Science, Griffith University, Gold Coast, Queensland, Australia.

Glutamate is the principal excitatory neurotransmitter in the central nervous system which acts by the activation of either ionotropic (AMPA, NMDA and kainate receptors) or G-protein coupled metabotropic receptors. Glutamate is widely accepted to play a major role in the path physiology of migraine as implicated by data from animal and human studies. Genes involved in synthesis, metabolism and regulation of both glutamate and its receptors could be, therefore, considered as potential candidates for causing/predisposing to migraine when mutated. The association of polymorphic variants of GRIA1-GRIA4 genes which encode for the four subunits (GluR1-GluR4) of the alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) receptor for glutamate was tested in 244 migraineurs with and without aura (MA and MO) and 260 healthy controls. Two variants in the regulative regions of GRIA1 (rs2195450) and GRIA3 (rs3761555) genes resulted strongly associated with MA (P=0.00002 and P=0.0001, respectively), but not associated with MO, thus suggesting their role in cortical spreading depression. Whereas, the rs548294 variant in GRIA1 gene showed association with MO and MA phenotypes (Mig. all p=0.00009; MO p=0.0003; MA p=0.004), supporting the hypothesis that MA and MO phenotypes could be genetically related. Possible additive interactions of the two associated SNPs in GRIA1 (rs548294) and GRIA3 (rs3761555) genes were evaluated in those subjects who had both SNPs characterization. In Migraine patients, the p-value for the sole risk allele of the GRIA1 gene (TT/TT, CT/TT genotypes) was 0.03, OR 1.68 (CI = 1.02-2.77); the p-value for the sole risk allele of the GRIA3 gene (CC/TC, CC/CC genotypes) was 0.005, 2.28 (CI = 1.27-4.11) and the p-value for the combined two risk alleles (TT/TC, TT/CC, CT/TC, CT/CC genotypes) was 0.00001, OR 3.35 (CI = 1.96-5.74). Therefore, in migraine patients, when both mutant alleles are present, the risk to develop migraine is merely the sum of the risk effect carried by each single mutant allele. Preliminary functional studies showed that these variations modify binding sites for transcription factors suggesting a role in the regulation of the expression of GRIA1 and GRIA3 genes in different conditions. These results represent the first genetics evidence of a link between glutamate receptors and migraine and confirm that genetic variants in GRIA1 and GRIA3 genes are important in migraine aetiology.

HLA class I genes involved in the triggering of multiple sclerosis. *J. Link[1], I. Kockum[1], A.R. Lorentzen[2], B.A. Lie[2], E.G. Celius[2], M. Schaffer[1], B. Brynedal[1], H.F. Harbo[2], J. Hillert[1].* 1) Karolinska Institutet, Stockholm, Sweden; 2) Oslo University Hospital, Oslo, Norway.

Aim: Our aim was to elucidate the role of alleles of human leukocyte antigen (HLA)-A, -B, -C and -DRB1 in the Scandinavian population in multiple sclerosis (MS) and in particular to study the previous suggested signals within the HLA.

Background: Several studies have reported associations with the class I genes in MS. Both HLA-A*02, HLA-C*05 and HLA-B*44 have been implicated to be responsible for this association. We have previously reported the possibility of two independent associations from class I in the Scandinavian population, HLA-A*02 and HLA-C*08.

Material and Methods: The study population consisted of 1230 patients and 1060 controls from Sweden together with 550 patients and 600 controls from Norway generating a Scandinavian population of 1780 patients and 1660 controls. The subjects were low resolution genotyped for HLA-A, -B, -C and -DRB1 giving the study an advantage over studies in which HLA genotypes were inferred from single nucleotide polymorphism data.

Results: Results from allele association with regard to already known risk factors in HLA will be presented as well as analyses of previously suggested signals within HLA class I. An investigation of interactions between genes will be performed and the dependence on HLA-DRB1*15 of novel MS associations will be assessed.

2553/W

Systematic Identification of new loci for non-specific autosomal recessive mental retardation. *R. Abou Jamra[1,3], A. Ekici[1], A. Abboud[2], B. AlHallak[2], S. Ibrahim[2], S. Muhammad[2], M. Fakher[2], A. Khateeb[2], J. Schumacher[3], M. Nöthen[3], A. Reis[1].* 1) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Bavaria, Germany; 2) Paediatrician in private clinics, Syria; 3) Institute of Human Genetics, University of Bonn, Bonn, NRW, Germany.

Autosomal recessive forms of non-specific mental retardation (ARMR) make up a substantial part of mental retardation cases, but are poorly understood to date. Positional cloning in consanguineous families with multiple affected children currently represents the best strategy to identify causative genes. We interviewed and examined 68 consanguineous families of Syrian descent, with 1 - 5 affected children each. Genotyping of the first 35 families using SNP chips (Illumina or Affymetrix) allowed genome wide homozygosity mapping. We identified a single candidate region in each of 10 families: 3p26-p26 (3Mb), 4q26-4q28 (13Mb), 5q21-q21 (7Mb), 6p12-q12 (17Mb), 6q12-q15 (22Mb), 12q13-q15 (19Mb), 14q11-q-12 (9Mb), 15q23-q26 (23Mb), 16p12-q12 (24Mb), and 18p11-p11 (1.2Mb). In the remainder of the families more than one homozygous region was identified. These unique regions do not overlap. By comparing our results with published data we found that the candidate region in family MR019 (16p12-q12) overlaps with the recently described locus MRT10, and that of family MR061 (14q11-q12) with MRT9. Ongoing is the genotyping of further 33 families and whole exome sequencing of families with single linked loci. Our results support the previous observation that ARMR is extremely heterogeneous. It appears that only systematic analysis of large numbers of consanguineous families and identification of several mutations in each gene will allow identification of causative genes and ultimately contribute to understanding the neuronal network underlying normal and abnormal brain functioning. Supported by grants from the DFG and BMBF within the German Mental Retardation Network (MRNET).

Crosstalk between histone modifications and DNA methylation in patients with intellectual disability due to JARID1C mutations. *B. Chung[1,2], D. Grafodatskaya[2], D.T. Butcher[2], S.W. Scherer[3], F.E. Abidi[4], C.E. Schwartz[4], R. Weksberg[1,2].* 1) Clinical & Metabolic Gen, Hosp Sick Children, Toronto, ON, Canada; 2) Genetics and Genome Biology, Hosp Sick Children, Toronto, ON, Canada; 3) The Centre for Applied Genomics, Hosp Sick Children, Toronto, ON, Canada; 4) Greenwood Genetic Center, South Carolina, USA.

BACKGROUND: Genes that function in epigenetic regulation play an important role in normal neurodevelopment. However, the molecular mechanisms by which multiple hierarchical epigenetic marks drive normal development are not well understood and the critical genomic targets are largely unknown. Therefore, disorders caused by mutations in genes that apply or remove epigenetic marks at specific genomic targets provide a unique opportunity to study the pathophysiology of epigenetic dysregulation in human disease. The X-linked gene, JARID1C, encodes a H3K4 demethylase. Mutations in this gene cause intellectual disability (ID). We hypothesized that JARID1C mutations would dysregulate DNA methylation at specific genomic targets. METHOD: A genome-wide approach was used to analyze sodium bisulfite modified genomic DNA from white blood cells of patients with known JARID1C mutations (n=13). The Illumina Methylation 27 Microarray with probes for 27,578 CpG sites covering >14,000 genes was used. DNA methylation profiles of patients were compared to sex- and age- matched controls. Differentially methylated CpG sites were identified using the Mann-Whitney test (absolute methylation difference >17% and p-value cut-off <0.05) with correction for multiple testing. RESULTS: Differential methylation analysis identified 17 genes with loss of CpG methylation. For 5 genes demonstrating the most significant loss of methylation in patients, the array findings were validated by pyrosequencing. Bioinformatic analyses showed that the DNA methylation alterations co-localized with the expected types of histone modifications in the target genes. CHIP-qPCR and expression array analyses, using lymphoblastoid cell lines from the same patients, are in progress. CONCLUSION: Our study has identified a specific pattern of DNA methylation alterations in patients with JARID1C mutations. These data demonstrate the functional specificity of these epigenetic regulators and also the cross-talk that occurs between histone modifications and DNA methylation in chromatin-mediated transcriptional regulation.

2555/W

Frequent disruption of SYNGAP1 in non-syndromic intellectual disability. *F.F. Hamdan[1,6], H. Daoud[2,6], A. Piton[2,6], J. Gauthier[2,6], S. Dobrzeniecka[2,6], J-C. Lacaille[3], L. Mottron[4,6], M. Beauchamp[1,5], G.A. Rouleau[2,6], J.L. Michaud[1,6], Synapse to Disease (S2D).* 1) Sainte-Justine Hospital Research Center, Montreal, QC, Canada; 2) Centre Hospitalier de l'Université de Montréal Research Center, and the Department of Medicine, University of Montreal, Montreal, QC, Canada; 3) Le Groupe de Recherche sur le Système Nerveux Central, Department of Physiology, Université de Montréal, Montréal, Canada; 4) Centre de Recherche Fernand-Séguin, Hôpital Rivière-des-Prairies, Montréal, Canada; 5) Departement of psychology, University of Montréal, Qc., Canada; 6) Centre of Excellence in Neuromics of Université de Montréal and Synapse to Disease (S2D) group, Montréal, Canada.

Background. Little is known about the genes associated with autosomal dominant non-syndromic intellectual disability (NSID). We recently identified de novo truncating mutations in *SYNGAP1*, which encodes a Ras/Rap GTPase activating protein that is critical for cognition and synapse function, in 3 out of 94 (3%) sporadic NSID cases that were screened and none in controls [Hamdan etal., 2009 *NEJM* 360(6):46-52)], suggesting that *SYNGAP1* disruption may represent a common cause of autosomal dominant NSID. In order to further explore this possibility, we sequenced in this study all *SYNGAP1* exons and intronic boundaries in 50 additional sporadic cases of NSID and 380 control individuals. **Results**. We identified a splicing mutation (c.2294+1G>A) and a 1-bp deletion causing a frameshift (c.2677delC, p.Q893RfsX183) in *SYNGAP1* in 2 patients with NSID whereas no splicing or truncating mutations were found in controls. RT-PCR and sequencing showed that the c.2294+1G>A mutation causes skipping of exon-13, resulting in a frameshift and a premature stop codon. Both mutations are de novo and are predicted to truncate SYNGAP1 upstream of important functional domains. No truncating or deleterious mutations were identified in controls. **Conclusions.** These results further confirm that de novo truncating mutations in SYNGAP1 represent a common cause of NSID, explaining ~ 3% of the sporadic cases.

Mitochondrial Polymorphisms Impact Mitochondrial Function and Outcomes Attained after Severe Traumatic Brain Injury. *Y. Conley, D. Okonkwo, S. Deslouches, S. Alexander, D. Ren.* University of Pittsburgh, Pittsburgh, PA.

Aim: Determine the impact of mitochondrial genome variation on mitochondrial function and outcomes attained after a severe traumatic brain injury (TBI). Methods: Subjects had a severe (GCS£8), non-penetrating head injury with cerebrospinal fluid (CSF) sampling, 16-70, not brain dead, and no history of cardiovascular-related diseases. Outcomes included Glasgow Outcome Scale (GOS), Disability Rating Scale (DRS), and Neurobehavioral Rating Scale (NRS) at 3/6/12 and 24 months. ATP, measured using luminometry, and lactate/pyruvate, measured using HPLC/UV detection, were measured from CSF every 24 hours for the first five days. Genotyping used a multistage design. SNPs spanning the mitochondrial genome, using the mitochip, were assessed for n=136. Then SNPs significantly associated with outcomes, neurochemical levels or both; were assessed using TaqMan® or RFLP for n=336. Multivariate and trajectory analyses were used. Results: T195C, T4216 and A10398G were significantly associated with lactate/pyruvate levels (p=0.0134, p=0.0218, p=0.0167) but only in females. T195C was associated with ATP trajectory group (p=0.0098) in the total sample. T195C was associated with GOS at 3 months (p=0.0098), but only in females, while A10398 was associated with DRS at 6 and 12 months in the total population. Conclusions: Mitochondrial genetic variation impacts outcomes attained after a severe TBI as well as mitochondrial function during the acute period, providing a potential explanation for variability in outcomes in this population. A window of opportunity exists during the acute phase following injury when intervention may impact long term outcomes. This project helps elucidate this acute period, which could lead to interventions to improve patient outcomes.

Investigating Mitochondrial Variation in Autism. *J.L. McCauley[1], A. Hadjixenofontos[1], M.A. Schmidt[1], I. Konidari[1], W.F. Hulme[1], P.L. Whitehead[1], H.H. Wright[2], R.K. Abramson[2], R.K. Menon[3], S.M. Williams[4], D.J. Hedges[1], M.L. Cuccaro[1], J.R. Gilbert[1], E.R. Martin[1], J.L. Haines[4], M.A. Pericak-Vance[1].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) University of South Carolina School of Medicine, Columbus, SC; 3) Dept. of Epidemiology and Dept. of OB & Gyn, Rollins School of Public Health, Emory University, Atlanta, GA; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Despite the increasing speculation that oxidative stress and abnormal energy metabolism may play a role in Autism Spectrum Disorders (ASD), and the observation that patients with mitochondrial defects have symptoms consistent with ASD, there are no comprehensive published studies examining the role of mitochondrial variation in autism. We have employed a multiphase approach to the examination of mitochondrial DNA (mtDNA) variation in autism. In our first phase, we examined 128 mitochondrial single-nucleotide polymorphisms (SNPs) common to both the Illumina 1M and Illumina 1M Duo BeadChip arrays in a dataset of Caucasian cases and controls (964 probands, 923 father controls, and 723 pediatric controls). In phase two we resequenced the entire mtDNA in a subset of these Caucasian samples, ~400 proband-father pairs (379 probands, 372 father controls), using the Affymetrix Human Mitochondrial Resequencing Array 2.0. In phase three we genotyped our entire autism cohort and pediatric controls on additional SNPs which define the major European haplogroups, using the Sequenom MassARRAY iPLEX and TaqMan genotyping platforms. Case-control tests of association for both SNPs and haplogroups were performed ultilizing Fisher's exact, χ^2, and logistic regression procedures. Examination of heteroplasmy within our resequencing dataset is ongoing. In phase one, we found no significant association between autism and any of the 128 SNPs analyzed from the Illumina GWAS panel. Our resequencing efforts identified eighteen SNPs within the entire mtDNA that demonstrated nominally significant (p£0.05)association with autism. However these SNPs failed to replicate in our extended dataset of autism cases and pediatric controls. In our third phase we analyzed 987 Caucasian autism cases and 1145 Caucasian controls (including fathers and pediatric controls). We found no evidence to suggest a significant association between any of the major European haplogroups (H,I,J,K,T,U,V,W, and X) and autism in our Caucasian dataset. These data indicate there is no strong evidence for the role of mtDNA variation in Caucasian ASDs. We cannot however rule out the potential for a more subtle or interactive effect.

Invastigation of 22 mitochondrial tRNA genes in Persian Alzheimer's disease patients. *S. Sheibani nia[1,4], M. Houshmand[2,4], F. Assarzadegan[3].* 1) Science and Research Branch, Islamic Azad university, Tehran, Iran; 2) National InstituTe of Genetic Engineering and Biotechnology,Tehran, Iran; 3) Shahid beheshti university, Tehran,Iran; 4) special medical lab, Tehran,Iran.

Alzheimer's disease (AD) shows itself as a gradual loss of episodic memory (for instance, forgetting that a conversation took place the day before). A lot of evidence suggests that neurodegenerative diseases, including AD, stem from the abnormal accumulation of harmful proteins in the nervous system . In AD,these include Aβ peptides, the lipid-carrier protein apolipoprotein E (apoE), the microtubuleassociated protein tau, and the presynaptic protein α-synuclein, which is also involved in growth factors. A form of apolipoprotein E, apoE4, contributes to the abnormal accumulation of Aβ and tau, but probably also damages mitochondria and the cellular cytoskeleton. small number of patients (probably fewer than 1%) have early-onset AD because they have inherited autosomal dominant mutations in genes whose protein products APP, presenilin 1 (PS1) or PS2 are involved in the production of Aβ peptides. Mitochondria play important role in apoptosis. Epidemiological studies suggest an increased risk of late-onset AD in offspring of mothers with AD compared to those of fathers with AD, consistent with maternal transmission patterns in AD. Moreover, advanced maternal age at birth may constitute an independent risk in the offspring. Mutations in mtDNA were suspected to be causally related since mtDNA is maternally inherited in a non-Mendelian way. The human mitochondrial genome is composed of a circular double-stranded DNA of 16 569 bp, which encodes 37 genes. These include 22 tRNAs, 2 rRNAs and 13 subunits of respiratory enzyme complexes. Since mtDNA partly encodes four out of five complexes in the oxidative phosphorylation pathway, mutations in mtDNA may result in defective energy homeostasis. A mutation identified as increased in AD patients affects a mitochondrial tRNA gene. Possible consequences for mitochondrial protein synthesis, particularly for complex I have been suggested. An increased sensitivity of cells bearing a variety of mtDNA mutations to Calcium-dependent oxidant stress was shown. Both qualitative and quantitative defects of mtDNA have been implicated in the pathogenesis of AD. 22 tRNA genes in mitochondrial genome were investigated by PCR-sequenced method for 24 AD Iranian Patients. Common deletions (~5 kb) were also determined by real-time PCR. Our results showed new mutations in tRNA genes and also percentage of mtDNA deletion was varied from patient to patient.

2559/W

A high resolution Genome-Wide Association of Prepulse Inhibition for 37 mouse inbred strains. *N. Alliey, C. Liu.* Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL. USA.

Prepulse Inhibition (PPI) of the startle response is a largely studied endophenotype related to psychosis and mental disorders that is studied similarly in humans and mice. Based on data mining, we retrieved PPI data from 37 different inbred mouse strains from the publicly available Mouse Phenome database, and ran a Genome-Wide association analysis using 2 different platforms, with 132K and 4M SNPs respectively, using the EMMA Server at UCLA. Statistically significant association with PPI is found in a region of Chromosome 1 containing the gene Scg2, only region that survived Bonferroni multiple test correction. Scg2 is expressed in brain, involved in the packaging or sorting of peptide hormones and neuropeptides into secretory vesicles, and is highly conserved among mammals. Pathways and comparative analyses to human are also performed. Our finding of this Scg2 is consistent with a previous report using low resolution genetic map, but only a single region produced strong association using high density mapping. Scg2 is proposed as candidate gene for the studied trait.

TAA repeat variation in the GRIK2 gene does not influence age at onset in Huntington's disease. *J.H. Lee[1], J.M. LEE[1], M. Ramos[1], T. Gillis[1], L. Mysore[1], A.E. Hendricks[2], R.M. Myers[2], V.C. Wheeler[1], M.E. MacDonald[1], J.F. Gusella[1].* 1) Molecular Neurogenetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA 02114, USA; 2) Department of Neurology, Boston University School of Medicine, Boston, MA 02118, USA.

In Huntington's disease (HD), genetic modifiers in addition to the HD CAG repeat lengths play a significant role in determining age at onset (AO). GRIK2, a mediator of excitatory neurotransmission in the brain, has been suggested to be a modifier gene, but the results are still controversial. To confirm GRIK2 modifier effect in HD, we collected all available samples over twenty-five hundreds from different cohorts and tested this using different analysis methods (linear regression analysis using both global regression line and own regression line, extreme analysis). No significant associations of the GRIK2 TAA repeat polymorphism for HD modifier were seen in all analysis from the large sample size. However, the subgroup analysis using brain samples shows a trend towards association but did not reach statistical significance. These results indicate that GRIK2 does not have significant HD modifier effect and previously shown positive association may be due to unrepresentative small sample size.

Case-control association study of PARK2 exon rearrangements in Parkinson disease using an array comparative genomic hybridization analysis. *J. Mitsui[1], Y. Takahashi[1], T. Matsukawa[1], J. Goto[1], Y. Saito[2], S. Murayama[3], S. Tsuji[1].* 1) Dept of Neurology, Univ of Tokyo, Tokyo, Japan; 2) Dept of Pathology, National Center Hospital of Neurology and Psychiatry, Tokyo, Japan; 3) Dept of Neuropathology, Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan.

[Background] PARK2 is the responsible gene for autosomal recessive juvenile parkinsonism (AR-JP), which are estimated to account for as much as 30-40% of early-onset Parkinson disease (PD). It has been reported that most of the mutations in PARK2 are gross exon rearrangements. Since single heterozygous mutations in PARK2 in sporadic cases may also increase susceptibility to PD, the knowledge of the frequency and spectrum of PARK2 variants in both PD cases and controls is needed. [Patients and Methods] We screened 145 PD cases (mean age at onset, 50.1 years old) and 148 controls for PARK2 exon deletions and duplications using an array comparative genomic hybridization analysis. All the participants were Japanese, and the PD cases were not selected based on an age at onset or a family history of PD. In 145 PD cases, 27 were early-onset (age at onset younger than 40) and 118 were late-onset (age at onset older than 40). Forty-three cases (29.7%) had a family history of PD. [Results] In 27 early-onset PD cases, 8 (29.6%) had homozygous or compound heterozygous rearrangements that were compatible with AR-JP. In 118 late-onset PD cases, 2 (1.7%) had homozygous or compound heterozygous rearrangements that were compatible with AR-JP (ages at onset were 43 and 47 years old, respectively), and 1 (0.8%) had a heterozygous rearrangement (age at onset was 75 years old). None of the 148 controls had any PARK2 rearrangements. The one carrier patient was a 76-year-old man when examined. At 75 years of age, he showed irritability and suffered from hallucination. Three months after onset, he developed bradykinesia and rigidity with gait disturbance. It was revealed that his sister also developed parkinsonism and dementia at 80 years of age, and that she had the same heterozygous rearrangement. [Conclusions] Among early-onset PD, the frequency of patients with AR-JP was similar to what has previously been reported. Although further large-scale studies will be needed to determine the implication of the heterozygous rearrangement in PARK2 in late-onset PD, the frequency of a heterozygous rearrangement was low in the present study, which suggests that it is likely irrelevant in the majority of late-onset PD.

***LINGO1* is not associated with Parkinson's disease in German patients.**

S. Thier[1], S. Klebe[1], D. Lorenz[1], M. Nothnagel[2], S. Schreiber[3], C. Klein[4], J. Hagenah[4], M. Kasten[4], D. Berg[5], K. Srulijes[5], T. Gasser[5], G. Deuschl[1], G. Kuhlenbäumer[6]. 1) Neurology, University Hospital Schleswig-Holstein, Campus Kie, Kiel, Germany; 2) Institute of Medical Informatics and Statistics, Christian-Albrechts University, Kiel, Germany; 3) Institute of Clinical Molecular Biology, Christian-Albrechts University Kiel, Germany; 4) Section of Clinical and Molecular Neurogenetics at the Department of Neurology, University of Lübeck, Germany; 5) Hertie-Institute for Clinical Brain Research, Tübingen, Germany; 6) Institute of Experimental Medicine, Christian-Albrechts University, Kiel, Germany.

Background: Essential tremor (ET) and Parkinson's disease (PD) are the most common movement disorders and show clinical, genetic and pathophysiological overlap. Single nucleotide polymorphisms (SNPs) in the leucine-rich repeat (LRR) and immunoglobulin (Ig) domain-containing, Nogo receptor-interacting protein gene (*LINGO1*) are associated with ET. *LINGO1* is overexpressed in the substantia nigra (SN) of PD patients and inhibition of LINGO1 can protect dopamineric neurons against degeneration in a rodent model of PD. **Objectives:** Three *LINGO1* SNPs (rs8030859, rs9652490, and rs11856808), which were recently associated with ET, were tested for association with PD in three German case-control samples. **Methods:** Three large independent German case-control samples with 1798 cases and 1482 controls were genotyped for the three *LINGO1* SNPs associated with ET. Association was assessed using allele and genotype based tests in each of the three samples separately, in the combined sample, and in subsets of patients with early-onset PD (<50 years) and of patients with a positive family history of PD. **Results:** Neither of the three samples alone nor the combined sample showed evidence for association between *LINGO1* SNPs and PD. The subsets with early-onset PD or a positive family history did also not reveal evidence for association. **Conclusion:** SNPs in the *LINGO1* gene associated with ET could not be shown to be associated with PD in our three independent large German samples. Despite clinical and pathophysiological overlap a molecular-genetic link between the two common neurological disorders PD and ET is still missing.

The Paradox of Williams Syndrome: An imaging genetics study of non-social anxiety and hypersociability.

J.U. Blackford[1], E.M. Dykens[2,3], T.A. Thornton-Wells[2,3,4]. 1) Psychiatry, Vanderbilt University, Nashville, TN; 2) Kennedy Center for Research on Human Development, Vanderbilt University, Nashville, TN; 3) Psychology & Human Development, Vanderbilt University, Nashville, TN; 4) Center for Human Genetics Research, Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN.

Williams syndrome (WS) is a neurodevelopmental disorder caused by a microdeletion of about 25 genes on chromosome 7q11. Anxiety and fears are robustly associated in the general population with inhibited temperament. However, persons with WS are engaging and socially disinhibited while still having significant nonsocial fears. We employed two novel control groups—persons with inhibited (IT) or uninhibited temperament (UT)—to provide a match for the two key features of this dissociation. Ten subjects (4 females) per group were recruited. A functional MRI study was conducted using a block design in which subjects passively viewed social and non-social images of three different emotional valences (fear, neutral, or happy). We performed a region of interest analysis comparing amygdala response to the nonsocial and social images for each emotion. Continuous measures of brain activation were extracted for genetic analysis. Candidate genes were chosen from genetic pathways related to mood, sociability and appetite, including GTF2IRD1, located in the WS deletion region. 38 SNPs and 6 CNVs in these genes were assayed using TaqMan technology and passed quality control. There were significant group differences in amygdala response to the nonsocial and social stimuli for the fearful stimuli, with lower amygdala activation to viewing social versus nonsocial fear stimuli in the WS and UT groups, which might underlie heightened sociability, or decreased social inhibition. In contrast, the IT group had similar amygdala activation to social versus nonsocial stimuli, reflecting a more general, indiscriminate fear response, or hyper-vigilance. Logistic regression using an additive allelic model showed a trend for association between amygdala activation to non-social fear stimuli and 2 SNPs---rs1042713 in 5-HTT and rs1629816 in GHRL. Association was dependent on group status, with IT and WS groups showing similar genotype-dependent responses to non-social fearful stimuli. Larger sample sizes will be needed to confirm these moderate effects (estimated Cohen's f=0.09).

Novel mutation in *VAMP1* gene causes hereditary spastic ataxia in 3 Newfoundland families mapping at the *SAX-1* locus.

C.V. Bourassa[1], I.A. Meijer[1], N.D. Merner[1], K.K. Grewal[2], M.G. Stefanelli[2], E.J. Ives[2], P.A. Dion[1], G.A. Rouleau[1,3]. 1) The Centre of Excellence in Neuromics, CHUM Research Center and the Department of Medicine, Montreal, Quebec, Canada; 2) Discipline of Medical Genetics and Division of Neurology, Faculty of Medicine, Health Sciences Center, Memorial University, Saint John's, Newfoundland; 3) Sainte-Justine Hospital, Montreal, Canada.

Hereditary spastic ataxia (HSA) is a large group of neurodegenerative disorders characterized by lower-limb spasticity and generalized ataxia. The neuronal tracts involved are pyramidal and cerebellar, which is why the phenotype is different from spinocerebellar ataxia (SCA) and hereditary spastic paraplegia (HSP). Three large families from Newfoundland were found to have an autosomal dominant form of this disease, and they were all linked to the *SAX-1* locus on chromosome 12p13 in 2002; which was the first locus mapped for autosomal dominant HSA. Since then, the causative gene has been looked for actively and we recently observed a variant in the synaptobrevin 1 gene (*SYB1*); also known as vesicule-associated membrane protein 1 (*VAMP1*). VAMP1 is one of the three soluble N-ethylmaleimide-sensitive factor attachment protein receptors (SNAREs) proteins involved in neuronal exocytosis in response to calcium; these proteins are thought to drive the fusions of opposing membranes. A direct sequencing of a few key family members from all 3 pedigrees has revealed a heterozygous base pair change that is predicted to affect the splicing of the VAMP1A and VAMP1B isofoms, one being cytoplasmic and the other mitochondrial. *VAMP1* has another annotated isoform, deemed to be cytoplasmic, and the missense variant is predicted to be damaging to this protein, according to SIFT and SNAP; the other softwares could not align the sequence properly due to the fact that other species lack this specific isoform. The validation of the mutation involved sequencing of all three families through which we found the variant to be segregating in the family members with the *SAX-1* haplotype. Moreover, the family members that do not have the haplotype do not have the variant and sequencing of random population controls allows us to see if this variant is common in the Newfoundland population. Also, sequencing of cDNA from two patients and one control sample, a French-Canadian person, allows us to test for the effect of the splicing. Further validation of this *VAMP1* variant will consist on protein expression using lymphoblastoid cell lines derived from key HSA patients and cerebellum of human control samples.

Strong evidence that multiple genes involved in glutamate neurotransmission interact to modulate risk of schizophrenia.

L.M. Brzustowicz[1], Y. Huang[2], S.C. Seok[2], J.E. Hayter[1], J.S. Messenger[1], R.A. Zimmerman[1], A.S. Bassett[3], V.J. Vieland[2]. 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 3) Department of Psychiatry, University of Toronto, and Centre for Addiction and Mental Health, Toronto, ON, Canada.

We have previously demonstrated linkage between 1q23 and schizophrenia and linkage disequilibrium (LD) with markers within NOS1AP, a gene involved in glutamate neurotransmission, in a set of Canadian families of European descent. We have reported significantly increased expression in schizophrenia of NOS1AP in postmortem brain samples. We have shown that rs12742393, a SNP within NOS1AP, is in strong LD with schizophrenia, and that the disease associated allele can significantly increase expression from the NOS1AP promoter in a cell culture system. To search for possible epistatic interactions between NOS1AP and other risk genes we have reanalyzed our microsatellite genome scan data from the Canadian families, conducting a two-locus linkage analysis with rs12742393 set as a fixed locus. A baseline, single locus linkage scan produced four peaks (1p, 2p,13q,17q) with Posterior Probabilities of Linkage >20% in addition to the peak at NOS1AP (PPL=97%). Excluding the region around NOS1AP, the two-locus analysis produced eight peaks with a PPL>20%. SNPs from under these linkage peaks available from Affymetrix 6.0 arrays were then tested for evidence of association to schizophrenia in these families individually and in a two locus analysis allowing for epistatis with NOS1AP. Six peaks (1p, 2p, 2q, 3p, 7p, 13q) contained clusters of multiple SNPs that produced Posterior Probabilities of Linkage Disequilibrium Given Linkage (PPLD|L) >20%. SNPs within the genomic extent of GRM7 and GPR39, genes also involved in glutamate neurotransmission, produced evidence of LD in epistasis with NOS1AP. We next sought to extend these results to another sample and used subjects from the schizophrenia collections in dbGAP. Despite no significant evidence of association of either gene individually with schizophrenia in this sample, we obtained significant evidence of an epistatic interaction between NOS1AP and GRM7 that modulates schizophrenia risk. Our results support the possibility that epistatic interactions can obscure linkage and association signals and could contribute to inconsistent "replication" across data sets. Using a 2-locus method, we have demonstrated strong evidence of gene x gene interaction between NOS1AP and additional schizophrenia susceptibility loci involved in glutamate neurotransmission.

Regulators of CHRNA5 gene expression and their association with nicotine dependence: A systems biology approach. *R.F. Clark[1], L.J. Bierut[2], A.M. Goate[2], J.A. Stitzel[3], E.O. Johnson[1].* 1) RTI International, Research Triangle Park, NC; 2) Dept of Psychiatry, Washington University School of Medicine, St Louis, MO; 3) Institute for Behavioral Genetics, University of Colorado, Boulder, CO.

Differences in gene expression in the brain influence behavior and disease susceptibility. However, the contribution of single genes to complex behavioral phenotypes is usually small. Therefore, such phenotypes need to be described in terms of networks of interacting genes. The established association between the α5 cholinergic nicotinic receptor subunit gene (*CHRNA5*) and nicotine dependence (ND) presents an attractive point from which to identify a network of co-expressed genes that may influence nicotine addiction. In this study we used *in silico* systems biology tools to identify networks of genes that are co-regulated with Chrna5 in mice and to evaluate the association of nominated regulatory candidate genes with ND in humans.

We used expression-QTL mapping to identify the sources of variation in gene expression in the mouse hippocampus and to enable global mapping of factors regulating such transcriptional responses. We investigated natural genetic variation in gene expression levels of >39,000 transcripts in related mouse strains in two RI panels of C57BL/6J and DBA/2J to gain insights into molecular networks that might alter the transcription of Chrna5 mRNA. SNPs in positive candidate genes were then tested for association with ND in humans.

We found that the expression of >25 proximal genes on chromosome 9 (including Chrna5) in mice are coordinately expressed and cis-regulated. We additionally found that Chrna5 has two statistically significant trans-QTLs on chromosomes 13 and 17. Genes whose expression correlates most similar to those of Chrna5 in both RI panels include three genes proximal to Chrna5 on chromosome 9 and two genes located within the trans-eQTL loci for Chrna5. SNPs within the human homologues of these two genes were associated with ND in humans with odds ratios of ~1.2 and p-values <0.05.

These analyses suggest that we have found two good candidate genes for regulating hippocampal expression of Chrna5 in mice (and *CHRNA5* in humans). Both genes are highly expressed in the hippocampus, as well as in several other brain regions. Furthermore, these two genes are novel candidates for involvement in nicotine addiction pathways. These findings emphasize the utility of a systems biology approach to analyze complex data to model interacting biological processes.

2567/W

Association analysis of AVPR1A in Finnish autism families. *K. Kantojärvi[1], P. Onkamo[2], J. Oikkonen[1,2], L. Ukkola-Vuoti[1], R. Vanhala[3], I. Järvelä[3,4].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Department of Biological and Environmental Sciences, University of Helsinki; 3) Department of Child Neurology, Helsinki University, Helsinki, Finland; 4) Laboratory of Molecular Genetics, Helsinki University Central Hospital, Helsinki, 00029, Finland.

Autism spectrum disorders are characterized by defects in language development and social communication as well as by routines and rituals. In humans as well as other mammals the hormone arginine vasopressin (AVP) has a prominent role in affecting many social, emotional and behavioral traits, including pair bonding and altruism (Donaldson and Young 2008). The AVP receptor 1A, that is coded by the AVPR receptor 1A gene, mediates the influences of the AVP hormone in the brain (Fink et al., 2007). We have previously shown association of the AVPR1A haplotypes with auditory structuring ability in music (KMT) (Ukkola et al., 2009). Three independent studies have reported an association of AVPR1A and autism (Kim et al.,2002; Wassink et al., 2004; Yirmiya et al., 2006). Based on comparative phylogenetic analyses the site of regulation of AVPR1A expression is currently unknown (Rosso et al., 2008). We have analyzed the association of AVPR1A in Finnish families with autism and compared the allele and haplotype associations with those obtained in musical families (Ukkola et al., 2009). A total of 170 Finnish families with 626 members, each with at least one autistic proband, participated in the study. The diagnosis was based on ICD-10 and DSM-IV. Highly variable microsatellites RS1 and RS3 residing in the promoter region and the AVR microsatellite in the intron of the AVPR1A gene were genotyped. The allele 4 at marker RS3 showed nominally significant association with autism (p=0.042) using FBAT. In previous studies RS3 have been associated in autism with differing alleles (Kim et al. 2002; Wassing et al. 2004, Yirmia et al. 2006). The global haplotype analysis of all three markers RS3-RS1-AVR showed overall association in autism (UNPHASED p-value 0.0490). Previously, the same 3-marker area has shown positive association in autism (p-value 0.004) (Yirmiya et al. 2006). Furthermore, a specific AVPR1 haplotype, containing allele 4 from RS3 and allele 4 from AVR, suggested a positive association in autism (p-value 0.041). Interestingly, this haplotype has also been associated with musical aptitude (p=0.005) (Ukkola et al. 2009). Similar AVPR1A haplotypes showing association with two very different phenotypes, autism and musical aptitude, might suggest that the regulatory region of AVPR1A will reside outside the promoter region. Currently, more families are being genotyped and thus, refined results will be presented in the meeting.

Search for mutations in the DMXL1 gene on chromosome 5 associated to a Prader-Willi like phenotype. *J.L Mandel[1,2,3], C. Seifert[2], C. Gasnier[2], N. Haumesser[1], J. Böhm[1], J. Laporte[1], J. Muller[1,2], N. Calmels[2].* 1) IGBMC (CNRS, INSERM, Universite de Strasbourg), Illkirch Cedex, France; 2) Laboratoire de Diagnostic Genetique, NHC, CHU Strasbourg; 3) College de France, Paris.

The DMXL1 gene has been proposed recently to be mutated in patients with a Prader-Willi like phenotype (Gokhale et al., abstracts at ASHG 2008 and ASHG 2009), with the finding of novel heterozygous missense variants in 14/114 patients. It was orally reported at ASHG that most of these variants occurred in exons 20-24 of this gene, encoding a large (3027aa) WD repeat protein. We have sequenced either directly (the large exon 24) or after HRM screen (exons 20-23) these exons that encode 20% of the protein, in more than 300 patients refered to our molecular diagnostic lab for a broadly defined Prader-Willi like phenotype, and in whom no chromosome 15 anomalies were observed. We found 7 novel missense variants, 5 of which observed in a single patient each. The two recurrent missenses appear non pathogenic, as they have been found in controls (M1589V), or (I2000V) in one patient later found to carry a 16p11.2 deletion. Among the 5 variants observed only once, 3 were predicted as possibly or probably pathogenic using Polyphen. We expect to be able to analyse the parents to investigate whether the variants occurred *de novo* and will report on the phenotype of the patients. Our results suggest a rarer frequency of possibly pathogenic variants than reported by Gokhale et al.

2569/W

A Common *SNCA* Allele Modifies Risk for Parkinson's Disease, Independent of REP1, and is Associated with Increased Plasma α-Synuclein. *I.F. Mata[1,2], M. Shi[3], P. Agarwal[4], K.A. Chung[5,6], K.L. Edwards[7], S.A. Factor[8], D.R. Galasko[9], C. Ginghina[3], A. Griffith[4], D.S. Higgins[10], D.M. Kay[11], H. Kim[1,2], J.B. Leverenz[1,2,12], J.F. Quinn[5,6], J.W. Roberts[13], A. Samii[1,2], K.W. Snapinn[7], D.W. Tsuang[1,12], D. Yearout[1,2], J. Zhang[3], H. Payami[11], C.P. Background: Rare missense mutations and multiplications in *SNCA*, which encodes α-synuclein, result in autosomal dominant Parkinson's disease (PD). Our group and others have also shown that common *SNCA* variants, including the "REP1" promoter repeat polymorphism and several noncoding SNPs, modify susceptibility for non-Mendelian PD. Families with *SNCA* triplications display elevated expression of α-synuclein in a variety of tissues, including brain and blood, but whether a similar relationship exists for common risk alleles is unknown. We sought to further explore the association between common *SNCA* variation and PD, determine whether evidence of allelic heterogeneity exists, and examine the correlation between PD-associated variants and plasma α-synuclein levels. Methods: We performed a two-tiered analysis of 1,956 PD patients and 2,112 controls from the NeuroGenetics Research Consortium. In Tier 1 (n=692 cases and 692 controls), we genotyped a comprehensive set of 13 tagSNPs, and two additional SNPs selected from the literature. SNPs associated with PD under an additive model (α=0.05) in Tier 1 were then validated in Tier 2 (n=1,277 cases and 1,422 controls). Previously published REP1 genotypes were also included. Plasma α-synuclein was assayed in 86 cases and 78 controls using a highly sensitive Luminex assay. Results: Five SNPs were associated with PD under an additive model in Tier 1 (α=0.05). Of these, four were successfully replicated in Tier 2. In the combined sample, the most significant marker was rs356219 (OR, 1.41; CI, 1.28-1.55; p = 1.6 x 10-12) located ~ 9 kb downstream from the gene. The effect of this marker was similar in early onset, late onset, familial, and sporadic disease. A regression model containing rs356219 alone best fit the data. The linkage disequilibrium correlation coefficient between this SNP and REP1 was low (r^2=0.09). The risk-associated C allele of rs356219 was also correlated with higher transformed plasma α-synuclein levels in cases under an adjusted additive model (p= 0.005). Conclusions: Our data suggest that one or more unidentified functional *SNCA* variants tagged by rs356219 modify risk for PD, and that the effect is larger than, and independent of, REP1. We have also demonstrated for the first time that a common PD-associated *SNCA* allele correlates with increased levels of α-synuclein protein in vivo, in a dose-dependent manner.

Genome-wide Association Analysis of Age-At-Onset in Late-Onset Alzheimer Disease Implicates Genetic Variation on Chromosome 9. *Y.S. Park[1], A.C. Naj[1], G.W. Beecham[1], M.A. Slifer[1], E.H. Powell[1], P.J. Gallins[1], I. Kondari[1], P.L. Whitehead[1], G. Cai[2], V. Haroutunian[2], J.D. Buxbaum[2], H.E. Gwirtsman[3], J.R. Gilbert[1], J.L. Haines[4], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, Dr. John T Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Psychiatry, Mount Sinai School of Medicine, New York, NY; 3) VA Medical Center, Nashville, TN; 4) Vanderbilt Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

While Alzheimer disease (AD) is diagnosed in fewer than 1% of those age 65 years and younger, it affects as much as 40% of the population after age 90. AD is highly heritable (h2~70%), with much of the genetic effects uncharacterized. We examined age-at-onset (AAO) among Late-onset AD (LOAD) cases from a genome-wide association study (GWAS) to identify novel loci for LOAD, testing the variants most strongly associated with AAO for association with LOAD risk. We evaluated the association of 483,399 single nucleotide polymorphisms (SNPs) with AAO in a discovery dataset of 821 cases, with replication in a genotyped and imputed dataset of 1,243 cases from four additional case-control GWAS datasets (three publicly available). Our analyses used linear regression under an additive model with correction for population substructure in PLINK (v1.07). Associations with P£10^{-5} were followed up by (a) evaluating association in the replication case set and jointly in combined discovery/replication case sets, and (b) examining association with LOAD risk in our GWAS case-control dataset. We also examined SNP associations within strata of cases with 0, 1, or 2 copies of the APOE ε4 allele. We confirmed the association of APOE with AAO (rs2075650, P=3.387×10^{-10}; rs8106922, P=2.40×10^{-7}). We also observed a number of strong associations with AAO for SNPs on chromosome 12 in a region of linkage for LOAD (rs1010096, P=3.37×10^{-7}; rs1010095, P=1.58×10^{-6}) but these did not replicate. Only the top SNPs near APOE, rs2075650 and rs8106922, showed highly statistically significant associations with both AAO and LOAD. Stratifying by number of APOE ε4 alleles, two intronic SNPs within the Dopamine beta-hydroxylase precursor (DBH) gene demonstrated associations with lower AAO (rs1108581, P=1.76×10^{-7}; rs3025388, P=5.55×10^{-6}) among ε4/ε4 cases. DBH encodes dopamine beta-hydroxylase, an enzyme converting dopamine to noradrenalin, which is involved in catecholamine biosynthesis and norepinephrine biosynthesis pathways. Furthermore, DBH deficiency has been hypothesized to affect memory consolidation of emotional events in mice. Examining AAO in 821 cases from a GWAS of LOAD, we confirmed associations of APOE variants and observed strong associations of SNPs in a new locus of interest, DBH, with AAO among APOE ε4/ε4 cases, meriting further investigation.

Mitochondrial DNA tRNACys mutation in a family with Frontotemporal Dementia and Parkinson's disease. *G. Provenzano[1], M. D'Amelio[4], P. Tarantino[1], V. Greco[1], V. Scornaienchi[1], S. Realmuto[4], F. Annesi[1], F.E. Rocca[1], E.V. De Marco[1], D. Civitelli[1], C. Cupidi[4], I. Manna[1], G. Savettieri[4], A. Quattrone[2,3], G. Annesi[1].* 1) Institute of Neurological Sciences, National Research Council, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 3) Neuroimaging Research Unit, National Research Council, Catanzaro, Italy; 4) Department Experimental BioMedicine and Clinical Neurosciences, University of Palermo, Palermo, Italy.

Objective Mitochondrial dysfunction has been implicated in the pathogenesis of some neurodegenerative diseases, including Parkinson's disease (PD) and Frontotemporal dementia (FTD), because of the essential role of mitochondria in energy metabolism and apoptosis. FTD is the second most common type of primary degenerative dementia. Some patients present an overlap between PD and FTD both in neuropathological and clinical aspects. This may suggest a similar physiopathology and an involvement of mitochondrial DNA in FTD, as it has been associated to PD. Patients and Methods In order to explore whether mitochondrial mutations contribute to the susceptibility of these diseases, we analysed an italian family with parkinsonism and FTD. Genomic DNA was isolated from whole blood and the entire mitochondrial gene was amplified by PCR and sequenced. We also screened the proband of the family for PINK1, DJ-1, LRRK2, PGRN and TAU genes and we excluded mutations in these gene. Results From the sequencing of the entire mitochondrial genome, we identified a G5783A homoplasmic mutation, already reported in literature. This mutation was identified in the proband (FTD + PD), in his brother (FTD), in his maternal uncle (PD), in his mother, in his sister but not in his father. Restriction enzyme digestion revealed absence of the mutation in 50 controls. Conclusion This mutation occurs at the T arm of tRNAcys, resulting in the disruption of the stem structure, which may reduce the stability of the tRNA. In conclusion, we provided further evidence of the involvement of mitochondrial DNA variation in PD and FTD.

***IL1B* and *PTPRM* genes are associated with mesial temporal lobe epilepsy.** *R.O. Santos[1,4], M.S. Silva[1,4], R. Secolin[1,4], C.L. Yasuda[2,4], T.R. Velasco[3,4], A.C. Sakamoto[3,4], F. Cendes[2,4], I. Lopes-Cendes[1,4], C.V. Maurer-Morelli[1,4].* 1) Department of Medical Genetics, Faculty of Medical Sciences, University of Campinas, Campinas-SP, BRAZIL; 2) Department of Neurology, Faculty of Medical Sciences, University of Campinas, Campinas-SP, BRAZIL; 3) Department of Neurology, Psychiatry and Clinical Psychology, University of São Paulo, Ribeirão Preto-SP, BRAZIL; 4) CINAPCE - Interinstitutional Cooperation for Brain Research.

BACKGROUND: Epilepsies are a group of chronic neurological disease characterized by recurrent seizures. Mesial temporal lobe epilepsy (MTLE) is one of the most common and intractable forms of epilepsy showing a complex mode of inheritance. Previous studies have associated polymorphisms in pro-inflammatory cytokine interleukin 1-beta (*IL1B*) gene and increased predisposition to MTLE associated; however these findings are still controversial. In addition, we have found that the protein tyrosine phosphatase, receptor type, M gene (*PTPRM*) is up-regulated in brain tissue from patients with MTLE. *PTPRM* gene product regulates a variety of cellular processes including cell growth, differentiation and mitotic cycle. OBJECTIVE: To investigate if *IL1B* and *PTPRM* genes are associated with the phenotype in mesial temporal lobe epilepsy (MTLE). DESIGN/METHODS: DNA samples were obtained from 204 unrelated patients with MTLE, as well as 204 unrelated controls, with no history of epilepsy. We selected five SNPs within *IL1B* and 110 SNPs within *PTPRM* from HapMap database. SNPs were genotyped using the SNPlex™ genotyping system (Applied Biosystems). Minor allele frequency (MAF>0.05), linkage disequilibrium (r^2>0.8) and Hardy-Weinberg equilibrium (HWE $_{pvalue}$>0.05) were estimated using the HAPLOVIEW software. Statistical analysis was performed by a logistic regression model with Bonferroni correction for multiple comparisons. RESULTS: We found association between SNP rs3730364 in the *IL1B* gene and MTLE (p=$1.4\text{x}10^{-14}$, OR=0.11; 95%CI: 0.06 - 0.21). Furthermore, we found 11 SNPs in with *PTPRM* gene which were significantly associated with MTLE (rs727037, rs638251, rs671369, rs1443616, rs1016188, rs583909, rs565798, rs9807775, rs8087904, rs3786368, rs727027 and rs634438) (p=$1.2\text{x}10^{-11}$, OR= 0.12; 95%CI: 0.07-0.24 for rs727027). CONCLUSIONS/RELEVANCE: Our association study shows that there is a relationship between one SNP in the *IL1B* gene as well as several SNPs in the *PTPRM* gene and MTLE. However, none of these SNPs appear to be functional variants. Although much progress has been made in the characterization of genes for the monogenic and rare forms of epilepsy the common epilepsy syndromes, usually showing complex inheritance remain a major challenge for gene identification, our study hopes to shed some light into this area. Supported by FAPESP.

Deletions of the *DCC* gene cause congenital mirror movements. *B. Tarshish[1], A. Moreno-de-Luca[1], L. Wang[2], H. Mao[2], K.R. Schmidt[1], K. Rudd[1], L.M. Knight[1], C.L. Martin[1], D.H. Ledbetter[1], M.R. Rossi[1].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Department of Radiology, Emory University School of Medicine, Atlanta, GA.

Mirror movements (MM) are contralateral involuntary movements that mirror voluntary ones. MM are occasionally present in healthy children, but persistence beyond age 10 is considered abnormal. Mutations in the *DCC* (deleted in colon cancer) gene were recently identified as the cause of congenital MM in two pedigrees with multiple affected family members (Srour et al. 2010). Here, we report an 11-week-old female referred to genetics for agenesis of the corpus callosum, ventriculomegaly, and colpocephaly with thinning of the periatrial white matter. She was generally non-dysmorphic, but was noted to have a marked frontal hair upsweep, suggestive of abnormal brain development. We performed array comparative genomic hybridization analysis and identified a 655 kb interstitial deletion of chromosome 18q21.2 that includes the 3' end (exons 23-29) of the *DCC* gene (chr18:49229956-49884580; hg18 genome assembly). Subsequent FISH analysis on the proband's father revealed that he has the same deletion. Interestingly, he has a history of MM since early childhood that is not associated with other neurologic abnormalities. To further characterize this condition, we performed a brain MRI exam on the father using high-resolution T1 and T2-weighted structural MRI, diffusion tensor imaging and tractography, and functional MRI. MRI findings suggested an abnormal corpus callosum with a thin genu and thick splenium, the presence of a fifth ventricle, and mild atrophy in the superior portion of the cerebellum. In conclusion, our findings confirm that haploinsufficiency of the *DCC* gene causes MM, possibly due to a defect in axonal midline guidance and inter-hemisphere connection. Furthermore, these results expand the phenotype associated with *DCC* mutations to include structural brain abnormalities, especially of the corpus callosum. We therefore recommend mutation analysis of *DCC* in individuals with similar phenotypes.

2574/W

Resequencing of a ~60Kb genomic region at Chr1q21 centered on the GBA locus in Ashkenazi Jewish Parkinson's Disease cases and controls. *M. Verbitsky, J. Lee, K. Marder, L.N. Clark.* Taub Institute, Columbia University, New York, NY.

Mutations in the Glucocerebrosidase gene (GBA) located at Chr1q21 are the cause of Gaucher Disease (GD). We and others have shown that mutations in GBA are also a risk factor for Parkinson's disease (PD). More than 200 mutations have been described in the GBA gene in patients with GD including point mutations, small indels and recombinant mutations that involve a nearby pseudogene. The frequency of specific alleles varies in different populations; for example, the mutations N370S, L444P, c.84insGG and IVS2+1 G>A are the most frequent mutations in the Ashkenazi Jewish (AJ) population. Fewer point mutations have been reported in AJ PD patients (the most common mutations reported are N370S and c.84insGG) and CNVs at the GBA locus have not been described. Given the clinical and genetic heterogeneity at the GBA locus we hypothesize that additional genetic changes at the GBA locus may contribute to PD. To identify additional genetic variation, including new mutations and genetic modifiers at the GBA locus we performed deep resequencing of a ~60Kb genomic DNA region at 1q21 centered on the GBA locus in a total of 47 AJ subjects. The AJ subjects consisted of 3 groups: PD cases carrying GBA mutations (N = 22), PD cases without known GBA mutations (N = 13) and matched controls (N = 12). In addition to GBA the region analyzed included the following genes: GBAP, MTX1, MTX1P, Clorf3, CLK2 and COTE1. Libraries were prepared from equimolar pools of thirteen 4-6 kb amplicons for each sample and sequencing was performed on a Roche 454 GS titanium FLX system. Data from the sequencing run on the Roche 454 GS titanium FLX was processed using 454's standard data analysis software and aligned to the reference sequence. (Chr1:155,177,506-155,243,197, GRCh37/hg19). SAMtools was used to call targeted bases, with valid-adjacent base calls that deviate from the reference treated as potential variations (SNP/indel) and assigned a coverage-dependent Phred-scaled mutation probability. CNV-seq was used to predict CNVs in the dataset. A preliminary analysis identified an average of 38 high confidence variants per subject. We have compiled a comprehensive catalog of genetic variation at the Chr1q21 region containing GBA. Our results may shed light on the modifying effects that genetic variation in regulatory regions and genes in the vicinity of GBA have on the genetic risk for PD. This study was funded by the National Institute of Health NS050487 and NS060113 (Clark).

Distinct genetic effects lead to different forms of panic disorder. *R. Subaran.* Biostatistics, Columbia Univ, New York, NY.

Panic Disorder is common and complex disorder characterized by recurrent and debilitating bouts of uncontrollable fear. While clearly influenced by genetic contributions, the strong heritability seen in panic disorder has been contrasted by paucity in discoveries of genes exerting a strong effect. Various genetic models, including the existence of locus heterogeneity, can explain this missing heritability. Locus heterogeneity, the presence of more than one causative disease gene in a population, drastically reduces power to detect a genetic effect for any given locus. One approach to overcome this is to examine large numbers of cases and controls. However, this approach has often yielded only modest effect sizes for common diseases making it difficult to justify the resources needed to undertake such studies. Another means of addressing potential heterogeneity is to apply strict phenotypic constraints in hopes of separating different genetic contributions through differential phenotypic assignments. Using the latter approach, we previously showed that a syndrome, in which panic disorder is accompanied by comorbid phenotypes including the rare bladder disorder interstitial cystitis (IC), is a genetically distinct form of panic disorder syndrome linked to a region of chromosome 13q. We also showed that in a separate sample, panic disorder is associated with polymorphisms in the serotonin transporter-encoding SLC6A4 gene. In our current study, we have revisited this association, this time stratifying all panic disorder cases by the presence or absence of accompanying phenotypes, including IC. We found that panic disorder cases without IC sufficiently explain the association at SLC6A4, while panic disorder cases with IC show no significant association. This suggests that panic disorder with IC has distinct genetic underpinnings from panic disorder without IC. Currently, we are examining in our stratified sample, a panel of markers consisting of a subset of SNPs reported to be associated with panic disorder in the literature. Our preliminary results are again consistent with a model of underlying genetic differences in phenotypically separated strata of panic disorder cases. Taken together our results suggest that careful stratification of individuals in cases-control analysis can be a powerful tool in resolving the common problem of locus heterogeneity in traits such as panic disorder.

Early cannabis exposure: genetic contributions and epistatic interactions relevant to addiction risk. *M.M. Jacobs[1], X. Wang[2], E. Keller[3], D. Dow-Edwards[4], Y.L. Hurd[1].* 1) Departments of Psychiatry, Neuroscience and Pharmacology, Mount Sinai School of Medicine, New York, NY, USA; 2) Department of Clinical Neuroscience, Karolinska Institute, Stockholm, Sweden; 3) Department of Forensic Medicine, Semmelweis University, Budapest, Hungary; 4) Department of Pharmacology, State University of New York, Downstate Medical Center, New York, NY, USA.

Vulnerability to drug addiction is thought to be caused by a combination of genetic and developmental environmental factors. Human studies have linked prenatal marijuana (Cannabis sativa) exposure with increased susceptibility to drug abuse later in life. But, little is known regarding the neurobiology underlying this increased risk and there is minimal insight regarding the contributions of genetic risk to drug addiction vulnerability associated with prenatal exposure. To address these questions, we examined brain tissue from human fetuses (18-22 weeks) whose mothers used cannabis during pregnancy (95 controls and 45 cannabis exposed) for single nucleotide polymorphisms (SNPs) of genes within the endocannabinoid, dopaminergic, opioid and glutamatergic systems that are direct and indirect targets of THC and known to be important in addiction risk. SNPs within the fatty acid amide hydrolase (FAAH) gene, the dopamine receptor 1 (DRD1) gene and the cannabinoid receptor 1 (CNR1) gene were significantly associated with fetal cannabis exposure ($P<0.05$). Given the functional overlap between the neural systems of interest, we also asked if interactions between SNPs might produce larger genetic effects than individual SNPs alone. The most significant two-locus epistatic interactions were found between rs13356332 and rs4323213 of homer homolog 1 (HOMER1) and rs2075572 of opioid receptor, mu 1 (OPRM1) ($P=0.0002$ and 0.009, respectively). None of these markers were significant at the single locus level, suggesting that the combination of these SNPs increase addiction risk more than either alone. We have begun to delineate the specific gene expression profile linked to these epistatic interactions in the fetal brain. Our data demonstrate that the HOMER1 SNPs invert the normal pattern of OPRM1 mRNA expression in discrete brain regions, suggesting a possible neurobiological mechanism by which these genetic alterations may act. We also observe the same HOMER1 x OPRM1 epistatic interactions and brain mRNA expression level changes in adult heroin abusers, lending further evidence that these SNP interactions may be responsible for some genetic risk in this unique fetal sample at high risk for drug abuse. These findings demonstrate specific genetic dysregulation of neural systems involved in addiction in individuals at increased risk for later drug abuse and begin to shed light on the interaction of genetic and environmental risk for drug abuse.

Interrogating the complex genetic effects of chromosome 16p13.13 in multiple sclerosis susceptibility. *D. Mortlock[1], R. Zuvich[1], W. Bush[1], J. McCauley[2], A. Beecham[2], P. De Jager[3,4], A. Ivinson[5], A. Compston[6], D. Hafler[4,7], S. Hauser[8,9], S. Sawcer[6], M. Pericak-Vance[2], L. Barcellos[10], J. Haines[1], International Multiple Sclerosis Genetics Consortium.* 1) Ctr Human Gen Res, Vanderbilt Univ Sch Med, Nashville, TN; 2) John P. Hussman Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL; 3) Program in NeuroPsychiatric Genomics, Center for Neurologic Diseases, Department of Neurology, Brigham & Women's Hospital and Harvard Medical School, Boston, MA; 4) Program in Medical & Population Genetics, Broad Institute of Harvard University and Massachusetts Institute of Technology, Cambridge, MA; 5) Harvard NeuroDiscovery Center, Harvard Medical School, Boston, MA; 6) University of Cambridge, Department of Clinical Neurosciences, Addenbrooke's Hospital, BOX 165, Hills Road, Cambridge, CB2 2QQ, UK; 7) Department of Neurology, Yale School of Medicine, New Haven, CT; 8) Department of Neurology, School of Medicine, University of California, San Francisco, CA; 9) 9 Institute for Human Genetics, School of Medicine, University of California, San Francisco, CA; 10) Division of Epidemiology, School of Public Health, University of California, Berkeley, CA.

Multiple sclerosis (MS) is characterized as a neurodegenerative, autoimmune disease of the central nervous system. Various family studies have shown that MS has a strong genetic component. With the advent of collaborative efforts in genotyping and analysis, at least thirteen non-MHC genes have been associated with MS in the past three years. With MS as for other diseases, independent candidate gene or pathway approaches have often indicated independent genetic signals arising from physically overlapping genomic regions, clouding interpretation of which specific genes are functionally involved. A ~600 KB stretch of chromosome 16 contains several MS-associated genes that were the focus of three recent publications: a candidate gene study of CIITA, an extensive follow-up analysis of CLEC16A, PRM1, PRM2, and PRM3 from a GWAS performed by the International Multiple Sclerosis Genetics Consortium (IMSGC), and a candidate pathway approach examining genes involved in the IL7RA-IL7 pathway including SOCS1. We subsequently genotyped 149 SNPs across this region (bp: 10,870,067-11,462,368). Sixty-three of the SNPs (42%) in this region had significant results (p-values<0.05); while, 43 SNPs (29%) had very significant results (p-values<0.001). Additionally, some of the SNPs near CIITA and SOCS1 had differentially significant results when the dataset was stratified by a surrogate SNP (rs3135388) for the HLA-DR*1501 allele (59/149 SNPs from HLA+ (presence of at least one risk allele) group, 36/149 SNPs from HLA- (absence of a risk allele) group, and 70/149 unique SNPs). By investigating the linkage disequilibrium in the region and using interaction analyses within logistic regression analysis, we have determined that this region may harbor three independent disease loci. Thus, we hypothesize that there may be evolutionary pressures underlying this unique genomic configuration in the etiology of MS. For the genes in this region, whole-genome expression data was examined for the possibility of correlated expression in lymphoblastoid cell lines. Two of the three independent disease loci (CLEC16A and SOCS1) show significant correlation. This could be explained by co-regulation, but functional studies will be necessary to understand the importance of this chromosome 16 region in MS pathogenesis.

2578/W

Two stage case-control association study of chromosome 6p SNPs in schizophrenia: extension of recent genome-wide association studies. *M. Bamne[1], J. Wood[1], H. Mansour[1], F. Dickerson[2], R. Yolken[3], B. Devlin[1,4], V. Nimgaonkar[1,4].* 1) Dept Psychiatry, Univ Pittsburgh, Pittsburgh, PA; 2) Sheppard and Enoch Pratt Hospital, Baltimore, MD, USA; 3) Stanley Laboratory of Developmental Neurovirology, Department of Pediatrics, Johns Hopkins School of Medicine, Blalock 1104,600 N Wolfe St., Baltimore, Maryland, USA; 4) Department of Human Genetics, University of Pittsburgh, Graduate School of Public Health, Pittsburgh, Pennsylvania 15213, USA.

Objective: To evaluate the role of variations in the HLA region in schizophrenia (SZ) genesis. The study was motivated by recent schizophrenia genome-wide association studies (GWAS), as well as our earlier published studies of MHC class I chain-related genes B (MICB). The GWAS observed genome-wide significant associations for single nucleotide polymorphisms (SNPs) across the HLA region. Our earlier studies suggested interactions between host genetic variation in the MICB gene located in HLA region and exposure to neurotropic herpes viruses in SZ risk. **Method**: In phase I, we comprehensively genotyped 61 'tag' SNPs from a ~ 100 KB region around MICB [31546573 -31657535 (NCBI genome build 36.1)] among Caucasian SZ cases (n= 517), and screened adult controls (n=314). In Phase II, we integrated SNPs from Phase I showing significant associations with selected SNPs from recent GWAS. The SNPs were genotyped among independent African-American SZ cases (n=600) and controls (n=404). **Results**: In Phase I, SNP-based tests yielded significant associations (p-value £ 0.05, uncorrected) for 11 SNPs. Phase II results also showed 8 SNPs with significant association (p-value £ 0.05). Of these, five SNPs were derived from the GWAS (rs12214031- BTN3A2_3UTR, p= 0.006; rs6932590- BTN3A2, p= 0.007; rs12199613- BTN3A2, p= 0.02413; rs9393709, p= 0.02471; rs926300, p= 0.05587). In addition, Phase II analyses continued to implicate two SNPs in the vicinity of MICB (rs6940467, p= 0.0343, OR 1.25 & rs6915833, p=0.079, OR 1.93) that were also associated in the Phase I samples. **Conclusion**: Variations in the HLA region may be associated with schizophrenia risk. Additional studies integrating exposure to neurotropic infectious agents are warranted.

Mental Retardation Associated With Retinitis Pigmentosa in the Xp11.3 Deletion Syndrome: ZNF674 in the Dock. Guilty or Innocent? *J. Kaplan[1], N. Delphin[1], D. Bonneau[2], X. Zanlonghi[3], S. Gerber[1], JP. Bonnefont[1], A. Munnich[1], JL. Dufier[4], O. Roche[4], JM. Rozet[1].* 1) Department of Genetics, Paris Descartes University, INSERM Unit 781, Hôpital Necker-Enfants Malades, 75015 Paris, France; 2) Biochemistry - Genetics, INSERM U694 - Angers University and CHU, Angers, France; 3) Ophthology, Clinique Sourdille, Nantes, France; 4) Ophthalmology, Ophthalmology - Paris Descartes University - CHU Necker, Paris, France.

Purpose: X-linked retinitis pigmentosa (XLRP) are among the most severe retinal dystrophies owing to their early onset (1stdecade) and their rapid progession (blindness in the 3rd-4th decades). Two genes account for almost all XLRP cases: RPGR (Xp21.1-11.4; ca.70% of XLRP) and RP2 (Xp11.23; ca.30% of XLRP). In the 90s, a 1.2 Mb deletion in the Xp11.3 region was reported in two independent families segregating XLRP with mental retardation (MR). While the retinal dystrophy was ascribed to the deletion of the RP2 gene, the mental retardation was suggested to be accounted for by the loss of the ZNF674 gene which mutations were independently reported to account for isolated XLMR. Here, we report two unrelated families with XLRP with no mental retardation harbouring a large Xp11.23 deletion. The purpose of this study was to characterize the deletion boundaries and to determine whether the absence of mental retardation could be accounted for by the absence of ZNF674 deletion. Methods: Two large unrelated families were ascertained gathering respectively 7 and 2 males affected with severe forms of XLRP. Indirect studies with highly polymorphic markers of the RP3 and RP2 loci were undertaken to direct the molecular study towards one gene or the other. The Xp11.23 deletion identified in both families was characterized by PCR using STS markers of the region.Results and Conclusions: Indirect studies at the RP3 and RP2 loci in both families suggested the existence of a large deletion encompassing RP2 and polymorphic markers flanking the 5 'region of the gene. PCR-based studies of STS markers in the Xp11.23 region demonstrated that in one of the family the deletion included PHF16 (first two exons) RP2, SLC9A7, CHST7, and ZNF674 while in the second the deletion encompassed the first three exons of RP2, SLC9A7, CHST7, and ZNF674. The breakpoints of both deletions are under characterization. Owing to the loss of ZNF674, affected males patients were interviewed and examined to state on their mental development. None of them presented with any mental disabilities raising the question to know whether the loss of ZNF674 accounted for the mental retardation in families co-segreating the feature with XLRP.

Barcelona, Spain.

Fragile X-associated tremor/ataxia syndrome is a late-onset neuropsychiatric degenerative disorder that occurs predominantly in male *FMR1* premutation carriers (55-200 CGG repeats). Clinical symptoms appear in patients in their 50s or later, and they usually begin with an action tremor. Afterwards, different findings including ataxia, loss of sensation in the distal lower extremities and autonomic dysfunction may occur and gradually progress. Cognitive deficits are also observed, including memory problems and executive function deficits, with a gradual progression to dementia in some individuals. Some patients also have Parkinsonian symptoms and experience neuropsychological disturbances, including anxiety, reclusive behavior, and irritability or mood lability. Magnetic resonance imaging demonstrates cerebellar and brain atrophy, as well as white matter hyperintensities. Additionally, hyperintensities in the middle cerebellar peduncles on T2 have been described as a characteristic finding. Although FXTAS was firstly identified among older male premutation carriers, to date, it has also been described among premutated women. Even though, it has been suggested to occur less frequently, having a milder phenotype and onset at an older age. As more female cases of FXTAS are being described, a wider clinical spectrum is being reported. Nevertheless, dementia has only been described in two patients. Herein, the molecular, neurological, neuropsychiatric, psychological, cognitive, and neuroradiological features of two fragile X syndrome families with a mother-daughter FXTAS transmission are described and, interestingly, dementia is present in both mothers. ACKNOWLEDGMENTS We thank Dr. Willemsen (Rotterdam, ND) for kind antibody donation and the families for their cooperation. This work was supported by FIS 07-0770, and FIS 09-00413. Improving Access to Clinical and Genetic Data on Mental Disorders. *J.L. Ambite, S. Sharma, C.N. Hsu, Y. Arens.* Information Sciences Institute, University of Southern California, Marina del Rey, CA.

The NIMH Center for Collaborative Genetic Studies of Mental Disorders (CGSMD) - nimhgenetics.org - maintains a large collection of phenotypic and genotypic data on studies of autism, bipolar disorder, schizophrenia, depression, Alzheimer's disease, anorexia nervosa, attention-deficit hyperactivity disorder and obsessive-compulsive disorder, with biological samples on the corresponding affected and control individuals and families stored at the Rutgers University Cell and DNA Repository (RUCDR). The collection comprises over 64,000 subjects, over 7,000 distinct phenotypic variables, and over 2,700,000 genetic markers. These data was previously disseminated through the nimhgenetics.org website to NIMH-authorized researchers as file-based distributions (in file formats such as csv, SAS, plink, etc) for each disorder. While these distributions made this wealth of data broadly available to the community, the file-based format required a researcher to spend significant effort processing and collating data from many files in a variety of formats to select individuals of particular characteristics for further analysis. To improve the efficiency of data analysis, we developed the CGMSD Data Warehouse and Explorer. The CGSMD Data Warehouse is a relational database that includes all the data previously available as file-based distributions, but further harmonized and presented through a uniform schema that allows the researcher to query within and across diseases in a more convenient way. The warehouse not only provides more efficient and flexible access, but it also enables better curation, since many quality control checks can be implemented as database queries. Although expert users may benefit from direct access to the database, we expect that most researchers would prefer a simpler, more intuitive access to the data. Thus we developed the CGSMD Data Explorer that provides a web-based access-controlled intuitive query interface to the warehouse. A researcher can easily identify individuals that satisfy given demographic, pedigree, genetic and phenotypic characteristics (e.g., all the African-American autistic children, with samples at RUCDR, with particular value ranges on the Autism Diagnostic Interview, and their alleles for SNPs in the BDNF gene). We expect that the CGSMD Data Warehouse and Explorer will empower scientists to efficiently test novel scientific hypotheses that will lead to a better understanding of genetic architecture of mental disorders.

Do glucocerebrosidase mutations affect the neurobiology of PD? : Dopamine synthesis and regional brain activity in *GBA*-associated parkinsonism. *O. Goker-Alpan[1, 3], J. Masdeu[2], A. Ianni[2], G. Lopez[1], D. Eisenberg[2], P. Kohn[2], C. Groden[1], M. Chalfin[2], K.F. Berman[2], E. Sidransky[1].* 1) Section on Molecular Neurogenetics, I MGB/NHGRI, NIH, Bethesda, MD; 2) Section on Integrative Neuroimaging, Clinical Brain Disorders Branch, NIMH, NIH, Bethesda, MD; 3) Center for Clinical Trials, Springfield VA.

Mutations in the gene encoding glucocerebrosidase (GBA), the enzyme deficient in Gaucher disease (GD), are a common genetic risk factor for parkinsonism. Subjects with Parkinson disease (PD) are five times more likely to carry *GBA* mutations. Although the clinical phenotype of patients carrying *GBA* mutations may resemble sporadic PD, the age-of-onset of parkinsonian manifestations is earlier, and cognitive impairment is more prevalent. We investigated whether *GBA* mutations alter the neurobiology of PD, studying *in vivo* brain dopamine synthesis as a marker of neurodegeneration, and resting regional Cerebral Blood Flow (rCBF) as an index of brain activity in 103 subjects (38F/65M). Positron emission tomography (PET) was performed using ^{18}F-Fluorodopa (FDOPA) and $H_2{}^{15}O$ to evaluate regional brain dopamine synthesis and resting rCBF respectively. Eight subjects had sporadic PD [mean age 60±6 years]; 8 had GD and parkinsonism [54±10 years]; 10 had GD but no parkinsonism [50±13 years]; and 7 were Gaucher carriers, but did not exhibit parkinsonism [50±18 years]. Subjects in the last two groups had a family history of PD. All PD subjects had similar UPDRS scores and disease duration. As the age-of-onset was earlier among *GBA* mutation carriers, each study group was compared to its own age and sex matched healthy control group, made up by twice the number of study subjects. Data were assessed with both region of interest and voxel-based methods. Striatal dopamine synthesis was markedly decreased in PD subjects regardless of *GBA* mutation status, with a greater loss in the caudal striatum (51% loss in putamen Ki), and relative sparing of the caudate (29% loss). Striatal dopamine was decreased ($p < 0.05$) in the putamen of somesubjects with GD and a family history of parkinsonism, without overt signs of parkinsonism. rCBF was decreased only in the patients with GD and parkinsonism, in a pattern resembling that in diffuse Lewy body disease. This, the first *in vivo* study evaluating the pattern of neurodegeneration in both *GBA* hetero- and homozygotes, demonstrates that although the pattern of dopamine loss in *GBA*-associated parkinsonism is similar to sporadic PD, the resting brain activity is decreased in areas affected in diffuse Lewy body disease, potentially explaining the increased cognitive impairment. The absence of a gene dosage effect may support the gain-of function-hypothesis as a mechanism for the development *GBA*-associated parkinsonian pathology.

2583/W

Disease severity and parkinsonism in rapid-onset dystonia-parkinsonism, DYT12. *B.M. Snively[1], L.J. Ozelius[2], D.F. Hill[1], L.S. Light[1], M.A. Stacy[3], A. Brashear[1].* 1) Wake Forest University School of Medicine, Winston-Salem, NC; 2) Mount Sinai School of Medicine, New York, NY; 3) Duke University and Medical Center, Durham, NC.

Rapid-Onset Dystonia-Parkinsonism (RDP), DYT12, is characterized by rapid onset and stabilization of symptoms without recovery. RDP is caused by mutation of the α3 subunit of the Na+/K+-ATPase gene (ATP1A3) and is dominantly inherited with reduced penetrance. Onset of RDP has been associated with triggers including physical and life stress, and alcohol use. To date, factors specifically associated with RDP severity have not been systematically studied. We collected movement disorder rating scale data by neurologic examination of 35 carriers of ATP1A3 mutations, including E277K, T613M, S712P, A714T, I758S, D801Y, and D923N. Each mutation was represented by one family or individual, except T613M, which was represented by two families and two unrelated individuals. Thirty mutation carriers manifested RDP, with RDP severity scores from 1 (mild limb dystonia) to 4 (severe bulbar and limb involvement with inability to walk; mean= 3.2, SD=1.0). Parkinsonism was scored 1 to 4 (absent, possible, probable, definite) by two reviewers and the two scores were averaged (mean=3.3, SD=0.7). Ages at onset of movement disorder symptoms ranged from 2 to 61 years (mean=24, SD=14). RDP severity score, Burke-Fahn-Marsden movement disorder rating scale (BFM), and Unified Parkinson's Disease Rating Scale motor score (UPDRS) did not differ by proband status, gender, and mutation origin (paternal, maternal, de novo or unknown). Parkinsonism scores were lower in probands (mean difference=0.36 versus non-probands, p=0.025) and did not differ by gender and mutation origin. Differences by ATP1A3 mutation were not evaluated due to limited numbers of independent families and individuals. RDP severity was inversely related to age at onset: Spearman correlations (SC) with onset age were -0.21 (p=0.27), -0.43 (0.019), and -0.30 (0.11) for RDP severity, BFM, and UPDRS, respectively. Age at onset and parkinsonism were unrelated (SC=0.071, p=0.71; SC=-0.17 adjusted for age at exam, p=0.38). Familial aggregation was low to moderate for age at onset (Intraclass correlation, ICC=0.0), RDP severity (0.10), BFM (0.11), and UPDRS (0.28), and was greatest for parkinsonism (ICC=0.42). In conclusion, we observed an inverse relationship between RDP age at onset and severity as measured by the BFM scale in individuals with various ATP1A3 mutations. Familial aggregation of the parkinsonism component of RDP may be due to ATP1A3 or genetic modifiers. This work is supported by NINDS grant R01NS058949 (AB).

Expanding the phenotype of Autosomal Dominant Leukodystrophy associated with LMNB1 duplication. *C. Toro[1], SG. Ziegler[2], C. Groden[1], CD. Blair[3], K. Cao[3], H. Carlson-Donohoe[2], DR. Simeonov[2], FS. Collins[3], WA. Gahl[1,2].* 1) Undiagnosed Diseases Program, NHGRI, National Institutes of Health, Bethesda, MD; 2) Medical Genetics Branch, NHGRI, National Institutes of Health, Bethesda, MD; 3) Genome Technology Branch, NHGRI, National Institutes of Health, Bethesda, MD.

Autosomal Dominant Leukodystrophy (ADLD) is a rare disease due to duplications of LMNB1, encoding lamin B1. Patients typically present in the third or fourth decade of life, with progressive dysautonomia, spasticity and cerebellar dysfunction. Patients with ADLD are often misdiagnosed early on in their disease with multiple sclerosis. Dominant inheritance, distinct MRI features of widespread subcortical demyelination with sparing of subcortical U fibers, involvement of corticospinal tracts and middle cerebellar peduncles, and absence of inflammatory CSF changes, support the diagnosis. Histopathological abnormalities available in a few cases are restricted to glial cells. Over-expression of LMNB1 has been suggested as the mechanism leading to ADLD. We expand the phenotype of ADLD by describing an otherwise previously healthy 47 year-old man with a 5-year history of dysautonomia, spasticity, ataxia and lower extremity pain. An Illumina Omni-Quad Chip identified a ~360 Kb duplication encompassing the LMNB1 gene on chromosome 5q23.2, confirmed by multiplex PCR. The absence of family history suggested a *de-novo* duplication. PAS positive bodies in eccrine sweat glands were present in a forearm skin biopsy. Sural nerve biopsy had no axon or Schwann cell abnormalities. Immunofluorescence staining for nuclear envelop proteins revealed abnormal nuclear morphology. The patient's cultured fibroblasts had increased nuclear blebbing at passage 7 (30% compared to 11% in controls); cellular senescence was also enhanced, as measured by senescence associated β-galactosidase assay. Melanocytes grew slowly, with ballooned cytoplasm and misshapen nuclei (76% blebbed vs 47% in controls; 11% binucleated vs 0% in controls). However, qRT_PCR and Western blotting revealed that lamin B1 mRNA and protein were not over-produced in our patient's cultured fibroblasts. The role of lamin B1 as an integral structural component of the nuclear envelope explains the morphological changes expressed in cultured cell lines from our patient. In addition, lamin B1 exerts transcription regulatory roles through its dynamic interactions with chromatin. A disturbance in these regulatory processes might be central to the emergence of demyelination in AOLD. Our patient's cells provide a model system to study the LMNB1-dependent events, including those required for myelin maintenance in the adult human brain. The cells also provide a venue in which to investigate therapeutic interventions.

Clinical and Behavioural phenotype associated with 12q24.3 subtelomeric duplication. *A.D. Rasalam[1], J.C. Dean[2].* 1) Learning Disability Team, Royal Aberdeen Childrens Hosp, Aberdeen, United Kingdom; 2) Department of Clinical Genetics, Ashgrove House, Foresterhill, Aberdeen, United Kingdom.

In Aberdeen, Scotland, children with developmental delay undergo genetic testing for identification of an underlying cause for their difficulties. This includes standard karyotyping, Fragile X testing and MLPA for subtelomeric duplications and deletions and also for microdeletions and duplications commonly associated with a learning disability. Among the children who have had an underlying cause identified, there are 3 families with a subtelomeric duplication of 12q24.3 including ZNF10. Two of the index cases are boys and the other is a girl. The duplication was paternally inherited in two of the families. All the children have developmental delay and speech and language difficulties. Features of inattention, hyperactivity and impulsiveness are more prominent in the boys. Their symptoms fulfil diagnostic criteria for Attention Deficit Hyperactivity Disorder (ADHD). We have achieved good control of the symptoms using Atomoxetine and Methylphenidate in one of the children and are in the process of initiating treatment in some of the others. All the children are in receipt of special educational support and treatment from Speech and Language Therapy. We have assessed one of the fathers who also carries the duplication and he had features that are consistent with ADHD as a child and he has continued to have difficulties into adulthood. Studies into ADHD have previously found susceptibility loci on Chromosome 12q. Cappellacci et al, American Journal of Medical Genetics Part A 140A:1203-1207 (2006) published a case report of pure 12q22q24.33 duplication with features of developmental delay and ADHD responsive to Fluoxetine treatment. Our cases are described to contribute to the clinical phenotype associated with 12q subtelomeric duplication.

Mutations in Polynucleotide Kinase 3' Phosphatase Cause the Novel Neurological Disease, Microcephaly with Seizures. *E.C. Gilmore[1,2], J. Shen[3], C.A. Marshall[3], M. Haddadin[4], J.J. Reynolds[5], W. Eyaid[6], A. Grix[7], R.S. Hill[3], M. Topcu[8], K.W. Caldecott[5], A.J. Barkovich[9], C.A. Walsh[1,3,10].* 1) Division of Genetics, Children's Hospital Boston, Harvard Medical School, Boston, MA; 2) Division of Child Neurology, Department of Neurology, Massachusetts General Hospital, Harvard Medical School, Boston, MA; 3) Howard Hughes Medical Institute, Department of Neurology, Beth Israel Deaconess Medical Center and Program in Neuroscience, Harvard Medical School, Boston, MA; 4) Department of Pathology, Al-Bashir Hospital, Ministry of Health, Amman, Jordan; 5) Genome Damage and Stability Centre, University of Sussex, Falmer, Brighton, UK; 6) Genome Damage and Stability Centre, University of Sussex, Falmer, Brighton, BN1 9RQ, UK 6Genetics & Endocrinology, Department of Pediatrics Mail Code 1510, King Fahad National Guard Hospital, King Abdul Aziz Medical City, Saudi Arabia; 7) Department of Medical Genetics, Kaiser-Permanente Point West Medical Offices, Sacramento, CA; 8) Hacettepe University, Ihsan Dogramaci Children's Hospital, Section of Pediatric Neurology, Ankara, Turkey; 9) Department of Radiology, University of California at San Francisco, San Francisco, CA; 10) Broad Institute of Massachusetts Institute of Technology and Harvard, Cambridge, MA.

We have identified a novel autosomal recessive disease that we have called microcephaly with seizures. Patients with this disease are generally born with microcephaly that becomes very severe with time and intractable seizures starting in infancy. Interestingly, the patients have structurally normal MRIs except for the small brain size, indicating no neuronal migration abnormality. We have identified the cause of the disease as mutations in the DNA repair gene, polynucleotide kinase 3' phosphatase (PNKP). Since identifying the genetic cause of the disease, we have found an additional family with a likely less detrimental mutation with significantly less clinical severity. This indicates the clinical spectrum of this disease is wide and the burden of this disease remains to be determined. EBV transformed lymphocytes derived from the patients have abnormalities in multiple DNA repair pathways. However, the patients do not appear to be at a greater risk for cancer or immunodeficiency, in contrast other DNA repair mutations that lead to microcephaly. In addition, the presence of seizure is unique among non-degenerative neurological diseases associated with DNA repair. We believe novel pattern of neurological symptoms reflect the various pathways that require PNKP and give insight into the requirements of DNA repair in the brain.

2587/W

Fragile X premutation rCGG repeats alter the nuclear export of specific mRNAs. *A. Qurashi, P. Jin.* Dept Human Molec Genetics, Emory Univ Sch Med, Atlanta, GA.

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a neurodegenerative disorder in fragile X premutation carriers with FMR1 alleles containing 55-200 CGG repeats. Using a Drosophila model of FXTAS, we previously demonstrated that transcribed premutation repeats alone are sufficient to cause neurodegeneration, suggesting that rCGG repeat-binding proteins (RBPs) may be sequestered from their normal function by rCGG binding. Recently we identified Pur alpha and hnRNP A2/B1 as RBPs, which could modulate the rCGG-mediated neuronal toxicity. To further investigate the role of Pur alphain rCGG-mediated neurodegeneration, we have taken a proteomic approach to identify the proteins that interact with Pur alpha. Over 100 proteins, including several known interactors such as Fmrp, were found to directly interact with Pur alphain vitro. To evaluate the potential contribution of Pur alpha-interacting proteins to rCGG-mediated toxicity, we further tested their genetic interactions with rCGG repeats using the FXTAS fly model, and identified several interactors of Pur alpha that indeed could genetically modulate the toxicity caused by rCGG repeats. Of particular interest among them is Rm62, the Drosophila ortholog of the p68 RNA helicase. Rm62, physically interacting with Pur alpha, could influence rCGG-mediated neurodegeneration negatively. Biochemically, fragile X rCGG repeats could decrease the soluble protein level of Rm62, leading to the accumulation of Hsp70 transcript, a previously identified target of Rm62, in the nucleus. Further microarray analyses revealed the nuclear accumulation of additional mRNAs involved in stress and immune responses in fragile X premutation flies. These findings suggest an unexpected nuclear export deficit of specific mRNAs caused by fragile X premutation rCGG repeats, and indicate that the altered nuclear export of these mRNAs could contribute to the pathogenesis of FXTAS.

2588/W

Quantitative mapping of deleted mitochondrial DNA and gene expression analysis of the the brain region with highly accumulated deleted mitochondrial DNA in transgenic mice exhibiting bipolar disorder-like phenotypes. *A. Takata[1,2], T. Kasahara[1], S. Kanba[2], T. Kato[1].* 1) 1Laboratory for Molecular Dynamics of Mental Disorders, RIKEN Brain Science Institute, Saitama, Japan; 2) Department of Neuropsychiatry, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan.

Bipolar disorder (BD) is a psychiatric disease characterized by recurrent episodes of mania and depression and is one of the ten leading causes of disability worldwide. To elucidate the pathological mechanism of BD, numerous neuroimaging and post mortem brain studies have conducted and implicated involvement of several brain regions. However the responsible neural system, such as substantia nigra dopaminergic neurons in Parkinson's disease, has not been identified. Based on the mitochondrial hypothesis of BD, we previously created the transgenic mice (Tg mice) expressing defective mitochondrial DNA (mtDNA) polymerase in forebrain neurons and they exhibited BD-like phenotypes. In Tg mice, these phenotypes were caused by functional alternations due to accumulation of aberrant mtDNA. Therefore, we hypothesized that the most damaged region in Tg mice brain could be revealed by the quantitative analysis of aberrant mtDNA. The results would also provide some insights into identification of the neural system responsible for BD. In this study, we conducted semi-comprehensive quantitative mapping of deleted mtDNA (Δ-mtDNA) using laser microdissection and quantitative PCR technique. As a result, we found large amounts of Δ-mtDNA in some mood disorder-related regions including mouse equivalent of subgenual cortex and nucleus accumbens. The most prominent accumulation of Δ-mtDNA was detected in paraventricular thalamic nucleus (PVT), which plays a role in stress response and circadian behavior and has connections with many mood disorder-related regions such as subgenual cortex, insular cortex, nucleus accumbens, amygdala, suprachiasmatic nucleus and midbrain monoaminergic neurons. To investigate the consequence of Δ-mtDNA accumulation in PVT of Tg mice, we analyzed global gene expression profile of PVT. Gene Ontology analysis suggested alternation of genes related to regulation of neurological system, protein complex assembly and cell death. Involvement of PVT dysfunction and alternation of these biological processes in bipolar-disorder like phenotypes in Tg mice and the pathophysiology of human bipolar disorder should be tested in further experiments.

2589/W

Gly269Ser mutation in compound heterozygosity with Leu127Arg is associated with adult onset of Tay-Sachs: a case report from south Italy. *P. Spadafora[1], M. Liguori[1], M. Caracciolo[1], G. Tagarelli[1], A. Bagalà[1], I.C. Cirò Candiano[1], G. Spinelli[1], A. Gambardella[1,2], A. Quattrone[2].* 1) Inst Neurological Sci, National Research Council, Mangone (CS), Mangone, Italy; 2) Department of Medical Sciences, University "Magna Graecia", Catanzaro, Italy.

Tay-Sachs disease (TSD) is an autosomal recessive neurological disorder characterized by significant deficiency of the lysosomal enzyme β-Hexosaminidase A (HexA) that results in cerebral GM2 ganglioside accumulation. Mutations in HEXA gene are responsible for deficiency or reduced activity of β-Hexosaminidase A that correlate directly with disease severity. HEXA gene is located on chromosome 15q23-q24; it contains 14 exons and encodes for the α-subunit of β-Hexosaminidase A. We describe an Italian family in which the proband showed psychiatric symptoms, ataxia and other cerebellar signs, seizures and proximal weakness of arms and legs. Proband's parents, originated from the same isolated village in southern Italy, were consanguineous. Materials and methods. HexA activity was assayed in homogenates of leucocytes using MUG as substrate. All exons and flanking intronic boundaries of HEXA gene were analysed by direct sequencing on ABI 3130XL. Results. In the proband, in vitro determination of HexA activity showed a 10% residual activity. Molecular analysis of HEXA gene revealed Gly269Ser mutation in compound heterozygosity with Leu127Arg, which is one of the infantile Tay-Sachs alleles. Proband's father and mother were heterozygous for Gly269Ser and Leu127Arg alleles, respectively. Discussion and conclusions. We identified a Tay-Sachs patient from southern Italy by biochemical and molecular analysis. This subject was compound heterozygous for Gly269Ser and Leu127Arg HEXA mutations. Gly269Ser is one of the most common mutations found in late-onset TSD, either in Jewish and non-Jewish populations. This genetic variation leads to defective processing and association of α-chain with β-chain of β-Hexosaminidase A giving rise, however, to some residual activity. On the contrary, Leu127Arg mutation is responsible for infantile onset of TSD in Italy. As in our observation, several studies reported that patients with Gly269Ser showed milder and slowly progressive disease with more pronounced behavioral or psychiatric problems, and proximal weakness. The identification of two different mutations in HEXA gene from an isolated village of southern Italy, together with the finding that the proband's parents were second-degree cousins, suggested the presence of Ashkenazi Jews ancestors in this country. In fact, the incidence of TSD in Ashkenazi Jewish population is 1/3900 birth. Evidences derived from the genealogical tree seem to furher support this hypothesis.

2590/W

Clinical Genetic Clues to the Origins and Outcomes of Autism Spectrum Disorders. *E. Lopez[1,2,7], L. Kasmara[1,2,7], K. Calli[1,2,7], M.J. Hildebrand[1,2,7], P. Carrion[1,2,7], L. Swinton[1,2,7], C. Tyson[3,7], M.A. Hrynchak[3,7], J.J.A. Holden[4,5,7], E. Rajcan-Separovic[2,6,7], M.E.S. Lewis[1,2,4,7].* 1) Dept of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Child and Family Research Institute, Vancouver, BC, Canada; 3) Cytogenetics Research Laboratory, Dept. of Pathology, Royal Columbian Hospital, New Westminster, BC, Canada; 4) Department of Physiology, Queens University, Kingston, ON, Canada; 5) Department of Psychiatry, Queens University, Kingston, ON, Canada; 6) Department of Pathology, University of British Columbia, Vancouver, BC, Canada; 7) The Autism Spectrum Interdisciplinary Research (ASPIRE) Program of ASD-CARC (www.AutismResearch.com).

Purpose: The Autism Spectrum Disorders (ASDs) are the most common childhood developmental disorder. The ASD population is heterogeneous and despite high prevalence and clear evidence that early interventions can optimize development, ASDs are often not recognized until age 3 years or older. In up to 40% of cases, ASD behaviours are recognized as a component of specific medical, genetic or chromosomal disorder. In most others, affected children can have seizures, co-existing psychiatric disorders, intellectual disability, and major or minor physical anomalies. These co-morbidities often occur as clusters of symptoms, suggesting syndromic relationships to each other and to ASDs. We aim to identify reliable biomarkers of ASD susceptibility, etiology and co-morbidity that may lead to earlier detection and improved management. **Methods:** We applied a series of standardized measurement tools to identify specific genetic, medical and teratogenic conditions known to co-exist with ASDs amongst a randomly selected cohort of >300 individuals with an ADOS-G and ADI-R confirmed ASD. All individuals received standardized clinical genetics consultation by a certified medical geneticist including review of family, medical and developmental history and dysmorphology exam. Standard clinical investigations included Fragile X gene testing, karyotype, subtelomeric and targeted FISH testing for common rearrangements of autism-associated loci at 2q37, 7q11, 15q11, 22q11 and 22q13. Data were analyzed to identify ASD clusters/subgroups that may differ in etiology, associated co-morbidities, outcome and genetic measures. **Results:** Comprehensive clinical genetic assessments revealed heightened frequency of co-existing intellectual disability (ID), as well as craniofacial, systemic, growth and neuroclinical anomalies (seizures, vision) within each different ASD-associated genetic, chromosomal, genomic syndromic and non-syndromic disorders. **Conclusions:** By identifying several cases sharing the same phenotypic pattern of symptoms, co-morbidities and/or clinical genetic/syndromic contributors to ASDs, we can begin to generate guidelines to facilitate optimal anticipatory management and functional outcomes for individuals and families living with ASDs. Our findings aim to set the standard for Clinical Genetic and Child Health Services critical to recognizing and managing brain and body features/co-morbidities of autism to improve individualized therapies and management.

2591/W

Decreased Wnt signaling pathway is associated with augmented APC in a mice Mk-801 model of schizophrenia. *DH. Cui[1], JF. Yu[1,2], D. Qi[3], MJ. Xing[1], KD. Jiang[1], YW. Peng[2].* 1) Shanghai Mental Health Center, Shanghai Jiao Tong University School of Medicine, Shanghai, Shanghai, China; 2) Department of Anatomy, Histology and Embryology, Shanghai Medical College, Fudan University, Shanghai, China; 3) The Section of Cardiovascular Medicine, Department of Internal Medicine, Yale University School of Medicine, New Haven, USA.

Background: The wingless (Wnt) pathway is relatively new to the psychiatric literature, particularly in relation to schizophrenia. Some members of the Wnt signal transduction pathway were recently found to be altered in schizophrenia. Our recent study showed that the level of adenomatous polyposis coli (APC) mRNA, a negative regulator of the Wnt signaling, in peripheral blood leucocytes of patients with schizophrenia was significantly increased. The current study investigated the role of Wnt signaling components in an animal model of schizophrenia, induced by the non-competitive NMDA antagonist (MK801). MK-801 was chosen to be studied since it produces a state of NMDA receptor hypofunction in rats that may be analogous to the one hypothesized to occur in schizophrenia. **Methods:** Male C57BL/6 mice received intraperitoneal injections of MK-801 or vehicle (controls) for 7 days. Behavioral tests were performed first. Then Prefrontal cortex (PFC) and ventral tegmental area (VTA)of mice were removed for measuring APC, glycogen synthase kinase 3 β (GSK-3β) and β-catenin mRNA and protein levels and activities using western blotting analysis and real-time PCR measurement. Pheochromocytoma (PC12) and SK-N-SH cells were also used to elucidate how APC affected the neural proliferation and differentiation by immunofluorescence staining technique with and without transfection of APC siRNA. **Results:** In experimental mice, MK-801 produced characteristic behavioural changes that modeled schizophrenia. MK-801 treatment induced a significantly increased phosphorylation and inactivation of glycogen synthase kinase 3 β (GSK-3β) in PFC and VTA, which was disassociated with augmented β-catenin phosphorylation, whereas APC mRNA and protein levels in the PFC and VTA were significantly increased, but was associated with increased β-catenin phosphorylation. Furthermore, APC protein showed to facilitates neural growth in vitro in cultured SK-N-SH and PC12 cells. **Conclusions:** These data suggest that treatment with an NMDA receptor antagonist MK-801 can produce a hypoactive Wnt pathway, which may be associated with increased APC protein levels. Furthermore, APC may facilitate neural growth independent of Wnt signaling. **Key words:** Canonical Wnt Signaling Pathway, adenomatous polyposis coli, Schizophrenia, PFC, VTA.

Phosphorylation of serine-710 in DISC1 activates a molecular switch from progenitor proliferation to neuronal migration in the developing cortex. *N. Katsanis[1], K. Ishizuka[2,3], A. Kamiya[2,3], J. Robinson[1], E.C. Oh[1], N. Mitsuma[1], K. Furukori[2,3], S. Seshadri[2,3], B. Huang[2,3], A. Hayashi-Takagi[2,3], K. Kubo[4], K. Nakajima[4], A. Sawa[2,3].* 1) Dept Cell Biol, Duke Univ, Durham, NC; 2) Department of Psychiatry and Behavioral Sciences; 3) Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21287 USA; 4) Department of Anatomy, Keio University School of Medicine, 35 Shinanomachi, Shinjuku-ku, Tokyo 160-8582, Japan.

Regulatory mechanisms governing the sequence from progenitor cell proliferation to neuronal migration during corticogenesis are poorly understood. Disrupted-In-Schizophrenia-1 (DISC1), a major susceptibility factor for schizophrenia and related disorders, is highly expressed in both progenitor cells and postmitotic neurons in the developing cerebral cortex. Here we report that a specific phosphorylation of DISC1 at serine-710 (S710) acts as a molecular switch from maintaining proliferation of mitotic progenitor cells to activating migration of postmitotic neurons. Non-phosphorylated DISC1 at S710 regulates canonical Wnt signaling via an interaction with GSK3β, whereas phosphorylation of this residue triggers the recruitment of Bardet-Biedl-Syndrome (BBS) proteins to the dynein motor complex associated with the centrosome. Knockdown of DISC1 leads to deficits in both cell proliferation and neuronal migration; however a phospho-dead mutant A710-DISC1 can only rescue the former, while phospho-mimic mutant E710-DISC1 rescues specifically and exclusively the latter. These data highlight a dual role for DISC1 in corticogenesis and suggest that phosphorylation of this protein at S710 represents a key developmental switch.

3D digital morphometry of craniofacial dysmorphology in the Simons Simplex Collection of Autism. *C.K. Deutsch[1,2], A.R. Shell[1], R.W. Francis[1], J.R. Cuomo[1], A.T. Hunt[1], L. Kowalski[3], C. Lord[3].* 1) Psychobiology Program, Eunice Kennedy Shriver Ctr UMMS, Waltham, MA; 2) Harvard Medical School, Boston, MA; 3) University of Michigan Autism and Communication Disorders Center, Ann Arbor, MI.

This project documents for the first time craniofacial anomalies in simplex autism utilizing new 3D morphometry methods. These methods provide reliable, quantitative measures of dysmorphology, and employ a new digital craniofacial normative database that permits conditioning on age, gender, and ethnicity. Both face and brain derive from common embryonic primordia and are shaped by shared forces; thus, a genetic or environmental insult that disrupts early development could manifest itself both as brain pathology and craniofacial dysmorphology. We have adopted an embryologically-derived approach that permits hypothesis testing about the underlying biology of dysmorphogenesis in autism. Here, we present findings by regions of primordia (Anlagen). These initial results focus on the first cohort of probands (N=70) seen within the quantitative dysmorphology section of the Simons Simplex Collection (SSC), imaged using 3D stereophotogrammetry at the University of Michigan Autism & Communication Disorders Center (C Lord, Director). All probands met criteria for autism based on ADI-R and ADOS criteria. We established the degree to which craniofacial anomalies are statistically overrepresented among SSC probands, using full-scale scores and combinations of individual anomalies chosen to reflect embryological factors. There was a marked statistical overrepresentation of full-scale summary scores (anomaly counts) among the probands with autism ($p < .0001$). Anomalies were frequent in several Anlagen derivatives, particularly within the frontonasal and mandibular regions (both $p < .0001$). Several laboratories, including ours, have found excessive cranial dimensions associated with autism. In the present study, we noted marked increases in the skull base width ($p < .0001$). Further, the magnitude of these measurements was significantly correlated with the full-scale scores ($p < .015$). Stratification on skull base width identified particularly dysmorphic cases, and conceivably may provide a tool for delineating more homogeneous subgroups of autism. *Acknowledgements:* The authors would like thank the Simons Foundation (SSC, SFARI) for their generous support, and NIH (R42 DE016442; FaceValue normative database). We are also grateful to the families within the SSC who participated in these studies.

Genotype-controlled analysis of Serum Dopamine β-hydroxylase across Pregnancy in Women seeking care for Mental illness. *D.L. Perdomo[1, 2], W. Li[2], R.W. Bonsall[3], Y-L. Tang[2], D.J. Newport[3], B. Knight[3], Z.N. Stowe[3], J.F. Cubells[2, 3].* 1) Graduate Program in Genetics and Molecular Biology, Emory University, Atlanta, GA, 30322; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA , 30322; 3) Department of Psychiatry and Behavioral Sciences, Emory University, Atlanta, GA, 30322.

DBH encodes Dopamine Beta Hydroxylase (DβH), a vesicular enzyme that plays a crucial role in the catecholaminergic pathway by converting dopamine into norepinephrine. DβH activity levels are easily assayed in serum due to the release of DβH along with NE from noradrenergic neurons as well as from chromaffin granules of the adrenal medulla. Early efforts to use serum DβH as an index of sympathetic activity rapidly led to the finding that serum DβH activity is regulated largely by genetic inheritance. Subsequent work has demonstrated conclusively that *DBH* is the major quantitative trait locus regulating serum DβH [1]. Norepinephrine is an essential neurotransmitter in development: Dbh -/- mouse embryos die *in utero* and mothers of persons born with the rare Mendelian disorder of DβH deficiency report high rates of miscarriage [2]. Prior studies have demonstrated slight fluctuations in the serum DβH activity of women over the menstrual cycle or after administration of oral contraceptives [3,4]. However, those studies did not account for the large stable effect of *DBH* genotypes on serum DβH activity. Normal pregnancy associates with increased maternal sympathetic activity to meet the demands of increased cardiac output necessary to support the growth of the fetus. In the current study, we examine serum DβH activity across pregnancy in women seeking care for mental illness. We hypothesize that: (1) serum DβH activity will increase over the course of pregnancy, reflecting increased activity of the sympathetic nervous system; (2) maternal stress associated with depressive symptoms will elevate serum DβH activity beyond the physiological increase in uncomplicated pregnancy. Serum samples were drawn during the pre-conception period, the 1st, 2nd, and 3rd trimester, and the early (first 4 weeks) and late (8- 15 weeks) post postpartum period. To control for the effect of *DBH* genotype, we will examine the residual activities after accounting for rs1611115, a well-documented functional SNP at *DBH* that accounts or ~50% of the variance in serum DβH activity.

2595/W

Mutational Analysis of the DCX, LIS1 and FLNA genes in patients with neuronal migration disorder from Southern Italy. *V. Greco[1], E.V. De Marco[1], F.E. Rocca[1], F. Annesi[1], D. Civitelli[1], G. Provenzano[1], P. Tarantino[1], V. Scornaienchi[1], A. Labate[2], A. Gambardella[1,2], G. Annesi[1].* 1) Institute of Neurological Sciences, National Research Council, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Classical lissencephaly (LIS) and subcortical band heterotopia (SBH) or 'double cortex syndrome', are neuronal migration disorders associated with epilepsy and mental retardation. SBH is usually caused by mutations in the doublecortin (DCX) (Xq22.3-q23) gene, and much less frequently in the LIS1 (17p13.3) gene. Both genes encode proteins involved in microtubule homeostasis. DCX mutations predominantly cause SBH in heterozygous females and severe lissencephaly in males, although rare males with SBH and DCX mutations have been reported. Periventricular nodular heterotopia (PNH) is another human neuronal migration disorder in which a subset of neurons fails to migrate into the developing cerebral cortex and is often associated with focal epilepsy. Most sporadic as well as familial female patients carry a heterozygous FLNA mutation (Xq28) predicted to result in loss of function due to protein truncation. In this study, we have analyzed familial and sporadic patients with SBH or LIS from Southern Italy to investigate abnormalities of the DCX and LIS1 genes. Furthermore, we are attempting to evaluate the occurrence of mutations in FLNA gene in familial patients affected by PHN. We have performed by direct sequencing a mutational analysis of DCX and LIS1 genes in 5 patients (4 sporadic and 1 familial) with SBH or LIS. We are also carrying out the analysis of the FLNA gene in 2 familial patients with PNH from Southern Italy. Esonic rearrangements of DCX, LIS1 and FLNA were performed by multiplex ligatio-dependent probe amplification (MLPA). We have found 2 different nonsense mutations of the DCX gene in 2 unrelated female with SBH: a mutation previously described (R303X) in the exon V and a novel mutation (Tyr151X) in the exon 2. We did not detect mutations in LIS1 gene in the DCX-negative patients. We have excluded deletions and duplications in DCX, LIS1 and FLNA gene by MLPA in all the patients. The analysis of the FLNA gene in the patients affected by PNH, is still in progress. These preliminary data suggest an involvement of DCX gene in the pathogenesis of double cortex syndrome. However, since a small percentage of genetically undiagnosed cases of lissencephaly have been reported, it would be interesting to extend our study to other genes, such as ARX, TUBA1A, involved in cortical development.

2596/W

SPINOCEREBELLAR ATAXIA WITH HYPOGONADISM: AN INTRIGUING GROUP OF GENETIC DISORDERS. *C. Lourenco, C. Sobreira, A. Barreira, W. Marques Jr.* Neurology, Univ Sao Paulo, Ribeirao Preto, Sao Paulo, Brazil.

INTRODUCTION The association between cerebellar ataxia and hypogonadism was first described in four sibs by Holmes, and since has become known as Holmes type ataxia. At the time of his description, it was not possible to determine whether hypogonadism was hypogonadotropic or hypergonadotropic hypogonadism. Although the clinical pictures may share similar phenotype, the pathogenic mechanism involved in the two types of hypogonadism is different. Several syndromes with hypo/hypergonadotrophic hypogonadism and ataxia have been published, however there is a remarkable clinical heterogeneity among them. Here, we present the clinical data and molecular/biochemical studies of fifteen Brazilian patients with cerebellar ataxia and hypogonadism. MATERIAL AND METHODS All patients were evaluated in the neurogenetics clinics by geneticists, neurologists and endocrinologists. Brain MRI, ophtalmological exam, EMG/NCV, hormone and biochemical tests, screening for CDG, karyotype, muscle biopsy with chain respiratory enzyme assays and measurement of coenzyme Q10, molecular tests for Friedreich ataxia and for SCAs 1,2,3,6 and 7 were performed in the course of the investigation. RESULTS All patients had cerebellar ataxia, but the age of the onset was variable; it was worthy to note that ten patients had early onset ataxia. Consanguinity of parents was noted in two families; five patients had hypergonadotropichypogononadism. Mental retardation was seen in two u nrelated girls with hypergonadotropic hypogononadism. None of the patients had chromosomal anomalies. Molecular tests for Friedreich and SCAs were all negative. Optic atrophy and retinochoroidal degeneration were found in five patients; axonal neuropathy was present in four patients. Cerebellar atrophy with pons or prominent vermis involvement was a constant feature. In two patients, coenzyme Q10 deficiency was confirmed in muscle biopsy. CONCLUSIONS One family have features consistent with a rare neurological disorder, Boucher-Neuhauser syndrome; two other unrelated patients had coenzyme Q10 deficiency; CDG Ia was identified in one adult patient. The remaining patients had features that may fit in the Gordon-Holmes phenotype although we believe this entity should not be an homogenous disorder. Thus, the association between cerebellar ataxia and hypogonadism comprise hetereogenous entities whose clinical investigation can elighten the pathological basis of these fascinating neuroendocrinological syndromes.

2597/W

An Evidence-Based Approach to Treatable Metabolic Disorders Causing Intellectual Disability. *C.D. van Karnebeek[1], S. Adam[2], A.G. Leenders[3], J.F.M. Friedman[2], S. Stockler-Ipsiroglu[1].* 1) Div Biochemical Diseases, Dept Pediatrics, BC Children's Hospital, Vancouver, Canada; 2) UBC Dept Medical Genetics, BC Children's & Women's Health Centre, Vancouver, Canada; 3) Emma Children's Hospital, Academic Medical Center, Amsterdam, The Netherlands.

Background: Intellectual disability (ID), a debilitating condition with deficits in cognitive functioning (IQ<70) and adaptive skills, affects 2.5% of children and adults worldwide. Studies reporting the yield of complex diagnostic work-up in individuals with ID and developmental delay (DD) have focused primarily on the frequency of causal conditions. However, the primary aim of every clinician should be not to miss the small but increasing subset of treatable conditions, foremost inborn errors of metabolism (IEMs). **Aims:** To provide the clinician with an overview of the currently treatable IEMs causing ID/DD, and establish evidence-based guidelines for a structurd diagnostic approach. **Methods:** Two independent researchers used the Cochrane Collaboration methodology to identify and evaluate published information on potentially treatable IEMs that may cause ID/DD: formulation of definitions, search (strategy) in Pubmed (1965-2010) & '*The Online Metabolic and Molecular Bases of Inherited Disease*', selection & categorization of ' treatable IEMs', and establishing clinical guidelines. **Results:** Inherent to rare diseases, available evidence for effect of therapy is scarce and often of limited quality. A total of 65 treatable IEMs known to cause ID/DD were identified. An overview of the genetic, biochemical and clinical features of these conditions is provided. Therapeutic modalities (ranging from standard of care to experimental) include diet, co-factor/vitamin supplements, substrate inhibition, enzyme replacement, stem cell transplant. Outcomes (effect on: IQ, developmental test scores, behaviour, epilepsy, neuro-imaging) varied from improvement to halting or slowing neurocognitive regression. Side-effects are summarized. Using this evidence a stepwise diagnostic protocol was formulated: A 1st tier 'metabolic screening' detects 30% of 65 treatable IEMs: glucose, ammonia, lactate, plasma amino-acids, urine organic acids, acylcarnitine profile. The 2nd tier is based on clinical findings, frequency, invasiveness: a specific biochemical (metabolite, enzyme assay, profile) or gene analysis. For those conditions without reliable biomarkers, a High-Throughput Sequencing technique was designed, which potentially allows screening large ID/DD groups for multiple genes simultaneously (in pilot phase). **Conclusions:** This literature review generated the evidence needed to formulate guidelines to aid the clinician in recognition of treatable conditions causing ID/DD.

Contribution of copy number variation in familial Parkinson disease. *A.L. Torres[1], S. Zuchner[1,2], C. Jauregui[1], E.R. Martin[1,2], W.K. Scott[1,2], J. Vance[1,2], L. Wang[1,2].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

PARK2, SNCA, DJ1, PINK1, ATP13A2 and LRRK2 are known familial Parkinson disease (PD). A comprehensive assessment of the contribution of copy number variations (CNVs) in these genes to PD risk is important for medical genetic testing strategies and molecular genetic understanding of disease mechanisms. We used high-density custom comparative genomic hybridization (CGH) arrays to evaluate CNVs in the introns, exons, and 5 kb flanking regions of the six PD genes in 182 PD cases and 67 unaffected controls. The average probe spacing was 150 bp. A DNA pool of 16 (8 males and 8 females) CEPHs was used as reference. CGH data were analyzed using Nexus 4.0 Copy Number software. No CNVs were found in DJ-1, ATP13A2, PINK1, and LRRK2. In both SNCA and PARK2, intronic CNVs were found at similar frequency in cases and controls. In SNCA, a duplication of the entire gene was found in one sporadic PD case with age-at-onset (AAO) of 36 years, which is consistent with the literature on rare duplication of SNCA. In PARK2, CNVs involving one or multiple exons were found in 19 individuals and 17 of them (16 cases and 1 control) were confirmed using a second method (Multiple Ligation Probe Amplification, Illumina Human610-SNP chip, and/ or quantitative PCR). Exonic CNVs in PARK2 were more frequent in cases than in controls (9.4% vs 1.5%, p= 0.05) and the difference was mainly driven by early-onset cases (AAO£40) (14.5% vs 1.5%, p=0.01). Since PARK2 is known as a recessive gene for juvenile Parkinsonism, we attempted to evaluate the contribution of PARK2 compound heterozygotes in PD with different AAO. HPLC and sequencing were used to search for additional missense variations in individuals with heterozygous PARK2 exonic CNVs. Family structure was used to determine the phase whenever necessary. We have finished complete evaluation of 11 individuals (6 early- and 5 late-onset cases). All evaluated early-onset cases and no late-onset case carry two alleles (a homozygote or a compound heterozygote) of PARK2 exonic variations (structural or sequence) (p= 0.002). In summary, exonic but not intronic CNVs in PARK2 were found to confer risk to PD, but CNVs were not a major contributing mechanism for the other PD genes examined. Additional studies are underway to evaluate compound heterozygote in more PD patients. Our study stresses the importance of determining compound heterozygote in PARK2 evaluations.

Determining Prevalence Rates and Characterizing the Autism Spectrum Disorder Phenotype in the Old Order Amish. *J. Lee Robinson[1], L. Nations[1], S. Sacharow[1], T. McGregor[2], N. Suslowitz[2], R. Laux[2], J. Haines[2], M. Pericak-Vance[1], M. Cuccaro[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

The prevalence of Autism Spectrum Disorders (ASDs), most recently 1 in 110 children (CDC, 2009), makes it one of the most common neurodevelopmental disorders. It is etiologically complex and its genetic architecture has been difficult to determine. The study of genetically homogeneous populations, such as the Old Order Amish, may provide clues as to the genetic etiology of ASDs. However, little is known about prevalence rates of ASD in this population. It has been postulated that ASD is rarely found among the Amish. Thus, a study to determine the prevalence rate of ASD in the Amish is a crucial first step. Our study seeks to determine the rate of ASD in two Amish communities: Holmes County, Ohio and Elkhart-Lagrange County, Indiana. All Amish children between the ages of 3 to 21 in those counties (~8000) will be screened for the presence of an ASD. Trained clinicians ascertained door to door using a published Amish Directory. Families were approached and asked to participate in a brief interview regarding their children's development. Two primary screening instruments were used: the Social Communication Questionnaire (SCQ) and the DSM-IV-TR Checklist (created by authors). A dysmorphology screen and family history including questions specific to the ASD phenotype were also collected. Children screening positive on either screener received a comprehensive clinical evaluation by two licensed psychologists. This included the Autism Diagnostic Observational Schedule (ADOS) and Autism Diagnostic Interview (ADI), in which items were modified to exclude mention of modern technology and toys the Amish do not typically use and include toys and examples in alignment with Amish lifestyle. From September 2008 to April 2010, 2211 Amish children were screened in the two communities. A total of 26 children screened positive for ASD. Of those 26 children, 17 were evaluated (three were excluded for other reasons; six declined follow-up) and nine children were diagnosed with ASD using the ADI, ADOS, and/or clinical judgment. Interestingly, all nine children identified reside in Holmes County, Ohio. Four of the children had a prior ASD diagnosis. Preliminary data have identified the presence of ASD among the Amish at a rate of approximately 1 in 228 children (.4% of those screened) using standard ASD screening and diagnostic tools. Accurate determination of the ASD phenotype in the Amish is an initial step in the design of genetic studies of ASD in this population.

2600/W

Calpain: A facile diagnostic marker for identifying the true Carriers in Duchenne muscular dystrophy. *M. V. Rao[1,2], MPJS. Anandraj[1].* 1) Department of Biocemistry& Molecularbiology,Institute of Genetics and Hospital for genetic diseases,Osmania University,Begumpet,Hyderabad-500016,India.E:mail mohan777r@yahoo.com; 2) MoncoBiotechnologies, Plot.no 7-1-562, Near MRO Office,Ameerpet,Hyderabad-500016,INDIA mohan@moncobiotechnologies.com,.

DMD is the most frequent and best known of the childhood muscular dystrophies. The incidence rate is in the range of 13 to 33 per 100,000 yearly or about one in 3300 live male births in every part of the world. Approximately 30 percent of patients have a negative family history and are said to represent spontaneous mutations.The available methods for carrier detection such as PTT, S.Blot, STR, Q-PCR, SSCP, DHPLC and SCAIP analyses yield definitive results but they are labor intensive, expensive and are in the realm of special laboratory methods requiring special skills. Assessment of m-Calpain for true Carrier detection, if validated by parallel assessment of DNA mutations would standardize the diagnostic value of Calpain index. The platelet m-calpain levels were elevated 10 folds in DMD patients and true carriers (32-6ng/μg) when compared to age and sex matched controls(2.9-1.4ng/μg).

Using the18 exons of dystrophin by qantitaive M- PCR for 10 females at risk the gene dosage was quantified and it was identified that 6 showed low dosage and conformed the carrier state.Of 9 (5deletional and 4 nondeletional) families at risk for DMD were analyzed by radioactive PCR for 4 STRs (44,45,49and 50) polymorphism markers and it was found that 8 families were informative for all STR markers and in one family, all the 4 STR markers were non informative. Of 10 females at risk analyzed for these 4 STR polymorphisms it was found that 8(86%) were heterozygotes as compared to controls.

Of the same 10 females at risk analyzed calpain analysis by ELISA it was found that all 9(90%) were informative as compared to M-PCR and STR analysis it was found that the enhanced level of m-calpain as measured by ELISA and the presence of deletions or the mutant chromosome tracked by inherited STR polymorphisms while validating (ELISA was 100% reliable diagnostic method) the status of m-calpain as marker for diagnosis of disease/true carrier state, would form part of a strategy for definitive diagnosis of true carriers and prenatal diagnosis. Such a marker would also help in population screening.

2601/W

Genotype - phenotype correlations in Pontocerebellar Hypoplasia. *Y. Namavar[1], PG. Barth[2], PR. Kasher[1], F. van Ruissen[1], VRC. Eggens[1], WB. Dobyns[3], F. Baas[1], BT. Poll-The[2], PCH consortium.* 1) Department of Neurogenetics, Academic Medical Center, University of Amsterdam, Meibergdreef 9, 1105 AZ Amsterdam, The Netherlands; 2) Division of Pediatric Neurology, Emma's Childrens Hospital, Academic Medical Center, University of Amsterdam, Meibergdreef 9, 1105 AZ Amsterdam, The Netherlands; 3) The University of Chicago, Department of Human Genetics, 920 E. 58th Street, Chicago, IL 60637, USA.

Pontocerebellar hypoplasia (PCH) is a group of autosomal recessive neurodegenerative disorders with prenatal onset. The common characteristics are cerebellar hypoplasia with variable atrophy of the cerebellum and the ventral pons and progressive microcephaly. Neocortical atrophy and ventriculomegaly are present in variable degrees. So far, mutations in the tRNA splicing endonuclease subunit genes (TSEN54, TSEN2, TSEN34) and the mitochondrial tRNA arginyl synthetase gene (RARS2) were found to be associated with PCH types 2 and 4 and 6. We studied a large cohort of 169 PCH patients for mutations in these genes, of whom 106 patients tested positive for mutations in one of the TSEN genes or the RARS2 gene. We compared this group with 63 patients suspected of PCH who were negative on mutation analysis. We found a strong correlation between TSEN54 mutations and flat cerebellar hemispheres in which the vermis is relatively spared. We present evidence that the common homozygous mutation in TSEN54 can be predicted reliably from the PCH2 phenotype. Nonsense or splice site mutations in TSEN54 are associated with a more severe phenotype of more perinatal symptoms, ventilator-dependency and early death. Our data provide further evidence that the homogeneity of the phenotype, both from a clinical perspective and by neuroimaging, correlates strongly with the genotype and can facilitate early diagnosis and assist in molecular genetic testing. Furthermore, we show that PCH1 together with elevated CSF lactate may be caused by RARS2 mutations. Our study will enhance the clinical description of PCH and will assist with the neuroradiological and genetic diagnosis of PCH.

Using genetic information in risk prediction for alcohol dependence in the Collaborative Study on the Genetics of Alcoholism GWAS sample. *J. Yan[1,2], F. Aliev[2], V.S. Williamson[2], B.T. Webb[2], A.M. Goate[3], J. Kramer[4], J.I. Nurnberger Jr[5], M.A. Schuckit[6], J.A. Tischfield[7], J.M. Quillin[1], D.M. Dick[1,2].* 1) Human and Molecular Genetics, Virginia Commonwealth University, Richmond, VA; 2) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA; 3) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO; 4) Department of Psychiatry, University of Iowa College of Medicine, Iowa City, IA; 5) Department of Psychiatry, Indiana University School of Medicine, Indianapolis, IN; 6) Department of Psychiatry, University of California-San Diego, La Jolla, CA; 7) Department of Genetics, Rutgers University, Piscataway, NJ.

A number of studies investigating the clinical utility of genetic variants associated with complex disorders have illustrated the limitations and potential benefits of using genetic information in risk prediction for complex traits (Evans, D. M., Visscher, P. M., Wray, N. R., 2009, Human Molecular Genetics. 18(18), 3525-3531; Janssens, A.C., van Dujin, C.M., 2008, Human Molecular Genetics. 17(2), R166-R173.). The focus of this study was to assess the clinical validity of previously published genes associated with alcohol dependence (AD) in predicting risk for AD in an independent sample. The predictive ability of these genes was compared to family history. Using the Collaborative Study on the Genetics of Alcoholism (COGA) genome wide association study (GWAS) sample, we performed receiver operating characteristic (ROC) curve analysis to estimate the ability of a panel of SNPs to correctly classify cases and controls for DSM-IV AD. Specifically, sum scores of risk alleles were generated for a panel of 24 semi-independent SNPs, covering 15 genes, that had reported associations with alcohol dependence in the COGA family-based association sample. We identified a subset of individuals consisting of 627 cases and 454 controls from the COGA GWAS sample that were not part of the original family-based association sample and performed ROC analysis for the sum scores in this subset. These analyses did not result in significant discriminative ability for the sum scores; the area under the ROC curve (AUC) was 0.498 (95% CI = 0.463, 0.533, $p > 0.05$), suggesting that the SNPs are not predicting better than chance. The presence or absence of family history for AD was a better classifier of case control status in the COGA sample, with an AUC of 0.686 (95% CI = 0.654, 0.718, $p < 0.001$). This study shows that these SNPs currently have limited clinical utility and illustrates the need for further expansion of prediction panels for a complex disorder that encompasses both environmental and genetic risk factors of small effect such as AD.

2603/F

Concurrent mutations in AFG3L2 and paraplegin in patients with spinocerebellar degeneration. *S. Magri[1], V. Fracasso[1], M. Plumari[1], S. Caldarazzo[1], E. Sarto[1], C. Gellera[1], C. Mariotti[1], C. Pantaleoni[2], P. Plevani[3], F. Lazzaro[3], M. Muzi-Falconi[3], D. Di Bella[1], F. Taroni[1].* 1) Genet Neurodegen Metab Dis, IRCCS Ist Neurol Carlo Besta, Milan, milan, Italy; 2) Unit of Developmental Neurology, IRCCS Ist Neurol Carlo Besta, Milan, Italy; 3) Dept. Biomolecular Sciences and Biotechnology, University of Milan, Italy.

Autosomal dominant spinocerebellar ataxias (SCA) are a heterogeneous group of neurological disorders characterized by cerebellar dysfunction. We recently showed that *AFG3L2* mutations cause dominant ataxia SCA28 (Di Bella *et al*, *Nat Genet* 2010). AFG3L2 and its partner protein paraplegin, which causes recessive spastic paraplegia SPG7, are components of the *m*-AAA complex, involved in mitochondrial protein quality control. Since yeast functional studies showed that paraplegin coexpression can complement AFG3L2 mutations in some cases, we investigated the possible coinheritance of *AFG3L2* and *SPG7* mutations in patients with spinocerebellar syndromes. We identified 3 probands with heterozygous mutations in both the *AFG3L2* and the *SPG7* genes. Two ataxic patients carry an *AFG3L2* mutation affecting highly conserved amino acids located in the ATPase (E428D) or in the proteolytic (R702Q) domains of the protein along with paraplegin^{A510V}. Paraplegin^{A510V} occurs in a highly-conserved region of the ATPase domain and results in dramatically-reduced levels of paraplegin in homozygous patients. In one family, double heterozygosity for AFG3L2^{R702Q} and paraplegin^{A510V} resulted in a full-blown ataxic phenotype while AFG3L2^{R702Q} heterozygotes manifested only moderate cerebellar atrophy at MRI and paraplegin^{A510V} heterozygous carriers were completely unaffected. The third proband carry a *de novo* AFG3L2 mutation (R468C) in the highly conserved SRH region of the ATPase domain along with the inherited deletion of SPG7 exons 4-6. Notably, the R468C substitution abolishes the arginine finger in the AFG3L2 ATP-binding site which is necessary for ATP hydrolysis and crucial for intersubunit communication and/or catalysis. The clinical presentation of this patient is characterized by early-onset optic atrophy and a L-dopa-responsive spastic-ataxic syndrome with extrapyramidal signs. Muscle biopsy revealed an isolated defect of mitochondrial respiratory chain complex I. Functional analysis of AFG3L2 and SPG7 mutants in *m*-AAA-deficient yeast showed respiratory deficiency and defective substrate processing. In conclusion, our data indicate that a loss-of-function mutation in the AFG3L2 partner paraplegin may act as a disease modifier for heterozygous AFG3L2 mutations. Moreover, concurrent mutations in both components of the mitochondrial *m*-AAA complex may result in a complex phenotype, thus expanding the clinical spectrum of AFG3L2-associated mutations. [Telethon grant GGP09301 to FT].

Mutations detected in the SHANK2 synaptic scaffolding gene in autism spectrum disorder and mental retardation affect dendritic spine morphology. *S. Berkel[1], C.R. Marshall[2], B. Weiss[1], U. Moog[3], G. Schratt[10], J. Howe[2], R. Roeth[1], V. Endris[1], W. Roberts[4], P. Szatmari[5], M. Bonin[6], A. Riess[6], H. Engels[7], R. Sprengel[8], S.W. Scherer[2,9], G.A. Rappold[1].* 1) Human Molecular Genetics, Institute of Human Genetics, Heidelberg, Germany; 2) The Centre for Applied Genomics, The Hosptal for Sick Children, University of Toronto, Toronto, Ontario, M5G 1L7, Canada; 3) Department of Human Genetics, Heidelberg University, Heidelberg, Germany; 4) Autism Research Unit, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, M5G 1Z8, Canada; 5) Department of Psychiatry and Behavioural Neurosciences, Offord Centre for Child Studies, Mc Master University, Hamilton, Ontario, L8N 3Z5, Canada; 6) Department of Medical Genetics, Institute of Human Genetics, Tuebingen University, Tuebingen, Germany; 7) Institute of Human Genetics, Rheinische Friedrich-Wilhelms-University Bonn, Bonn, Germany; 8) Max Planck Institute of Medical Research, Heidelberg University, Heidelberg, Germany; 9) Department of Molecular Genetics, University of Toronto, Ontario, M5S 1A8, Canada; 10) Interdisciplinary Center for Neurosciences, Heidelberg University, Heidelberg, Germany.

Autism spectrum disorder (ASD) and mental retardation (MR) represent clinically distinct neurodevelopmental disorders with a complex genetic etiology. Using microarrays we identified *de novo* copy number variations in the *SHANK2* synaptic scaffolding gene in two unrelated ASD and MR patients. DNA sequencing of *SHANK2* in ASD and MR revealed additional deleterious variants including a *de novo* nonsense C-terminal mutation and 7 rare inherited changes (six missense and one exonic microduplication). We demonstrated that three of these alterations reduced the ability of the SHANK2 protein to enlarge dendritic spines in primary hippocampal neurons. SHANK2 truncation leads to a complete loss-of-function while two more subtle mutations significantly impair spine enlargement indicating that haploinsufficiency of SHANK2 (like SHANK3) is etiologic in ASD. Our finding that SHANK2 is also independently involved in MR further links common genes between ASD and intellectual disability, and in this case dysregulation of dendritic spine formation is an underlying mechanism.

Drosophila models of TDP-43 proteinopathies reveal that both cytoplasmic and nuclear accumulations of the protein are neurotoxic. *M. Lecourtois, L. Miguel, T. Frebourg, D. Campion.* Inserm U614, Institute for Medical Research, Rouen University, Normandy, France.

Physiologically, the TAR DNA-binding protein-43 (TDP-43) is a highly conserved protein, ubiquitously expressed and primarily located to the nucleus. TDP-43 protein has been implicated in several steps of gene expression regulation including transcription, RNA splicing, RNA transport, and translation. Recently, TDP-43 has been identified as a major constituent of nuclear and/or cytoplasmic ubiquitin-positive inclusions in patient with amyotrophic lateral sclerosis or frontotemporal lobar degeneration. Pathological proteins are abnormally hyperphosphorylated and partially cleaved to generate C-terminal fragments (TDP-43 CTF). Although the identification of alteration of the TARDBP gene, which encodes TDP-43 itself, in patients demonstrate that abnormal forms of TDP-43 can directly trigger neurodegeneration, the molecular mechanisms underlying TDP-43 toxicity are currently not understood. To address this question, we developed new Drosophila transgenic models expressing different variants of full-length human TDP-43 proteins presenting different subcellular localizations or the hTDP-43 CTF fragment. Using an inducible GAL4 system, we showed that both cytoplasmic and nuclear accumulations of TDP-43 are neurotoxic in flies. This toxicity occurs regardless of inclusions formation. Biochemical data showed that TDP-43 expression in flies recapitulates several key biochemical features of human TDP-43 proteinopathies, including abnormally phosphorylation on the disease-specific Ser409/Ser410 site and processing. Finally, to address the molecular mechanisms underlying TDP-43 toxicity in vivo, we tested focused genetic interactions and identified several Drosophila splicing regulators, as genetic modulators of cytoplasmic TDP-43 toxicity, highlighting that alteration of RNA processing could be a key mechanism in TDP-43 pathogenesis.

Development of a mouse model of primary open angle glaucoma reveals a disease mechanism. *G.S. Zode[1], K. Bugge[1], C.C. Searby[1], E.M. Stone[1], M.H. Kuehn[2], V.C. Sheffield[1].* 1) Howard Hughes Medical Institute, Univ. of Iowa, IA 52242; 2) Department of Ophthalmology and Visual Sciences, University of Iowa Carver College of Medicine, Iowa, IA 52242.

Primary open angle glaucoma (POAG) is a common cause of blindness characterized by retinal ganglion cell (RGC) death and is associated with elevated intraocular pressure. Heterozygous myocilin (MYOC) mutations cause 2-4% of POAG cases, but the pathogenic mechanisms remain largely unknown. The objective of this study was to develop a mouse model of POAG and determine the pathogenic mechanisms involved. Transgenic mice (Tg) were generated which express the human Tyr437His MYOC mutation under the control of the CMV promoter. Mutant MYOC expression in the anterior segment of Tg mice was demonstrated by RT-PCR, immunohistochemistry and western blot analysis. Tg mice expressed higher levels of myocilin in the trabecular meshwork than wild type littermates. Starting at 3-months of age, Tg mice exhibited significantly higher intraocular pressure and demonstrated progressive loss of RGCs and axonal damage. In addition, Tg mice demonstrated significant lower response in pattern ERGs indicating functional loss of retinal ganglion cells. Interestingly, expression of mutant myocilin in the trabecular meshwork of Tg mice induces ER stress and activates the unfolded protein response (UPR). ER stress in the Tg mice switched from the UPR to the pro-apoptotic response as demonstrated by upregulation of chop and processing of pro-caspase-12. In addition, anterior chamber injection of tunicamycin or mutant myocilin virus significantly elevated IOP and activated UPR in control mice. Our observations indicate that Tg mice exhibit pathological changes similar to those in glaucoma patients validating this as a novel genetic animal model of glaucoma. Furthermore, this work reveals that expression of the Tyr437His mutation of human myocilin leads to ER stress and activation of UPR in the trabecular meshwork. These data indicates that sustained UPR compromises trabecular meshwork function leading to outflow deficiency, elevated intraocular pressure, and RGC death in glaucoma patients with myocilin mutations.

Mechanisms underlying recessive mutations in Human Hyperekplexia. *S. Chung[1], A. Robinson[1], J. Vanbellinghen[2], MI. Rees[1,3].* 1) Institute of Life Science, School of Medicine, Swansea University, United Kingdom; 2) Laboratoire de Génétique Moléculaire, University of Liége, Liége, Belgium; 3) Wales Epilepsy Research Network, School of Medicine, Swansea University, United Kingdom.

Glycinergic neurotransmission is a major inhibitory influence in the CNS and defects are associated with paroxysmal neuromotor disorder, hyperekplexia which is characterized by exaggerated startle reflexes and hypertonia in response to sudden, unexpected auditory or tactile stimuli. Mutations in the genes encoding the glycine receptor (GlyR) α1 subunit (GLRA1) and the presynaptic glycine transporter GlyT2 (SLC6A5) are the most common cause of hyperekplexia. DNA sequencing of GLRA1 in 88 hyperekplexia patients revealed 19 variants in 30 index cases; 21 were inherited in recessive mode or part of compound heterozygosity. The expression levels and functional properties of these hyperekplexia mutants were analyzed using a high-content imaging system and patch-clamp electrophysiology. Hyperekplexia mutants with low level expression of functional GlyRs were further investigated for the surface expression. Biotinylation of cell-surface proteins revealed that the reduction in the number of functional channels observed in recessive mutants is due to the decreased cell-surface expression of GlyRs. Although the whole-cell expression of recessive mutants was comparable to that of WT GlyR α1, cell-surface expression levels were significantly decreased. This indicates that subcellular localization defects were the major mechanism underlying recessive mutations. For the dominant mutations, there was no alteration in the cell-surface expression indicating that the decreased level of dominant GlyRs is due to non-functional surface-targeted channels rather than a reduction in surface-expression. The discovery of hyperekplexia associated mutations and subsequent mechanisms underlying the mutations will provide invaluable opportunities to study the pathophysiology of the ancient startle response.

An Integrated Examination of the Relationship of Genotype, Thyroid Function and Major Depression in Three Independent, Ethnically Diverse Longitudinal Samples. *R.A. Philibert[1], T.D. Gunter[2], S.R. Beach[3], C. Cutrona[4], D. Russell[4], G. Brody[3], N. Hollenbeck[1], M. Vijayendran[1], L. Elliot[1], D. Gugliano[1].* 1) Psychiatry, University of Iowa, Iowa City, IA; 2) Psychiatry and Neurology, St. Louis University, St. Louis, MO; 3) University of Georgia, Athen, GA; 4) Iowa State University, Ames, IA.

Thyroid function and major depression are complex disorders that are hypothesized to have overlapping diatheses. However, the exact nature of these overlapping diatheses remains completely undefined. In an effort to understand the pathophysiology of interlinked complex illnesses such as hypothyroidism and depression, we genotyped 1500 subjects from three longitudinal, ethnically diverse populations, for a series of 17 SNPs identified in prior genome wide association analyses of thyroid function. We demonstrate robust associations at least three of those SNPs from iodothyronine doiodinase, type 1 (DIO1) and phosphodiestarase 7B (PDE7B) with serum free thyroxine levels (FT4) and show strong evidence that these same SNPs also confer increased risk for major depression. The strength of the associations with both thyroxine levels and major depression appear to be gender and ethnicity specific. In summary, we confirm certain prior GWAS findings with respect to thyroid function in general population samples of both white and African-American ancestry and suggest that these SNPs may also contribute to alter vulnerability to major depression.

Role of microRNAs in Fragile X-associated Tremor/Ataxia Syndrome. *H. Tan, P. Jin.* Department of Human Genetics, Emory University School of Medicine, Atlanta, GA 30322.

Fragile X-associated tremor/ataxia syndrome (FXTAS), a late age of onset neurodegenerative disorder, has been recognized in older males of fragile X premutation carriers, which is uncoupled from Fragile X syndrome. Using a Drosophila model of FXTAS, we previously demonstrated that transcribed premutation repeats alone are sufficient to cause neurodegeneration. MiRNAs are sequence specific regulators of posttranscriptional gene expression and are believed to regulate the expression of thousands of target mRNAs, with each mRNA targeted by multiple miRNAs. To determine the role of miRNAs in rCGG repeat-mediated neurodegeneration, we have analyzed the expression of all known miRNAs and identified select miRNAs, including miR-14 and miR-277, that are altered specifically in the brains derived from the Drosophila model of FXTAS. To evaluate the potential contribution of these miRNAs to rCGG-mediated toxicity, we further tested their genetic interactions with rCGG repeats using FXTAS fly model, and found that miR-277 could modulate rCGG repeat-mediated neurodegeneration. Using several miRNA target prediction algorithms, we have also identified several mRNA targets of miR-277 that could modulate rCGG repeat-mediated neurodegeneration. These results together suggest that selective miRNAs aberrantly expressed could modulate the pathogenesis of FXTAS by post-transcriptionally regulating the expression of specific mRNAs that are involved in FXTAS.

Brain region-specific increased PKA activity is associated with alterations in behavioral responses to stress in Prkar1a-defective mice. *M.F. Keil[1, 3], G. Briassoulis[1], M. Nesterova[1], N. Gokarn[1], A. Batistatos[1], T.J. Wu[2], C.A. Stratakis[1].* 1) NICHD,SEGEN, National Institutes of Health, Bethesda, MD; 2) Program in Neuroscience, Uniformed Services University of the Health Sciences; 3) Graduate School of Nursing, Uniformed Services University of the Health Sciences.

Background: The role of the cAMP/PKA signaling in molecular pathways involved in fear and memory is well established. We recently reported that a Prkar1a heterozygote (HZ) knock-out (KO) mouse that was developed in our lab to investigate Carney complex (CNC), the disease caused by PRKAR1A mutations, exhibits an anxiety-like behavioral phenotype (Keil, 2010). Prior studies in our lab reported that transgenic mice with a down-regulated Prkar1a gene (Griffin, 2004) exhibited behavioral abnormalities including anxiety (Batista, 2005) and depression (Batista, 2006). In addition, several research groups have reported CNS effects in PKA KO mouse models for R1beta, R2alpha, and R2beta, and the PKA catalytic subunits. Methods: We measured PKA activity in brain areas involved in the stress response in HZ KO Prkar1a adult mice compared to wild-type (WT) littermates after mice were exposed to a stressor [novelty (saline) vs. predator (fox urine odor)] for 5 minutes; behavior was recorded (2x2 factorial design). Ninety minutes after stress exposure, mice were euthanized and brains were procured and immediately frozen. Biopsies of various brain nuclei were obtained for PKA analysis. Results: There were significant differences between HZ and WT in the behavioral response to stress. WT mice showed the expected response of decrease in exploratory behavior (rearing and stretch attend postures) ($p<0.02$) and an increase in defensive behavior (digging) ($p<0.03$) during predator (fox urine) vs. novelty (saline exposure) stress. However, HZ mice did not show alterations in behavior (exploratory or defensive) with exposure to different stressors (novelty vs. predator). Both HZ and WT mice showed similar pattern of decrease in grooming behavior (non-defensive behavior) during predator (fox urine) vs. novelty (saline) stress. Multivariate analysis showed that basal and total PKA activity was independently associated with genotype ($p<0.02$) and stress ($p<0.01$), with an interaction between genotype and stress ($p<0.03$). HZ mice had higher PKA activity (basal and total) in amygdala (basolateral and central), hypothalamus, and thalamus in response to predator (fox urine) vs. novelty (saline) stress. Conclusion: These results suggest that the alteration in PKA signaling in Prkar1a HZ KO mice is not ubiquitous in the brain; tissue-specific effects of the cAMP/PKA pathway are related to stress responses and fear sensitization.

Cis-regulatory variants on chromosome 15q25 affect CHRNA5 mRNA expression and risk for smoking related illnesses. *J.C. Wang, N. Spiegel, J. Budde, L.J. Bierut, A.M. Goate.* Psychiatry, Washington Univ, St Louis, MO.

Variants within the gene cluster encoding α3, α5, and β4 nicotinic receptor subunits are major risk factors for substance dependence. The strongest impact on this risk is associated with variation in the CHRNA5 gene where we see at least two mechanisms: amino acid variation and variation in mRNA expression levels. These two mechanisms also affect risk for lung cancer. The risk allele of the non-synonymous variant (rs16969968) primarily occurs on the low mRNA expression allele of CHRNA5. The non-risk allele at rs16969968 occurs on both high and low expression alleles tagged by rs588765 within CHRNA5. When the non-risk allele occurs on the background of low mRNA expression of CHRNA5, the risk for nicotine dependence and lung cancer is significantly lower compared to those with the higher mRNA expression. Because there are 50 variants spanning 100 kb in the CHRNA5-A3-B4 gene cluster region that are highly correlated with rs588765 in European populations, it is not clear which of these variants are contributing to the changes in CHRNA5 mRNA expression. To narrow the number of putatively function variants that affect the CHRNA5 mRNA expression, we performed quantitative allele specific gene expression using brain tissue derived from European Americans. This method measures allele-specific transcript levels in the same individual, which eliminates other biological variation that occurs when comparing expression levels between different samples. With this measurement we are able to determine whether the nicotine and other substance dependence associated variants have a cis-regulatory (direct) effect on CHRNA5 transcript levels and identify variant(s) that are responsible for modulating mRNA expression. Our analysis has narrowed the number of possible functional variants from 50 to approximately 6. These variants are located in a region of ~14 kb upstream of CHRNA5, including the promoter region. This work may provide genetic information that will lead to better prevention and intervention for substance use disorders.

Searching for functional variants in STAT3-region in Finnish multiple sclerosis patients. *V. Leppa[1,2], A.-M. Sulonen[1,2], P. Ellonen[1], H. Almusa[1], E. Jakkula[1,3], P. Tienari[4], K. Koivisto[5], I. Elovaara[6], T. Pirttila[7], M. Reunanen[8], A. Palotie[1,9], L. Peltonen[1,9], J. Saarela[1].* 1) Institute for Molecular Medicine FIMM, Helsinki, Helsinki, Finland; 2) The National Institute for Health and Welfare, Helsinki, Finland; 3) Laboratory of Molecular Genetics, HUSLAB, Helsinki, Finland; 4) Dept. of Neurology, Helsinki Univ. Central Hospital, Helsinki, Finland; 5) Central Hospital of Seinajoki, Seinajoki, Finland; 6) Dept. of Neurology, Tampere Univ. Central Hospital, Tampere, Finland; 7) Dept. of Neurology, Kuopio University Central Hospital, Kuopio, Finland; 8) Oulu University Central Hospital, Oulu, Finland; 9) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

Multiple sclerosis (MS) is a complex autoimmune disease of the central nervous system. In Southern Ostrobothnia (SO) region in Finland the prevalence of MS is 2-fold compared to other populations of Northern European descent. We previously published a GWAS using distantly related SO MS patients and identified variants in STAT3 to associate with MS (Jakkula et al. 2010). This association was replicated in a sample set of 4638 cases and 10279 controls from 7 populations (rs744166, p 2.75 x 10E-10, OR 0.87).

We targeted 111 kb of the STAT3-STAT5A region using SureSelect target enrichment method and used Illumina GAII -sequencing to refine our understanding of the association and to identify potential functional variants. We chose ten MS samples based on the homozygous genotype for the potentially protective A-allele of rs744166 and pooled the samples. Four pools with total of 34 MS samples and three pools with total of 19 controls were sequenced. We obtained on average 31 x coverage per pool. In the rs744166 AA homozygous pool the preliminary analysis identified 303 unreported variants of which twenty are missense or nonsense mutations. None of the new variants were found in all pooled MS cases homozygous for rs744166, but 13 were specific to the MS pool. We are currently validating these mutations and in addition to this we are analyzing expression of STAT3 and near-by genes in PBMCs of 30 MS and 30 control samples to monitor if any of the genes are differentially expressed and if the expression correlates with the genotypes of the associated variants.

2613/F

Haploinsufficiency of Shank3 leads to deficits in synaptic plasticity. *O. Bozdagi, T. Sakurai, J.D. Buxbaum.* Psychiatry, Mount Sinai Sch Med, New York, NY.

Haploinsufficiency of SHANK3, caused by chromosomal abnormalities or mutations, leads to a neurodevelopmental syndrome that includes absent or severely delayed speech, intellectual disability, and autism spectrum disorder. The SHANK3 protein forms a key structural part of the postsynaptic density and in vitro studies have shown that expression of SHANK3 is sufficient to trigger the formation of glutamatergic synapses. We have developed a mouse with a disruption of Shank3 and are studying synaptic structure and function, as well as behavior. We examined excitatory glutamatergic synaptic transmission in hippocampal slices from Shank3 heterozygous and wildtype littermates. We performed conventional extracellular recordings from 1-3 month old mice, as well as whole-cell patch-clamp recordings in 3-month mice. To examine the properties of basic synaptic transmission in Shank3 heterozygous synapses, we performed extracellular recordings in Schaffer collateral-CA1 synapses in hippocampal slices and further monitored spontaneous miniature postsynaptic currents using whole-cell recordings. Both the amplitude of miniature excitatory postsynaptic currents from hippocampal CA1 pyramidal neurons of Shank3 heterozygous mice and the input-output function determined by field potential recordings were significantly lower than those of control mice, indicating a reduction in basal transmission due to a postsynaptic effect. We next examined the effect of Shank3 deficiency on synaptic plasticity at Schaffer collateral/CA1 synapses. Long-term potentiation (LTP) induced either with theta-burst or high-frequency stimulation was impaired in Shank3 heterozygous mice with no significant changes in long-term depression (LTD) induced by either low frequency (LFS) or paired-pulse-LFS stimulation. To investigate the AMPA and NMDA receptor-mediated contributions to evoked excitatory postsynaptic potentials, the input-output function was analyzed in the presence of antagonists. We observed that the AMPA receptor component of the input-output curve was significantly lower in Shank3 heterozygous mice. The results are consistent with an hypothesis where loss of one functional copy of SHANK3 leads to abnormal development and function of glutamatergic synapses with associated changes in synaptic plasticity. The studies indicate that AMPA receptors and glutamatergic transmission represent therapeutics targets in SHANK3 haploinsufficiency syndromes.

2614/F

Impact of genetic variation in the serotonin system on smoking cessation: Identifying the brain mediators with functional MRI. *A.J. Jasinska[1], H.F. Chua[2], S.S. Ho[3], L. Rozek[4], T.A. Polk[5], V.J. Strecher[2].* 1) Neuroscience Program, University of Michigan, Ann Arbor, MI; 2) Health Behavior and Health Education, University of Michigan, Ann Arbor, MI; 3) Psychiatry, University of Michigan, Ann Arbor, MI; 4) Environmental Health Science, University of Michigan, Ann Arbor, MI; 5) Psychology, University of Michigan, Ann Arbor, MI.

Twin studies suggest that genetic factors account for over 50 percent of the variance in smoking cessation outcomes but the specific genetic variants involved are mostly unknown. Identification and characterization of these genetic variants, and a better understanding of the neurobiological processes through which they influence smoking behavior, could guide the design and selection of the most effective treatment for each smoker. In the current study, we combined genetics, functional MRI, and health communication techniques to examine the role of genetic variation in the serotonin system on the brain processes related to smoking cessation. We focused on the 5-HTTLPR/rs25531 and STin2 polymorphisms in the serotonin transporter gene. Because prior neuroimaging work has shown that tailored health messages preferentially activate the self-related processing network, including the medial prefrontal cortex (MPFC), we examined whether the influence of the 5-HTTLPR/rs25531 and STin2 polymorphisms on smoking cessation is mediated by the response of the self-related processing network to tailored smoking cessation messages. Ninety-one smokers interested in quitting (44 females and 47 males; mean age 37.5 ± 11.5 years) were recruited for the study. All participants completed a web-based tailored smoking cessation program. Complete data (including genotyping results, fMRI data, and a smoking cessation outcome at 4-month follow-up) were available from eighty-four participants and these results are reported. We found evidence that the response to tailored health messages in the dorsal MPFC within the self-related processing network mediated the influence of STin2 genotype on the smoking cessation outcome at the 4-month follow-up (p less than 0.05). These findings may be relevant to a broad area of research on the genetics and neurobiology of smoking cessation and may point towards genetically-tailored smoking cessation treatments in the future.

Analyzing *in vivo* function of the *ENGRAILED 2* ASD-associated haplotype. *S. Kamdar[1,2], T. Rahman[2], P.G. Matteson[2], L. Shinkarow[3], J.H. Millonig[1,2].* 1) Dept Neuroscience, UMDNJ, Piscataway, NJ; 2) Center for Advanced Biotechnology and Medicine UMDNJ-Robert Wood Johnson Medical School; 3) James Madison University.

Autism Spectrum Disorders (ASD) is a complex neuropsychiatric disorder with a strong genetic basis. *ENGRAILED 2 (EN2)*, a homeobox transcription factor, is expressed throughout CNS development and regulates several important developmental processes including connectivity and neurotransmitter development (Millen *et al.* 1995, Baader *et al.* 1998, Brunet *et al.* 2005, Sgaier *et al.* 2007). Previous work demonstrated the common alleles (underlined) of two intronic *EN2* SNPs, rs1861972 (A/C) and rs1861973 (C/T), are associated with ASD (A-C haplotype in 518 families, 2336 individuals, P-value < .000001) (Benayed *et al.* 2005). *In vitro* molecular genetic experiments (luciferase assays, Electro Mobility Shift Assays,) demonstrate the ASD-associated A-C haplotype increases gene expression (Benayed *et al.* 2008). After observing the above results, the next important step is to test for A-C haplotype function *in vivo*. *En2* has a dynamic expression pattern throughout CNS development, which leads us to ask if A-C haplotype is functional at more than one developmental time point, in more than one cell type, and if the haplotype always affects gene expression levels during CNS development?

To investigate the *in vivo* developmental regulation of the A-C haplotype, transgenic mouse lines were generated using ~25 kb of flanking *EN2* cis-regulatory sequence, which drives expression of a fluorescent reporter instead of the functional *EN2* protein. The same DNA sequence was used to make two transgenes: one has the ASD-associated A-C haplotype (A-C) and the other has the G-T haplotype (G-T). 6 A-C and 8 G-T lines were established. RT-qPCR analyses done to measure expression level differences between the two haplotypes, revealed that A-C haplotype increases reporter gene expression in the postnatal day 7 (96% increase, P-value<0.0001, n = 18) and adult (>P30) brain (200% increase, P-value<0.00001, n = 44). Ongoing experiments are investigating the effect of the A-C haplotype on spatial/temporal expression during CNS development as well as mRNA levels at different embryonic stages (E9, E12, and E17).

Together with our *in vitro* analysis, the above data demonstrate that the A-C haplotype functions *in vivo* as a transcriptional enhancer.

2616/F

A functional link between DYT1 and DYT6 dystonia: Regulation of *DYT1* gene expression by the transcription factor activity of THAP1 (DYT6). *A. Osmanovic[1], A. Erogullari[1], A. Rakovic[2], D. Braunholz[1], N. Uflacker[2], T. Lohnau[2], M. Albrecht[1], G. Gillessen-Kaesbach[1], C. Klein[2], K. Lohmann[2], F.J. Kaiser[1].* 1) Institut für Humangenetik, Universitätsklinikum, Lübeck, Germany; 2) Section of Clinical and Molecular Neurogenetics at the Department of Neurology, Lübeck, Germany.

While dystonia is clinically characterized by involuntary twisting, repetitive movements and abnormal postures, its molecular pathophysiology is not well understood. Mutations in two genes have been associated with monogenic forms of primary (isolated) dystonia: i) mutations in the *TOR1A* gene cause DYT1 dystonia; ii) mutations in the recently identified *THAP1* gene lead to the phenotypically similar DYT6 dystonia. The *THAP1*-encoded THAP1 protein consists of 213 amino acids with a characteristic DNA-binding THAP zinc-finger domain at the N-terminus. Recent studies demonstrated that THAP1 is involved in transcriptional regulation. To gain insights into the molecular mechanisms explaining the phenotypic overlap of DYT1 and DYT6 dystonia, we tested whether the transcription factor THAP1 directly regulates *TOR1A* promoter activity. For this, a fragment of 1kb representing the predicted *TOR1A* promoter was amplified and inserted into the pGL4 luciferase reporter plasmid. Co-transfection with full-length wild-type THAP1 expression plasmids decreases the *TOR1A* promoter activity in a concentration dependent manner. By analyzing a set of different truncated TOR1A promoter constructs in reporter gene assays, we narrowed the most critical region for promoter activity down to a stretch of about 220 bps 5' of exon 1 which contains two predicted THAP-binding motifs. In addition, DYT6 dystonia-associated mutant THAP1 proteins generated by site-directed in-vitro mutagenesis showed impaired THAP1-mediated repression of the *TOR1A* promoter activity. To proof that THAP1 binds to the *TOR1A* promoter, we performed chromatin immuno-precipitation assays (ChIPs) with purified nuclear fractions of human neuroblastoma cells (SH-SY5Y). By subsequent PCR, we confirmed that THAP1 specifically binds within the *TOR1A* promoter region. Our data clearly show that THAP1 directly regulates the activity of the *TOR1A* promoter, providing experimental evidence linking the molecular pathways underlying DYT1 and DYT6 dystonia. The function of THAP1 in regulation of gene expression establishes transcriptional dysregulation as a cause of dystonia. Identification of additional target genes will further elucidate the pathophysiology of dystonia.

2617/F

Candidate Genes and Educational Attainment: Screening for Novel Associations with Nicotine Dependence. *E. Johnson[1], R. Grucza[2], P. Hipp[2], N. Breslau[3], L. Bierut[2].* 1) Behavioral Health Epidemiology, RTI International, Res. Triangle Pk, NC; 2) Department of Psychiatry, Washington University, Saint Louis, MO; 3) Department of Epidemiology, Michigan State University, East Lansing, MI.

Genome-wide association studies of smoking phenotypes have successfully identified and confirmed associations with SNPs in the in the *CHRNA5-CHRNA3-CHRNB4* cholinergic nicotinic receptor subunit gene cluster on chromosome 15q24-25. Taken together, however, these associations account for less than 10% of the phenotypic variance. It is expected that additional unidentified genetic variants and the interplay with environmental risk factors will help to account for additional phenotypic variance. Educational attainment (EDU) is an important indicator of socioeconomic status and strongly associated with a number of smoking phenotypes including nicotine dependence (ND). The purpose of this study was two-fold: 1) to use the power of SNP x EDU interaction to discover novel gene - ND associations; and 2) to better understand the interplay between EDU and genetic risk for ND. Subjects were from the Collaborative Genetic Study of Nicotine Dependence (COGEND): 797 cases ascertained for Fagerström nicotine dependence, and 811 non-nicotine dependent smokers as controls, all of European descent. The two degrees of freedom test was used to screen 3,369 SNPs from 349 candidate genes, comparing a main-effect modhael with SNP x EDU interaction models. The top 20 findings, ranked by 2 df p-value, were followed up in control subjects from the GAIN Schizophrenia study available through dbGaP. Genes that were previously associated with ND and novel gene associations were among the top 20 SNP x EDU models (2 df p-values from 0.00005 to 0.004). Of these, six SNP x EDU models showed parallel associations in the replication sample tagging four genes previously not associated with ND(secretogranin V (*SCG5*), solute carrier family 8 member 1 (*SLC8A1*), solute carrier family 12 member 6 (*SLC12A6*), and protein kinase C epsilon (*PRKCE*)) and one gene that has been associated with ND: gamma-aminobutyric acid, receptor A, subunit 4 (*GABRA4*). Application of the 2 df test of SNP x EDU interaction to assessing a panel of candidate genes for nicotine dependence identified new associations for follow-up and highlighted potential differences in specific gene associations with nicotine dependence in varying environmental contexts as measured by educational attainment.

Gene-Environment Interactions in Psychiatry: True Results or Type I Errors? *L.E. Duncan[1,2], M.C. Keller[1,2].* 1) Department of Psychology and Neuroscience, University of Colorado at Boulder; 2) Institute for Behavioral Genetics, Boulder Colorado.

Introduction: Measured gene-environment interaction (GxE) studies have typically been conducted in a candidate GxE (cGxE) fashion, analogous to the candidate gene association studies that have been used to search for genetic main effects. Such cGxE research in psychiatry has received widespread attention and acclaim, yet cGxE findings are also controversial. We were interested in trying to understand whether positive cGxE findings reported in the psychiatric literature were robust and might help to explain some of the missing heritability in psychiatric genetics or if, in aggregate, cGxE findings were consistent with the existence of publication bias, low power, and type I errors. **Method**: We conducted analyses on data extracted from all published studies (to our knowledge, 97 studies) from the first decade (2000-2009) of cGxE research in psychiatry. **Results:** Most novel cGxE studies were significant (95%) but only a minority of replication attempts were significant (29%), findings consistent with the existence of publication bias among novel cGxE studies. There may also be publication bias among replication attempts because significant replication attempts had *smaller* sample sizes, on average, than null replication attempts. Power calculations using observed sample sizes suggest that most studies were underpowered, perhaps severely so. Low power dictates that type I errors will outnumber true results among positive findings if, as is likely to be the case, most cGxE hypotheses that could be investigated are actually null. For example, given certain realistic assumptions, cGxE studies may have a rate of ~200 type I errors for every one true result. Finally, we show that low power biases the observed form of interactions (i.e. 'crossover' vs. 'non-crossover') toward the 'crossover' variety. **Conclusion**: These results suggest reason for caution in interpreting cGxE studies in psychiatry. They suggest that the cGxE literature in psychiatry is biased toward positive reports and that many positive cGxE findings are type I errors. In addition, even if true interactions are identified, the observed form of the interaction will often be incorrect.

Cognitive Flexibility is Modulated by BDNF and Its Interaction with Substance Dependence. *N. Li[1], H. Zhang[1], H.R. Kranzler[2], J. Poling[1], A.I. Herman[1], J. Gelernter[1].* 1) Yale Univ Sch Med, West Haven, CT; 2) Uconn, Storrs, CT.

Cognitive flexibility is the ability to switch behavioral responses based on the context of a situation. Features of this important executive function vary between individuals, with possible genetic contributions to these differences largely undetermined. Brain derived neurotrophic factor (BDNF), a member of the nerve growth factor superfamily, plays a key role in regulating complex behaviors including memory and attention. We examined the association of variation in the BDNF gene with a measure of cognitive flexibility, a key cognitive function, in 519 African Americans [AAs; 443 substance (alcohol or drug) dependent individuals] and 391 European Americans [EAs; 337 substance (alcohol or drug) dependent individuals]. Subjects' cognitive flexibility was assessed using the Wisconsin Card Sorting Test (WCST). We examined the effects of six BDNF single nucleotide polymorphisms (SNPs) [including the functional Val66Met (rs6265)] and their interaction with substance dependence on cognitive flexibility using a multivariate analysis of variance and the haplotype program HAPSTAT. Subjects' sexes, age, years of education, and ancestry proportions (based on Bayesian clustering) were used as covariates in the model. In EAs, although none of the six SNPs showed a main effect on cognitive flexibility, the interaction of three SNPs (rs1519480, rs7124442 and rs11030121) with substance dependence significantly influenced two domains of WCST performance (perseverative responses: P=0.009, 0.017, and 0.012, respectively and perseverative errors: P=0.008, 0.016 and 0.010, respectively). Moreover, two specific haplotypes, C-C (consisting of alleles of rs1519480 and rs7124442 in haplotype Block I) and Val-G-T-T (consisting of alleles of Val66Met, rs7934165, rs11030121 and rs12273363 in haplotype Block II), were associated with significantly more perseverative responses (C-C: P=0.002; Val-G-T-T: P= 0.005) and perseverative errors (C-C: P=0.002; Val-G-T-T: P=0.005). There was greater cognitive flexibility in substance dependent subjects with these two haplotypes, as evidenced by significantly fewer perseverative responses: P=0.002 for C-C and 0.006 for Val-G-T-T; and significantly fewer perseverative errors: P=0.002 for C-C and 0.002 for Val-G-T-T). In AAs, we found no evidence of a genetic or gene-substance dependence interactive effect on cognitive flexibility. We conclude that variation in BDNF can moderate an individual's cognitive flexibility in a population-specific way.

Mitochondrial DNA Haplogroups in Patients with Multiple Sclerosis in Bogota. *W. Cardenas Cuadros[1], M. Lattig[1], M. Torres[1], C. Perea[1], C. Guio[2], J. Toro[2], H. Groot[1].* 1) Biology, Universidad de Los Andes, Bogota; 2) Grupo de Neurologia, Fundacion Santa Fe, Bogota.

Multiple sclerosis (MS) is a chronic inflammatory disease of the central nervous system considered as a multifactorial disorder in which both environmental and genetic factors are involved. According to Kurtzkee 1975, the prevalence of MS can be divided into three risk areas based on the disease frequency: low (<5/100.000 inhabitants), medium (5-30/100.000) and high (>30/100.000). In Bogota, an area of defined low risk for the disease, an MS prevalence rate of 4,4/100.000 was previously reported by our group. It has been widely reported that MS prevalence is high in populations of Caucasian origin. We hypothesized that in Colombia, individuals with MS might have a Caucasian origin and therefore a higher prevalence to develop the disease even if they are living in a low prevalence zone. To start exploring this hypothesis we looked at the mitochondrial DNA (mtDNA) hypervariable segment I (HVSI) in order to define the various mtDNA haplogroups present in our population. To determine the haplogroups, we sequenced the HVSI segments of mtDNA in 58 MS patients and 58 control subjects to determine their maternally inherited ethnic origin of mitochondria in a heterogeneous population of Bogotá, Colombia. The percentage of mitochondrial haplogroups found in the study where: A= 32%, B=26%, C=14% and D=7% (Amerindian); L=5% (African); T1% and J=4% (Caucasian). No statistical differences were found between the affected and control individuals and their mtDNA haplogroup, however a vast majority of Amerindian haplogroups were found in the study population. When we analyzed the female population, the haplogroup distributions in the patients were: A= 33%, B=35%, C=9% and D= 11% (Amerindian); L=4% (African); and J=4% (Caucasian) and in the controls were: A= 25%, B=11%, C=20% and D=6% (Amerindian); L=6% (African); T=2% and J=6% (Caucasian), observing a significant association (FISHER, p=0.046) between the B haplogroup and the MS patients, and also a significant association (FISHER, p=0.026) with the C haplogroup and the control population. This is the first study in Colombia in which maternal mitochondrial haplogroups together with a disease such as Multiple Sclerosis has been explored.

Genome-wide Association Analysis of Gender Difference in Major Depressive Disorder in the Netherlands population sample from NESDA and NTR registries. *N.R. Aragam, K.S. Wang.* Dept. of Biostatistics & Epidemiology, East Tennessee State University, Johnson City, TN.

Superscript TextBackground: Major depressive disorder (MDD) is a universally prevalent, genetic, and environment dependent mental condition that disables people of every culture, race, gender, and age. The gender differences for MDD has been widely reported in literature with a prevalence in women more than twice that of men and with odds ratios estimated between 1.4 and 2.0. However, few genome-wide analyses of gender differences has been reported to date. In this study, a sample European population database (from the National Institutes of Health Genetic Association Information Network) derived from the registries of Netherlands' Twins (NTR) and study of depression and anxiety in Netherlands (NESDA), is used to conduct a genome-wide association study of gender differences for MDD. Methods: PLINK software was used to analyze the genome-wide gender differences of MDD among 3356 individuals (1726 cases and 1630 controls; 1150 males and 2206 females) with 437547 SNPs. Results: We identified a total of 66 MDD associated SNPs with p-values less than 10^{-4}. The best SNP was rs1558477 in ADCYAP1R1 gene ($p = 2.07x10^{-7}$). Furthermore, two SNPs in LAPTM4A (rs7565124 and rs12471796, $p= 1.19 \times 10^{-6}$ and $1.71x10^{-6}$, respectively) and two SNPs in PCLO (rs2522833 and rs2522840, $p = 3.06x10^{-6}$ and $5.53x10^{-6}$, respectively) showed strong associations with MDD. In addition, we found 38 SNPs showing geneder differences with p-values less than 10^{-4}. The best SNP showing gender difference was rs12692709 ($p = 5.75x10^{-6}$) in GRB14 gene located at 2q24.3. The next four best SNPs showing gender differences were rs11039588 in OR4B1 ($p = 1.16x10^{-5}$), rs6856020 in LCORL ($p = 1.47x10^{-5}$), rs1589263 in PLD5 ($p = 1.60x10^{-5}$), and rs1507061 in SNX7 ($p = 1.61x10^{-5}$). Conclusions: Our findings provide a starting point for the genome-wide study of gender differences for MDD and related phenotypes, and the gene x gender interactions.

Speech delay modulated by the interplay between paternal age and WNT2 gene in autism spectrum disorder. *P. Lin[1,2], Y. Chien[1], S. Gau[1].* 1) Dept Psychiatry, National Taiwan Univ Hosp, Taipei, Taiwan; 2) Maryland Psychiatric Research Center, Univ Maryland School of Medicine, Catonsville, Maryland, MD, USA.

Background: Delay in speech is the hallmark feature of autism spectrum disorder (ASD). Previous evidence suggests that language development is modulated by genetic factors, such as the FOXP2 gene (e.g., Fisher et al., 1998; Lai et al., 2001; Vernes et al., 2008), and SHANK gene (Wilson et al., 2003). Some but not all previous studies have also reported that these two genes are associated with risk of ASD. Additionally, paternal/maternal age has been found to be associated with cognitive functions in ASD (Saha et al., 2009). In the current study, we aimed to explore the effect of variants in and near FOXP2 and SHANK3 genes on speech delay inherent to ASD. We also assessed if paternal/maternal age modifies these genetic effects on language development. Methods: A total of 593 individuals diagnosed with ASD were ascertained in the current study. We selected 22 single nucleotide polymorphisms (SNPs) within the FOXP2 and SHANK3 genes and nearby genes. Genotyping was performed by MALDI-TOF (matrix-assisted laser desoption/ionization - time of flight) spectrometry for SNP analysis. We used two quantitative phenotypes, age of first words (AFW) and age of first phrases (AFP), to assess the degree of speech delay in these subjects. To study the genetic effect on speech delay, we used general linear model to examine the association between AFW/AFP and 22 SNPs. Covariates including gender and intelligence quotient were adjusted. Finally, we tested the interaction between associated SNP and paternal/maternal age. Results: The results show that rs2396753 on FOXP2 gene was significantly associated with AFW (regression coefficient = -5.09, p = 0.0108). Another SNP rs2896218 on the WNT2 gene was associated with AFP (regression coefficient = -6.81; p = 0.0045). A three-locus haplotype in the WNT2 gene was significantly associated with age of first phrases (rs4727845-rs2228946-rs2896218; regression coefficient = 6.57; p = 0.00026). Finally, we detected a significant interaction effect between paternal age and rs2228946 on both AFW (p = 0.0123) and AFP (p = 0.0387). Minor allele (A allele) at rs2228946 (located in 3' UTR region of WNT2 gene) was associated with older AFW/AFP in individuals with younger paternal age, while associated with younger AFW/AFP in individuals with older paternal age. Conclusion: This study suggests that the effect of WNT2 polymorphism on speech delay may depend on paternal age in ASD.

DNA methylation in brain in Major Depressive Disorder. *Q. Chen, L. Cheng, C. Chen, D. Zhang, G. Elliot, C. Liu.* Dept Psychiatry, University of Chicago, Chicago, IL.

Environmental stressors modulate subsequent vulnerability to depression. Epigenetic studies of DNA methylation(DNAm) and direct measurement of gene expression in brain allowed us to combine genetic and environmental study of this complex disorder. We studied cerebellum brain tissue methylation differences between 15 major depression patients and 47 healthy controls. The Nimblegen 2.1M DeLuxe Promoter Array enables identification of methylated DNA regions across biologically significant regulatory elements in the genome. This array uses methylated DNA immunoprecipitaion(MeDip) technology and tiles with the 100bp probe spacing through around 10kb region of all annotated 32k gene promoters, 28k CpG islands and 475 miRNA promoters. We used CHARM software to do microarray data quality assessment, pre-processing/normalization, probe-level percentage of methylation estimates, and identification of differentially methylated regions (DMRs). We found 689 differentially methylated regions ($p<0.05$) between depression patients and controls. None can survive multiple testing correction(FDR<0.05). The length of the DMRs is 240-2926bp and average length is 616bp. We further evaluated the location distribution of variable DNA methylation relative to genes and to CpG islands. Because epigenetic alteration may correlate with expression changes, we are analyzing the genes in promoter regions of DMRs for the correlation of methylation difference and expression change.The whole genome methylation and expression analyses may suggest some novel genes related etiology of major depression.

The role of TpH1-218A>C, TpH2-1463G>A and SLC6A4-5HTTLPR polymorphisms in development of post partum depression: A study in Jordanian population. *O.F. Khabour[1], E.A. Bani-Hani[2], B. Amarneh[3].* 1) Medical Laboratory Sciences, Jordan Univercity of Science and Technology, Irbid, Jordan; 2) Department of Biology, Jordan Univercity of Science and Technology, Irbid, Jordan; 3) Department of Public Health, Jordan Univercity of Science and Technology, Irbid, Jordan.

Postpartum depression (PPD) is a mood disorder occurs in (20 -28)% of women who have recently given birth and may extended during the first year after delivery. The presence of PPD has many adverse effects such as, marital problems, adverse behavioral and cognitive effects on the child, so as searching for predisposing genetic and environmental elements seems an important deal. Among the genetic factors that might contribute to PPD are variations in genes that involved in serotonergic neurotransmitter system like tryptophan hydroxylase -1(TpH1), tryptophan hydroxylase-2 (TpH2) and serotonin carrier family 6 member 4 (SLC6A4). In this study we investigated the frequency of TpH1-218A>C(rs 1800532), TpH2-1463G>A and SLC6A4-5HTTLPR among postpartum depressed women compared to postpartum healthy non depressed control women in Jordan. In addition, we examined the possible correlation between certain environmental factors including socio-demographic variables like mother age, intra-partum variables like pregnancy problems and psycho-social variables like depression history with postpartum depression among the same postpartum Jordanian women. A total of 130 depressed women and 240 normal controls were randomly selected from five maternity centers from north of Jordan. Genotyping of polymorphisms were performed using PCR technology. The results showed no significant correlation in the genotype distribution or allelic frequency of the three examined polymorphisms {TpH1 (A218C), TpH2 (G1463A) and SLC6A4-5HTTLPR} between depressed and normal controls ($P > 0.05$). Both allele S and L of the SLC6A4 polymorphism are common among Jordanian women (51% & 49% respectively), while allele C of TPH1 polymorphism is more common than allele A (64% versus 37% respectively). Regarding TPH2 polymorphism allele A is absent from all the examined women. However, three socio- demographic variables were found to be significantly associated with postpartum depression: depression history, pregnancy problems and economic status ($P < 0.05$). The results suggest that the stronger influence of environmental factors on PPD might cover or minimize the weaker genetic effect.

Development of a hiPSC model for the study of gene-environment interactions in Parkinson's disease. *A.B. Bowman, A.M. Tidball, P. Hedera, K.C. Ess, M.D. Neely.* Dept Neurology, Kennedy Ctr for Research on Human Development, Vanderbilt Univ, Nashville, TN.

The proximate cause of Parkinson's disease (PD) is the degeneration of the dopaminergic neurons in the substantia nigra pars compacta and the ensuing loss of striatal dopamine innervation. Although the discovery of genes linked to rare familial forms of PD has provided some insights into the mechanisms underlying this disease, the majority of PD cases likely result from complex interactions between genetic and environmental factors. This multifactorial nature of PD makes the development of adequate models difficult. Recently, methods to derive dopaminergic neurons from patient fibroblasts have been developed. This approach provides us with a powerful tool to assess the multifactorial nature of PD. We have derived human induced pluripotent stem cell (hiPSC) lines from two brothers who lack a functional PARK2 allele and from a control patient who shows no neurological symptoms. Interestingly, one of the brothers carrying the PARK2 mutations (now 47 years old) reported childhood onset resting tremor and dystonia. Clinical diagnosis of PD occurred at ~30 years of age. The other brother carrying the identical PARK2 mutations (now 41 years old) shows no clinical symptoms of PD. This observation highlights the multifactorial nature of the mechanism underlying PD pathogenesis. We are presently deriving dopaminergic neurons from the hiPSC-lines of both brothers and the control patient and are comparing their general characteristics and their sensitivities to different PD-relevant stressors, such as mitochondrial toxins and metals. These studies lay the foundation for the assessment of gene-environment interactions in dopaminergic neurons derived from a much larger group of PD patients (both familial and iodiopathic cases) with the goal of determining possible patterns of patient-specific sensitivities to PD-associated stressors and developing patient-specific approaches to neuroprotective therapies.

Transcriptome and Genome-wide Association Data Implicate PCLO Gene in Bipolar Disorder. *K. Choi[1], B. Higgs[2], J. Wendland[3], J. Song[1], F. McMahon[3], M. Webster[1].* 1) Stanley Med Res Inst, Rockville, MD; 2) Elashoff Consulting, Redwood City, CA; 3) Genetic Basis of Mood and Anxiety Disorders Unit, National Institute of Mental Health, NIH, Bethesda, MD.

Genetic variation may contribute to differential gene expression in the brain of individuals with psychiatric disorders. We explored potential association between genes differentially expressed in the prefrontal cortex (PFC) of bipolar disorder subjects and single nucleotide polymorphisms (SNPs) adjacent to those genes. Postmortem brain tissue of bipolar disorder (N=40) and unaffected controls (N=43) was profiled using genome-wide expression and SNP microarrays. We identified 367 genes as being differentially expressed (fold change > 1.3 and FDR-adjusted q-value < 0.05) in the PFC of bipolar disorder subjects. We then identified local SNPs (100 kb up- and down-stream of each gene) that are associated with expression of those genes. Using those local SNPs, we tested disease association with the results derived from a meta-analysis of genome-wide association studies (GWAS) including 4,936 bipolar disorder cases and 6,654 controls. We identified 45 local SNPs that are associated with genes differentially-expressed in bipolar disorder (FDR q-value < 0.05). Expression levels of HBS1L (15 SNPs), HLA-DPB1 (15 SNPs), AMFR (8 SNPs), PCLO (2 SNPs) and WDR41 (2 SNPs) were associated with multiple local SNPs. Among those SNPs, rs13438494 in an intron of the piccolo (PCLO) gene was significantly associated with bipolar disorder (FDR-adjusted $p < 0.05$) based on the meta-analysis of GWAS. These results are consistent with recent findings implicating PCLO in mood disorder and demonstrate the utility of combining the data from postmortem brains and a large scale GWAS in order to enhance our understanding of the genetic contribution to bipolar disorder.

2627/F

Genome-Wide Analysis of Copy Number and LOH Events in Alzheimer's Disease. *S. Shams.* BioDiscovery, Inc, El Segundo, CA.

We used computational methods to identify genomic areas of interest in Alzheimer's Disease (AD). We used genome-wide SNP array data generated by Alzheimer's Disease Neuroimaging Initiative (ADNI) and processed through Nexus Copy Number version 5.1 (BioDiscovery, Inc.) to identify regions of copy number change as well as Loss-of-Heterozygosity (LOH). We used the built-in SNP-Ranks Segmentation algorithm on 617 samples consisting of 168 Normals, 188 AD, and 261 Mild Cognitive Impairment (MCI) samples. We assessed the quality of the samples using neighboring probe variance across the genome (discarding the top 3% most varied probes to compensate for expected copy number changes). Using a maximum of 0.15 variance provided 460 samples that we used for further analysis. This set contained 130 Normals, 140 AD, and 190 MCI samples. We performed a Fisher's Exact test comparing the AD group with the Normal group requiring a minimum of 1% difference and a p-value of 0.01 to identify regions of significant copy number or LOH differences between the groups. We then looked at the areas of maximum significant within these regions to identify a total of 82 genes. Using a unique Markov-Process p-value computation, we explored Gene Ontology (GO) categorize that are over represented and genomically dispersed with these 82 genes. These included "Positive regulation of calcium-dependent exocytosis" and "regulation of timing of neuron differentiation" among other terms. These terms led to the identification of some interesting genes, such as SCAMP5 which was LOH in 25% of AD cases and 10.8% in Normal and SOX5 with 18.6% deleted in AD and 13.1% in Normal. Both genes are implicated in cognitive development.

2628/F

Ashkenazi Jewish PD GWAS and combined analysis of public domain datasets. *L. Clark[1], R. Cheng[2], M. Verbitsky[1], X. Liu[1], K. Marder[1,2], J. Lee[1,2].* 1) Taub Institute for Research on Alzheimer Disease and the Aging Brain, Columbia University Medical Center, 630 West 168th street, New York, NY 10032; 2) Gertrude H. Sergievsky Center, Columbia University Medical Center, 630 West 168th street, New York, NY 10032.

We conducted a GWAS on AJ subjects with PD and controls frequency matched for age, sex and ethnicity. They were participants in a study of the genetic epidemiology of PD (GEPD, NS36630) and the Ashkenazi Jewish PD study (NS050487, NS060113) at Columbia University (CU). To replicate the most promising signals from the discovery stage we examined the positive signals in two previously published PD GWAS: The NINDS dataset (Fung et al., 2006; Simon-Sanchez et al 2009), and the joint dataset from the Progeni/GenePD studies (Pankratz et al., 2009). This provided a dataset for analysis with a combined sample size of 2,076 cases and 1,805 controls. All AJ cases (N=272) were recruited from the Center for Parkinson's disease and Other Movement disorders at CU. All met research criteria for PD . The majority of AJ controls (N=172) were recruited by random digit dialing and were frequency matched by age, gender, ethnicity and area code/exchange. The remaining AJ controls were recruited from a 50% sample of Medicare recipients aged >65 who resided in the Washington Heights community. All controls underwent the same evaluation as cases, which included a medical history, UPDRS and mMMS. Family history of PD and related disorders in first-degree relatives was obtained using a structured interview. Information on Jewish ancestry in each of the grandparents was obtained during that interview. Sixty percent of samples were genotyped using the Illumina Human 610-quad bead arrays and the remainder of samples were genotyped using the Illumina Human 660-quad bead arrays. All DNAs were derived from whole blood. Quality scores were determined from allele cluster definitions for each SNP as determined by the Illumina Genome Studio Genotyping Module and the combined intensity data from 100% of study samples. Overall, the NINDS dataset consisted of 886 PD cases and 791 controls of European American background. A total of 44 subjects (37 PD cases and 7 controls) were excluded from the analysis because population cluster analysis revealed that these individuals do not share the same ethnic background as the rest of the samples. The Progeni/Gene PD dataset consisted of 900 cases and 867 controls. None of the SNPs in our PD phenotype analysis reached genome-wide significance in the Ashkenazi Jewish PD study from CU. However, 61 SNPs with a P value <9.5x10-5 were selected for further analysis and meta-analysis with the dbGAP datasets.

2629/F

Endophenotype Ranking Facilitates Identification of Novel QTLs for Recurrent Major Depression. *D. Glahn[1,2], J.W. Kent[3], L. Almasy[3], R.L. Olvera[4], M. Carless[3], A.M. Winkler[1,2], J.E. Curran[3], J.C. Charlesworth[3], M.P. Johnson[3], H.H.H. Göring[3], T.D. Dyer[3], E.K. Moses[3], P. Kochunov[5], R. Duggirala[3], P.T. Fox[5], J. Blangero[3].* 1) Olin Neuropsychiatric Ctr, IOL & Yale, Hartford, CT; 2) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 3) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 4) Department of Psychiatry, UT Health Science Center at San Antonio, San Antonio, TX; 5) Research Imaging Institute, UT Health Science Center at San Antonio, San Antonio, TX.

Although genetic studies of mental illness have made progress in recent years, identification of risk genes for psychiatric disorders has lagged behind discoveries in other complex diseases. The use of quantitative allied phenotypes or endophenotypes could significantly improve the pace of progress in psychiatric genetics. An optimal endophenotype is a highly heritable quantitative trait that is genetically correlated with disease liability, and can be measured in affected and unaffected family-members, inherently providing much greater power to localize disease-related genes than affection status alone. Unfortunately, a priori selection of the most effective endophenotype is often impossible for mental illness, a limitation that is compounded by an inability to directly compare these measures. Here, we present the Endophenotype Ranking Value (ERV), a novel index of the genetic utility of an endophenotype for any heritable illness. The ERV, an index of the standardized genetic covariance, provides an unbiased and empirically derived method for objectively ranking endophenotypes before conducting molecular genetic analyzes. To demonstrate the utility of the ERV, we ranked behavioral, neurocognitive, neuroimaging and transcriptional candidate endophenotypes for recurrent major depressive disorder (rMDD). 1122 randomly selected Mexican-Americans from 75 extended pedigrees, 215 (19%) with lifetime rMDD, participated in the study. The heritability estimate for the illness was 0.570 (p=4.2x10-4). Top-ranked endophenotypes included the Beck Depression Inventory (BDI; p=2.3X10-5), a neuroticism questionnaire (1.7X10-4), a test of declarative memory (5.4X10-2), bilateral diencephalon volume (1.3X10-3), parietal white-matter hyperintensity volume (3.9X10-3), left hippocampal volume (7.8X10-3), and the lymphocyte-based transcripts RNF123 (5.2X10-6), PDXK (1.1X10-5), and ZFP64 (2.0X10-5). Bivariate GWA analyses conducted with the BDI and rMDD diagnosis and utilizing the Illumina 550K reveals several SNPs at genome-wide significance with pleiotropic effects on both traits. These results demonstrate the utility of the ERV and provide two novel genome-wide significant QTLs for recurrent major depression.

Identification of Novel Candidate Genes for Alzheimer Disease by Autozygosity Mapping Using Genome Wide SNP Data From an Israeli-Arab Community. *R. Sherva[1], C. Baldwin[1], R. Inzelberg[2], B. Vardarajan[1], A. Cupples[1], K. Lunetta[1], A. Bowirrat[3], A. Naj[4], M. Pericak-Vance[4], R. Friedland[5], L. Farrer[1].* 1) Boston University, Boston, MA; 2) Tel Aviv University, Tel Aviv, Israel; 3) Ziv Medical Center, Safed, Israel; 4) University of Miami, Miami, FL; 5) University of Louisville, Louisville, KY.

Wadi Ara, a genetically isolated Arab community in northern Israel, has a high prevalence of Alzheimer disease (AD) despite a low *APOE* ε4 allele frequency. The goal of this study was to exploit the genetic structure of this population to identify AD risk genes. AD cases (N=124) and controls (N=142) were genotyped for a genome-wide set of > 300,000 SNPs which were used to calculate measures of population stratification and inbreeding, and to identify regions of autozygosity. Despite its isolation we found evidence for admixture and stratification in Wadi Ara, identifying three distinct ancestry clusters. Although a high degree of relatedness was evident in both cases and controls, controls were significantly more related and contained more autozygous regions than cases (P=0.004). Eight autozygous regions on seven chromosomes were significantly more frequent in controls than cases, and 105 SNPs in these regions, primarily on chromosomes 6 and 9, were nominally associated with AD in logistic regression models. We attempted to replicate these findings in four independent GWAS datasets containing 2861 cases and 2416 controls. Three SNPs in *NOTCH4* were nominally associated with AD in both Wadi Ara and the meta-analysis: rs3132946, (OR_{meta}=1.14, P_{meta}=0.02), synonymous coding SNP rs1044506, (OR_{meta}=1.13, P_{meta}=0.04), and rs3131294 (OR_{meta}=1.14, P_{meta}=0.03). Rs3130286 in a nearby gene, *TNXB*, was also replicated in the meta-analysis (OR_{meta}=1.12, P_{meta}=0.03), as was intergenic SNP rs13271711 on chromosome 8 (OR_{meta}=1.13, P_{meta}=0.04). *NOTCH4* is a member of a gene family involved in controlling cell fate decisions during development. Proteolysis of NOTCH4 is regulated by γ-secretase, whose activity is responsible for the final cleavage of the amyloid precursor protein to release Aß peptide. SNPs in *TNXB* have previously been associated with schizophrenia. Analysis of the full Wadi Ara GWAS dataset revealed 99 SNP associations with AD at P £ 10^{-5}, but none of these were confirmed in the replication datasets. Lack of association of *APOE* in Wadi Ara afforded a unique opportunity to determine whether associations of AD with *TOMM40* and *PVRL2*, genes near *APOE*, are independent of *APOE*. However, we did not observe association with any *TOMM40* or *PVRL2* SNPs. The unique population structure of Wadi Ara enhanced efforts to identify genes not previously associated with AD that may account for some of the risk of the disorder in this and other outbred populations.

2631/F

Most reproducibly-identified genes for addiction phenotypes: dependence and smoking cessation. *G. Uhl[1], T. Drgon[1], C. Johnson[1], D. Walther[1], J. Rose[2], W. Eaton[3], N. Ialongo[3].* 1) Dept Molec Neurobiology, NIDA/NIH, Baltimore, MD; 2) Dept Psychiatry and Center for Nicotine and Tobacco Reserach, Duke University, Durham NC; 3) Dept of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore MD.

While classical genetics supports ca 50 percent genetic contributions to vulnerability to addiction and ability to quit smoking, no reproducible findings of genome wide significance have been identified for these phenotypes. Chromosomal regions and genes have been identified by clusters of SNPs that achieve nominal significance in each of 9 or more independent samples for each of these phenotypes. Genes that are identified much more frequently in this way than expected by chance include cell adhesion molecule (esp CDH13 and CSMD1). A splicing regulator(A2BP1)and genes involved in glutamatergic neurotransmission(GRM5) are also identified frequently. Data obtained in independent samples from the same racial/ethnic background provides more frequent identification of the same chromosomal regions than data from samples from different racial/ethnic backgrounds (racial differences are much larger than differences between studies using pooled vs indivdual genotyping). While statistical confidencein the polygenic effects at these loci does not approach the oligogenic influences of the flushing syndrome alcohol dependence results in Asians or the chr 15 nicotinic receptor loci variants on smoking quantity/frequency, the overall degree to which these results are replicated appears to be as great as those for most polygenic variants in other complex phenotypes.Seeking chromosomal regions that are identified by clustered results that achieve nominal statistical significance in multiple independent samples is likely to provide different sensitivities and specificities than SNP by SNP metaanalyses, especially in the face of allelic heterogeneity. This approach provides strong evidence for reproducible identification of a number of genes whose variants contribute to individual differences in these addiction related phenotypes, and a basis for postGWAS studies. (Support: NIDA, NIMH,unrestricted funding from PM USA to JR).

2632/F

Genetic control of sleep: Genome-wide association study of the nocturnal electroencephalogram (EEG). *M. Kawashima[1], S.C. Warby[1], O. Carrillo[1], R. Apple[2], J. Faraco[1], L. Lin[1], P. Peppard[2], T. Young[2], E. Mignot[1].* 1) Ctr Narcolepsy, Stanford University, Palo Alto, CA; 2) School of Medicine and Public Health, University of Wisconsin-Madison, Madison, WI.

In humans, sleep proceeds in predictable successive cycles of non-rapid eye movement (NREM) sleep (stage 1, 2, slow wave sleep) and rapid eye movement (REM) sleep. Each sleep stage has a distinct set of scalp electroencephalogram (EEG) features. The EEG measures the summed activity of post-synaptic currents of cortical neurons, which is influenced by deeper structures in the brain. A simple yet reliable way to analyze this complex signal is spectral analysis, which uses Fourier transform to decompose EEG into power values at various frequency ranges, typically divided into delta, theta, alpha, sigma, beta, and gamma bands. Unlike sleep duration or sleep timing, EEG features are stable within an individual over time, but highly variable between unrelated individuals (inter-individual). Twin studies have established heritability estimates of EEG within each sleep stage as high as 0.75-0.95, making EEG features one of the most heritable human traits. EEG changes have been associated with numerous disorders, and may be a useful endophenotype in complex neuropsychiatric disorders. To uncover genetic factors explaining inter-individual differences in EEG profiles, we assessed 1,876 polysomnographs (PSGs) in 1,300 adult individuals from the Wisconsin Sleep Cohort. Six hundred and sixtynine individuals had more than two PSGs separated by 4 years, so we could assess the stability of EEG features within an individual over time. Correlations of absolute and relative EEG power, and power in various frequency bands (and in various sleep stages) were examined to select suitable phenotypes. REM sleep and NREM sleep stage 1 and 2 but not slow wave sleep (known to be associated with sleep debt) were found to be most stable. Theta (θ: 4-8 Hz), alpha (α: 8-12 Hz), and sigma (σ: 12-16 Hz) frequency bands were found to have the highest correlation coefficient values. Based on this data, we selected 10 phenotypes for GWAS analysis (Affymetrix 6.0 array). A small set of SNPs, none of which have been previously linked to this phenotype, were detected with genome-wide significance. Replication study is currently underway as we extend the GWAS to additional cohorts. We believe sleep EEGs may be a useful way to study brain activity independent of sensory inputs, providing insight into normal and abnormal brain circuitry and its genetic basis.

15q24.1 Microduplication in an Autistic Multiplex Family May Narrow a Region of Susceptibility for Developmental Disability and Autistic Disorder. *S.J. Sacharow[1,2], H.N. Cukier[1], D. Salyakina[1], S.F. Blankstein[1], J.L. Robinson[1], H.H. Wright[3], R.K. Abramson[3], R. Menon[4], S.M. Williams[5], J.L. Haines[5], M.L. Cuccaro[1], J.R. Gilbert[1], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 3) Department of Neuropsychiatry, University of South Carolina School of Medicine, Columbia, SC; 4) Department of Epidemiology and Department of Obstretrics & Gynecology, Rollins School of Public Health, Emory University, Atlanta, GA; 5) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Copy number variations (CNVs) of 15q24.1 have been implicated in a range of phenotypes including mental retardation, developmental delay, autism and Asperger's syndrome. The majority of CNVs in this area have breakpoints near five low-copy repeat clusters. Prior studies demonstrate a minimal critical region of 0.766 Mb for deletions and 1.33 Mb for duplications. Here we report two cousins with autistic disorder who carry a ~10,000 base pair microduplication in the 15q24.1 critical region. **Case presentation:** Patient 1 has speech and language deficits, ADHD and autistic disorder. His full scale IQ is 46, and he is nondysmorphic. He has a brother with autistic disorder and mental retardation, hypotonia, motor delay, and congenital hip dislocation; however, the brother was unavailable for genetic testing. Patient 2 is a maternal first cousin of Patient 1. He has high functioning autism, mood disorder, ADHD, and dyslexia. His IQ is 99, and he is nondysmorphic. **Methods:** This multiplex autistic family was genotyped with the Illumina Human 1M Beadchip. The PennCNV algorithm using the Log R ratio and B allele frequency was used to identify CNVs which co-segregate with autism. TaqMan real-time PCR copy number assays were then utilized for validation and refinement of the CNVs. **Results and Discussion:** Two microduplications were identified to co-segregate in patient 1, patient 2, and their mothers. The first CNV is a ~10 kilobase microduplication on 15q24.1 that falls within the region previously reported in patients with autism and developmental delay. The second CNV is a novel ~348 kilobase duplication on chromosome 7p21.3. Neither duplication was identified in 676 Caucasian pediatric controls. Two other first degree relatives unavailable for genetic testing also have mental retardation and autistic features, suggesting a potentially strong but incompletely penetrant genetic component in this family. The 15q24.1 microduplication does not appear to be caused by the previously delineated low-copy repeats. This CNV contains the first 4 exons of the *ubiquitin-like 7 gene* (UBL7) and a hypothetical gene, *LOC440288*. This is the smallest duplication in the region reported to be associated with autistic disorder, potentially narrowing the critical region.

2634/F

Duplication of SLIT3 on 5q35.1 Predisposes to Major Depressive Disorder. *C.E. Kim[1], J.T. Glessner[1], K. Wang[1], P.M.A. Sleiman[1], H. Zhang[1], J.H. Flory[1], J.P. Bradfield[1], M. Imielinski[1], E.C. Frackelton[1], H. Qiu[1], F. Mentch[1], S.F.A. Grant[2], H. Hakonarson[2].* 1) Ctr Applied Genomics, CHOP, Philadelphia, PA; 2) Division of Genetics, Department of Pediatrics, The Children's Hospital of Philadelphia University of Pennsylvania School of Medicine Philadelphia, PA, 19104, USA.

Major depressive disorder (MDD) is a common psychiatric and behavioral disorder. To discover novel variants conferring risk to MDD, we conducted a whole-genome scan of copy number variation (CNV), including 1,693 MDD cases and 4,506 controls genotyped on the Perlegen 600K platform. The most significant locus was observed on 5q35.1, harboring the SLIT3 gene (P=2x10-3). Extending the controls with 30,000 subjects typed on the Illumina 550k array, we found the CNV to remain exclusive to MDD cases (P=3.2x10-9). Duplication was observed in 5 unrelated MDD cases encompassing 646 kb with highly similar breakpoints. SLIT3 is integral to repulsive axon guidance based on binding to Roundabout receptors. Duplication of 5q35.1 is a highly penetrant variation accounting for 0.7% of the subset of 647 cases harboring large CNVs, using a threshold of a minimum of 10 SNPs and 100 kb. This study leverages a large dataset of MDD cases and controls for the analysis of CNVs with matched platform and ethnicity. SLIT3 duplication is a novel association which explains a definitive proportion of the largely unknown etiology of MDD.

2635/F

Copy number variants in schizophrenia: confirmation of 5 previous findings and new evidence for association of 3q29 microdeletions and VIPR2 duplications. *D.F. Levinson[1], J. Duan[2], S. Oh[1], K. Wang[3], A.R. Sanders[2], J. Shi[4], N. Zhang[1], P.V. Gejman[2].* 1) Dept Psychiatry, Stanford Univ, Palo Alto, CA; 2) Northshore University Healthcare Research Institute, Evanston, IL; 3) University of Pennsylvania and Children's Hospital of Philadelphia, Philadelphia, PA; 4) National Cancer Institute, Bethesda, MD.

Introduction: To evaluate previously-reported and possible new associations of copy number variants (CNVs) to schizophrenia, we analyzed CNVs in the Molecular Genetics of Schizophrenia (MGS) sample and additional available data. Methods: After sample and CNV QC, 3,945 MGS cases and 3,611 controls were available for analysis using GWAS data from the Affymetrix 6.0 array. CNV analyses were carried out with Birdseye (Birdsuite 2.0) plus visual inspection and re-analysis of interesting regions with a second method. CNV call thresholds were chosen which maximized duplicate concordance in 151 duplicate specimens. Combined analyses with additional publicly-available data (ISC case-control and CHOP control datasets) were carried out where possible. Analyses of pointwise association and of genome-wide CNV counts were carried out using PLINK, and Fisher's exact tests were used to evaluate association of specific regions and of exonic CNVs in individual genes. Results: Five previously-reported associations were strongly supported (long deletions in 1q21.1, 15q13.3 and 22q11.21, duplications in 16p11.2 and exonic CNVs in NRXN1) with combined analyses producing ORs of 8 or greater. The strongest evidence for new candidate assocations were for the 3q29 mmicrodeletion region (1.6 Mb deletions containing 21 genes from TFRC to BDH1), observed in 0.1% of cases and 0 controls (p=0.004)); and 76-648kb duplications in VIPR2 (chromosome 7q), observed in 0.19% of cases and 0.03% of controls (p= 0.002). Other suggestive associations will be presented. The hypothesis of a global increase in gene-containing CNVs received modest support for large (>100kb) deletions but not for duplications. Conclusions: Association of schizophrenia with 1q21.1, 15q13.3, 22q11.21 and exonic NRXN1 deletions and with 16p11.2 duplications should be considered clearly established. It is likely that 3q29 deletions and VIPR2 duplications are also associated with moderate to high penetrances. Additional associations are likely to be confirmed from other candidate regions from this and other studies. This work was supported by NIMH grants U01MH079469 and U01MH079470. Grateful acknowledgement is made to study participants and to MGS investigators and clinical teams.

2636/F

Analysis of Heterogeneity in a Genome-wide Association of Late-Onset Alzheimer Disease Confirms Limited Heterogeneity for Strongest Associations. *A. Naj[1], R. Rajbhandary[1], G.W. Beecham[1], E.R. Martin[1], P.J. Gallins[1], E.H. Powell[1], I. Konidari[1], P.L. Whitehead[1], G. Cai[2], V. Haroutunian[2], W.K. Scott[1], J.M. Vance[1], M.A. Slifer[1], H.E. Gwirtsman[3], J.R. Gilbert[1], J.L. Haines[4], J.D. Buxbaum[2], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, Dr. John T Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Psychiatry, Mount Sinai School of Medicine, New York, NY; 3) VA Medical Center, Nashville, TN; 4) Vanderbilt Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Alzheimer Disease (AD) is highly genetic (estimated H^2~70%), but until recently, genome wide association studies (GWAS) have only observed consistent genetic associations with late-onset AD (LOAD) in APOE, possibly due to heterogeneity such as etiologic heterogeneity and ascertainment bias. To determine whether associations are being masked potentially by heterogeneity in a previous GWAS of LOAD, we used multinomial logistic regression analyses in SAS (v9.2) to re-evaluate associations of 483,399 SNPs among 931 cases and 1104 controls by two potential sources of heterogeneity, stratifying cases by autopsy confirmation of AD clinical diagnosis (370 autopsy-confirmed/561 clinically-confirmed), and stratifying cases by Ashkenazi Jewish (AJ) background in our sample (174 AJ/757 non-AJ). Stratifying by autopsy-confirmation status, we confirmed associations with SNPs in or near APOE on chromosome 19 in comparisons of both autopsy-confirmed cases (rs2075650, $P=1.63247\times10^{-22}$) and clinically-confirmed cases (rs2075650, $P=3.2\times10^{-29}$) to controls. A SNP association meeting genome-wide statistical significance in unstratified analyses, rs11754661 (OR (95% CI): 2.03 (1.58, 2.62); $P=4.70\times10^{-8}$), still demonstrated strong associations for autopsy-confirmed (OR (95% CI):1.84 (1.26, 2.68); P=0.00146) and clinically-confirmed (OR (95% CI): 2.04 (1.55, 2.70); $P=4.20\times10^{-7}$) comparisons. Stratifying by AJ/non-AJ ethnicity, we found similar patterns of peak associations in comparisons of non-AJ cases with controls, but found different peak associations comparing AJ cases with controls. The strongest among these is an association at rs10178614 on chromosome 2 (OR (95% CI): 0.346 (0.217, 0.554); $P=9.68\times10^{-6}$), located in CNTNAP5 (contactin associated protein-like 5), a gene in the neurexin family which function as cell adhesion molecules and receptors in the nervous system. In summary, stratification by autopsy-confirmation status found effect sizes of associations within stratum similar to those in non-stratified GWAS analyses of LOAD, though with reduced statistical significance, likely due to smaller sample sizes of the strata. Weak heterogeneity by autopsy-confirmation status may reflect improved accuracy of clinical AD diagnosis; further investigation is needed. Stratifying by AJ/non-AJ ethnicity identified a different set of peak associations among those with an AJ background, although additional replication in other AJ datasets is necessary to confirm this association.

2637/F

Identification and characterisation of endophenotypes for epilepsy through MRI. *G. Cavalleri[1], S. Alhusaini[1], C. Scanlon[2], L. Ronan[2], G. Borgulya[1], S. Maguire[4], P. Brennan[4], A. Fagan[5], P. Iyer[3], G.E. Boyle[6], J.F. Meaney[5], C.P. Doherty[3], M. Fitzsimons[2], N. Delanty[1,2].* 1) MCT, Royal College Surgeons, Dublin, Ireland; 2) Departments of Neurophysics and Neurology, Beaumont Hospital, Dublin 9, Ireland; 3) Department of Neurology, St James' Hospital, Dublin 8, Ireland; 4) Radiology Department, Beaumont Hospital, Dublin 9, Ireland; 5) Department of Radiology, St. James's Hospital, Dublin, Ireland; 6) Department of Medical Physics and Bioengineering, St James's Hospital, James's Street, Dublin 8, Ireland.

The experience of the research community to date has shown that endophenotypes are required to augment the power of genetic mapping studies in complex forms of epilepsy. We are applying in-vivo quantitative magnetic resonance imaging to identify subtle structural variations in the brain which are both heritable and involved in the development of temporal lobe epilepsy. Our study design involves scanning index patients with temporal lobe epilepsy together with an unaffected same gender sibling and healthy controls. We have applied numerous sets of analysis across these three groups to identify brain structures showing characteristics of good endophenotypes for epilepsy - heritable, associated with the disease and measureable in healthy controls. Results to date have highlighted several candidate endophenotypes structures including the thalamus and cingulate. These novel endophenotypes are being measured in a larger cohort of epilepsy patients for whom whole genome association data is already available.

2638/F

A Genome-Wide Association Study of Symptomatic Epilepsy in Han Chinese Detects Multiple Variants. *S.S. Cherny[1], Y.L. Guo[1], P.C. Sham[1], L. Baum[2], P. Kwan[3].* 1) Department of Psychiatry, The University of Hong Kong; 2) School of Pharmacy, The Chinese University of Hong Kong; 3) Division of Neurology, Department of Medicine & Therapeutics, The Chinese University of Hong Kong.

Epilepsy is one of the most common serious neurological disorders, affecting approximately 1% of the population. While idiopathic epilepsy has been the most studied form and has the most evidence for genetic influence, there has also been converging evidence for genetic influences on the more common symptomatic form, where the epilepsy is a result of a known brain injury or lesion. We conducted a genome-wide association study (GWAS) of 504 symptomatic epilepsy cases and a cohort of shared control samples of 1947 subjects participating in several GWAS of complex disease and an additional 1000 healthy individuals. All cases and controls were Han Chinese. We employed the Illumina HumanHap 610-Quad platform, which assays approximately 600,000 SNPs. From analysis of this initial GWAS, we identified three loci containing variants that confer epilepsy risk, in addition to confirming a previously known association with the *GRIK2* gene. One of the loci (rs4853352, $p < .000002$) on chromosome 2p12 was intragenic but near neural developmental genes, including *LRRTM1* and *LRRTM4* (SLIT proteins), which may play a role in the development and maintenance of the vertebrate nervous system. At 13q31.1, a genome-wide significant SNP (rs9519914, $p < .000000005$) is near the *SLITRK6* gene, a member of the integral membrane proteins with 2 N-terminal leucine-rich repeat (LRR) domains similar to those of SLIT proteins, which is expressed predominantly in neural tissues and has neurite-modulating activity. The strongest signal (rs12148329, $p < .00000000002$) is in the intronic region of the *FAM108C1* gene on chromosome 15q25.1, which is expressed in human atherosclerotic lesions and significantly elevated in patients with unstable angina. These SNPs and approximately 70 others are being replicated in a larger independent sample of Chinese epilepsy patients and controls.

2639/F

Genome-wide Association Study for Dementia in the Amish finds non-APOE regions. *A.C. Cummings[1], L. Jiang[1], D. Velez Edwards[2], R. Laux[1], L.L. McFarland[1], P.J. Gallins[3], L. Caywood[3], L. Reinhart-Mercer[3], D. Fuzzell[1], C. Knebusch[3], C.E. Jackson[4], J.L. McCauley[3], W.K. Scott[3], M.A. Pericak-Vance[3], J.L. Haines[1].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Vanderbilt Epidemiology Center, Vanderbilt University Medical Center, Nashville, TN; 3) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 4) Scott & White, Temple, TX.

Late Onset Alzheimer disease (LOAD) is the leading cause of dementia in the elderly. While evidence for an underlying genetic etiology of AD is strong, it has proven to be quite challenging to elucidate. Polymorphisms in APOE account for less than half of the susceptibility and thus other genetic factors are likely to be involved. Genetic heterogeneity is a major complicating factor hindering further gene identification. To overcome this problem and maximize our power to identify AD risk genes, we are studying the genetically isolated and well-defined Amish populations of middle Ohio and northern Indiana. To date we have enrolled over 2200 Amish individuals with 135 of these having either probable or possible dementia. Through the use of the Anabaptist Genealogy Database, we have accurately defined the kinship coefficients and the family structure among our collected individuals. We performed a genome-wide association study (Affymetrix Human SNP Array 6.0) and successfully genotyped 830 Amish individuals (125 with LOAD). Because of the relatedness of these individuals, we employed a novel test of association using the MQLS test, which uses kinship coefficients to correct for relatedness. We performed parametric and nonparametric 2-pt and parametric multipoint linkage analysis (Merlin, MINX) after using PedCut to divide our large pedigree into smaller, more computationally tractable sub-pedigrees. We conducted parametric multipoint linkage analysis in regions in which a 2-pt lod score ≥ 3 was calculated. Following extensive QC procedures, 614,957 SNPs were analyzed. Using the MQLS test, our most significant p-value (1.7 x 10-7) was at rs1236195 on chromosome 13 in SPATA13, a spermatogenesis gene. Fourteen additional SNPs generated p-values <1x10-5, but none are near known or strongly suspected AD loci (APP, PS1, PS2, PICALM, CLU, CR1). A total of 45 regions contained at least one SNP with a lod ≥ 3. The highest multipoint peak (lod=5.82, recessive model) was calculated at 2p12. Six genes lie within the 1-lod-unit interval, none of which to our knowledge have previously been associated to LOAD. Three additional regions had a multipoint lod score >3: 3q26, 9q31, and 18p11. The GWAS results suggest novel non-APOE genetic effects for LOAD in our Amish dataset, with the most compelling evidence on chromosomes 2, 3, 9, 13, and 18. Further detailed analyses to explore these results are ongoing.

2640/F

Genome-wide linkage and association study of ADHD in adults. *D. Boomsma[1], V. Saviouk[1], G. Willemsen[1], B. Penninx[2], J. Smit[2], P. Slagboom[3], E. DeGeus[1], J. Hottenga[1].* 1) Dept Biological Psychology, Vrije Univ, Amsterdam, Netherlands; 2) Dept Psychiatry VU University Medical Centre, Amsterdam, Netherlands; 3) Dept Molecular Epidemiology, Leiden University Medical Centre, Nettherlands.

There have been several genetic linkage and GWA studies for ADHD in children, showing mixed results. The aim of our study is to detect the genomic loci that influence ADHD in (young) adults and compare these to results from studies in children. ADHD data from > 12,000 adults were analyzed with structural equation modeling, linkage (N= 752 sib pairs) and genome-wide association (GWA) tests (N = 2475 unrelated subjects). ADHD was assessed by the Conners Adult ADHD Rating Scales (CAARS; Conners CK, Erhardt D & Sparrow E (1999)) from twin families registered with the Netherlands Twin Register and subjects participating in the Netherlands Study of Depression and Anxiety. Phenotype data from over 12,000 twins, siblings and parents were analyzed with genetic structural equation modeling to estimate heritability. ADHD heritability in adults was estimated at 30% in men and women, after correction for assortative mating. All familial transmission was explained by genetic inheritance. Genome-wide linkage and association (GWA) analysis of quantitatively assessed ADHD features in adults may uncover loci influencing susceptibility to adult ADHD. We carried out linkage and association analyses in subsamples with micro-satellite data and SNP data. Genome-wide linkage analysis showed linkage to 2p25.2 - 2p25.1 (max LOD = 3.58 (p=0.037) based on parametric linkage analysis) for the ADHD index and to 18q21.2 - 18q22.1 for Inattention (max LOD = 4.58 (p=0.0026) based on VC). The ten highest p-values from the GWA study (1.51E-06 - 9.05E-06) were observed on chromosomes 8, 11, 18 and 21. We acknowledge support from NWO/ZonMW: 904-61-090; 904-61-193; 480-04-004; SPI 56-464-14192; NBIC-Bioassist; Center for Medical Systems Biology; Neuroscience Campus Amsterdam and EMGO+. the Centre for Neurogenomics and Cognitive Research (CNCR-VU); Genetics of Mental Illness (ERC-230374); the European Union (EU/WLRT-2001-01254), ZonMW (geestkracht program, 10-000-1002), NIMH (RO1 MH059160) and matching funds from participating institutes in NESDA and NTR. Genotyping was funded by the Genetic Association Information Network (GAIN) of the Foundation for the US National Institutes of Health. VS is a Marie Curie fellow supported by the EUTwinsS network (RTN, FP6).

Variants in BDNF and CHRNA5-CHRNA3-CHRNB4 are associated with smoking persistence in African-Americans. *A. Hamidovic[1], N. Benowitz[2], K. Buttler[3], S. Buxbaum[3], N. Francescini[5], S. Gharib[6], R. Goodloe[7], B. Hitsman[1], J. Kasberger[2], D. Levy[4], S. Preiss[4], S. Redline[7], B. Spring[1], E. Tong[9], W. White[3], K. Wiggins[6], T. Young[8], E. Jorgenson[2].* 1) Northwestern University , Chicago , IL; 2) University of California San Francisco, CA; 3) Jackson State University Jackson, MS; 4) National Heart, Lung and Blood Institute Bethesda, MD; 5) University of North Carolina Chapell Hill, NC; 6) University of Washington Seattle, WA; 7) Case Western University Cleveland, OH; 8) Broad Institute Boston, MA; 9) Univeristy of California Davis, CA.

To date, most genome-wide association studies (GWAS) of smoking behavior have been conducted in populations of European ancestry, and many of these studies have focused on phenotypes that measure smoking quantity (i.e. cigarettes per day). Additional association studies in diverse populations with different linkage disequilibrium patterns can aid the search for functional variants. Furthermore, more precise phenotype measures that account for changes in smoking patterns over time may better describe smoking behavior. For these reasons, we undertook an association study of smoking persistence, as measured by pack-years of cigarette smoking, in unrelated African-American participants from The National Heart, Lung, and Blood Institute's Candidate Gene Association Resource (CARe) (n= 1490). Multiple markers in and around Brain-Derived Neutrophic Factor (BDNF) on 11p14.1 and a cluster of genes encoding nicotinic acetylcholine receptor subunits (CHRNA5-CHRNA3-CHRNB4) on 15q25.1 were associated with smoking persistence. We then imputed additional common SNPs in the 11p14.1 and 15q25.1 loci using data from the 1,000 Genomes project in order to more precisely map functional variants. Our analysis is among the first to use data from the 1,000 Genomes project in African-Americans in order to provide new information to mapping and characterizing loci underlying complex traits.

2642/F

Genome-wide association study in bipolar patients with co-morbidity - The challenge of rare variants. *B. Kerner[1], C.G. Lambert[2], B.O. Muthén[3].* 1) Department of Psychiatry, David Geffen School of Medicine, University of California, Los Angeles, CA, USA; 2) Golden Helix Inc., Bozeman, MT, USA; 3) Professor Emeritus, University of California, Los Angeles, CA, USA.

Background: Bipolar disorder is a severe psychiatric disorder with high heritability. Co-morbid conditions are common and might define latent subgroups of patients that are more homogeneous in respect to genetic risk factors. **Methodology/Principal Findings:** In the GAIN bipolar disorder sample of 1000 Caucasian cases and 1034 controls we tested the association of single nucleotide polymorphisms with patient subgroups defined by co-morbidity. The most significant association was found with rs16904801 ($p=4.5x10^{-9}$) on 8q24 in bipolar patients with low probability for substance abuse and alcohol dependence. This rare genomic variant is located in the gene Thyroglogulin precursor (TG) (HGNC:11764). Two additional rare variants in expressed sequences of unknown function approached the genome-wide level of significance in this latent class, rs1039002 ($p=1.6x10^{-8}$) on 6q27, and rs12563333 ($p=5.9x10^{-8}$) on 1q41. The genomic variants were present only in cases and absent in controls. Bipolar disorder with high probability of alcohol dependence and substance abuse was associated with rs2727943 ($p=3.3x10^{-8}$) on 3p26.3 in a non-coding region. **Conclusions/Significance:** Conceptualizing bipolar disorder as a heterogeneous disorder with regard to co-morbid conditions might facilitate the identification of genetic risk alleles. Rare variants might contribute to the susceptibility to bipolar disorder. Given the small sample size of our study and the rare nature of the variants, a replication of our results in an independent larger study or a confirmation through re-sequencing would be desirable to support our results.

Genetics of human episodic memory: Understanding complexity through genome-wide studies. *A. Papassotiropoulos[1], C. Vogler[1], A. Heck[1], D.J.F. de Quervain[2].* 1) Molecular Psychology, University of Basel, Basel, Switzerland; 2) Cognitive Neurosciences, University of Basel, Basel, Switzerland.

Experimental work in animals has shown that memory formation depends on a cascade of molecular events. In humans, heritability estimates of ~50% suggest that genetic factors have an important impact on this fundamental brain function. Therefore, our study aims at identifying memory-related genes and gene-clusters in humans and at translating the findings to memory-related disorders. Gene identification is done by combining unbiased genome-wide association studies (GWAS), gene clustering, and functional MRI (fMRI) in populations which are carefully tested for memory performance and for the presence or absence of diseases related to impaired memory function. We show that variability of human memory performance is highly significantly related to variability in the gene encoding beta catenin-like 1 and to a cluster of genes encoding proteins of core molecular signaling cascades. Functional magnetic resonance imaging revealed that GWAS-derived genetic profiles correlate with activations in memory-related brain regions. The search for genes related to human memory processes provides new insights into the genetic basis of this cognitive ability and is promoting the targeted treatment of memory disorders by identifying relevant genetic pathways in humans.

Genome-wide association study suggests a risk locus for pediatric-onset bipolar disorder on chromosome 5q. *D.T. Chen[1], N. Akula[1], C.J.M. Steele[1], N. Craddock[3], H.M.D. Gurling[4], J.W. Smoller[2], P.H. Lee[2], F. McMahon[1].* 1) Unit on the Genetic Basis of Mood & Anxiety Disorder, National Institute of Mental Health, National Institutes of Health, U.S. Dept of Health and Human Services, Bethesda, Maryland 20892, USA; 2) Psychiatric Genetics Program in Mood and Anxiety Disorders, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts 02114, USA; 3) MRC Centre for Neuropsychiatric Genetics and Genomics, Henry Wellcome Building, School of Medicine, Cardiff University, Heath Park, Cardiff CF14 4XN, UK; 4) Molecular Psychiatry Laboratory, Department of Mental Health Sciences, University College London Medical School, Windeyer Institute of Medical Sciences, London, United Kingdom.

Pediatric-onset bipolar disorder (PBPD) is a strongly familial, often chronic and disabling condition. The American Academy of Child & Adolescent Psychiatry (AACAP) defines PBPD as onset of mania <12 years. To date, no clear genetic markers of PBPD have been identified. We conducted a genome-wide association study (GWAS) of PBPD by comparing cases with age at onset < 12 years (n = 197) to controls (n = 1033) in the NIMH Genetics Initiative sample, which had been genotyped with approximately 1 million single nucleotide polymorphisms (SNPs) under the auspices of the Genetic Association Information Network (GAIN). A total of 768,000 SNPs passed quality control and were analyzed for association using PLINK. Two markers on chromosome 5q25, in the vicinity of BNIP1 and C5orf41, showed evidence of association with PBPD at the $p < 5 \times 10^{-7}$ level, with odds ratios in the range of 2.59-2.60. When case definition was restricted to first mania before age 12 in a post-hoc analysis, odds ratios at these markers increased to the range of 2.9-3.0, suggesting that the locus is important in cases meeting strict AACAP criteria for PBPD. After imputation against HapMap Phase 2 data using MACH 1.0, 2 additional SNPs were identified with case-control association p-values in the 10^{-7} range. Supportive results were obtained in a second cohort of ~1600 cases and controls, with consistent direction of association and combined p-values less than 4×10^{-8}. However, replication results in STEP-BD/UK/WTCCC were negative. Further explorations for replication are ongoing. BNIP1 is involved with apoptosis and alpha-SNAP binding, related to endoplasmic reticulum organization and membrane fusion. Future studies will focus on additional replication testing and deep resequencing. BNIP1 may be an important neurobiological target for some childhood-onset psychiatric disorders.

2645/F

A group of intracellular translocases including *TOMM40* is associated with Alzheimer disease. *M.G. Hong, J. Prince.* Medical Epi and Biostatistics, Karolinska Institutet, Stockholm, Sweden.

The output of genome-wide association studies (GWAS) which are proliferating and successfully identifying genetic determinants of traits and diseases often include data on a large number of marginally associated SNPs, which are frequently neglected by stringent alpha values at the genome-wide level. As an attempt to utilize those possibly informative data, pathway approaches have been conducted in some of GWAS, which search a group of genes with similar characteristics that are over-represented among the marginally significant markers. However, pathways have been defined with genes, not genetic markers. The process to convert to gene lists is required and we developed a tool facilitating the task and applied to a recent GWAS for Alzheimer disease (AD) in a French population. The tool reads the output of GWAS and generates a list of genes with gene-wise significance correcting for problems that longer genes are likely to have lower P-values purely by chance and that the markers are often correlated because of linkage disequilibrium (LD). With the AD study data set, a significant enrichment of genes involved in the biological process of intracellular transmembrane protein transport was observed. The products of genes of the pathway include several transport proteins across the mitochondrial membrane and nuclear envelope. The SNP, rs2075650, which was associated with highest significance with AD status is located in *TOMM40*, which encodes the channel-forming subunit of the translocase of the outer membrane complex of mitochondria. The fact that the marker is only about 16kbp away from rs429358, the key SNP of the *APOE* e4 isoform, may imply the strong association was observed because of LD between the two markers. However, considering the fact that a group of transporting proteins was also associated with AD including *TOMM40* may imply that genetic variance in the gene itself possibly contributes to the development of AD together with other translocases.

Schizophrenia GWAS in a large Ashkenazi cohort. *T. Lencz[1], S. Guha[1], J. Rosenfeld[1], A. Malhotra[1], I. Pe'er[2], A. Darvasi[3].* 1) Dept Psychiatry Res, Zucker Hillside Hosp, Glen Oaks, NY; 2) Dept. of Computer Science, Columbia University, New York, NY; 3) Dept. of Genetics, Hebrew University, Jerusalem, Israel.

Background: Recent genomewide association studies (GWAS) in schizophrenia have, for the first time, provided strong support for several susceptibility loci. While the strongest evidence has emerged for loci in the major histocompatibility complex (MHC), disentangling the true source of this signal in heterogeneous outbred populations has proven challenging. Moreover, the overwhelming majority of genetic risk for schizophrenia, a highly heritable disorder, remains unknown. Consequently, we performed a GWAS in a large (total n>3000), ethnically homogeneous case-control cohort of Ashekenazi Jewish individuals from Israel. **Methods:** At the time of submission, genotyping of the cohort on the Illumina 1M Omni-Quad platform is nearly complete. Interim analyses were conducted using PLINK on the first half of the sample (n=649 cases with schizophrenia and 1187 controls), after eliminating population outliers identified using STRUCTURE. **Results:** In the interim analyses, signals approaching genomewide significance were observed in the MHC. Genomic inflation was low, and careful examination of population parameters appears to permit further refinement of the signal. Additionally, several other promising candidate loci emerged at genomewide ($p<10^{-7}$) or near genomewide ($p<10^{-6}$) levels. Additionally, cases were observed to have excess runs of homozygosity (ROHs), compared to controls. **Conclusions:** Full GWAS results for SNPs, ROHs, and CNVs in the entire sample will be presented. Preliminary results suggest that examination of an ethnically homogeneous founder population may increase power for detection of at least a subset of susceptibility loci.

2647/F

Meta-analysis of genome-wide association studies identifies three new multiple sclerosis susceptibility loci: *EOMES*, *MLANA*, and *2p21*. *N.A. Patsopoulos[1, 2, 3], F. Esposito[4,5], L. Introduction Multiple Sclerosis (MS) is thought to have a complex genetic background with environmental triggers. Besides the known association with MHC, genome-wide association studies (GWASs) have identified several other loci. Here, we perform a meta-analysis of several GWASs, and explore the functional consequences of the newly identified risk-associated alleles. **Methods** Seven GWAS datasets of MS were included and, after quality checks, we imputed all datasets with HapMap phase II as reference. We analyzed each dataset using the imputed dosages, correcting for population structure. Per dataset we used the Odds Ratio (OR) and the standard error, corrected for the dataset specific inflation factor (λ), to perform a meta-analysis under the per-allele model. To leverage the list of susceptibility loci associated with inflammatory diseases, we tested known SNP from 7 inflammatory diseases (Crohn's disease (CD), ulcerative colitis (UC), celiac disease (CE), type 1 diabetes (T1D), rheumatoid arthritis (RA), systemic lupus erythematosus (SLE) and psoriasis (PS)) for a role in MS. Finally, we performed eQTL analysis in 228 cases with MS and used the Ingenuity Systems software to identify pathways and networks of interacting genes. **Results/Discussion** 5,545 cases, 12,153 controls and 2,529,394 SNPs passed QC and were included in the meta-analysis. We observed 3 new loci with $p<5x10^{-8}$. $rs170934^{T}$ at locus 3p24.1 near *EOMES* (OR=1.17, P= $1.6x10^{-8}$), $rs2150702^{G}$ in the second intron of *MLANA* on chromosome 9 (OR=1.16, P=$3.3x10^{-8}$), and $rs6718520^{A}$, which maps to an intergenic region on chromosome 2p21 (OR=1.17, P=$3.4x10^{-8}$). Another 10 independent SNPs had p-value<10^{-6}, of which $rs1738074^{T}$ in *TAGAP* (OR=0.87, P= $3.7x10^{-7}$) is also associated with CE, T1D, and RA. A comprehensive comparison of *bona fide* associations with other inflammatory diseases revealed a substantial overlap of susceptibility loci. More SNPs that predispose to UC and CE are associated in MS (9 of 15 and 12 of 26 at a nominal level , respectively) than those of the other inflammatory diseases. Although eQTL analysis didn't reveal a strong *cis* effect for the newly identified SNPs, pathway and network analysis uncovered a remarkable level of interconnectedness in the transcriptomic effects of the known and novel MS susceptibility loci.

Genome-wide supported schizophrenia-associated genes: regulation by REST/NRSF, network organization and primate-specific evolution. *M.J. SIMONNEAU[1], Y. LOE-MIE[1,2], A-M. LEPAGNOL-BESTEL[1], G. MAUSSION[1], A. DORON-FAIGENBOIM[3], S. IMBEAUD[4], H. DELACROIX[4], L. AGGERBECK[4], T. PUPKO[3], P. GORWOOD[1], J-M. MOALIC[1].* 1) INSERM U894, Paris, F, France; 2) CNRS-UPR2589, Information Génomique & Structurale, 163 Avenue de Luminy, Marseille, France; 3) Department of Cell Research and Immunology, George S. Wise Faculty of Life Sciences, Tel-Aviv University,Israel; 4) Molecular Genetics, CNRS, Gif, France.

The SMARCA2 gene encodes the ATPase BRM in the SWI/SNF chromatin-remodeling complex. SMARCA2 was recently identified as being associated with schizophrenia (SZ) in a genome-wide association study (GWAS). Polymorphisms in SMARCA2, associated with the disease, were identified as able to produce changes in the expression of the gene and/or in the encoded amino acid sequence. We showed that an SWI/SNF-centered network including the mouse Smarca2 gene was modified when REST/NRSF was down-regulated in a mouse neuronal cell line. REST/NRSF down-regulation also modifies the levels of Smarce1, Smarcd3 and SWI/SNF interactors (Hdac1, RcoR1 and Mecp2). We asked if Smarca2 down- regulation was sufficient to generate an intermediate phenotype of SZ and found that Smarca2 deregulation generated an abnormal dendritic spine morphology. We further found that 8 (CSF2RA, HIST1H2BJ, NOTCH4, NRGN, SHOX, SMARCA2, TCF4 and ZNF804A) out of 10 GWAS supported SZ-associated genes are part of an interacting network (including SMARCA2), 5 members of which encode transcription regulators. The expression of TCF4, SMARCA2 and CSF2RA out of the 10 genome-wide supported SZ-associated genes was modified when the REST/NRSF-SWI/SNF chromatin-remodeling complex was experimentally manipulated either in mouse cell lines or in transgenic mouse models. This REST/NRSF-SWI/SNF deregulation also results in the differential expression of genes that are clustered in chromosomes. This result suggests that REST/NRSF deregulation is able to induce genome-wide epigenetic changes. Finally, we studied primate-specific evolution of SMARCA2 interactors and the genome-wide supported SZ-associated genes. We found that these repertoires are considerably enriched in genes displaying positive selection in primates and in the human lineage which suggests the occurrence of novel protein interactions in primates. Altogether, these data identify the SWI/SNF chromatin-remodeling complex including SMARCA2 as a key component of the genetic architecture of SZ. [Loe-Mie et al., SMARCA2 and other genome-wide supported schizophrenia-associated genes: regulation by REST/NRSF, network organization and primate-specific evolution. Hum Mol Genet. 2010].

Genome-wide association study of personality measures in bipolar disorder. *J.S. Strauss[1], Q. Cheng[2], A. Noor[1], S.V. Parikh[3], V. De Luca[1], J.L. Kennedy[1], W. Xu[2], J.B. Vincent[1].* 1) Centre for Addiction and Mental Health, Toronto, ON, Canada; 2) Princess Margaret Hospital/University Health Network, Toronto, ON, Canada; 3) Toronto Western Hospital, University Health Network, Toronto, ON, Canada.

Background: Much of the molecular genetic study of personality phenotypes has included candidate gene studies of monoaminergic loci, often in antisocial personality disorder and related phenotypes, such as alcohol abuse, or in traits measured by TPQ or NEO. Personality traits have been associated with symptoms of bipolar disorder. Methods: We recruited 431 adult Caucasian patients with DSM-IV/ICD-10 Bipolar I or II Disorder (BP I or II). Personality QTL data was obtained using the 90-item Eysenck Personality Questionnaire (EPQ). We used four QTLs -three from the EPQ: Extraversion(E), Neuroticism(N), Psychoticism(P), in addition to the Brief Life Events Questionnaire (BLEQ) for first episode. 523,407 SNPs were genotyped using Illumina HumanHap550 BeadChip microarrays. We checked for potential genotype errors, obtained descriptive statistics, and their LD patterns using Haploview. PLINK was applied to test for Hardy-Weinberg equilibrium (HWE) for each SNP. For genotyped polymorphisms, we excluded variants with a call rate of less than 90 percent; or strong deviation from HWE. We also excluded subjects with a completion rate of less than 90 percent; or whose reported sex did not match with the inferred sex based on the heterozygosity rate from the sex-chromosomes. Principal components (PC) analysis was undertaken to adjust for population heterogeneity using EIGENSTRAT. Population outliers were detected and subsequently excluded from the analysis. Results: After data quality control filtering, 427 subjects with 503,528 SNPs were used for analysis. The most significant PC-adjusted p-values for each of the four QTLs were-- E: 5.937x10-7 (3q28, rs4686964); N: 3.542x10-6 (15q21.3, rs12903062); P: 1.283x10-6 (3p14.2, rs7625594); BLEQ: 4.238x10-7 (1p12, rs12757996). The most significant SNP at each of three EPQ QTLs in our BP sample exists in a linkage region previously implicated in BP - linkage on 3q28 (Zandi et al. 2007), on 15q21 (Fullerton et al. 2008) and on 3p14 (Etain et al. 2006). Conclusion: While no single marker reaches genome-wide significance (p<5x10-8), given the context of previous studies, our strongest findings are suggestive of genetic overlap between personality traits and BP. Future directions include an increased sample size, with EPQ and BLEQ data, to increase statistical power.

2650/F

A Genome-wide Meta-analysis Identifies Novel Loci Associated with Schizophrenia and Bipolar disorder. *K. Wang, X. Liu, N. Aragam.* Department of Biostatistics and Epidemiology, College of Public Health, East Tennessee State University, Johnson City, TN.

Schizophrenia and bipolar disorder both have strong inherited components. Recent studies have indicated that schizophrenia and bipolar disorder may share more than half of their genetic determinants. In this study, we performed a meta-analysis for genome-wide association data of the Affymetrix Genome-Wide Human SNP array 6.0 to detect genetic variants influencing both schizophrenia and bipolar disorder using European-American samples (691 bipolar cases and 1081 controls, 1172 schizophrenia cases and 1379 controls). The best associated SNP rs11789399 ($p = 2.38x10^{-6}$, $5.74x10^{-4}$, $5.56x10^{-9}$, for schizophrenia, bipolar disorder and meta-analysis of schizophrenia and bipolar disorder, respectively) was at 9p33.1, with eight additional SNPs showed associations in meta-analysis within the haplotype block of the best SNP (p-values ranged from 9.11×10^{-6} to 1.55×10^{-8}). The next best SNP was rs12201676 ($p = 2.67x10^{-4}$, $2.12x10^{-5}$, $3.88x10^{-8}$ for schizophrenia, bipolar disorder and meta-analysis, respectively) located at 6q15, with two additional SNPs showed associations in meta-analysis within the haplotype block of this SNP ($p = 8.1 \times 10^{-5}$ and 7.75×10^{-7}, respectively). The third interesting SNP rs802568 ($p = 8.92x10^{-4}$, $1.38x10^{-5}$, $1.62x10^{-7}$ for schizophrenia, bipolar disorder and meta-analysis, respectively) was at 7q35 within CNTNAP2 while meta-analysis showed three additional SNPs within the haplotype block of this SNP (p-values ranged from 9.68×10^{-5} to 7.00×10^{-7}). Through meta-analysis, we found two additional genes NALCN (the top SNP is rs2044117, $p = 4.57 \times 10^{-7}$) and NAP5 (the top SNP is rs10496702, $p = 7.15 \times 10^{-7}$). The three genes (CNTNAP2, NALCN and NAP5) have been previously reported to be associated with psychiatric disorders such as ADHD, autism, bipolar disorder, and or schizophrenia. Haplotype analyses of above five loci indicated stronger associations than single-marker analyses in schizophrenia and bipolar disorder. These results provide evidence of common genetic variants influencing schizophrenia and bipolar disorder.

2651/F

A genome-wide association study of attempted suicide. *V.L. Willour[1], F. Seifuddin[1], P.B. Mahon[1], D. Jancic[1], M. Pirooznia[1], J. Steele[2], B. Schweizer[1], F.S. Goes[1], F.M. Mondimore[1], D.F. MacKinnon[1], R.H. Perlis[3], P.H. Lee[3], J.R. Kelsoe[4], P.D. Shilling[4], M. Rietschel[5,6], M. Nöthen[7,8], S. Cichon[8,9], H. Gurling[10], S. Purcell[3], J.W. Smoller[3], N. Craddock[11], J.R. DePaulo[1], T.G. Schulze[2], F.J. McMahon[2], P.P. Zandi[1], J.B. Potash[1], The Bipolar Genome Study (BiGS) Consortium.* 1) Department of Psychiatry and Behavioral Sciences, Johns Hopkins University, Baltimore, MD; 2) Genetic Basis of Mood and Anxiety Disorders Unit, National Institute of Mental Health Intramural Research Program, National Institutes of Health, US Department of Health and Human Services, Bethesda, MD; 3) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 4) Department of Psychiatry, University of California, San Diego, La Jolla, CA; 5) Department of Genetic Epidemiology in Psychiatry, Central Institute of Mental Health, Mannheim, Germany; 6) Department of Psychiatry, University of Bonn, Bonn, Germany; 7) Institute of Human Genetics, University of Bonn, Bonn, Germany; 8) Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 9) Institute of Neuroscience and Medicine (INM-1), Research Center Juelich, Juelich, Germany; 10) Department of Mental Health Sciences, University College London, London, UK; 11) Department of Psychological Medicine, School of Medicine, Cardiff University, Cardiff, UK.

The heritable component to attempted and completed suicide is partly related to psychiatric disorders and also partly independent of them. While attempted suicide linkage regions have been identified on 2p11-12 and 6q25-26, there are likely many more such loci, the discovery of which will require a much higher resolution approach, such as the genome-wide association study (GWAS). With this in mind, we conducted an attempted suicide GWAS that compared the single nucleotide polymorphism (SNP) genotypes of 1,201 bipolar subjects with a history of suicide attempts to the genotypes of 1,497 bipolar subjects with no history of suicide attempts. 2,507 SNPs with evidence for association at $p<0.001$ were identified. These associated SNPs were subsequently tested for association in a large and independent bipolar disorder sample set. None of these SNPs were significantly associated in the replication sample after correcting for multiple testing, but the combined analysis of the two sample sets produced an association signal on 2p25 (rs300774) at the threshold of genome-wide significance (p= 5.07 X 10-8). The associated SNPs on 2p25 fall in a large linkage disequilibrium block containing the *ACP1* gene, a gene whose expression is significantly elevated in bipolar subjects who have completed suicide. Furthermore, the ACP1 protein is a tyrosine phosphatase that influences Wnt signaling, a pathway critical to lithium's effects. This connection to lithium is intriguing given that lithium is the best-established medication used to reduce the rate of suicidal behavior, thus making *ACP1* a strong functional candidate for involvement in the phenotype. Larger GWAS sample sets, such as the ones being compiled by the Psychiatric GWAS Consortium (PGC), will be required to confirm the signal on 2p25 and to identify additional genetic risk factors increasing susceptibility for attempted suicide.

eQTL analysis of human brain compared to lymphoblastoid cell lines. *E.M. Schmidt[1], B.J. Keller[2], V. Strumba[3], M. Flickinger[4], J.Z. Li[5], M.H. Dai[1], F. Meng[1], R.C. Thompson[1], E. Sliwerska[1], A.F. Schatzberg[6], E.G. Jones[7], W.E Bunney[8], R.M. Myers[9], S.J. Watson[1], H. Akil[1], M. Boehnke[4], L.J. Scott[4], M. Burmeister[1].* 1) Molecular & Behavioral Neuroscience Inst, Univ of Michigan, Ann Arbor, MI; 2) Dept of Computer Science, Eastern Michigan Univ, Ypsilanti, MI; 3) Addiction Research Center, Univ of Michigan, Ann Arbor, MI; 4) Dept of Biostatistics and Center for Statistical Genetics, Univ of Michigan, Ann Arbor, MI; 5) Dept of Hum Genetics, Univ of Michigan, Ann Arbor, MI; 6) Dept of Psychiatry, Stanford Univ, Stanford, CA; 7) Center for Neuroscience, UC Davis, Davis, CA; 8) Dept of Psychiatry & Hum Behavior, UC Irvine, Irvine, CA; 9) HudsonAlpha Inst for Biotechnology, Huntsville, AL.

Our current understanding of psychiatric disorders is likely to be greatly improved by investigating the genetic control of gene expression in the human brain through genome-wide expression quantitative trait loci (eQTL) mapping. Many of the previous studies of brain eQTLs have been hampered by limited brain tissue availability and lack of brain region-specific samples. In contrast, large eQTL data sets are publicly available for lymphoblastoid cell lines (LCL). Our goal is to compare overall cortex and brain region specific eQTLs with eQTLs detected in publicly available LCL data to determine the extent to which gene regulation is the same or different between brain and LCLs, and to identify brain specific regulatory variants.

We quantified mRNA expression levels from 6 different brain regions in a single unrelated collection of approximately 40 controls and 60 cases per region from individuals with 1 of 3 psychiatric disorders including bipolar, schizophrenia, and depression. Samples were genotyped with a 550k Illumina chip, and an additional 2 million SNPs were imputed based on HapMap genotypes. We regressed the transcript expression levels for 18,187 probes in 16,254 genes on the expected SNP allele counts using linear regression with adjustment for age, gender, and disease status. For each brain region we performed 1.47×10^7 tests of SNPs in cis with genes (within the gene plus 500kb from either end) and observed 5,888 associations with $p < 3.4 \times 10^{-9}$ in 253 genes, the top 36 of which had p-values of 10^{-20}. Using LCL gene expression from 60 unrelated CEU HapMap individuals, we performed 7.5×10^6 SNP-expression association tests of SNPs in cis with LCL transcripts resulting in 553 associations with $p < 7 \times 10^{-9}$ in 46 genes. Preliminary tissue comparison revealed 6.5×10^6 SNP-probe tests for cis association in common between brain and blood. Of the significant brain associations at the 3.4×10^{-9} p-value threshold, 168 associations were observed to be in common with significant LCL cis associations at the 7×10^{-9} threshold. When comparing significant LCL cis associations with all brain cis associations, we observed 481 cis associations present in both LCLs and brain. These comparisons in combination with genome-wide association study (GWAS) results of psychiatric disorders will help bridge the gap between disease-associated SNPs identified by GWAS and their potential functional consequences on gene expression.

An X-chromosome-wide association study identifies a novel autism spectrum disorder gene. *R.-H. Chung[1], D. Ma[1], K. Wang[2], D.J. Hedges[1], J.M. Jaworski[1], J.R. Gilbert[1], M.L. Cuccaro[1], H.H. Wright[3], R.K. Abrahamson[3], I. Konidari[1], P.L. Whitehead[1], G.D. Schellenberg[4], H. Hakonarson[2], J.L. Haines[5], M.A. Pericak-Vance[1], E.R. Martin[1].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 3) School of Medicine, University of South Carolina, Columbia, SC; 4) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA; 5) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder with a strong genetic component. The skewed prevalence toward males compared to females and evidence of suggestive linkage to the X chromosome in some studies support the presence of X-linked susceptibility genes for ASD. We conducted replication analysis of genome-wide association study data on the X chromosome in three independent autism GWAS datasets, using two family datasets (Miami/Vanderbilt (UM/VU) and AGRE) as a discovery dataset and a case-control dataset from The Children's Hospital of Philadelphia (CHOP) as a validation dataset. Association analysis was conducted in the individual datasets using the allele-based Chi-squared tests for the case-control analysis and the X-APL in families. We defined the replication threshold for p-value<0.0025 for each of the discovery and validation datasets. Although the threshold is liberal in the individual analyses, it is expected to control the chromosome-wide type I error rate when requiring replication in both datasets. In addition to replication analysis, we also performed joint analysis on the discovery and validation datasets combined. We used a modified version of the X-APL (X-CAPL) that combines family and unrelated case-control data and accounts for differential bias and population structure between datasets for the joint analysis. The final datasets included 2,557 samples from 735 ASD families in UM/VU, 3,289 samples from 721 ASD families in AGRE, and 1,204 cases and 6,472 controls from CHOP. One SNP rs17321050 in the TBL1X gene showed chromosome-wide significance in the joint analysis (p-value=4.53×10-6) for males and was close to the replication threshold of 0.0025 in each dataset. Two other SNPs in the same gene in LD with rs17321050 also showed significance close to the chromosome-wide threshold in the joint analysis but none of the three SNPs were predicted to be functional. Studies have shown deletions in the Xp22.2-Xp22.3 region containing TBL1X and surrounding genes were associated with several genetic syndromes, mental retardation and autistic features. Our results provide evidence through both replication and joint analyses that the gene may play a broader role in ASD risk.

Genome-wide association and linkage studies for Parkinson's Disease in the mid-western US Amish. *M.F. Davis[1], A.C. Cummings[1], L. Jiang[1], D. Velez Edwards[2], R. Laux[1], L.L. McFarland[1], P.J. Gallins[3], L. Reinhart-Mercer[3], D. Fuzzell[1], C. Knebusch[3], C.E. Jackson[4], W.K. Scott[3], M.A. Pericak-Vance[3], S.L. Lee[5], J.L. Haines[1].* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) Vanderbilt Epidemiology Center, Vanderbilt University Medical Center, Nashville, TN; 3) Hussman Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL; 4) Scott & White, Temple, TX; 5) Dartmouth College, Hanover, NH.

Parkinson's Disease (PD) is the second most common neurodegenerative disorder of adults. Previous evidence has shown that PD has a heritable component. Mutations in five known genes [α-synuclein (PARK1, PARK4), Parkin (PARK2), PINK1 (PARK6), DJ-1 (PARK7), and LRRK2 (PARK8)] cause Mendelian inheritance of PD. Consensus regions from genome-wide linkage and association studies of the more common non-Mendelian forms of PD implicate MAPT and SNCA. Other regions have been identified but the genes remain unknown. Genetic heterogeneity complicates the verification of likely genes and the identification of other susceptibility genes. Our approach to overcome the problem of heterogeneity is to study a population isolate, the mid-western Amish communities of Ohio. To date we have enrolled over 2200 Amish individuals with 40 of these diagnosed with PD. In this dataset we see a higher average kinship coefficient among our cases (.016) compared to the rest of our dataset (.012), suggesting that PD is heritable in the Amish. We have undertaken a genome-wide association study (Affymetrix Genome-Wide Human SNP Array 6.0) and genotyped 900 Amish individuals (38 with PD). Through the use of the Anabaptist Genealogy Database, we have determined the family structure for our collected individuals. Following QC, 614,957 SNPs and 830 individuals were analyzed. SNPs were analyzed by both linkage and association analysis. Linkage analysis was conducted using Merlin after cutting the pedigree into computationally feasible sub-pedigrees using PedCut. Seven regions generated a lod score ≥ 3 in 2-pt parametric linkage analysis on chromosomes 9, 10, 11, 12, 20, and 22. Multipoint analysis was conducted on these regions, and the lod score at 9p23 increased to 3.47. Association analysis was conducted using the MQLS test, which takes into account the relatedness of the individuals. Six SNPs reached genome-wide significance (p-value £1 × 10-7). One SNP (rs3935740) is in the intron of TMC3; all others are intergenic. We further investigated to see if the 2-pt linkage and association results overlap. Fifteen SNPs are significant in both studies with the criteria of lod ≥ 2 and p-value £ 1 × 10-4. These SNPs, as well as the region at 9p23, will be followed up for confirmation to indicate possible identification of novel PD-susceptibility genes.

Pathway Analysis of Late-onset Alzheimer Disease Genome-wide Association Data Highlights Inflammatory and Neurodevelopmental Pathways. *C.E. Humphries[1], A.C. Naj[1], Y. Edwards[1], R. Ulloa[1], G.W. Beecham[1], E.R. Martin[1], M.A. Slifer[1], E.H. Powell[1], P.H. Gallins[1], I. Kondari[1], P.H. Whitehead[1], G. Cai[2], V. Haroutunian[2], W.K. Scott[1], J.M. Vance[1], H.E. Gwirtsman[3], J.D. Buxbaum[2], J.R. Gilbert[2], J.L. Haines[4], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, Dr. John T Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL, USA; 2) Department of Psychiatry, Mount Sinai School of Medicine, New York, NY, USA; 3) VA Medical Center, Nashville, TN, USA; 4) Vanderbilt Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA.

Alzheimer disease(AD) is the most prevalent neurodegenerative disease in the developed world with heritability estimates ranging from 60-80%. Genome-wide association studies(GWAS) studies of AD have identified several genes with highly statistically significant associations, including APOE, CLU, PICALM, and CR1. Variation in these genes does not fully explain the majority of AD heritability. Pathway analysis approaches may help to identify additional genes that contribute to AD by highlighting biological pathways relevant to AD. Using P-values from logistic regression modeling of SNP associations with late-onset AD (LOAD) in a previously-described GWAS of 483,399 single nucleotide polymorphisms(SNPs) in 931 LOAD cases and 1,104 controls, all SNPs were mapped to the nearest gene within 20 kb-pairs upstream or downstream. SNP-mapped genes were then assigned to pathways from the Kyoto Encyclopedia of Genes and Genomes (KEGG). Pathway memberships for genes containing SNPs with statistically significant associations (n=5,096 with P<0.01), were compared against all pathways containing SNP-mapped genes. A hypergeometric model (as implemented in GOStats,v2.0) was used to test whether any pathways contained more genes with significant SNP associations than would have been expected. SNPs significantly associated with LOAD (P<0.01) were over-represented in several pathways: Systemic Lupus Erythematosus (KEGGID:05322, $P=2.48\times10^{-5}$) disease pathway, Cell adhesion molecule (CAM) pathways (KEGGID:04514, $P=1.38\times10^{-4}$), and Axon guidance (KEGGID:04360, $P=3.63\times10^{-4}$). Systemic Lupus Erythematosus pathway genes are predominantly involved in inflammatory response, and this may relate to AD as neuroinflammation has been associated with degeneration in AD brains, characterized by overexpression of acute phase proteins and proinflammatory cytokines in tissues proximal to lesions. Likewise, CAM pathways include neuronal cell-cell adhesion pathways, which have demonstrated significant roles in memory and learning. Pathway analyses of GWAS data have identified excess association with LOAD of variants in inflammatory and neurodevelopmental pathway genes highlighting potential pathways and gene families for functional genomic investigations. Future directions include validation of this pathway analysis with additional analytic approaches, including the SNP Ratio Test and PARIS pathway analysis, and further evaluation of the SNPs associated with LOAD among the top pathways identified.

2656/F

Web-based, genome-wide association studies of Parkinson's Disease. *N. Eriksson, C. Do, J.Y. Tung, A. Kiefer, K. Marton, L. Dorfman, D. Hinds, B. Naughton, J.M. Macpherson, S. Saxonov, A. Wojcicki, J. Mountain.* 23andMe, Mountain View, CA.

Over the past year, we have gathered over 3,500 participants who self-reported Parkinson's disease into an online community. Participants were genotyped, optionally filled out questionnaires on their diagnosis, symptoms, and medical history, and were provided with an opportunity to view their (interpreted) genetic data. We have performed a genome-wide association study using these participants as well as over 900 cases from NINDS and over 20,000 population controls from the 23andMe database. We have found 9 regions associated with PD in this study, including 4 that are novel (all with p-values under 1e-7): SNCA (rs356220), LRRK2 (rs34637584, rs33939927, and rs10878246), GBA (N370S, V394L, and R496H), MAPT (rs2316765), SLC41A4/PARK16 (rs708730), RIT2 (rs4130047), MCCC1/LAMP3 (rs10513789), DGKQ/GAK (rs11724804), and STBD1/SCARB2 (rs6812193). We have substantial confidence that the subjects actually have PD for two reasons. First, estimated odds ratios for replicated SNPs agree closely with those in previous papers. Second, most participants reported a history that met clinical definitions of PD, including gradual and unilateral onset, persistent asymmetry, a progressive course, and response to levodopa. We have collected age of onset and symptom data (using the UPDRS), allowing us to perform analysis of association studies with age of onset and with disease subtype and to investigate disease progression for various high penetrance mutations.

2657/F

Meta-analysis in genome-wide scans identified BIN1 locus associated with Alzheimer disease susceptibility. *X. Hu[1], E. Pickering[2], Y. Liu[3], S. John[1], S. Hall[1], E. Katz[1], H. Soares[4].* 1) Molec Med, Pfizer Global R&D, Groton, CT; 2) Research Statistics, Pfizer Global R&D, Groton, CT; 3) Research Statistics, Pfizer Global R&D, Shanghai, China; 4) Translational Medicine, Pfizer Global R&D, Groton, CT.

Alzheimer's disease (AD) is the leading cause of dementia in the elderly population. Apart from APOE, recent GWAS studies nominated promising candidate loci near APOJ, CR1 and PICALM. In this study, we conducted a genome-wide association study in an independent set of 1301 AD cases and 1381 controls using Illumina platforms coupled with meta-analysis with available GWAS data from GenADA and Harold et al. 2009 to identify and replicate genetic markers with significant associations with AD disease etiology. We replicated the variants from APOJ (rs11136000), PICALM (rs3851179) and CR1 (rs3818361) in at least one independent sample set and identified a marker in the BIN1 locus (rs744373) below the genome-wide significance level (p less than 10-9). These four variants were further tested for association with disease progression in 467 LEADe trial and 181 ADNI AD patients where longitudinal cognitive measures are available for up to 24 months. The PICALM variant showed significant association with cognitive decline as measured by change of CDR score from the baseline suggesting it might play a role in both disease susceptibility and disease progression. However, combination of these genetic markers may have limited clinical utility for progression prediction.

Genome-wide meta-analysis of pragmatic communication skills. *B. StPourcain[1], A. Whitehouse[2], N. Warrington[3], J. Golding[4], C. Steer[4], J. Kemp[1], G. MacMahon[1], N.J. Timpson[1], D.M. Evans[1], S.M. Ring[1], P. Deloukas[5], L. Palmer[6], C. Pennell[3], G. Davey Smith[1].* 1) MRC CAiTE/Dept Social Medicine, University of Bristol, Bristol, England, United Kingdom; 2) Telethon Institute for Child Health Research, University of Western Australia, Perth, Western Australia, Australia; 3) School of Women's and Infants' Health, The University of Western Australia, Perth, Australia; 4) Centre for Child and Adolescent Health, Department of Community Based Medicine, University of Bristol, Bristol, United Kingdom; 5) Wellcome Trust Sanger, Institute, Cambridge CB10 1SA, UK; 6) Centre for Genetic Epidemiology and Biostatistics, University of Western Australia, Perth, Australia.

Recent research showed that pragmatic communication deficits in the general population are associated with the same common genetic variant on chromosome 5p14 that also enhances risk for Autism Spectrum Disorder (ASD). This suggests the existence of underlying quantitative trait loci (QTL) that influence the entire autistic spectrum, and strongly supports theories that posit autism as a dimensional disorder. Our study performed a meta-analysis of genome-wide association study (GWAS) results on an index of pragmatic aspects of communication that was derived from the Children's Communication checklist (CCC). Severe problems with pragmatic aspects of language appear to be universal in ASD and are usually ascribed to an impaired theory of mind, i.e. an impaired understanding of other people's mind and mental state. Study participants were ~1100 9-year old children from the Western Australian Pregnancy Cohort (RAINE) Study and ~2850 10-year old children from the Avon Longitudinal Study of Parents and Children (ALSPAC) with imputed genome-wide data. We identified several meta-GWAS signals that met suggestive evidence for association (meta-p £ 1.0E-06). The strongest association was observed for a common variant near the *Cordon-Bleu (COBL)* gene, which is part of an imprinted region on chromosome 7p12 (meta-p < 3.4E-07). *COBL* is a conserved gene that plays a role in neural tube development and influences actin filament polymerisation. As a next step, the identified Meta-GWAS signals will be examined for replication within a further ~4000 10-year old ALSPAC children with available phenotype data and extracted DNA.

Genome Wide Association Study Identifies DACH1 Gene Associated with Epilepsy. *H. Zhang[1], K. Wang[1], M.R. Sperling[2], D.J. Dlugos[3], W.D. Lo[4], C. Hou[1], J.T. Glessner[1], J.P. Bradfield[1], P. Sleiman[1], Y. Guo[1], C. Kim[1], R. Chiavacci[1], F. Mentch[1], H. Qiu[1], B. Keating[1], S.F. Grant[1], M. Privitera[5], J.A. French[6], S.C. Schachter[7], P. Cossette[8], F.W. Lohoff[9], W. Berrettini[9], H. Basehore[10], T.N. Ferraro[9], R.J. Buono[10], H. Hakonarson[1].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Neurology, Thomas Jefferson University, Philadelphia, PA; 3) Division of Neurology, Children's Hospital of Philadelphia, Philadelphia, PA; 4) The Ohio State University and Nationwide Children's Hospital, Columbus, Ohio; 5) Department of Neurology, University of Cincinnati, Cincinnati, Ohio; 6) Department of Neurology, New York University, New York, NY; 7) Department of Neurology, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA; 8) Department of Medicine, University of Montreal, Montreal (Quebec), CANADA; 9) Department of Psychiatry, University of Pennsylvania, Philadelphia, PA; 10) Coatesville Veteran's Affairs Medical Center, Coatesville PA.

Epilepsy is a common chronic neurological disorder affecting more than 3 million people in the United States and having an overall incidence of about 1%. A major obstacle impeding the development of new treatments is lack of understanding of the neurobiological mechanisms that produce recurrent seizures, the hallmark of epilepsy. In an attempt to better characterize the genetic risk factors for epilepsy, we performed a genome-wide association study of 295 cryptogenic focal epilepsy patients and 2,282 healthy control subjects of European ancestry, as well as a second cohort of 412 idiopathic generalized epilepsy (IGE) patients and 3,876 control subjects of European ancestry genotyped by the Illumina HumanHap550 BeadChip. Genome wide association analysis identified DACH1 (dachshund homolog 1) on 13q22 as a susceptibility gene for epilepsy, with the most significant marker being rs9572727 (p=0.001, OR=1.93 in focal cohort and p=3.46x10-13, OR=2.89 in IGE cohort and p=1.71x10-14, OR=2.48 in combined cohort). Other candidate genes include MYH11 (p=1.3x10-9) and MMP8 (p=6.3x10-7) for epilepsy, ZNF695 and VGLL3 for focal group, C6orf103, ENPP2 and C7orf41for IGE. In addition, we have performed preliminary analysis on large copy number variation (CNV) on the subjects of European ancestry. Two IGE patients carry the 1.5Mb deletion on 15q13.3 previously associated with epilepsy, while one focal patient carries the reciprocal duplication. Furthermore, two unrelated generalized patients carry 1.2Mb deletion on 16p13.11. In conclusion, our results confirmed previously reported candidate CNVs in epilepsy susceptibility, but also identified potential novel genes worthy of further investigation and replication.

Common genetic variants near TRANK1 are associated with bipolar disorder in European and Asian ancestry populations. *J.R. Wendland[1], T.G. Schulze[1], A. Cheng[2], C.-H. Chen[2], N. Akula[1], J. Steele[1], M. Nöthen[3], S. Cichon[3], M. Rietschel[4], BiGS. Consortium[5], F.J. McMahon[1].* 1) Genetic Basis of Mood and Anxiety Disorders, NIMH, Bethesda, MD; 2) Inst. of Biomedical Sciences, Academica Sinica, Taiwan; 3) Dept. of Human Genetics, University of Bonn, Germany; 4) Central Institute of Mental Health, Mannheim, Germany; 5) Bipolar Genome Studies (BiGS) Consortium.

Bipolar disorder (BD) is a common neuropsychiatric disorder marked by recurring episodes of mania and depression. Although there is compelling evidence of high heritability, few genetic findings for BD have been consistently replicated. Here, we conducted a meta-analysis of six BD genome-wide association studies originating from five European ancestry and one Han Chinese population (N = 13,853 individuals in total). Genotypes for individuals or association statistics for genome-wide markers were obtained through collaborations, public databases and publications. In total, 893,707 autosomal markers were observed or imputed in at least four of the six populations and meta-analyzed with MetAL after careful quality control. We identified a genomic region on chromosome 3p22 harboring TRANK1 that was associated with BD. The lowest P-value (1.08E-10; odds ratio = 1.2; 95% confidence interval, 1.1-1.3) was observed at rs9834970, a common variant located 12.3 kbp telomeric of TRANK1, previously implicated at suggestive levels of significance in the Wellcome Trust Case-Control Consortium BD sample. The second-most significant association (P = 2.76E-9) was at rs4789, a polymorphism in the 3'-untranslated region of TRANK1, in linkage disequilibrium with rs9834970. For both markers, the major allele (T) was consistently overrepresented in cases of BD in all study populations. Genome-wide suggestive association signals were detected at SNPs near PBRM1 (McMahon et al., 2010), LMBR1L, and a region of 8q12 containing many genes.TRANK1 (also known as lupus brain antigen 1, LBA1) is the human ortholog of murine Lba1, which encodes a cell surface target of brain-specific autoantibodies observed in experimental models of neurobehavioral systemic lupus erythematosus. We conclude that common genetic variation in TRANK1 influences risk for BD in multiple populations.

2661/F

Clinical and Genetic studies in Kleine Levin Syndrome. *T. Rico, J. Faraco, L. Lin, J. Hallmayer, E. Mignot.* Stanford University Center for Narcolepsy, Stanford, CA.

Kleine-Levin Syndrome (KLS) is a very rare disorder (quoted prevalence~1 for 1million) characterized by relapsing-remitting episodes of profound hypersomnia accompanied by specific cognitive and behavioral disturbances. Episodes typically last 1-3 weeks and recur every few weeks to few months with no symptomatology between episodes. The disease affects primarily adolescent males, with onset in the teens, and subsides within 8-12 years (median duration), with significant impact on social and educational development. A viral prodrome frequently precedes episodes, but no specific infectious trigger has ever been identified. An increased risk in first and second degree relatives of KLS cases (5 of 105 cases had an affected family member), and increased prevalence in the Ashkenazi Jewish population suggest the implication of genetic risk factors. We hypothesize that KLS results from an abnormal response to a pathogenic trigger acting on a susceptible genetic background. We performed a pilot genome-wide association (GWA) in 225 KLS patients of various ethnic backgrounds and 617 matched controls genotyped on the Affymetrix 6.0 array. We identified SNP variations in three genomic regions (Chromosomes 8, 10, and 14) with genome-wide significant associations. These findings are currently being replicated and extended in additional patients. To do so, we are currently recruiting and forming collaborations. In addition to blood samples, nasal and throat swabs are being collected from controls and patients both during and between episodes to identify potential pathogenic triggers or other factors associated with episode onset. Recruitment is a significant challenge due to the rarity of the disease: to date we have an additional 134 patients of various ethnic backgrounds pending analysis. Results of genotyping will direct our follow up of susceptibility loci, versus extending our GWA with the larger and more statistically powerful overall cohort. Acknowledgments: We thank our other collaborators not listed here for contributing samples, cohort genotypes and participating in the genetic analysis. Funded by MH080957-03.

The microtubule network and bipolar disorder: biological theme of differentially expressed genes in lymphoblastoid cells from ill individuals. *H. Chen, M.G. McInnis.* Department of Psychiatry, University of Michigan Medical School, Ann Arbor, MI.

Cumulative evidence suggests that bipolar disorder is caused by multiple genetic variants interacting with environmental factors. We hypothesize that manifestation of this interaction may be "imprinted" in cellular systems and subsequently leads to altered gene expression. We measured the abundance of 22,184 genome transcripts in lymphoblastoid cell lines (LCL) from a sample of 19 bipolar individuals without psychosis features and 24 controls using Illumina's Refseq8-v2 BeadChips. This experiment identified 11,372 transcripts expressed in LCLs among the 22,184 transcripts assayed. Using the two-group unpaired algorithms implemented in the significant analysis of microarrays (SAM) statistics package, we identified 250 unique gene transcripts differentially expressed in LCLs from bipolar individuals, given a false discovery rate (FDR) cutoff point of 0.1 as statistical significance. 249 of the 250 transcripts show decreased levels, and one increased in LCLs from bipolar individuals compared to controls. Forty-one of the 250 transcripts show expression alteration in postmortem brains affected with bipolar disorder (35 in same direction change) based on results from our recent microarray analysis of postmortem brains for the same 11,372 transcripts. Biological path analysis of the 250 transcripts identifies six Gene Ontology terms with enrichment of genes involved in metabolic process (FDR < 0.01). Notably, the 41 genes commonly altered in expression in bipolar LCLs and postmortem brains are significantly enriched under "regulation of microtubule depolarization/polarization" (FDR < 0.01). For examples, MAP4 and CLASP2 encode microtubule-associated protein 4 and cytoplasmic linker associated protein 2, respectively, both show decreased levels in bipolar LCLs and postmortem brain. MAP4 and CLASP2 are best known for their microtubule-stabilizing activity and for proposed roles regulating microtubule networks in axon guidance and growth. Our results suggest that dysregulation of the microtubule network may contribute to the molecular basis of bipolar disorder, and provide candidate genes for further exploration of gene interaction networks and pathways involved in the etiology and pathogenesis of bipolar disorder.

Characterization of SGCE isoforms in human brain. *K. Ritz[1], B.D.C van Schaik[2], M.E. Jakobs[1], A.H. van Kampen[2,5], E. Aronica[3], M.A. Tijssen[4], F. Baas[1].* 1) Department of Neurogenetics, Academic Medical Center, University of Amsterdam, Meibergdreef 9, 1105AZ AmsterdamAcademic Medical Center, Amsterdam, Amsterdam, Netherlands; 2) Bioinformatic Laboratory, Academic Medical Center, University of Amsterdam, Meibergdreef 9, 1105AZ Amsterdam; 3) Department of Neurpathology, Academic Medical Center, University of Amsterdam, Meibergdreef 9, 1105AZ Amsterdam; 4) Department of Neurology, Academic Medical Center, University of Amsterdam, Meibergdreef 9, 1105AZ Amsterdam; 5) Biosystems Data Analysis, Swammerdam Institute for Lice Science, University of Amsterdam, Nieuwe Achtergracht 166, 1018WV Amsterdam, The Netherlands.

Myoclonus-Dystonia (M-D) is an autosomal-dominant inherited movement disorder characterized by jerky movements and dystonic features. About 50% of M-D patients have a mutation in the epsilon-sarcoglycan (SGCE) gene, which encodes a transmembrane protein that is widely expressed in several tissues. The function of SGCE and the pathophysiology of the disease with its brain-specific phenotype remains unknown. Recently, new brain-specific SGCE exons coding for a different C-terminal of the protein have been identified suggesting a alternative functions for those isoforms in the brain. We investigated SGCE exon structure with ultra deep sequencing (454 GS FLX, Roche) to characterize all alternatively spliced SGCE exons and their qualitative and quantitative distribution in different human brain regions. Further analysis of the major brain-specific isoform by qPCR showed a high expression in the cerebellum. Isoform-specific ISH confirmed its expression pattern and showed a predominant neuronal expression. We show that ultra deep sequencing is a powerful tool to study exon structure of a gene. We propose that loss of function of the major-brain specific SGCE isoform mainly affecting the cerebellum explains the specific M-D symptoms.

PRESENILIN ENHANCER-2 GENE MUTATIONS AND FAMILIAL ALZHEIMER'S DISEASE. *V. Andreoli, F. Trecroci, A. La Russa, M. Caracciolo, G. Di Palma, P. Spadafora, R. Cittadella.* Institute of Neurological Sciences, National Research Council, Piano Lago di Mangone, Cosenza-Italy.

During the last few years, much progress has been made in identifying new proteins involved in Alzheimer's disease (AD), the most prevalent form of progressive dementia in the elderly. It is characterized by extracellular amyloid plaques and neurofibrillary tangles in affected brains. Many studies have confirmed that beta-amyloid (Aβ) is the core ingredient of β-amyloid plaques; Aβ is produced in a process of proteolysis of amyloid precursor protein (APP) in which the γ-secretase complex plays a crucial role. Presenilin enhancer 2, a small integral membrane glycoprotein, is one of four components of the γ-secretase complex which cleaves APP to generate Aβ. Moreover, its gene (PEN-2) maps to a highly significant linkage region on chromosome 19q13. PEN-2 is an essential cofactor of this secretase complex, whose dysfunction could influence γ-secretase formation, reduce presenilins levels and impair nicastrin maturation. It is possible that a sequence variation of PEN-2 could accelerate AD pathology. To better assess the genetic contribution of PEN-2 to familial AD (FAD), we performed a systematic mutation analysis of this gene in 90 Italian patients with FAD. The whole PEN-2 promoter and its exons were screened by denaturing high performance liquid chromatography (DHPLC). Patients'chromatograms for each PCR fragments were compared with corresponding normal controls and the amplicons showing a variant DHPLC profile were sequenced in both directions. The sequencing analysis of the PEN-2 promoter identified a novel heterozygous 3 bp deletion mutation (—328_—326delGAA) in a subject with early-FAD. The patient was a 55-year-old woman, with a 3-year history of mild memory deficit. This deletion occurs directly in the proximal promoter of PEN-2 gene, which apparently contains important structural elements, indispensable for its function. The coding region of the PEN-2 was sequenced in this patient, which was also analyzed for mutations in PS1, PS2 and APP genes, in order to ensure that a second mutation will not be missed. This deletion was excluded in 150 aged cognitively intact controls. We conclude that —328_—326delGAA might represent the first pathogenic mutations in the promoter region of the PEN-2. This screening of the PEN-2 gene revealed a very rare mutation in a FAD patient, although the identification of additional mutations together with functional studies will be necessary, to further understand the pathogenesis resulting from PEN-2 mutations.

2665/F

Panthothenate kinase associated neurodegeneration: clinical description and genetic study in 3 large algerian familes. *H. Azzedine[1], S. Assami[2], S. Mahoui[2], E. Mundwiller[1], S. Nouioua[2], D. Grid[3], A. Brice[1,4], M. Djemai[5], G. Stevanin[1,4], M. Tazir[2].* 1) INSERM, U975 (formerly U679), Paris, France and UPMC Univ. Paris 6, UMR_S975, CNRS 7225, Centre de Recherche de l'Institut du Cerveau et de la Moelle épinière, Hôpital Pitié-Salpêtrière, Paris, France; 2) Department of Neurology CHU Mustapha and Laboratoire de Neurosciences, Université Benyoucef Benkhedda, Algiers, Algeria; 3) Généthon, Paris, France; 4) APHP, Department of Genetics, and Cytogenetics, Hôpital Pitié-Salpêtrière, Paris, France; 5) Service de Neurologie, CHU Bab el Oued, Algiers, Algeria.

We described 10 Panthothenate kinase associated neurodegeneration (PKAN) patients from 3 different kindreds with a mean age at onset in the first decade (5 ± 1.9, range 3 to 8 years) and peculiar clinical picture. Hyperkinetic syndromes with concentration difficulties were the first and striking features. They were followed by abnormal falls, gait or postural difficulties. Later on, examination showed dysarthria, oromandicular-facial and axial dystonia, pyramidal signs and cognitive impairment. Progression was rapid in the first decade with loss of independent ambulation at a mean age of 11.7 ± 1.9 years with generalized painful dystonia. Pigmentary retinopathy was observed in all the patients. T2-weighted brain MRI showed the specific pattern known as the eye of the tiger. We identified two homozygous truncating PANK2 mutations (c.846_847delAG / p.S282SfsX3 and c.1171_1174dupATTG / p.G392DfsX11) segregating with the disease in all patients in family 1 and 2, respectively. Interestingly, in the second branch of family 3, all the patients are double homozygous for two missense variants (c.457A_T / p.I153F and c.519C_G / p.H173Q). These variants were absent in 898 control chromosomes. However, the single patient of the first branch of this family, presents a particular genotype as he is a triple heterozygous. Indeed, he carries the truncating mutation (c.1171_1174dupATTG / p.G392DfsX11) identified in family 2, in a tans position to the missense variants present both in cis position in the second branch of family 3. The c.1171_1174dupATTG mutation found in family 2 as well as in the first branch of family 3 was associated with similar flanking haplotypes suggesting that these 2 families have a common ancestor. In conclusion, we report 4 mutations, 2 truncating mutations already described and 2 novel missense PANK2 mutations. These mutations were associated with severe PKAN. All patients presented pigmentary retinopathy and cerebellar ataxia, while hyperactivity was observed in some of them, extending the clinical profile of this disease.

A comprehensive mutation analysis of the PINK1 gene in Southern Italian patients with early- and late-onset parkinsonism. *E.V. De Marco[1], V. Scornaienchi[1], P. Tarantino[1], F.E Rocca[1], V. Greco[1], G. Provenzano[1], D. Civitelli D[1], F. Annesi[1], G. Nicoletti[2], A. Uncini[3,4], A. Quattrone[2,5], G. Annesi[1].* 1) Institute of Neurological Sciences, National Research Council, Cosenza, Italy; 2) Institute of Neurology, University of Magna Graecia, Catanzaro, Italy; 3) Neuromuscular Diseases Unit, Centre for Excellence on Aging, "G. d'Annunzio" University Foundation, Chieti, Italy; 4) Department of Human Motor Sciences, University "G. d'Annunzio", Chieti, Italy; 5) Neuroimaging Research Unit, National Research Council, Catanzaro, ItalY.

Mutations in the PINK1 gene are associated with both familial recessive and sporadic early-onset Parkinson's disease (EOPD) (onset £50 years) and have been found in populations of different geographical origins. Data on Italian EOPD patients show mutations in a relatively high percentage (8-9%). Although mutations in PINK1 predominantly involve EOPD patients, heterozygous or compound heterozygous mutations were also reported in a small number of late-onset PD patients (LOPD). In this study, we aimed at assessing the frequency and possibly the pathogenic role of PINK1 mutations in familial and sporadic patients with EOPD and LOPD coming from Southern Italy. We selected 115 patients, including 102 cases with EOPD, 9 of which had a positive family history, and 13 familial cases with LOPD. All the eight PINK1 exons and intron-exon boundaries were analyzed by PCR and sequencing. The MLPA method was used in the heterozygous patients in order to detect exon dosage changes, caused by genomic rearrangements, of the known PD genes. Four already know different mutations (three homozygous: Q126P, W437X , Q456X and one heterozygous: E476K) and one novel heterozygous mutation (R207Q) were found in five patients, giving a 4.3% frequency of PINK1 mutations in our total PD cohort. In particular, 4 out of 103 EOPD patients (3.9%) carried PINK1 mutations. This frequency is lower than previous studies on Italian EOPD have suggested (8-9%). Furthermore, a frequency of 1 out 13 (7.7%) in familial LOPD patient was found, thus confirming a certain influence of the PINK1 gene also in LOPD as observed in other studies. In conclusion, our study confirms the role played by the PINK1 gene mutations both in heterozygous and homozygous condition in PD development.

Molecular analysis of *REEP1* gene mutations in patients with familial and sporadic spastic paraplegia. *D. Di Bella[1], E. Sarto[1], M. Plumari[1], L. Brighina[2], C. Ferrarese[2], L. La Mantia[3], S. Baratta[1], F. Taroni[1].* 1) Genet Neurodegen Metab Dis, IRCCS Ist Neurol Carlo Besta, Milan, Italy; 2) Unit of Neurology, University of Milan-Bicocca, AO San Gerardo, Monza, Italy; 3) Movement Disorders, Neurology Unit 1, IRCCS Ist Neurol Carlo Besta, Milan, Italy.

Hereditary spastic paraplegias (HSP) are a clinically and genetically heterogeneous group of neurodegenerative disorders. Pure and complicated forms of the disease have been described. About half of HSP cases result from autosomal dominant mutations in spastin (SPG4) or atlastin-1 (also known as SPG3A). Mutations in the receptor expression-enhancing protein 1 (REEP1) gene have recently been reported to be associated with autosomal dominant (AD) pure or complicated HSP phenotypes (SPG31) with a variable frequency ranging from 2.3% to 6.5%. Recent data indicate that the HSP proteins atlastin-1, spastin, and REEP1 interact within the tubular ER membrane in corticospinal neurons to coordinate ER shaping and microtubule dynamics. We have analyzed a large cohort of Italian patients with spastic paraparesis for REEP1 mutations, including both point mutations and micro-rearrangements. The REEP1 gene was analysed by high-resolution melting analysis (HRM) and/or direct sequencing in 175 unrelated index cases, including 80 AD cases, and 95 sporadic cases, negative for SPG4 mutations. Moreover, a subgroup of patients was also screened for micro-rearrangements in the REEP1 gene by multiplex ligation-dependent probe amplification (MLPA) to assess the frequency of deletions/duplications. We have identified two novel different pathogenic mutations were found in the AD-HSP group (2.5%). No REEP1 mutations were identified in the sporadic group. No micro-rearrangements were identified in the analyzed patients. One deletion of 16 nucleotides (c.256_271del16) causing a frameshift and a premature stop codon was identified in exon 4 in two affected brothers and in their mildly affected mother while a splice site mutation (c.182+1 G>T) predicted to abolish the splice donor site was identified in exon 3 in another proband from an AD-HSP family with an uncomplicated spastic paraplegia phenotype. In conclusion, our data indicate that REEP1 mutations account for 2.5% of cases with autosomal dominant inheritance, suggesting that this form is relatively uncommon in an Italian population of spastic paraplegia patients. Clinically, the probands of our SPG31 families present with a pure spastic phenotype.

2668/F

Rare copy number and sequence variants in DOCK8 are involved in autism. *S.C. Lund, A.D. McGrew, J.S. Sutcliffe.* Department of Molecular Physiology & Biophysics and Psychiatry, Centers for Molecular Neuroscience and Human Genetics Research and Vanderbilt Kennedy Center. Vanderbilt University, Nashville, TN, USA.

Autism spectrum disorder (ASD) is a neurodevelopmental condition affecting approximately 1 in 110 individuals, predominantly males. ASD is characterized by deficits in reciprocal social interaction, communication, and patterns of repetitive behaviors and restricted interests. Twin and family studies indicate high heritability in ASD, and we now understand that copy number variation (CNV) is an important class of rare variation underlying risk and/or causation in ASD. We and others hypothesize that genes disrupted by de novo and/or inherited CNV harbor discrete functional (e.g. coding) variants that cause or increase risk for disease. We initially screened a series of 89 probands using the Affymetrix 6.0 platform. CNVs were predicted using multiple algorithms to maximize sensitivity and specificity of CNV detection. Among qPCR-validated variants, we identified DOCK8 (dedicator of cytokinesis 8) as disrupted in two probands. Moreover, the Autism Genome Project has detected two cases of de novo deletion of DOCK8, lending further support to this gene as a candidate. DOCK8 is a guanidine-exchange factor (GEF) of the Rho-family GTPase, identified in a yeast two-hybrid assay screening for Cdc42-interacting proteins. Compelling evidence shows that DOCKs have important roles in fundamental neurodevelopmental processes, moreover, DOCK8 gene disruption was reported in two unrelated patients with mental retardation. DOCK8 exons (n=48) were screened for novel variants in 183 unrelated probands and 200 controls using Sanger sequencing. Variants were validated and segregation determined by sequencing independent PCR products. Multiple bioinformatic tools were used to predict the functional effect of synonymous and nonsynonymous variation. Novel variants detected in more than one proband were subsequently genotyped using TaqMan ~950 families. To date, 15 novel nonsynonymous and 7 synonymous variants were detected in 20 and 8 probands, respectively, compared with 9 nonsynonymous and 2 synonymous variants in 11 and 2 ethnically matched controls, respectively. These data show trend in nonsynonymous variants in cases vs controls (p=0.061) and reveal a pronounced increased of all transcribed variants in cases vs. controls (p= 0.0075), indicating a putative increase in burden of exonic variants in ASD cases compared with a non-clinical comparison sample. The biological significance of these variants is under study and will help us to further interpret these data.

Whole genome sequencing in schizophrenia: the first genomes. *A. Need[1,2], J. McEvoy[2], H. Meltzer[3], D. Goldstein[1].* 1) Center for Human Genome Variation, Duke Univ, Durham, NC; 2) Department of Psychiatry, Duke Univ, Durham, NC; 3) Department of Psychiatry, School of Medicine, Vanderbilt University, Nashville, TN.

Genetic studies of neuropsychiatric illnesses such as schizophrenia have indicated that the common disease common variant hypothesis contributes less to the etiology of the disorders than previously thought. Studies of large copy number variants provide evidence for a much larger role of rare, highly penetrant genetic variants in these disorders, which can only be fully explored using next generation sequencing. Here we present whole genome and whole exome data from 50 schizophrenia patients, selected because either a strong family history or a treatment-resistant form of the illness indicates a highly penetrant genetic predisposition. We compare the whole genome and whole exome data, discuss candidate variants and outline analytical and technical challenges encountered when working with these novel data.

Molecular analysis of folate receptor genes in patients with Cerebral Folate Deficiency. *K. Segers[1], J. Hanson[3], V. Ramaekers[2], V. Bours[1].* 1) Dept Human Gen, CHU Sart Tilman, Liege, Belgium; 2) Neuropediatrie, CHU, Liege, Belgium; 3) Andre Vesale College, Liege, Belgium.

Folates are essential cofactors for a multitude of biological processes such as synthesis and repair of DNA, regulation of gene expression and synthesis of amino acids. Different inherited disorders of folate transport and metabolism are presently known, all of which cause systemic folate deficiency. Steinfeld (2009) identified an inherited brain-specific folate transport defect caused by mutations in the folate receptor 1 (FOLR1). Patients carrying FOLR1 mutations developed progressive movement disturbance, psychomotor decline, epilepsy and showed severe reduced folate concentration in the cerebrospinal fluid (CSF). In this study, we performed molecular analysis of the two folate receptor genes, FOLR1 and FOLR2 in 27 patients showing neurological symptoms and reduced folate concentration in CSF. Both genes (fetal and adult form) were studied by direct sequencing. Analysis was restricted to coding region and intronic bounderies. Three variants, including one splice variant, were identified but none of them affect the coding sequence. Familial study was performed for all the variants. The results lead to the conclusion that none of these variants were pathogenic. Despite the confirmed cerebral folate deficiency, we were not able to explain this deficiency by inactivation of the folate receptor genes.

2671/F

Whole exome sequencing identifies novel, nonsynonymous variants in a large pedigree with Tourette Syndrome. *S.K. Sundaram, A.H.M. Huq, B.J. Wilson, Z. Sun, W. Yu, L. Bennett, H.T. Chugani.* Pediatrics and Neurology, Wayne state university, Detroit, MI.

Objectives: To identify the causal mutation(s)/polymophisms in a large pedigree with Tourette Syndrome using whole exome sequencing. **Methods:** Nine members of a 3 generation pedigree with five showing Tourette Syndrome/chronic tic phenotype were evaluated with whole exome sequencing. Nimblegen 2.1M human exome microarray was used to prepare the exome library. The library contains approximately 180,000 exons targeting 34 million bases of the genome. Sequencing was performed with the Illumina Genome Analyzer II. Approximately 35 trillion bases of sequence data were obtained from the 9 subjects. The ELAND algorithm was used to align the reads to reference human genome (UCSC hg18) and single nucleotide polymorphisms (SNPs) were identified by filtering genomic positions with greater than 8x coverage and phred-scaled consensus quality greater than 20. Those variants that are known in dbSNP database were excluded. Novel, nonsynonymous SNPs that perfectly segregate with chronic tic phenotype under the assumption of autosomal dominant inheritance were identified. **Results:** We identified a list of 17 novel, nonsynonymous variants (clustered into 5 genomic regions) that segregate with chronic tic phenotype. While these variants were present in all the affected members, only 2 variants were not present in any of the unaffected members. The remaining 15 variants were present in all of the affected members and in one of the unaffected members. The inability to reduce to a single variant could be due to chance segregation of non-pathogenic variants, base calling/alignment errors or complex/oligogenic inheritance. **Conclusion:** Exome sequencing identifies 17 novel, nonsynonymos candidate variants in a multigenerational family with Tourette syndrome. Further studies in a larger sample, functional studies and improved base calling/alignment algorithms will clarify the importance of these variants in Tourette Syndrome.

2672/F

A case-control study focusing on rare variants obtained by comprehensive resequencing of the causative genes for familial amyotrophic lateral sclerosis (ALS) to identify disease-relevant alleles for sporadic ALS. *Y. Takahashi[1], J. Goto[1], A. Toyoda[2], A. Fujiyama[2], S. Tsuji[1].* 1) Dept Neurology, Univ Tokyo, Tokyo, Japan; 2) Research Organization of Information and Systems, National Institute of Genetics, Shizuoka, Japan.

[Background] Molecular pathogenesis of the majority of SALS patients remains unknown. Accumulating evidences suggested that resequencing of disease-related genes in patients might reveal multiple rare variants potentially associated with disease risks. However, resequencing of controls should also be necessary in order to conduct unbiased evaluation of the relevance of these rare variants to disease pathogenesis. [Object]To identify causative mutations and rare variants potentially associated with disease risks for SALS. [Subjects and Methods] One hundred and sixty SALS patients and 260 controls were enrolled in this study. All the exon and flanking intron sequences of *SOD1*, *ALS2*, *DCTN1*, *VAPB*, *CHMP2B*, *ANG* and *TARDBP* were analyzed employing a DNA microarray-based resequencing system TKYALS02. Resequencing of these genes in controls and that of *FUS* in patients and controls were conducted employing direct nucleotide sequence analysis. [Result]Three known causative mutations including *SOD1* S134N, *TARDBP* N352S and *FUS* R521C were found in 4 patients. In addition, twelve novel nonsynonymous variants were found, including those in *SOD1* (C6Y), *ALS2* (Q435L, P1016T, F1453C), *DCTN1* (D431G, G462E, Q738R, T778A, R997W), *CHMP2B* (E173A), *ANG* (N49S) and *FUS* (G206S). Resequencing of controls also revealed 13 novel nonsynonynous variants, including those in *ALS2* (P522L, R1330H, T1472M), *DCTN1* (A173V, R225W, Q488R, L615I, Q738R, R1261Q), *VAPB* (K188R), *CHMP2B* (P178H) and *FUS* (S147R, F353L). [Discussion]This study revealed unexpected abundance of novel nonsynonymous variants in controls as well as in SALS patients in the causative genes for FALS. This implied that the interpretation of the rare nonsynonymous variants specifically identified in SALS except for the three known causative mutations remained elusive, because the enrichment of multiple rare variants in these genes was not observed in SALS patients. Three novel nonsynonymous variants (*SOD1* C6Y, *ANG* N49S and *FUS* G206S) identified in SALS patients are likely disease-relevant alleles, because they were not identified in controls and located in mutation-clustered regions. Large-scale resequencing-based case-control studies or functional studies of identified variants will be necessary to confirm the implications of these rare nonsynonymous variants in SALS pathogenesis.

Copy Number Variations may be associated with the Chinese Autism patient. *ZM. Hu[1,3], GL. Xun[2], Y. Peng[1], XP. Li[1], LW. Long[1], Q. Pan[1], ZH. Zhang[1], XJ. Zhang[4], JP. Zhao[2], K. Xia[1,3].* 1) State key Laboratory of Medical Genetics, Central South University, 110 Xiangya Road, Changsha, Hunan, China; 2) Department of Psychiatry, Xiangya 2nd Hospital, Central South University, Changsha, Hunan, China; 3) The School of Biological Science and Technology, Central South University, Changsha, Hunan, China; 4) Institute of Dermatology and Department of Dermatology at No.1 Hospital, Anhui Medical University, Hefei, Anhui 230022, China.

Autism spectrum disorder (ASD) is a highly heritable neurodevelopmental disorder, recently study reveals copy number variations (CNVs) play an important role in pathogenesis of ASD. To assess the association between rare CNVs and autism in Chinese population, we screened 991 subjects (431 cases, 280 trio pedigrees) using HumanCNV370-Quad v3.0 SNP arrays. 1084 control samples were also genotyped with HumanCNV370-Quad v3.0 (90 samples) or Human610-Quad bead chip (994 samples). Four different copy number states using PennCNV software were detected. For the CNV calls from all ASD subjects, we identified 1037 homozygous deletions (CN=0), 14751 hemizygous deletions (CN=1), 4959 duplications (CN=3), and 77 duplications (CN=4). For the CNV calls in controls (90/994), we identified 109/1129 homozygous deletions (CN=0), 1116/12761 hemizygous deletions (CN=1), 341/12633 duplications (CN=3), and 8/1936 duplications (CN=4). In total, 21 autism-specific CNVs (>1M) were identified in ASD patients. Two duplications of 15q11-q13 known to be associated with ASD were identified. Duplications of 3p26.3 were confirmed in 2 ASD subjects. This variable region includes contactin 4 isoform c precursor (*CNTN4*) gene, which may play a role in the formation of axon connections in the developing nervous system. The other 17 CNV include 5p14, 20q13.31-q13.33 etc. Our study supports a role for rare CNVs in autism susceptibility.

A genome-wide evaluation of exonic copy number variations (eCNVs) in autism spectrum disorders. *D.Q Ma[1], H.N Cukier[1], A.J Griswold[1], D. Salyakina[1], J.M Jaworski[1], S. Williams[2], R. Menon[3], I. Konidari1[1], P.L Whitehead[1], J.R Gilbert[1], M.L Cuccaro[1], J.H Haines[2], M.A Pericak-Vance1[1].* 1) Hussman Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL;; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 3) Emory University (Department of Epidemiology and Department of OB & Gyn, Rollins School of Public Health, Emory University, Atlanta, GA.

Recent studies have shown consistent association of rare, large CNVs with autism spectrum disorders (ASDs) although the functional impact of common CNVs in ASDs remains uncertain. A comprehensive genome-wide evaluation of CNVs was carried out in an ASD case control study using samples of European ancestry, genotyping on the Illumina Human 1M Beadchip and utilizing PennCNV for CNV detection. A total number of 817 unrelated ASD cases and 593 pediatric controls survived the stringent quality control of sample call rate, intensity quality and population stratification. CNVs falling into centromeric, telomeric and DNA-origin artifact segment regions were excluded. Our preliminary results indicate a significantly heavier eCNV burden in cases rather than the global CNVs. This is mainly from exonic deletions (eDels) of all sizes (p=2.7e-05[10 vs 8], 10e-06[571kb vs 375 kb], 0.009[55 vs 47 kb] for the number of Dels per sample, total length spanned and average segment size respectively). Thus, the CNVs having ≥ 5 contributing SNPs and overlapping exonic regions were included in the analysis. We first examined large CNVs and found 15 Dels larger than 1Mb exclusively in ASD implicating potential novel CNV regions at 4q12,10q11,13q12 and 7p13. Secondly, we examined eCNVs of all sizes. Overall, 36 eCNV regions (27 eDels and 9 eDups) presented significant associations with empirical P-values ranging from 10e-06 to 0.047 using genome-wide permutation correction. Several novel candidate genes were revealed including Neurofibromatosis 1 (NF1) and ADAM8, however, both merit further validation. The final analysis targeted on rare case-unique eCNVs, of which 4418 were identified. These included CNVs in previously reported candidate gene regions NRXN1(Del: N=5), SHANK3(Del: N=2), CNTN4(Dup: N=1), PTEN(Del: N=6), EN2(Del: N=6), DISC1(Dup: N=1), GABRG1(Del: N=2), and PARK2(Del: N=3). However, no cases carry either exonic or intronic CNVs in recently reported candidate genes CNTNAP2, SHANK2, BZRAP1, SYNGAP1 and DLGAP2. In addition, our analysis reveals an enrichment of case-unique eCNVs disrupting novel candidate genes involved in signal transduction (DOCK1, SDCBP2), cytoskeleton arrangement (NCAM2, SLITRK5) and cell adhesion (COL27A1, CDH8, CDH13, CDH17). In conclusion, our results suggest the possible involvement of common eCNVs in specific biological pathways as contributing to autism risk and target more novel potential ASD candidates for further validation.

Enrichment of rare inherited and de novo copy number variants in autism. *A. Nord[1], W. Roeb[2], D. Dickel[1], T. Walsh[2], M. Kusenda[3,4], K. Lewis[5], D. Malhotra[6], S. McCarthy[3], C. Rippey[1], S. Stray[2], S. Taylor[2], J. Sebat[6], B. King[7], M-C. King[1,2], J. McClellan[8], STAART Psychopharmacology Network.* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Medical Genetics, University of Washington, Seattle, WA; 3) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 4) Graduate Program in Genetics State University of New York, Stony Brook, NY; 5) National Institute of Standards and Technology, Gaithersburg, MD; 6) Department of Psychiatry, Department of Cellular and Molecular Medicine, Institute for Genomic Medicine, University of California, San Diego, La Jolla, CA; 7) Seattle Children's Hospital, University of Washington, Seattle, WA; 8) Department of Psychiatry, University of Washington, Seattle, WA.

Previous studies have demonstrated that individuals with autism are significantly more likely than controls to harbor large de novo copy number variants (CNVs). We tested whether individuals with autism are also more likely to harbor extremely rare, smaller CNVs (≥ ~10 kb), either de novo or inherited. Subjects were 41 probands with autism and their parents and 367 NIMH controls. Controls were split into a population copy number polymorphism discovery set (n=244) and a rare CNV analysis set (n=123). Based on evaluation of genomic DNA by high-resolution array comparative genomic hybridization (Nimblegen HD2 platform), 63% of cases and 41% of controls carried a rare deletion that impacted a gene or genes (OR = 2.52, P=0.02). Enrichment in autism cases was greater for deletions than for duplications and increased with CNV size. Rare CNVs in cases disproportionately included genes associated with DNA binding and transcriptional regulation, nervous system development, and signaling. De novo deletions and rare inherited CNVs in patients disrupted genes and genomic regions previously linked to autism, including PRODH, CNTNAP2, GRIK2 and chromosomes 15q11 and 11p15. Collectively these results implicate smaller, rare, inherited CNVs, as well as large, de novo CNVs, in the pathogenesis of autism.

2676/F

Exploring the correlations between mutations in EFHC1 and the phenotype of patients with juvenile myoclonic epilepsy. *F. Conte[1], T. Peluzzo[1], L. Betting[2], F. Cendes[2,3], I. Lopes-Cendes[1,3].* 1) Dept Medical Genetics, UNICAMP, Campinas, SP, Brazil; 2) Dept of Neurology, UNICAMP, Campinas, SP, Brazil; 3) CInAPCe Program, Brazil.

Purpose: Mutations in EFHC1 were implicated with some types of idiopathic generalized epilepsies (IGEs), mainly juvenile myoclonic epilepsy (JME), in rare patients from Central America, Europe and Japan. It was recently shown that EFHC1 associates with microtubules, being a component of the centrosome, the mitotic spindle and of flagella and cilia. In neurons, it was observed that EFHC1 loss-of-function interferes with the organization of the mitotic spindle, arrests cell cycle, induces the aggregation of microtubules and increases the rate of apoptosis. Moreover, it was shown that during the development of central nervous system, EFHC1 participates in the process of radial migration, controlling both the division of neuronal progenitors as well the locomotion of post-mitotic neurons. Thus, EFHC1 loss-of-function could lead to changes in cortical and sub-cortical architectures, which may be one of the causes of IGEs. The aim of this study was to search for mutations in EFHC1 in a large group of unrelated patients with JME and to explore the presence of genotype-phenotype correlations. Method: Genomic DNA of 52 unrelated patients with JME was submitted to direct sequencing. The chromatograms were analyzed for the presence of polymorphisms and/or mutations by the alignment with EFHC1 sequences available in the public databases. Results: We found mutations in 4 out of 52 patients, which give a frequency of 7.7%. There were two different mutations among the 4 patients. The first was a previously described thymine to cytosine transition in position 685 of exon 4, resulting in a phenylalanine to leucine change. This mutation was observed in 3 patients, corresponding to a frequency of 5.7%, almost 4 times greater than the one reported in a previous work (1.5%). The second mutation has never been reported previously and was found in only 1 patient. It is an adenine to guanine transition in position 896 of exon 5, resulting in a lysine to an arginine (K229R) change. Although there is a change between two positively charged amino acids, its relevance to the pathogenesis of epilepsy is unclear. In addition, we did not find any significant phenotypic difference between patients with and without EFHC1 mutations. Conclusion: We found a higher frequency of EFHC1 mutations than previously reported, including a new missence mutation; however, no clinical differences between patients with and without EFHC1 mutations were observed.

2677/F

Exome-sequencing of medically-intractable juvenile myclonic epilepsy patients. *E.L. Heinzen[1], G.L. Cavalleri[2], M. McCormack[2], S. Alhusaini[2], G. O'Connor[3], R.A. Radtke[4], C. Depondt[5], S.M. Sisodiya[6], N. Delanty[2], D.B. Goldstein[1], EpiGen Consortium.* 1) Center for Human Genome Variation, Duke University Medical Center, Durham, NC; 2) The Department of Clinical Neurological Sciences and Molecular and Cellular Therapeutics, RCSI Research Institute Royal College of Surgeons in Ireland, and Division of Neurology, Beaumont Hospital, Dublin, Ireland; 3) Department of Clinical Neurological Sciences, Division of Neurology, Beaumont Hospital, Dublin, Ireland; 4) Department of Medicine (Neurology), Duke University Medical School, Durham, NC; 5) Department of Neurology, Hoêpital Erasme, Universite' Libre de Bruxelles, Brussels, Belgium; 6) Department of Clinical and Experimental Epilepsy, UCL Institute of Neurology, Queen Square, London, UK.

Juvenile myoclonic epilepsy (JME) is a common form of idiopathic generalized epilepsy. While the majority of patients with JME are well-controlled on antiepileptic medications, a small fraction of patients continue to have seizures regardless of pharmacotherapeutic interventions. Despite high estimates of heritability of this disorder, few genetic variants have been identified that clearly confer risk of JME. In this study we sought to identify genetic variants that increase JME susceptibility using next-generation sequencing. Agilent's All Exon capture technology was used to sequence the exomes of 50 refractory JME patients. One hundred exome or whole-genome sequenced controls, not enriched for seizure phenotypes, were used to evaluate the frequency of candidate rare variants and to ascertain the likelihood of the variants increasing the risk for JME. Alignments of the sequenced fragments to the reference genome were performed using BWA software. Approximately 165000 exons (~18500 genes) were targeted with this technology, and on average we successfully sequenced >96% of these exonic regions (success defined by >80% of the bases comprising the exon sequenced with >5-fold coverage). Single nucleotide variants (SNVs) and small insertion-deletions (indels) were called from the sequence data using SAMTools. Annotation and statistical analyses were performed with Sequence Variant Analyzer. On average, 23638 high-quality SNVs and 1908 indels were identified in each sequenced JME exome, including approximately 600 SNVs and 165 indels predicted to alter the coding sequence of the protein and not observed in any control sample. Similar numbers of variants, both rare and common, were observed in control exomes. Targeted analysis of *GABRA1* and *EHFC1*, Mendelian genes known to harbor susceptibility variants to JME, identified no rare, functional mutations in patients with JME. One rare, intronic, heterozygous variant, not observed in any sequenced control, was observed in *GABRA1* in one JME patient. To evaluate the likelihood of all candidate susceptibility variants identified in the exome-sequencing data to impact susceptibility to JME, we genotyped the mutations in 200 non-refractory JME patients, in more than 2000 neuropsychiatrically-normal controls, and also in a subset of affected and unaffected family members of exome sequenced JME patients. We continue to explore the possibility that rare variants likely contribute to the susceptibility of refractory JME.

2678/F

A familial whole-genome sequencing approach to identify genetic variants influencing epilepsy susceptibility. *E.K. Ruzzo[1,3], E.L. Heinzen[1,3], R. Ottman[2,3], D.B. Goldstein[1,3].* 1) Center for Human Genome Variation, Duke University School of Medicine, Durham, North Carolina 27708, USA; 2) G. H. Sergievsky Center and Departments of Epidemiology and Neurology, Columbia University, and Division of Epidemiology, New York State Psychiatric Institute, New York, NY, USA; 3) Epigen Consortium.

Epilepsy susceptibility has clear a genetic component, but, despite years of research, the etiology of the vast majority of cases remains elusive. We have a unique cohort of multiplex epilepsy families that has enabled a new approach to primary discovery of epilepsy variants. We postulated that relatives harboring a rare, highly penetrant contributor to epilepsy explain the high incidence of non-acquired epilepsy in most of these families (average of 8 affected per family). Under this model, screening whole-genome sequences (WGS) for rare variants shared by related coaffecteds will identify a small set of candidates. To reduce the number of nonpathogenic shared variants, we selected the two most distantly related coaffecteds from each family. We obtained WGS data from 18 epilepsy patients-two in each of nine multiplex families. All 18 genomes were sequenced to an average coverage of ~31x using the Illumina GAIIx, and aligned to the reference genome using BWA software. Single nucleotide variants and small insertion-deletions were called using SAMTools software. We annotated and analyzed all identified variants using Sequence Variant Analyzer software. The genomes of affected relative pairs from each family were analyzed simultaneously to identify rare shared functional variants. We defined functional variants as nonsynonymous, protein truncating, or splice site-disrupting variants, and rare variants as those present at a frequency lower than the cumulative incidence of epilepsy in the general population (~3%) based on comparison to HapMap and a set of 80 whole-genome or whole-exome sequenced controls from our laboratory. No variant was present in all 18 epilepsy genomes and no shared functional variants were found in any of 12 genes already known to play a role in Mendelian forms of epilepsy. The number of rare, shared functional variants averaged 108 (min 49, max 201) across the 9 families. Very few of the shared variants were found in multiple families, indicating that different genetic factors are responsible for epilepsy in most of the families. This work defines a set of 974 candidate variants that can be followed up by genotyping in larger cohorts, and in other members of the same families. This work demonstrates that sequencing of coaffecteds in multiplex families is a powerful strategy for reducing the number of candidate variants emerging from sequencing studies.

2679/F

Novel mutation in the NF1 gene associated with an atypical NF1 clinical presentation. *S.L. Sawyer[1], L. MacLaren[1], C. White[2], O. Suchowersky[1,2].* 1) Department of Clinical Medical Genetics, Alberta Children's Hospital, Calgary, Alberta, Canada; 2) Department of Clinical Neurosciences, University of Calgary, Alberta, Canada.

Care Presentation: A 45 yo patient was seen in the Neurogenetics clinic for assessment of possible Neurofibromatosis. He had multiple intraspinal and plexiform neurofibromas and bilateral Lisch nodules, but no café au lait macules or axillary freckling. He also has a peripheral neuropathy, for which no other cause could be identified. Other affected family members had similar findings. The NFI gene was sequenced in this patient, and an unclassified missense mutation was found that was not present in 2000 controls. Bioinformatic analysis suggested that the mutation was likely pathogenic; it was highly conserved evolutionarily and Polyphen predicted the amino acid changing variant to be probably damaging. Sequencing of the NF1 gene in his unaffected sister and his affected mother showed that his mother carried the same c.6905T>C polymorphism, and his healthy sister did not, thus demonstrating that the mutation is segregating with the disease in this family and lending further evidence for its' pathogenicity. To our knowledge this is the first report of a NF1 phenotype associated with the c.6905T>C mutation. In our family, intraspinal neurofibromas and a peripheral neuropathy are the main clinical features.

The development of high-throughput gene scanning system for autism spectrum disorders by a PCR coupled high-resolution melting curve analysis. *K. Yanagi[1], T. Kaname[1], K. Morita[2], S. Ikematsu[2], H. Maehara[1], Y. Fukushima[3], K. Naritomi[1].* 1) Dept Medical Genetics, Univ Ryukyus, Nishihara, Japan; 2) Dept Bioresources Engineering, Okinawa Natl College Technol, Okinawa, Japan; 3) Dept Medical Genetics, Shinshu University, Graduate School of Medicine, Matsumoto, Japan.

It is important to establish an easy and reliable system to detect mutations or variations for gene examination and genetic association study. High-resolution melting curve analysis (HRM analysis) is a method, which allows simple and rapid detection of gene variations. We developed a system for scanning gene variations in *NLGN3*, *NLGN4X*, and *c-MET*, which mutations were found in the patients with autism spectrum disorders (ASDs). There is a possibility that those variations are associated with ASDs. Since it is, however, estimated that small number of patients will be affected by variations in those genes, a scanning system is needed to investigate correlations between the gene variations and ADS patients, which allows rapid detection of variations in large scale. We set up the PCR/HRM system for exons of the *NLGN3*, *NLGN4*, and *c-MET* gene using combination with SYTO9 fluorescent dye (Invitrogen), Ex-Taq polymerase (TAKARA), and LightCycler 480 Instrument (Roche). Evaluation of the PCR/HRM system for those genes in 48 Japanese controls by confirming direct sequencing, resulted complete detection of all the known and novel variations. Next, we scanned variations in those genes in 62 ASD patients. The novel three variations were found in each gene. The system is a valuable method for rapid and reliable detection of variations in ASD patients.

Deep resequencing in a family with X-linked ataxia dementia. *N. Pankratz[1], B. Craig[2], B. Marosy[2], K. Hetrick[2], J. Rosenfeld[1], L. Padgett[1], E. Pugh[2], H. Ling[2], M. Barnhart[2], S. Griffith[2], M. Econs[1], M. Farlow[1], K. Doheny[2], T. Foroud[1].* 1) Indiana University School of Medicine, Indianapolis, IN; 2) Center for Inherited Disease Research (CIDR) and Genetic Resources Core Facility (GRCF) High Throughput Sequencing Center (HTS), John Hopkins School of Medicine, Baltimore, MD.

X-linked ataxia dementia (XLAD) is a neurodegenerative disease with early-onset ataxia, pyramidal tract signs, and adult-onset progressive dementia. Linkage analysis using the only known kindred with this syndrome yielded a maximum LOD score of 5.29 with DXS1231 at θ=0. Key recombinants delineated a 24 Mb region using microsatellite markers. Illumina Omni1-Quad array data ruled out the presence of a large causative CNV and narrowed the region further to ~19 Mb. Next generation sequencing of the X chromosome for two affected cousins and one of their unaffected siblings was then performed in collaboration with the Center for Inherited Disease Research (CIDR). The Agilent SureSelect Human X Chromosome Demo Kit was used to capture exons on the X chromosome and was followed by 75 bp paired-end sequencing using the Illumina GAIIx. BWA was used to align the data, and consensus base calling was performed with SAMtools. Average capture specificity was 79.0%, and ≥10X depth was achieved for 98.7% of targeted bases. Variants were filtered for presence in both affected cousins and absence in the unaffected brother. Given the rarity and severity of the phenotype, all SNP and indel variants present in dbSNP were excluded from further consideration. Four short indels (i.e. <10 bp) were reviewed using the Integrative Genomics Viewer (IGV); however all are present in the pilot 1 dataset of the 1000 Genomes Project. Three nucleotide substitutions located in an exon or UTR were present in the 19 Mb region in both affected cases. One is a synonymous variant in exon 8 of NOX1, chrX:99992932C->T, and is predicted by SKIPPY (http://research.nhgri.nih.gov/skippy/) to introduce 3 exon splicing silencers and thus may cause exon skipping during mRNA processing. Knocking out NOX1 in a mouse model of a neurodegenerative disorder modifies disease severity. Another variant, 102932576G->A, is in the 3' UTR of PLP1, which is associated with Pelizaeus-Merzbacher disease (PMD) where childhood ataxia and cognitive impairment are typical. These variants were not identified in 182 HapMap samples available from pilot 1 of the 1000 Genomes Project. We are currently genotyping these variants in 2000 control subjects and will have additional data to present at the meeting. Identification of the mutated gene in this unique family has the potential to increase our understanding of nervous system function, pathogenesis of neurodegenerative conditions, and possible treatments for such conditions.

Comprehensive resequencing of *PEX5* gene in patients with X-linked adrenoleukodystrophy (ALD) and association studies with the phenotypes of ALD. *T. Matsukawa[1], Y. Takahashi[1], J. Goto[1], Y. Suzuki[2], N. Shimozawa[2], O. Onodera[3], M. Nishizawa[3], S. Tsuji[1].* 1) Dept Neurology, Univ Tokyo, Tokyo, Japan; 2) Gifu University, Gifu, Japan; 3) Niigata University, Niigata, Japan.

Background & Purpose: Adrenoleukodystrophy (ALD) is an X-linked disorder affecting primarily the white matter of the central nervous system occasionally accompanied with adrenal insufficiency. The ages at onset and the clinical presentations of ALD are substantially broad. There are various kinds of phenotypes, like Childhood cerebral ALD (CCALD), Adult cerebral ALD (AdultCer), Adrenomyeloneuropathy (AMN). Despite the discovery of the causative gene, *ABCD1*, clear genotype-phenotype correlations have not been established. *ABCD1* gene encodes adrenoleukodystrophy protein (ALDP), which is localized to the peroxisomal membrane. *ABCD1* mutant mice show a milder AMN phenotype. On the other hand, mice lacking *PEX5* gene expression, which is related to formation process of peroxisome, in their oligodendrocytes develop cerebral demyelination involving the corpus callosum and the anterior commissure as occurs in CCALD. Association studies based on SNPs identified by comprehensive resequencing of gene related to *ABCD1* may reveal genes modifying the phenotypes of ALD. The purpose of this study is to investigate genotype-phenotype correlations and to explore the possibility of *PEX5* as the disease modifying gene. **Methods:** We analyzed 51 Japanese patients with ALD (CCALD 14, Adlescent Cerebral ALD 3, AdultCer ALD 6, AMN with cerebral (AMN-Cer) ALD 4, Cerebellobrainstem ALD 2, AMN 16, Addison disease 1, asymptomatic 2 and Unknown 3). Sequences of all of the exons, introns around the exon-intron boundary, 5'UTR and 3'UTR were analyzed by direct nucleotide sequence analysis. **Result:** 2 novel non-synonymous SNPs in exon, 1 novel SNP in intron, 2 novel SNPs in 3'UTR and 2 known SNPs in 3'UTR were detected. SNPs identified by comprehensive resequencing of *PEX5* were used for association studies. There were no significant associations between these SNPs of *PEX5* and ALD phenotypes in the Japanese population. **Conclusion:** The present study indicates that *PEX5* are less likely the disease modifying genes, necessitating further studies to identify genes modifying the phenotypes of ALD.

Familial Schizophrenia, Complete Genome and Exon Sequence Analysis. *C.T. Caskey[1], S. Sims[1], M.L. Gonzalez-Garay[1], A.J. Marian[1], A. Wassef[2], A. Swann[2], N. Williams[2].* 1) UT - IMM, Houston, TX. 1825 Pressler Street, Ste. 205 Houston, TX 77030; 2) Harris County Psychiatric Center 2800 South MacGregor Way Houston, TX 77021.

The genetic basis of schizophrenia is well established clinically and by molecular population studies using SNP and copy number variant (CNV) analysis. Heterogeneity of the genetic basis of the schizophrenia phenotype is anticipated. We have studied families with multiple affected individuals from the Harris County Psychiatric Center, in Houston, by complete genome sequencing with two approaches - 1) whole exome capture and deep sequencing (Illumina GAIIx), and 2) whole nuclear genomic DNA sequencing (Complete Genomics, Inc., Science- 1 January 2010 Vol 327). The observed sequence changes are being validated by comparison of results from both sequencing approaches. Where appropriate any candidate variants found are further confirmed by still a third method (genotyping or Sanger sequencing). Our study utilizes human genetics and complete genome sequencing to identify disease gene candidates for individual families. Families have been selected and the sequencing has been completed. Bioinformatic analysis focuses on non-synonymous coding and splice junction alterations, in addition to CNV analysis. We correlate any sequence variants discovered with known SNPs, CNVs, and regional brain gene expression of candidate alleles. Thus, we utilize a systems biology approach to candidate gene identification, taking into account family pedigrees, sequence variants, knowledge of pathways involved and expression information. The studies identify gene candidates for schizophrenia. New disease/gene candidates are the focus of our presentation.

2684/F

Comprehensive variant discovery in the new Late-Onset Alzheimer Disease susceptibility gene MTHFD1L using next-generation sequencing technology. *M.A. Kohli[1], J.M. van Baaren[1], N.C. Naj[1], G.W. Beecham[1], J.L. Haines[2], J.R. Gilbert[1], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, FL, USA; 2) Vanderbilt Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA.

Genome-wide association studies (GWAS) of Late-onset Alzheimer disease (LOAD) have consistently observed associations with APOE variants, and until recently, few statistically significant associations at other loci have replicated across studies. We recently reported a statistically significant association of rs11754661 with LOAD ($P=4.70\times10^{-8}$; Bonferroni-corrected P=0.022), a chromosome 6q25.1 single nucleotide polymorphisms (SNP) in the gene MTHFD1L (encoding the methylenetetrahydrofolate dehydrogenase 1-like protein) and we replicated this finding from our discovery GWAS of 932 cases and 1,104 controls in an independent replication GWAS dataset of 1,338 cases and 2,003 controls at P=0.002 ($P=1.90\times10^{-10}$ in combined analysis of discovery and replication sets).While this strongly associated SNP (odds ratio (OR) = 2.1 (95% confidence interval (CI): 1.7, 2.6) is located in an biological candidate gene which may influence homocysteine levels (a significant risk factor for LOAD), the risk allele of rs11754661 is rare (minor allele frequency = 0.07) and the SNP falls into an intronic region with linkage disequilibrium (LD) extending for only 32.6 kb of the genes total 236.7 kb length. To identify potential LOAD-related functional variants, we initially sequenced the MTHFD1L LD block containing rs11754661 using high-throughput next-generation sequencing (NGS). We captured the target region using amplicons of ~8kb length generated by long-range PCR in 43 LOAD cases and 59 controls, which are homozygotes or heterozygotes for the rs11754661 risk allele and negative for the APOE ε4 allele. Equimolar amounts of each PCR product per individual DNA sample were multiplexed using up to 12 individuals per single lane on an Illumina Genome Analyzer II sequencer to provide sufficient sequence depth for new variant discovery (>1,000-fold).

Analysis of genetic inheritance in autism spectrum disorders by whole exome sequencing. *H. Kuwabara[1], T. Shimada[3], M. Bundo[2], T. Sasaki[4], C. Kakiuchi[3], Y. Kano[1], K. Iwamoto[2], M. Tochigi[3], K. Kasai[3].* 1) Department of Child Psychiatry, Graduate School, Tokyo, Japan; 2) Department of Molecular Psychiatry, Graduate School of Medicine, University of Tokyo; 3) Department of Neuropsychiatry, Graduate School of Medicine, University of Tokyo; 4) Office for Mental Health Support, University of Tokyo.

Introduction: Although heritability of autism spectrum disorders (ASD) is up to 90%, genetic factors remain largely unknown. Genome-wide association studies revealed that common genetic variants explain a modest fraction of heritable risk for ASD, suggesting the important role of rare variants to the unexplained heritability. Recently, whole-exome sequencing combined with a series of refined filtering methods has proven to be effective to identify the gene underlying a Mendelian disease (Ng et al., Nature Genetics 2010). Furthermore, such approach is likely to provide important insights into the pathogenesis of complex disorders such as ASD. Method: We selected a multiplex family with Autism spectrum disorder, consisted of members across four generation, for exome analysis. The family includes a son and a mother with Asperger's disorder, grandfather and great grandfather with pervasive developmental disorders not otherwise specified (PDDNOS). Exome sequencing is performing on a son with Asperger's disorder and non-affected father and grandmother. Results: Identification of the pathogenic mutations is underway. To identify the pathogenic mutations, we are focusing on novel and nonsynonymous variants. In addition, we are comparing the variants between a patient and non-affected family members to scrutinize the pathogenicity. Conclusion: We discuss the availability of exome sequencing in a selected patient to identify the pathogenic mutations in the complex neuropsychiatric disorders such as ASD.

Extra-cerebral biallelic expression of the UBE3A gene: contribution to Angelman syndrome (AS) diagnosis. *C. Flament, J. Amiel, G. Royer, S. Lyonnet, J. Wong, A. Munnich, JP. Bonnefont, S. Gobin-Limballe.* INSERM U781, Paris Descartes University, Necker Hospital, Paris, France.

UBE3A anomalies, such as 15q maternal deletions, paternal 15q uniparental disomies, 15q imprinting center mutations, and mutations of UBE3A itself, are responsible for AS. The UBE3A gene (15q11-q13) is an imprinted gene, maternal monoallelic expression of which is restricted to specific cerebral areas, while its expression pattern is biallelic in other tissues. We took advantage of this particular pattern of expression to establish AS diagnosis in two unrelated children carrying a same atypical UBE3A sequence variant. 15q FISH and methylation profile at the SNRPN locus were normal in each of them. We identified in both a same heterozygous 14-bp deletion of UBE3A with a proximal break point at 21 nt downstream of the stop codon. This 3' UTR sequence variation had not previously been described as a disease-causing mutation or a neutral polymorphic variant, and no other sequence abnormality could be detected in coding exons and exon-intron junctions as well. Predicting softwares indicated that this deletion could alter hnRNPA1 protein binding to the UBE3A mRNA and therefore cause RNA instability. While the disease-causing effect of this deletion could neither be confirmed nor be excluded in Family 1, based on its familial transmission (inheritance from the healthy mother and maternal grandfather), it was finally excluded in Family 2 owing to its presence in the asymptomatic father and brothers. In an attempt at identifying a mutation undetected at the genomic level, we then analyzed the UBE3A cDNA, using RNA extracted from blood sample. In Family 2, cDNA sequencing detected the deletion at heterozygous state thus confirming the biallelic expression of UBE3A in white blood cells, but failed to detect any deleterious anomaly. In Family 1 however, the 14-bp deletion was no longer present in the proband's cDNA, suggestive of mRNA decay and therefore of the presence of a truncating mutation in cis of the 14-bp deleted allele. This putative mutation could however not be detected. This observation illustrates that the lack of extra-cerebral imprinting of UBE3A provides an easy access to both maternal and paternal co-expressed RNA species, thus enabling detection of mutations that escape analysis at the genomic DNA level.

2687/F

Rare Variants in Nicotinic Acetylcholine Receptors are Associated with Nicotine Dependence. *G. Haller[1], J. Budde[1], F. Vallania[2], T. Druley[2], R. Mitra[2], D. Hatsukami[3], J. Rice[1], L. Bierut[1], A. Goate[1].* 1) Department of Psychiatry, Washington University , Saint Louis, MO; 2) Center for Genome Sciences, Washington University, Saint Louis, MO; 3) Tobacco Use Research Center, University of Minnesota, Minneapolis, MN.

Genome-wide association studies (GWASs) have identified variation in both the *CHRNA5-CHRNA3-CHRNB4* and *CHRNA6-CHRNB3* gene clusters that contribute to nicotine dependence (ND). However, variation in these and the other nicotinic receptor genes have not been studied in depth in African American populations. Sequencing individuals at the extremes of a phenotypic distribution can be a powerful approach to identify novel associated variants. Rare (minor allele frequency <5%) variants, while individually infrequent, make up a large proportion of genetic diversity when taken in aggregate. To identify novel variants associated with nicotine dependence in African Americans we pooled DNA samples from individuals based on their Fagerström Test of Nicotine Dependence (FTND) score and the number of cigarettes smoked per day (CPD). In total, 176 nicotine dependent heavy smokers (FTND>5, mean CPD = 29) and 176 light smoking controls (FTND<1, mean CPD = 5) from the Collaborative Genetic Study of Nicotine Dependence (COGEND) were studied. The coding regions of each of the neuronally expressed nicotinic acetylcholine receptor (CHRN) genes (*A1-7, A9, A10, B1-4, G*, and *D*) were sequenced for each pool using Illumina sequencing. Variant locations and allele frequencies were then determined using algorithms that utilize large deviation theory to differentiate between polymorphisms and sequencing errors. Individuals comprising the sequenced pools were subsequently genotyped at all loci predicted to be polymorphic to confirm the sequencing results. Twenty-five novel missense SNPs in 11 genes (*A1,A2,A4,A5,A9,A10,B1,B2,B4,D,G*) were identified by this method and validated by Sequenom genotyping. To increase analytical power, we collapsed missense variants, both known and novel, in each gene into one aggregate genotype before running tests of association. Using a linear regression model, we find that carriers of missense variants in *CHRNA1* and *CHRNB4* have decreased CPD compared to non-carriers (*CHRNA1* P= 0.002, *CHRNB4* P=0.006), suggesting a protective role of variants in these genes with respect to the development of nicotine dependence. We tested each gene with at least two missense variants (8 genes) for association in this manner, making both of the above associations significant after correcting for multiple tests (Bonferroni P-value cutoff = 0.00625). This is the first example of an association between either *CHRNA1* or *CHRNB4* and a nicotine dependence phenotype.

2688/F

Genetic variation in APOE and neighbouring genes and risk of Alzheimer's disease. *S. Cervantes[1], Ll. Samaranch[1], J.M. Vidal[2], M.J. Bullido[3], F. Coria[4], A. Lleó[5], J. Clarimón[5], P. Pastor[1].* 1) Neurogenetics Laboratory, Center for Applied Medical Research, Pamplona, Navarra, Spain. Department of Neurology, Clínica Universidad de Navarra, Pamplona, Spain; 2) Pharmacology Unit, Pathology, Pharmacology and Microbiology Department, University of Barcelona School of Medicine, Barcelona, Spain; 3) Molecular Biology Department and CIBERNED, Instituto de Salud Carlos III, Centro de Biología Molecular Severo Ochoa (CSIC-UAM), Madrid, Spain; 4) Clinic for Nervous System Disorders and Service of Neurology, Hospital Universitario Son Dureta, Palma de Mallorca, Spain; 5) Department of Neurology, Hospital Santa Creu i Sant Pau, Barcelona, Spain CIBERNED, Instituto de Salud Carlos III, Spain.

Background: Genetic factors are responsible for 80% of Alzheimer's disease (AD) risk. Lipid metabolism has been involved in AD pathogenesis. In fact, APOE ε4 is the most important genetic risk factor for AD described thus far, with estimates of late-onset AD risk owing to APOE ε4 being around 50%. In this study we focused on APOE and genes located near APOE locus, such as APOC1, APOC4 and APOC2 and TOMM40. TOMM40 is a channel-forming protein of the outer mitochondrial membrane that could interact with Aβ in AD pathogenesis. Therefore, variants at these genes could alter the normal function of protein products and modulate AD risk. Methods: We performed long-range sequencing of promoter and regulatory regions of APOE, APOC1, APOC4, APOC2 and TOMM40 genes, in 29 subjects with MCI that progressed to dementia. In addition, we sequenced TOMM40 exons. We detected 49 variants, 19 of them novel. We analyzed with MatInspector (www.genomatix.de) effect of variants in transcription factors binding sites (TFBS), and Human Splicing Finder (www.umd.be/HSF/) was used to analyze their influence of splicing sites. Thirty-six variants (6 novel) with a potential regulatory effect were genotyped in 627 healthy controls and 619 subjects with AD. We used PLINK software for association analysis between AD cases and healthy controls. Results: Ten of the genotyped variants located in promoter regions (3 of them novel), had a potential effect in TFBS. Two variants (one of them novel) modified TOMM40 protein sequence. One variant showed a potential effect in modifying splicing of TOMM40 protein. In the single locus analysis, rs439358, which differentiates APOEε4 from non-ε4 individuals showed the strongest association with AD (OR=4.9; IC= [3.9-6.2]; p=1.42x10-46; q= 5.12x10-45). Independent effects analysis suggested that the SNPs rs5158 and rs10413089 could increase risk of AD independently from APOEε4 allele (p=0.009 and 0.01, respectively). Conclusions: Fine sequencing of APOE cluster genes revealed novel variants with a potential effect in transcription regulation and in splicing. Association analysis suggested that two variants near the 3' end of the region analyzed may increase risk of AD independently from APOE ε4 influence. TOMM40 variants analyzed showed no independent effect for AD risk.

2689/F

Exome sequencing of multiplex autistic families to define a risk region on chromosome 12. *H.N. Cukier[1], D.Q. Ma[1], D. Salyakina[1], H.H. Wright[2], R.K. Abramson[2], J.L. Haines[3], M.L. Cuccaro[1], J.R. Gilbert[1], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) University of South Carolina School of Medicine, Columbia, SC; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

There is a strong genetic component to autism, but studies to date have demonstrated that the underlying genetic architecture is complex, with numerous genes potentially involved. One strategy for uncovering these genes is the use of large, extended families with multiple, distantly related, affected individuals. Our previous genome-wide linkage study identified a 4 centimorgan region (75-79 cM) on chromosome 12 that demonstrated significant linkage (HLOD = 4.51) across eleven extended multiplex families with only male affected individuals. Our goal is to comprehensively evaluate the chromosome 12 candidate region in order to identify the genetic abnormalities that underlie the strong autism linkage peak. To test candidate genes for autism in these families we performed next-generation sequencing using the Illumina Genome Analyzer II to identify potential causative variants. We used the Agilent SureSelect Human All Exon kit in order to capture 38 Mb corresponding to the CCDS defined exons. Eight individuals, two affected pairs from four distinct multiplex autistic families, were selected and sequenced in a 2x76 paired end run for an average of 150x coverage. Using the MAQ program (Mapping and Assembly with Qualities), 43,000-53,000 single nucleotide polymorphisms (SNPs) were identified in each sample, with approximately 16,000 exonic variations per individual. We also identified between 3,200-7,000 insertion/deletions in each of our samples. When comparing SNP variants that fall in the chromosome 12 region of interest (60,000-68,000 Mb) in related patients, each family has 37-54 identical alterations between their two autistic individuals. Thus far, we have identified eight SNP variations that are identical across all four extended families, including four missense mutations that fall within *GRIP1*, *IRAK3*, and the hypothetical *C12orf66* gene. *GRIP1* (*glucocorticoid receptor-interacting protein 1*) is a particularly interesting candidate due to its presence throughout the nervous system and role in long-term potentiation. Additional analysis will be performed to determine if variants may cluster across families around a gene of interest. We will also evaluate variations that fall within regions across the genome that have previously been linked to autism. Further cataloguing of variations in these extended autistic families is currently underway and studies are ongoing to determine if any identified alteration play a role in the etiology of ASD.

2690/F

Targeted re-sequencing of a 150kb contiguous genomic region of chromosome 5p14.1 associated with autism. *J.R. Gilbert[1], A.J. Griswold[1], D.Q. Ma[1], H.N. Cukier[1], I. Konidari[1], W. Hulme[1], P. Whitehead[1], J. Jaworski[1], H.H. Wright[2], R.K. Abramson[2], M.L. Cuccaro[1], J.L. Haines[3], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) University of South Carolina School of Medicine, Columbia, SC, USA; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Genome-wide association studies (GWAS) have identified and validated in independent datasets a region with significant association to autism on chromosome 5p14.1. The 150kb peak region of association (25.9-26.1Mb) is flanked by the Cadherin 9 and Cadherin 10 genes located approximately 1Mb proximal and 1.5 Mb distal, respectively. The peak region itself lacks any annotated genes or known regulatory sequence elements, though the clustering of significant association signals suggests that a common variant(s) is responsible for the association. The goal of this study was to sequence the entire peak region of association in an attempt to identify a causative variant(s). We have amplified 145kb of the peak region using long-range PCR amplicons ranging from 5 to 11kb in 49 autism cases and 49 pediatric non-autistic controls. A 5kb region (chr5:26,030,927-26,035,873) was sequenced using traditional Sanger sequencing. Amplicons were pooled in equimolar amounts to generate sequencing libraries for each individual and were sequenced using multiplexed 2x75 paired-end sequencing on the Illumina Genome Analyzer IIx. Sequencing generated an average of 2.8 million reads per individual, corresponding to a depth of coverage of over 2000X over the 145kb target region. The sequencing reads were aligned to the human genome and variants were called using the Mapping and Assembly with Quality (MAQ) software package. Overall, MAQ identified 584 novel variants, 174 unique to cases, 227 unique to controls, and 183 common to both groups. Of the 174 novel variants found only in cases, 136 were identified in only a single case, while 21 were identified in more than 5 cases indicating significant overrepresentation of these variants using the Fisher Exact test. In addition, MAQ found variation at 611previously identified (dbSNP) sites, 20 only in cases, 49 only in controls, and 542 common to both groups. Of the 20 known variants unique to cases, 5 were frequent enough to be statistically significant. An additional 9 novel and 33 known variants, common to cases and controls, show statistical overrepresentation in cases. Cluster analysis of these overrepresented variants show that 19 of the 52 known variants cluster between rs1748297 and rs1835055 (chr5: 25937365-25940689), though no similar clustering is evident in novel variants. Overrepresented variants are being genotyped in a larger dataset and functionally assessed to determine their role in autism risk.

2691/F

Comprehensive re-sequencing of the autism associated GABRα4 to identify potential autism risk functional variants. *A.J. Griswold[1], D.Q. Ma[1], P. Whitehead[1], J. Jaworski[1], J.L. Haines[2], M.L. Cuccaro[1], J.R. Gilbert[1], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Previous studies have demonstrated association of autism with gamma-aminobutyric acid (GABA) receptor subunits, including *GABRα4* on chromosome 4p12. The GABAergic system is responsible for synaptic inhibition in the adult brain and is the key neurotransmitter directing neuron development. To identify functional variants within *GABRα4* contributing to autism risk, we comprehensively re-sequenced the entire gene and its regulatory regions in 84 Caucasian autism cases, homozygous for a previously associated allele (G/G at rs1912960), and 84 non-autistic pediatric Caucasian controls, 55 of which were homozygous for the associated allele. We amplified 88kb covering the entire transcript and 5kb up and downstream of the gene with 10 tiled long-range PCR amplicons. The amplicons were pooled in equimolar amounts to generate sequencing libraries for each individual and were sequenced using multiplexed 2x50 paired-end sequencing on the Illumina Genome Analyzer IIx. Sequencing generated 2.5 million reads per individual, corresponding to a depth of coverage of over 2000X across the 88kb target region. The sequencing reads were aligned to the human genome and variants were called using the Mapping and Assembly with Quality (MAQ) software package. Overall, MAQ identified 342 novel variants of which 87 varied only in cases and 177 only in controls. In addition, MAQ detected 421 previously identified (dbSNP) variants, 7 varied only in cases and 82 only in controls. When analyzing only those homozygous associated allele individuals (84 cases, 55 controls), there were 256 novel variants, 110 only in cases and 91 only in controls, and 175 known variants, 29 varied only in cases and 2 only in controls. In order to correct for genetic background effects, only these individuals were used for subsequent analysis. Since there is no statistical difference in the global burden of variation in cases and controls, and all identified variants were in non-coding regions of the gene, we analyzed individual variants for statistical overrepresentation in cases. Among the variants unique to cases, 6 novel variants were statistically overrepresented using the Fisher Exact test: 3 were within the 13.5kb first exon, 2 in the 3kb third intron, and the sixth located 7kb 5' upstream of the gene. Genotyping of these overrepresented variants in a larger dataset, and assessment of their functional impact is currently underway to determine their role in contributing to autism risk.

The role of KIF gene rare variants in the severity of multiple sclerosis. *A.E. Handel, G. DiSanto, G.C. Ebers, S.V. Ramagopalan.* WTCHG, University of Oxford, Oxford, United Kingdom.

Multiple sclerosis (MS) is a complex disease whose aetiology is generally thought to be a result of autoimmune processes primarily directed against myelin in the central nervous system. However, it is now clear that axonal loss is also a key aspect of MS pathogenesis and underlies the progressive disability seen in most people afflicted with this disease. The majority of genes identified thus far from genome wide association studies in MS have been immunological but recent studies are now identifying single nucleotide polymorphisms (SNPs) in neuronal genes that would be expected to contribute to axonal loss. In particular the kinesin family members KIF1B, KIF5A and KIF21B have been implicated in MS susceptibility. These are attractive candidates for involvement in MS axonal degeneration as they are involved in the transport of vesicles along axonal microtubules. We sequenced the entirety of KIF1B, KIF5A, KIF21B and KIFAP3 in 30 patients with an extremely severe form of MS and compared them to a group of patients with an extremely mild disease phenotype and healthy controls drawn from the HAPMAP project to establish whether any novel/rare variants influenced the clinical course of MS. We identified multiple new rare variants in all of the KIF genes. The frequency of some of these rare variants showed nominally significant differences between the MS and control cohorts. We genotyped further cohorts of MS patients and controls for these rare variants. Sequencing of multiple sclerosis candidate genes offers a powerful method to identify rare variants involved in disease susceptibility. By using an extremes-of-outcome approach we have been able to investigate the role of several candidate regions in the phenotypic expression of multiple sclerosis.

Promoter-wide DNA methylation analysis in neuronal nuclei derived from brains of patients with psychiatric diseases. *K. Iwamoto[1], M. Bundo[1], J. Ueda[2], K. Kasai[3], T. Kato[2].* 1) Department of Molecular Psychiatry, Graduate School of Medicine, University of Tokyo, Japan; 2) Laboratory for Molecular Dynamics of Mental Disorders, RIKEN Brain Science Institute, Japan; 3) Department of Neuropsychiatry, Graduate School of Medicine, University of Tokyo, Japan.

Epigenetic factors are believed to be important for the pathophysiology of major mental disorders such as schizophrenia, bipolar disorder and major depression. Although several studies have tried to identify the epigenetic mutations in brains of patients, interpretations of their results are usually difficult due to many confounding factors. One of main factors would be the cellular complexity in the brain. We have previously developed the method for the separation of neuronal and non-neuronal nuclei from the fresh-frozen postmortem brain, and have successfully performed genome-wide DNA methylation analysis. Here we performed a large-scale neuronal and non-neuronal methylation analyses using brains of patients with bipolar disorder (N = 35) as well as controls (N = 35). Neuronal and non-neuronal nuclei were obtained with the NeuN-based cell sorting using the brain samples obtained from the Stanley Medical Research Institute. Methylation profile was obtained using an Affymetrix promoter tiling array. Using the control subjects, we confirmed our previous finding of higher inter-individual variations in neuronal nuclei compared to non-neuronal nuclei. We did not observe the significant effects of sample pH, age and postmortem interval on the number of methylated genomic regions. In bipolar disorder, we identified several DNA methylation difference compared to control subjects. Some of differences were only found in neuronal nuclei. Our study revealed the importance of considering the cellular heterogeneity in brain in epigenomic studies using brains of patients with psychiatric disorders.

Exome capture for targeted resequencing in French Canadian patients with familial Essential Tremor (ET). *N. Merner[1], C. Bourassa[1], S. Girard[1], J. Gauthier[1], S. Diab[1], S. Chouinard[1], N. Dupre[2], P. Dion[1], G. Rouleau[1].* 1) Centre de Recherche du CHUM, Université de Montréal, Montreal, Canada; 2) Department of Neurological Sciences, CHA - Enfant-Jésus, Quebec City, Canada.

ET is one of the most common neurological disorders. It is characterized by postural tremor, which worsens with movement. The clinical phenotype is variable and a lack of consensus on diagnostic criteria has resulted in 30-50% of patients previously diagnosed with ET to be misdiagnosed. Most studies indicate that ET is hereditary in 50-70% of patients. Studies of large ET families have shown that a family history of ET usually means an early age of onset, and the phenotype is usually fully penetrant by the age of 65. Linkage studies on families with ET have identified three ET loci, but no causative gene has been identified. More recently, common sequence variants in LINGO1 have been associated with ET but the significance of these findings remains unclear. Exome sequencing has been recently validated as a method to identify rare coding variants that cause Mendelian disease. This approach allows the use of only a few selected affected individuals and controls to identify disease genes, which is beneficial when large families are not available for linkage. Large ET families are available however misdiagnosis hinders effective linkage analysis; the Rouleau lab has recruited 84 French Canadian ET families and linkage studies have been performed on several of them but the results are inconclusive. In order to overcome the diagnostic barrier associated with gene identification we will be carrying out 'exome' sequencing on affected individuals within ET families with a 'definite' ET diagnosis and age of onset under 40 years of age. We will perform the exome capture of genomic DNA using the Agilent Technology SureSelect Human All Exon Kit, and resequencing by massive parallel sequencing using microarrays specific for the ABI SOLiD3 DNA sequencer. The Mapping and Assembling Qualities software will be used for the assembly and base-calling, and Novoalign for the detection of small indels. The dbSNP database will provide a good filter for all the common SNPs, and additional computational tools will identify rare, potentially pathogenic variants. Any variants that are shared by all affected family members and not in control samples and variants common to a particular gene between families will be flagged. Variants will be validated through Sanger sequencing by screening healthy controls and additional affected individuals. This study has the potential to identify the first ET gene, which will provide the first insights towards disease mechanism.

2695/F

Frequency of common LRRK2 mutations and identification of two novel variants in Mexican patients with Parkinson's disease. *N. Monroy[1,2], P. Yescas[1], M. López[2], M.C. Boll[1], M. Rodríguez-Violante[1], U. Rodríguez[1], A. Ochoa[1], M.E. Alonso[1].* 1) Department of Genetics, division of Neurology, and Clinical Neurodegenerative Disease Research Unit. Instituto Nacional de Neurología y Neurocirugía Manuel Velasco Suárez, Mexico City, Mexico; 2) Department of Biological Systems, Universidad Autónoma Metropolitana-Xochimilco. Mexico City, Mexico.

Mutations in leucine-rich repeat kinase 2 gene (*LRRK2*) are estimated to account for as much as 5-6% of familial Parkinson's disease (PD) and 1-2% of sporadic PD. Although these mutations represent the most frequent cause of autosomal dominant PD, particularly in certain ethnic groups, there was no report about *LRRK2* mutations in Mexicans. For this purpose, we screened 319 consecutive PD cases (mean age at onset: 52.4 years) for *LRRK2* mutations in exons 31 and 41 and for the Y1699C mutation in exon 35. Seven additional subjects, relatives of PD mutated probands, were enrolled. Only six (1.88%) heterozygous patients, five sporadic and one familial case, with disease mean age at onset 50 years had *LRRK2* mutations. Five patients had four different mutations in exon 31 and another patient carried the G2019S mutation in exon 41. Two of the exon 31 mutations have been previously described (R1441G and R1441H) and the remaining two are novel variants (T1452R and K1471R). They are both located in the Roc domain of the LRRK2 protein and T1452R is probably pathogenic. The Y1699C mutation was absent from this PD sample. None of the five *LRRK2* mutations identified was present in 200 neurologically healthy Mexican control individuals. These findings have important implications for diagnosis and genetic counseling in PD Mexican patients.

2696/F

Mutational analysis of optineurin (*OPTN*) in familial amyotrophic lateral sclerosis in the Japanese population. *H. Naruse, Y. Takahashi, J. Goto, S. Tsuji.* Dept Neurology, Univ Tokyo, Tokyo, Tokyo, Japan.

[Objectives] To elucidate genetic epidemiology of familial amyotrophic lateral sclerosis (ALS) with *OPTN* mutations in the Japanese population. [Background] Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disorder characterized by progressive motor neuron degeneration. About 5-10% of ALS patients are familial, where mutations in *SOD1* account for about 20% of FALS. Mutations in *TARDBP* or *FUS/TLS* account for about 5%, whereas mutations of other causative genes are rare. Very recently, *OPTN*, the gene encoding optineurin, previously identified as the causative gene for rare autosomal-dominant familial glaucoma, has been reported as the causative gene for autosomal-dominant as well as autosomal-recessive familial ALS (FALS). Comprehensive mutational analysis of *OPTN* in independent FALS pedigrees should be mandatory to establish the genetic epidemiology and to delineate the clinical characteristics of ALS with *OPTN* mutations. [Materials and Methods] Thirty-six FALS pedigrees were enrolled in this study. Previous screening employing a DNA microarray-based resequencing system and direct nucleotide sequencing method revealed 14 pedigrees with *SOD1* mutations, 1 with *TARDBP*, and 2 with *FUS/TLS*, all of whom were excluded in this study. The remaining 19 pedigrees included 14 pedigrees with autosomal-dominant mode of inheritance, 2 pedigrees with affected sibs with consanguinity and 3 pedigrees with affected sibs without consanguinity. In addition, four sporadic ALS (SALS) patients with consanguinity were also enrolled. All the coding exons of *OPTN* were amplified with genomic PCR using specific primers for each exon and further subjected to direct nucleotide sequence analysis. [Results] Five variants were identified, including 4 known SNPs and a novel synonymous variant in exon 16. Neither novel nonsynonymous variants nor known mutations for ALS were identified in this cohort. [Conclusion]This study suggests that mutations in *OPTN* were not the frequent cause for FALS in the Japanese population. Further investigation in large-scale cohorts or in cohorts with different ethnic backgrounds should be necessary to establish genetic epidemiology of ALS with *OPTN* mutations.

2697/F

Exome Sequencing in Cases of Sporadic Autism. *B.J. O'Roak[1], L. Vives[1], A.P. MacKenzie[1], S. Girirajan[1], E. Karakoc[1], C. Lee[1], A. Adey[1], S. Ng[1], C. Baker[1], B. King[2], R. Bernier[2], J. Shendure[1], E.E. Eichler[1,3].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 3) Howard Hughes Medical Institute, University of Washington, Seattle, WA.

Autism is the most genetic of all neuropsychiatric syndromes. However, identifying the genetic factors involved has proved difficult in light of widespread genetic and phenotypic heterogeneity. Several lines of evidence support the hypothesis that sporadic cases of autism are enriched for causal *de novo* mutation events (O'Roak and State 2008). To evaluate this directly, we are performing global identification of *de novo* protein-altering events in parent-child trios. Specifically, we selected 20 trios with idiopathic autism, each showing a strong likelihood of sporadic disease, and subjected each of the 60 individuals to exome sequencing. *Methods*: In brief, standard Illumina sequencing libraries are prepared and hybridized in-solution to probes complementary for the CCDS exome (Nimblegen). After PCR enrichment of captured product, one lane of paired-end 76bp sequencing is performed on an Illumina GAII sequencer. Raw sequences are aligned to the build36 reference with BWA and variants called with samtools (Li et al. 2009). Proband variants meeting an 8X and phred-like quality 30 (q30) threshold are compared to the parents for non-Mendelian inheritance and against dbSNP, 1000 Genomes, and other sequenced exomes to identity potential novel *de novo* mutations. Variant reads are then visually inspected for artifacts and likely true mutations confirmed by Sanger sequencing. *Results*: Preliminary data from the first six trios completed shows an average Mendelian error rate of 0.75% for all variants and 0.52% for on-target variants. Target coverage has been ~90% at 8X/q30 for individual exomes, with ~88% of the target bases covered across the trio. Each trio has ~10 potential novel *de novo* mutations. As expected, many of these potential mutations are found in segmental duplication regions and likely reflect cross-talk from paralogous sequences. We have identified potentially *de novo* missense variants in two brain expressed transcripts, including a G protein-coupled receptor and ankyrin repeat domain-containing protein, as well as several inherited disruptive rare variants. *Conclusions*: Given the high coverage concordance, relatively small number of candidates (<10) per family, and low Mendelian error rates, our preliminary results show that exome sequencing in select families is a tractable method to identify novel candidate genes for autism and other complex disorders. These candidates can then be further evaluated in a much larger number of cases/controls.

2698/F

Chimeric Genes in Schizophrenia. *C.F. Rippey[1], A.S. Nord[1], J. McClellan[2], M-C. King[1,3].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Psychiatry, University of Washington, Seattle, WA; 3) Department of Medicine, University of Washington, Seattle, WA.

Our lab has shown that individually rare, gene-disrupting copy number variants (CNVs) are significantly more prevalent in individuals with schizophrenia than in unaffected controls. Several groups have replicated and extended this finding, yet it remains an open question as to which individual events are pathogenic. A subset of CNVs connects components of two separate genes into novel, often deleterious chimeric genes. We hypothesize that some rare CNVs create brain-expressed chimeric genes that contribute to schizophrenia pathogenesis. To test this hypothesis, we screened DNA from 124 individuals with schizophrenia using the Nimblegen HD2 array comparative genomic hybridization platform. We scanned genome-wide for CNVs >30 kb in length that were present in at least one case and no controls (n=367, same platform), and did not coincide with events in the database of genomic variants. From these events, we selected only those predicted to delete or duplicate the 5' end of one gene and the 3' end of another, as these CNVs should produce chimeras. We detected four such events in cases, three resulting from tandem duplications and one from a deletion. We confirmed the breakpoints of each of these events by PCR and sequencing. We also confirmed that in all cases, at least one of the two genes in the predicted chimera was expressed in brain. To test whether these events produced stable chimeric transcripts in the patients' lymphoblasts, we targeted PCR primers to the predicted chimeric mRNA. In three cases we were able to detect a stable transcript, confirmed by sequencing. In the fourth case, the gene contributing the 5' end of the chimera had no detectable expression in lymphoblasts, but was highly expressed in brain, so we expect the transcript to be brain-specific. For the chimeras with lymphoblast expression, we are performing western blots to ascertain protein stability and relative expression levels. We will then transfect neural cell lines with chimeric transcripts to test the effect of these fusion proteins on molecular and cellular phenotypes. In conclusion, we have detected rare CNVs that lead to stable expression of chimeric mRNA in individuals with schizophrenia. We propose that these events are likely to lead to aberrant expression of fusion proteins in the brains of these patients, and contribute to schizophrenia. This represents a novel genetic mechanism for major mental illness, as well as implicating new genes and pathways in schizophrenia.

2699/F

Whole Exome Sequencing of Two Unique Autism Pedigrees. *S.P. Strom[1], Z. Chen[1], S.P. Taylor[1], B. Harry[1], D.H. Geschwind[1,2,3,4], S.F. Nelson[1,2,3].* 1) Department of Human Genetics, University of California Los Angeles, Los Angeles, CA; 2) Center for Neurobehavioral Genetics, University of California Los Angeles, Los Angeles, CA; 3) Department of Psychiatry and Biobehavioral Sciences, University of California Los Angeles, Los Angeles, CA; 4) Department of Neurology, University of California Los Angeles, Los Angeles, CA.

While strongly heritable, few common alleles have been unambiguously identified as conferring risk to autism spectrum disorder (ASD). Attempts to significantly increase the sample size of ASD genome-wide association studies are ongoing, under the hypothesis that such studies to date have lacked sufficient statistical power to detect associated alleles of weak effect. Alternatively, the lack of common variant association signals in ASD suggests rare variation may contribute to genetic susceptibility more strongly than previously thought. Significant enrichment of rare genic copy number variants in ASD compared to neuropsychiatric normal control samples supports this alternate hypothesis. To comprehensively assess the spectrum of rare genic variation in two autism pedigrees, whole exome sequencing was performed. Using a combined approach employing commercially available target enrichment products and massively parallel DNA sequencing, over 32 million bases of targeted loci were sequenced at ten times or greater coverage depth in twelve individuals from two uniquely structured ASD pedigrees. Coverage, target enrichment, and variant analysis for both pedigrees are presented here as a proof of concept that exome sequencing of ASD families is a valuable approach to rare variant discovery in autism.

2700/F

Recessive paraplegin (SPG7) mutations in spastic paraplegia families with dominant pattern of inheritance. *F. Taroni[1], M. Plumari[1], S. Magri[1], V. Fracasso[1], C. Gellera[1], E. Salsano[2], S. Baratta[1], D. Di Bella[1].* 1) Unit of Genetics of Neurodegenerative & Metabolic Diseases, Fondazione IRCCS Istituto Neurologico Carlo Besta, Milan, Italy; 2) Unit of Neurology 8, Fondazione IRCCS Istituto Neurologico Carlo Besta, Milan, Italy.

Hereditary spastic paraplegias (HSP) are a clinically and genetically heterogeneous group of neurodegenerative disorders primarily affecting the corticospinal motor tracts. About half of HSP cases result from autosomal dominant mutations in the *SPG4* gene. Mutations in the *SPG7* gene are responsible for autosomal recessive HSP with both “pure” and “complex” phenotypes and, in our patients series, account for >10% of recessive or sporadic HSP patients. The *SPG7* gene encodes paraplegin, a component of the mitochondrial *m*-AAA metalloprotease. We report 3 unrelated families presenting an HSP phenotype with an autosomal dominant pattern of inheritance. Families 1 and 2 had a consanguineous marriage in one generation. Family 3 was compatible with autosomal dominant transmission with reduced penetrance. Molecular analysis of the *SPG4* gene was negative for point mutations and dup/del. Immunoblot analysis demonstrated absence or severe reduction of paraplegin protein in lymphocytes from the index cases. Molecular analysis of the *SPG7* gene revealed pathogenic mutations [2 missense mutations (A510V, T655P), 2 nonsense mutations (L78X, R457X), and deletion of exon 2] on both alleles in all the affected subjects analysed. In family 1, the proband presented with a pure HSP phenotype and was compound heterozygous for A510V and exon 2 deletion. In family 2, the two affected sibs, born to consanguineous parents, one of whom affected with spastic paraplegia, differed in genotype and clinical presentation (A510V/T655P, mild, and T655P/T655P, severe). Expression analysis of SPG7 mutants in yeast showed that the T655P mutation has a more drastic impact on paraplegin function. Interestingly, paraplegin protein levels were found to correlate with the severity of clinical phenotype. Analysis of paraplegin levels also allowed to exclude a pathogenic role for a third heterozygous variant (I297T) identified in one sister heterozygous for the pathogenic T655P but with no sign of HSP. In family 3, the proband (A510V/L78X) had spastic ataxia with a predominantly cerebellar phenotype. His half-nephew was similarly affected but exhibited a different genotype (A510V/R457X). Our findings indicate that recessive *SPG7* mutations are not an exceptional cause of spastic paraplegia in families with an apparently dominant pattern of inheritance and suggest that this might be due to the relatively high frequency of the A510V allele in the general population. [Telethon grant GGP09301 to FT].

2701/F

The genetic signatures of transposable elements (TEs) in schizophrenia. *F. Macciardi[1,2], E. Osimo[2], M. Vawter[1], F. Torri[2], A. Calabria[2], B. Lerer[4], S. Gaudi[3].* 1) Dept Psychiatry & Human Behavior, UCI, Irvine, CA; 2) Fondazione Filarete, Universita’ degli Studi di Milano (Italy); 3) Istituto Superiore di Sanità, Roma (Italy); 4) Hadassah Medical Organization / Hebrew University, Jerusalem (Israel).

Introduction. Understanding how the information in the human genome is utilized is one of the central question to unravel the genetics of complex diseases. Once completed, the human genome sequence has revealed being composed by transposable elements (TE) for about 45% and by coding genes in only 2%. Many genome wide association studies (GWAS) in complex diseases have mapped disease-associated variations to non-coding regions, presumably regulatory and endogenous retroviral. There are also recent evidences that not coding DNA sequences (known as “junk DNA”) tend to be enriched near genes involved in brain-cell function than in non-CNS genes, specifically in genes building connections between brain cells. **Methods.** Our aim is to investigate the functional relationship between TE-related sequences and genes identified as “best” candidates via SNP mapping in genome wide association studies (GWAS) of schizophrenia. We use gene expression data to identify and detect the expression level of TEs in blood and brain samples from schizophrenia samples and matched controls. We also extend our analyses to Transcriptional Start Sites (TSS) for the same genes. These analyses are then complemented with target-resequencing of the entire genomic area, to look for differences between subjects who do or do not present the associated risk SNPs. **Results and conclusion.** For a prototypal gene, AHI1 (Torri et al, 2010) we found an excess of Alu, Line1 and Line2 elements across the AHI1 genomic region, with a clear pattern of tissue-specific expression that looks regulated by CNS-specific TSS, with gene expression data on post mortem schizophrenic brain increased compared to LCL cells of the same patients. Initial sequencing in extreme subjects with and without the AHI1 risk haplotype shows marked differences in their respective sequences. We also observed differences in term of coverage and reads distance between the two patients. Within the 5’ of PDE7B we found that the patient with the schizophrenia risk haplotype displays a significantly different distance between the reads compared to the risk-haplotype-absent patient. This finding may suggest that these two extreme patients differ also in terms of genomic architecture. Our results strongly suggest that a detailed analysis of risk genes in complex disorders must include TE distribution and expression, and that it is perhaps only through inclusion of these elements that psychiatric diseases will be fully understood.

2702/F

Normal ATXN3 allele but not CHIP polymorphisms modulates age at onset in Machado Joseph Disease. *M.C. França Jr[1,2], V. Emmel[3], A. D’Abreu[2], C.V. Maurer-Morelli[1], R. Secolin[1], L.C. Bonadia[1], M.S. Silva[1], A. Nucci[2], L.B. Jardim[3], M.L. Saraiva-Pereira[3], W. Marques Jr[4], H. Paulson[5], I. Lopes-Cendes[1].* 1) Department of Medical Genetics, University of Campinas (UNICAMP), Campinas, Brazil; 2) Department of Neurology, University of Campinas (UNICAMP), Campinas, Brazil; 3) Department of Internal Medicine and Biochemistry, Federal University of Rio Grande do Sul (UFRGS), Porto Alegre, Brazil; 4) Department of Neurology, University of São Paulo (USP) at Ribeirão Preto, Ribeirão Preto, Brazil; 5) Department of Neurology, University of Michigan, Ann Arbor, MI,USA.

Length of expanded CAG at the ATXN3 gene accounts for part of the variability in the age at onset (AO) of patients with Machado-Joseph disease (MJD), but other genetic factors are probably involved. Experimental evidence indicates that the normal ATXN3 allele and the C-terminal heat shock protein 70 (Hsp70)-interacting protein (CHIP) may take part in the pathogenesis of MJD, thus making these two candidates for genetic modifiers of AO in patients with MJD. To investigate this, we determined the length of normal and expanded CAG repeats at the ATXN3 gene in 210 unrelated patients with MJD. In addition, we genotyped 5 single nucleotide polymorphisms (SNPs) within the CHIP gene. We first compared the frequencies of the different genotypes in two subgroups of patients who were highly discordant for age at onset after correction for length of the expanded CAG allele. The possible modifier effect of each gene was then evaluated in a stepwise multiple linear regression model.Mean AO was 35.7 (SD = 11.3) years. Mean length of expanded and normal CAG repeats were 72 (SD = 3.6) and 21 (SD = 5.3), respectively. AO was associated with length of the expanded allele CAG ($r2 = 0.596$, $p<0.001$). Frequencies of the normal CAG repeats at the ATXN3 gene and of CHIP polymorphisms were not significantly different in groups with highly discordant ages at onset. However, addition of the normal allele improved the model fit ($r2 = 0.601$, $p=0.014$). Therefore, we conclude that the normal CAG repeat at the ATXN3 gene has a small but significant influence in AO of MJD.

Expansion bias for transmission of expanded CGG-repeat murine Fmr1 alleles. *K. Kim[1,4], S. Taylor[1], B. Ta[4], P.J. Hagerman[2,4], R.F. Berman[3,4].* 1) Division of Biostatistics, Department of Public Health Sciences; 2) Department of Biochemistry and Molecular Medicine; 3) Department of Neurological Surgery; 4) the Neurotherapeutics Research Institute, School of Medicine, University of California Davis. Davis. CA.

The fragile X mental retardation 1 (FMR1) gene harbors a non-coding CGG repeat that is normally between 5-41 repeats in length. For larger alleles (gray zone, 41-54 CGG repeats; premutation, 55-200 repeats) the CGG is increasingly unstable upon transmission to the next generation, with expansions to between ~70-200 repeats resulting in increasing susceptibility to Fragile X-associated Tremor/Ataxia syndrome (FXTAS). To investigate the mechanisms underlying (CGG)n instability upon transmission, we conducted repeat instability analysis in expanded CGG-repeat knock-in (KI) mice to determine whether (1) the probability of expansion or contraction of CGG repeat numbers is functionally related to the parental number of CGG repeats, and (2) whether the parental origin of the repeat allele affects the magnitude or direction of instability. We have bred 2,354 KI mice over several generations to establish transgenic lines with varying expanded alleles up to 350 CGG repeats. These CGG-repeat KI mice showed moderate intergenerational instability upon paternal and maternal transmission, and both expansions and contractions were observed. To assess the probability of repeat instability, and any attendant bias towards expansion or contraction, as a function of parental CGG repeat length and parental origin of transmitting allele, we conducted multinomial logistic regression analyses built upon a generalized additive model to estimate the underlying function relationships. Our results showed an increasing relationship between the probability of instability in CGG repeat numbers and the parental repeat numbers. While a paternal bias for transmission of expansions was not evident, the magnitude of expansion increased with repeat sizes of alleles with maternal origin. As maternal repeat numbers increased, repeat numbers were more likely to expand than contract. More interestingly, at a maternal allele repeat number of about 100, the probability of expansion started to increase and continued to gradually increase up to 200 repeats. Supported by NIH NINDS RL1 NS062411, NIH Roadmap Consortium NIDCR UL1 DE19583 & NIA AG032119.

2704/F

Modeling SCA31 non-coding pentanucleotide expression in cultured cells. *Y. Niimi, N. Sato, K. Ishikawa, H. Mizusawa.* Neurology, Tokyo Medical and Dental University, Bunkyo-ku, Tokyo, Japan.

Background Spinocerebellar ataxia type 31 (SCA31) is caused by a pentanucleotide insertion expansion located in an intron shared by two genes (*BEAN* and *TK2*) transcribed in opposite directions (Sato N. and Amino T. et al. Am J Hum Genet 85: 544-557, 2009.). This insertion is a 2.5-3.8 kb-long genomic fragment containing (TGGAA)n, (TAGAA)n and (TAAAA)n stretches, among which (TGGAA)n is considered crucial for pathogenesis. The mechanism by which the complex insertion including (TGGAA)n repeat leads to neuronal dysfunction remains elusive. **Object** Our goal is to establish a SCA31 cell model for discovering pathogenesis of complex insertion. In parallel with creating cell models with insertions, we aimed to clarify whether intron sequences flanking the insertion are also involved in RNA foci. **Method** As an initial step, SCA31 insertion was cloned into a dual-expression vector, which could monitor the expression of gene-of-interest with recombinant green fluorescent protein (Cycle 3 GFP) driven by a different promoter. Besides insertions from SCA31 patients, control insertions without (TGGAA)n repeats were also cloned. Because the insertion is predicted to be transcribed in two directions (i.e., *BEAN* and *TK2* transcription orientations), two different clones corresponding sense and anti-sense transcripts were made from each insertion. Lipofection method was used for introducing the vector, and toxicity of the gene was assessed by MTS and LDH assays. For in situ hybridization (ISH), probes were designed to detect repeat sequences or intron sequences. RT-PCR was used to confirm expression in cultured cells. **Result** Insertion sequences were confirmed to be expressed as RNA in cultured cells by RT-PCR. When toxicity was assessed by MTS and LDH assays, UGGAA sequences derived from patient-specific (TGGAA)n repeat appeared toxic than control insertion sequences. We are currently examining on different cell lines to see whether (UGGAA)n on RNA level, is indeed toxic in cells. In patients' brains, we observed RNA foci include repeat sequences. Further studies are now underway to evaluate whether flanking intron sequences are also included in RNA foci besides transcribed repeat sequences.

A mouse model of CUG RNA toxicity in the brain. *J. Pruitt[1], D. Rudnicki[1], K. Pate[2], D. Swing[3], L. Tessarollo[3], R. Margolis[1].* 1) Psychiatry, Johns Hopkins University, Baltimore, MD; 2) Pathology, Johns Hopkins University, Baltimore, MD; 3) National Cancer Institute, National Institute of Health, Fredrick, MD.

Huntington's disease-like 2 (HDL2) is an autosomal dominant disorder with clinical and pathological features nearly indistinguishable from Huntington's disease (HD). HDL2 is a progressive adult onset neurodegenerative disorder caused by a CAG/CTG expansion mutation on chromosome 16q24.3, where the repeat falls within a variably spliced exon of junctophilin-3 (JPH3) in the CTG orientation. We have recently discovered that HDL2 brains contain intranuclear RNA foci, detectable by riboprobes against either CUG repeats or against JPH3 sequence flanking the repeat. These foci closely resemble the RNA foci detected in DM1 brains. We have also shown that overexpression of an untranslatable JPH3 construct containing an expanded CUG repeat is toxic to cultured cells. We therefore hypothesized that transcripts with an expanded CUG repeat may be toxic to the mammalian brain. To directly test this hypothesis, we have generated transgenic mice expressing an untranslatable fragment of JPH3 exon 2A, with either 10 or 100 CTG triplets, driven by the mouse prion promoter (PrP) vector. Preliminary data indicates that (CTG)100, but not (CTG)10, mice develop RNA foci by seven months. Behavioral analysis using an array of tests including: rotarod, open field, inversion, reach, and clasping suggest a modest impairment of motor function in the (CTG)100 mice compared to the (CTG)10 mice by six months of age. This phenotype is milder than observed in transgenic mice expressing polyglutamine repeats of a similar length under the same promoter, and suggests that factors in addition to CUG RNA toxicity, including loss of JPH3 expression, are likely to contribute to HDL2 pathogenesis.

2706/F

Pathogenic significance of the complex penta-nucleotide repeat insertion containing $(TGGAA)_n$ in spinocerebellar ataxia type 31. *N. Sato[1], Y. Niimi[1], T. Amino[1,2], T. Ishiguro[1], T. Makoto[1], K. Ishikawa[1], H. Mizusawa[1].* 1) Dept. of Neurology & Neurological Science, Graduate School, Tokyo Medical & Dental University, Tokyo, Japan; 2) Dept. of Neurology, Musashino Red Cross Hospital, Tokyo, Japan.

Background Spinocerebellar ataxia type 31 (SCA31) is a form of adult-onset neurodegenerative disorder that manifests pure cerebellar ataxia and slow progression. We previously mapped the SCA31 locus to 16q22.1, and identified a complex penta-nucleotide repeat insertion containing $(TGGAA)_n$ in every SCA31 patient's genome. The pathogenic effect of this insertion, however, does not appear straightforward; it is located in a non-coding region, and in rare occasions, control individuals have similar insertions lacking $(TGGAA)_n$ at the same position.

Purpose To clarify the pathogenic effect of the non-coding penta-nucleotide repeat insertion in SCA31.

Materials and Methods Fifty-six consecutive SCA31 patients, including 39 patients previously reported (Am J Hum Genet 2009;85:544-57), whose detailed clinical information had been obtained were enrolled in the study. The genomic DNA fragment spanning the insertion was amplified by PCR and the length of the insertion was measured by electrophoresis as described in our pilot study. The length of the insertion was compared with the patient's age of onset. The component of the insertion consisting of pure $(TGGAA)_n$ stretch was also amplified by PCR and its length was compared with the age of onset.

Results The length of the insertion was inversely correlated with the age of disease onset, with Pearson's product moment coefficient being -0.38 ($p=0.0044$). The length of pure $(TGGAA)_n$ component was also associated with earlier disease onset.

Conclusions Patients with longer penta-nucleotide repeat insertions tend to develop the disease earlier, and the pure $(TGGAA)_n$ component seems to be important for the development of SCA31.

Mice lacking glutamate receptor 3 associated with significantly increased aggressive behaviors. *A. Adamczyk[1], R. Mejías-Estévez[1], J. Calderon[1], K. Takamiya[2], R. Huganir[2], M. Pletnikov[3], T. Wang[1].* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Neuroscience, Johns Hopkins University, Baltimore, MD; 3) Department of Psychiatry, Johns Hopkins University, Baltimore, MD.

Glutamate mediates the majority of excitatory neurotransmission in the brain and is implicated in the modulation of behavioral phenotype. The AMPA glutamate receptor family has four different subunits (GluR1-4) that assemble into a tetrameric receptor complex consisting mainly GluR1/2 and/or Glu2/3 heteromers to form ion channels of distinct functional properties. Lack of GluR1 subunit in mice is associated with reduced levels of anxiety and aggressive behaviors while lack of GluR2 subunit in mice results in increased aggression. The genomic region encoding GluR3 (Xq24-27) has been implicated as a quantitative locus for male aggression in mice in a genome-wide scan. Genetic defects of GluR3 in humans cause moderate intellectual disability, bipolar or autistic phenotype. To understand the potential role of GluR3 in behavioral modulation, we studied GluR3-deficient mice generated by classical gene targeting and back-crossed to C57BL/6 background using a standard battery of mouse behavioral tests. Compared to their wt littermates (n=14), this cohort of GluR3-deficient male mice (n=13) had a significant increase in aggressive behaviors (total time of aggression, p=0.011 and number of attack, p=0.015) in the home cage intruder-resident test, a moderate increase in peripheral activity in Open Field test (p=0.037), but no significant deficit in learning and memory function in Morris Water Maze and Y-maze tests. These studies suggest an important role of AMPA glutamate receptor 3 in modulating behavioral phenotype in mice.

2708/F

Differential microRNA expression in AD hippocampus compared to AD cerebellum, control hippocampus and control cerebellum. *L.M. Bekris[1], C.E. Yu[2].* 1) Dept Med, Univ Washington, Seattle, WA; 2) Geriatric Research, Education, and Clinical Center (GRECC) VA Puget Sound Health Care System, Seattle, WA.

MicroRNAs play an essential role in gene regulation in the brain. However, little is known about their role in neurodegenerative diseases, such as late-onset Alzheimer's disease (AD). Characterizing expression profiles of microRNAs in AD brain may help elucidate the role of microRNA in the pathophysiology of AD and may lead to identification of AD specific biomarkers. The aim of this investigation was to demonstrate that AD hippocampus microRNAs are expressed differentially compared to AD cerebellum, control hippocampus or control cerebellum. MicroRNA arrays were utilized to measure post-mortem brain microRNA levels in AD hippocampus (n=21) compared to AD cerebellum (n=21), control hippocampus (n=21), or control cerebellum (n=21). In addition, in silico analyses were performed to predict target genes for differentially expressed microRNAs. We found several microRNAs to be differentially expressed in the AD hippocampus compared to controls. Of these microRNAs, several are predicted to target AD relevant genes. Two of these AD relevant genes (PSEN1, BACE2) contain genetic variants (SNPs) within the predicted microRNA binding site. In conclusion, in this investigation we demonstrate that hippocampus specific microRNAs are expressed differentially in AD compared to controls and are predicted to target AD relevant genes. SNPs within predicted microRNA binding sites may be of interest for further study into their contribution to AD risk. In addition, brain region and AD specific microRNAs identified in this study warrant further investigation into their specificity as biomarkers of neurodegenerative disease.

2709/F

Influence of Genomic Methylation on Brain Structure and Function. *M.A. Carless[1], D.C. Glahn[2,3], T.D. Dyer[1], R.L. Olvera[4], J.E. Curran[1], R. Dugirala[1], J. Blangero[1].* 1) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 3) Olin Psychiatric Research Center, Institute of Living, Hartford, CT; 4) Department of Psychiatry, University of Texas Health Science Center San Antonio, San Antonio, TX.

Epigenetic regulation is rapidly becoming a well-recognized regulatory mechanism contributing to the development of complex diseases. Given that many psychiatric disorders are poorly understood and currently known genetic factors only account for a small proportion of the phenotype, it is likely that epigenetic regulation plays an important role in the development of mental illness and this may be made apparent through testing of brain-related phenotypes. Using Illumina GoldenGate technology, we interrogated genomic methylation at 1,505 CpG sites, representing 807 genes, in lymphocytes derived from 95 Mexican Americans within the San Antonio Family Study (SAFS), for which we have extensive neurocognitive and neuroanatomical data. We have previously shown that approximately 25% of CpG sites exhibit relative methylation variation that is significantly heritable (median heritability = 0.11), reinforcing the biological validity and relevance of such epigenetic changes. We used SOLAR to identify correlations between neurocognitive and neuroanatomical traits and genomic methylation at CpG sites within highly relevant genes. One of the strongest associations detected was for methylation within *PDGFB*, a growth factor that stimulates fetal neural precursor cells, and face memory delay test (6.00×10^{-6}). Methylation within other genes demonstrated association with multiple phenotypes, such as the *SOX1* gene, which is involved in inhibition of neural differentiation and *FGFR1*, which gives rise to the auditory epithelium. Methylation in *SOX1* was associated with cortical thickness of the inferior parietal ($p=6.18 \times 10^{-5}$), precentral ($p=7.87 \times 10^{-4}$) and superior parietal ($p=9.59 \times 10^{-4}$) regions of the brain. Methylation within *FGFR1* was associated verbal intelligence estimates based on the reading of irregular words (Wechsler Test of Adult Reading Full-Scale IQ, $p=8.51 \times 10^{-5}$) and a measure of vocabulary from the Wechsler Abbreviated Scale of Intelligence ($p=8.42 \times 10^{-4}$). Further, methylation within *EGF*, previously implicated in schizophrenia, showed association with ventral diencephalon volume ($p=5.11 \times 10^{-5}$). These results suggest that genomic methylation may play an important role in a number of neuroanatomical and neurocognitive endophenotypes and may also have a significant impact on psychiatric disease.

Nicotine Dependence and Five-Factor Model of Personality: Examination of Specific Genetic Variants in Nicotinic Receptor Genes. *L. Chen[1], H. Xian[2], R.A. Grucza[1], N.L. Saccone[3], E.O. Johnson[4], N. Breslau[5], D. Hatsukami[6], L.J. Bierut[1].* 1) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO; 2) Department of Medicine, Washington University School of Medicine, St. Louis, MO; 3) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 4) Research Triangle Institute International, Reseasrch Triangle Park, North Carolina, NC; 5) Department of Epidemiology, Michigan State University, East Lansing, MI; 6) Department of Psychiatry, University of Minnesota, Minneapolis, MN.

Introduction: The associations between nicotine dependence and specific variants in the nicotinic receptor CHRNA5-A3-B4 subunit and CHRNA6-B3 subunit genes are irrefutable with replications in many studies. The relationship between the newly identified genetic risk variants for nicotine dependence and five-factor model of personality is unclear. We examined whether personality characteristics modified the genetic risk of nicotine dependence and whether these genetic variants were associated with personality characteristics. Methods: In a case control study of nicotine dependence with 2047 subjects of European descent, we used a systematic series of logistic and linear regression models to examine the risk moderation and pleiotropy. Nicotine dependence was assessed using Fagerstrom Test for Nicotine Dependence (FTND) and personality characteristics were assessed using neuroticism extroversion openness-five factor inventory (NEO-FFI). Results: When compared to non-dependent smokers, individuals with nicotine dependence were associated with high neuroticism (N), low extroversion (E), low openness (O), high agreeableness (A), and low conscientiousness (C), adjusting for age and gender. No evidence suggested that the risks for nicotine dependence associated with the genetic variants vary with personality characteristics in general, but the power was limited in detecting interactions. No evidence supported the associations between the genetic variants and these personality characteristics (pleiotropy). Conclusions: The risks for nicotine dependence associated with these genetic variants are not modified by personality characteristics measured by the five-factor model. The genetic risks of nicotine dependence associated with the CHRNA5-A3-B4 subunit and CHRNA6-B3 subunit genes were specific, and not shared with any specific personality characteristics. However, the power is an important limitation in studying the interplay of personality and genetic variants, and a meta-analytic approach would be needed to reach the appropriate sample size.

Regulation of human tyrosine hydroxylase by the male-specific factor SRY in the brain. *D. Czech[1, 2], H. Sim[1], F. Bagheri-Fam[1], P. Bernard[1], J. Lee[1], V. Harley[1].* 1) Human Genetics & Development Divison, Prince Henry's Institute of Medical Research, Clayton, Melbourne, Victoria, Australia; 2) Department of Biochemistry and Molecular Biology, Faculty of Medicine, Monash Univeristy, Clayton, Melbourne, Victoria, Australia.

SRY is the Y-chromosome switch gene which directs gonads to differentiate into testes rather than ovaries. SRY is a well characterised architectural transcription factor, binding and bending DNA though its high mobility group domain and activating downstream male-pathway targets. Recent studies in our laborartory using immunhistochemical staining localized SRY in catecholaminergic brain regions in rodents such as the ventral tegmental area (VTA), substantia nigra compacta (SNc) and locus coeruleus (LC). In the SNc, SRY localizes in tyrosine hydroxylase (TH) positive neurons. TH is the key rate-limiting enzyme controlling dopamine production in the striatum. Surprisingly, transient inhibition of SRY production in the SNc in rats, by injection of SRY antisense oligonucleotides, has been shown to reduce TH expression and consequent motor deficits reminiscent of Parkinson's disease. Others have now shown that SRY directly targets monamine oxidase A (MAOA), a key enzyme involved in breaking down dopamine in the SNc. Taken together, the evidence suggests that SRY has a significant role outside of testis development. We hypothesise that in the male brain, SRY is a transcriptional activator of the TH gene. The present study seeks to elucidate the role of SRY using human dopaminergic cell line models and human brain sections. A human SRY antibody was purified and tested. Dot blot, western blot, immunocytochemistry and peptide competition assays concluded that the peptide-affinity, column-purified antibody was specific to both transfected and endogenous SRY protein in multiple cell lines. Immunohistochemistry of post-mortem, male brain sections confirmed that SRY is also co-localised with TH positive cells in the human SNc. To investigate whether SRY affects TH transcription, a human pluripotent cell line NTera2, was differentiated into dopamine neurons with retinoic acid. Over 28 days, both SRY and TH mRNA and protein levels increased, as demonstrated by qRT-PCR and immunocytochemistry. A positive linear trend is observed between increasing SRY and TH protein levels. Overexpression of the SRY gene in transfected, FAC-sorted NT2N neurons resulted in a significant 2-fold upregulation of TH and MAOA mRNA levels. Similarly, overexpression of SRY in a human dopaminergic, neuroblastoma cell line, BE(2)-M17, showed the same level of TH and MAOA upregulation. Current studies are aimed at mapping putative SRY-responsive regions in the 11kb human TH promoter.

Molecular networks for lithium and valproate regulated genes highlight a marked enrichment of apoptosis functional clusters. *S. Detera-Wadleigh[1], T. Schulze[1], A. Gupta[1], N. Akula[1], V. Nagarajan[2], X. Jiang[1], W. Corona[1], N. Hunter[1], F. McMahon[1].* 1) NIMH/NIH, Bethesda, MD; 2) NIAID/NIH, Bethesda, MD.

The biological mechanisms by which lithium and valproate (VPA) stabilize mood in bipolar disorder are not fully understood. The role of inositol depletion and Wnt signaling in lithium action, and the inhibitory effect of VPA on histone deacetylases are well-documented. Published literature seems to suggest that lithium and VPA perturb disparate biological processes. Alternatively, the similar therapeutic effects of these drugs could indicate shared pathways. To explore this question, we identified genes that were differentially regulated by both lithium and VPA in gene expression studies. Twelve genes met the criteria for inclusion in subsequent analyses: a) significant differential expression of at least 1.4 fold, and b) identical direction of change in expression with both lithium and VPA in at least two studies. To explore the functional relationships of these genes, molecular networks were generated by two network-building tools which created complex interaction networks comprising multiple hubs. To determine the most-supported interactions we identified nodes that were identically recruited in both networks, upon which functional annotation was performed by using DAVID Bioinformatics Wizard. Apoptosis clusters were shown to be the most highly enriched functional clusters in the networks. This analysis further displayed significant enrichment of >20 canonical signaling pathways including neurotrophin, MAPK and ErbB. The predominant pathway constituent nodes were Akt1 and MAPK, suggesting a vital role in both lithium and VPA action. These findings also suggest a functional convergence of lithium and VPA involving the regulation of apoptosis which may feature prominently in the therapeutic efficacy of both medications.

2713/F

Clinical non-motor manifestations in Parkinson disease patients carrying GBA mutations. *G. Lopez[1], J. Choi[1], B. McElroy[3], C. Crews[2], M. Brooks[3], N. Gupta[1], A. Velayati[1], A. Britton[2], M. Hallett[3], E. Sidransky[1].* 1) NHGRI/NIH, Bethesda, MD; 2) NIA/NIH, Bethesda, MD; 3) NINDS/NIH, Bethesda, MD.

The association between parkinsonism and mutations in the glucocerebrosidase gene (GBA) is now well established. Patients with parkinsonism have a five-fold increased likelihood of carrying a mutation in GBA . Non-motor symptoms described in Parkinson disease include depression, sleep disorders, fatigue, olfactory problems, and cognitive difficulties. Non-motor symptoms are considered non-dopaminergic and therefore, refractory to dopaminergic supplementation. Non-motor manifestations often precede motor symptoms, and tend to intensify with disease progression, dominating the clinical picture in late-stages of the disease. Systematic evaluation of non-motor manifestations in subjects with Gaucher disease and GBA mutation carriers has not been extensively studied. We performed a uniform cross-sectional clinical study of 155 consecutive patients evaluated at the Parkinson disease clinic at the National Institutes of Health by a single neurologist. All 11 exons of GBA were sequenced and subjects were screened for the three most common LRRK2 mutations (G2019S, R1441H/C, and Y1699C). Eight patients were found to be heterozygous for a GBA mutation. Clinical evaluations included a detailed history and physical examination, neurological and UPDRS evaluation, detailed review of systems interview, Geriatric Depression Scale, Fatigue Scale, Epworth Sleep Scale, and smell evaluation using the University of Pennsylvania Smell Identification Test. Our study showed that patients with Parkinson disease who carried a GBA mutation were more likely to complain of memory problems when compared to Parkinson disease patients without mutations, although objective measurements with clinical cognitive screening tools did not demonstrate a cognitive deficit. While the small sample size limits generalization of this finding, more formal neurocognitive assessments are warranted. Both patients with Gaucher disease and GBA carriers are being prospectively followed at the National Human Genome Research Institute in order to study motor and non-motor symptoms in patients at increased risk of parkinsonism.

2714/F

Copy Number Variations in Autism Spectrum Disorders. *F. Mari[1], M.A. Mencarelli[1], M. Mucciolo[1], V. Disciglio[1], R. Canitano[2], F.T. Papa[1], A. Marozza[1], L. Radice[2], C. Castagnini[1], L. Dosa[1], M. Pollazzon[1], J. Hayek[2], A. Renieri[1].* 1) Med Gen - Mol Biol, Univ Siena, Siena, Italy; 2) Child Neuropsychiatry, University Hospital Siena, Siena, Italy.

Autism and related traits present a complex and heterogeneous aetiology with a strong evidence of a genetic involvement. The identification of copy-number variants (CNVs) by the application of comparative genomic hybridization (CGH) is beginning to provide some insights into the underlying genetic causes of neurodevelopmental disorders. Recently, recurrent microdeletions at 16p11.2, 16p13.1 and microduplications at 15q13.3 have been associated with susceptibility to autism spectrum disorder (ASD) in up to 1% of patients. Using oligonucleotide arrays with 44,000 probes with an average resolution of approximately 100 Kb (44K, Agilent), we have analyzed 95 unrelated subjects with ASD. Inheritance, whenever possible, was determined using the same technique. Patients were thoroughly investigated by both child neuropsychiatrists and clinical geneticists. Sixty patients were negative for rearrangement while 35 patients exhibited at least one private rearrangement. In these 35 patients, a total of 49 rearrangements were identified, 22 were deletions and 27 were duplications. Published data and gene content analysis indicated that 14 CNVs were in strong disease candidate regions while the remaining were assigned an unknown significance (detection rate: 15%). Among them, two were de novo CNVs (del16p11.2; delXq12) and 5 were CNVs in known susceptibility regions (dup16p13.11, dup15q13.3, dup17q12, del11p12, del15q11.2). Three patients presented two inherited rearrangements each, one inherited by the mother and the other inherited by the father, leading to hypothesize the possibility of a digenic or multigenic inheritance. In conclusion, our study has confirmed the array-CGH as an important diagnostic tool in ASD patients and it has provided additional data on genetic causes of ASD. Our most important finding from the clinical investigation was that CNVs are more common among the subgroup of patients with multiple congenital anomalies (40% versus 22%) and surprisingly, epilepsy was absent in the cohort of patients with pathogenic CNVs. Furthermore, these findings underscore a challenge in genetic counselling related to risk assessment of each CNV. Given the rapidly expanding knowledge on human CNVs we suggest, in clinical reports, to describe the private rearrangements identified and to include a statement indicating that the identified rearrangements cannot currently be excluded as possible cofactors for the phenotype.

2715/F

Early serotonin depletion and decreased dopamine release are associated with a chronic brain energy deficit in Huntington disease mice. *F. Mochel[1,2,3], B. Durant[3], R. Schiffmann[3], A. Durr[1,2].* 1) INSERM UMRS975, Hosp La Salpetriere, Paris, France; 2) Department of Genetics, Hosp La Salpetriere, Paris, France; 3) Institute of Metabolic Disease, Baylor Research Institute, Dallas, TX, USA.

Background: Dopaminergic and serotoninergic alterations may account for motor and non-motor manifestations of Huntington disease (HD). Cerebral energy deficit also plays an important role in HD. Objectives: To reliably characterize the locoregional and temporal brain neurotransmitter and energy profile in a HD mouse model, we used a microwave fixation system that instantly inactivates brain enzymes and preserves in vivo concentrations of adenine nucleotides. Methods: We used an automated high-resolution behavioral analysis in R6/2 mice at ages 4 weeks (presymptomatic), 8 and 12 weeks (symptomatic). Mice were then sacrificed by microwave fixation. Dopamine (DA), serotonin (5-HT) and their metabolites (3-MT, HVA and 5-HIAA), as well as high-energy phosphates (ATP, ADP, AMP and phosphocreatine) and creatine were measured by HPLC in striatum, hippocampus and frontal cortex. Results: Compared to WT mice, we found significantly decreased DA in the striatum of R6/2 mice at 8 and 12 weeks while DA release was already significantly reduced in 4 weeks old R6/2 mice. 5-HT and 5-HIAA were significantly decreased in the striatum, hippocampus and frontal cortex of R6/2 mice at 4, 8 and 12 weeks, associated with a decreased turnover of 5-HT. Increased stress-like behaviors - jumping and grooming - and altered spatial learning in R6/2 mice were identified at 4 and 6 weeks respectively. In addition, we found a significantly decrease of ATP in the striatum, hippocampus and frontal cortex of 8 and 12 weeks old R6/2 mice associated with significantly increased phosphocreatine and creatine. There was no difference in ATP levels at 4 weeks of age between R6/2 and WT littermates, yet phosphocreatine and creatine were already significantly elevated in the striatum and frontal cortex of R6/2 mice. Instead, after an intraperitoneal injection of 3-nitroproprionic acid in WT mice - an acute model of striatal energy deficit - we found a significant decrease of most high-energy phosphate metabolites (ADP, ATP and phosphocreatine). Conclusion: We identified the earliest alteration of DA and 5-HT metabolism in R6/2 mice associated with stress-like behaviors. These neurotransmitter abnormalities were coupled with compensatory processes - i.e. increased phosphocreatine and creatine - for the chronic brain energy deficit of HD and constitute targets for therapy. Our system can be used to characterize the brain neurotransmitter and energy profile of many neurogenetic disease models.

Evaluating endophenotypes for schizophrenia with the Endophenotype Ranking Value (ERV) statistic. *M. Zlojutro[1], R.C. Gur[2], M. Pogue-Geile[3], E. Hare[4], M.E. Calkins[2], K. Prasad[5], D. Glahn[6], J. Blangero[7], V. Nimgaonkar[7], R.E. Gur[2], L. Almasy[1].* 1) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Department of Psychology, University of Pittsburgh, Pittsburgh, PA; 4) Texas Tech Health Science Center, Paul L. Foster School of Medicine, El Paso, TX; 5) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA; 6) Department of Psychiatry, Yale University, Hartford, CT; 7) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Deficits have been observed for various cognitive measures in individuals with schizophrenia and their clinically unaffected family members, indicating that the deficits contribute at varying degrees to the genetic liability of schizophrenia and thus represent intermediate phenotypes or endophenotypes that lie on the causal pathway from genotype to disease outcome. Although the genetic analysis of cognitive measures is likely to be a powerful approach for identifying susceptibility loci in schizophrenia, each candidate endophenotype has its own complex genetic architecture and determining which are the most informative to the genetic underpinnings of schizophrenia has involved several criteria, with selection based mostly on their heritability and association with the disease. Here we introduce a new, quantitative measure for evaluating the suitability of traits as endophenotypes based on their shared genetic component with a disease of interest: Endophenotype Ranking Values (ERVs). The ERV represents a straightforward product of three estimates from bivariate genetic analyses of family data: square root of the heritability of the disease of interest (hd); square root of the heritability of the candidate endophenotype (ht); and the genetic correlation between the disease and endophenotype (ρg). The heritabilities represent the strength of genetic effects on the two traits and ρg the extent of pleiotropy or overlap in genetic influences. The ERV can be used to identify endophenotypes, as well as rank them to reduce multiple testing by using only the most promising traits in analyses. For a sample of 816 individuals from 43 families, with 79 participants diagnosed with schizophrenia or schizoaffective disorder-depressed type, the ERV was estimated for a battery of computerized tests designed to assess the following cognitive domains: abstraction and mental flexibility; attention; language; spatial processing; face memory; spatial memory; verbal memory; and emotion processing. The top scoring cognitive endophenotypes are abstraction and mental flexibility (0.317; p=0.002), language (0.284; p=0.03), attention (0.271; p=0.008), and emotion processing (0.269; p=0.003). These ERV estimates identify cognitive domains with genetic components that are significantly shared with the genetic liability of schizophrenia and thus represent appropriate endophenotypes for investigation into the genetic basis of this brain disorder.

Psychiatric Genetics Goes to the Dogs: A Canine Model of Compulsive Behaviour. *P.D. Arnold[1], K. Tiira[2], C. Escriou[3], A. Thomas[3], S. Renier[3], C. De Citres[3], L. Koskinen[2], B. Minassian[1], H. Lohi[2].* 1) Program in Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Canine Genomics Research Group, Department of Veterinary Biosciences, Department of Medical Genetics, Program in Molecular Medicine, The Folkhälsan of Institute of Genetics, University of Helsinki; 3) Veterinary School of Lyon, France.

Purebred dogs provide excellent genetic models for the study of human behaviours, since the history of inbreeding means that far fewer dogs are needed to map a given trait compared with humans. In this study, we set out to systematically characterize clinical and genetic features of tail chasing (TC) in purebred bull terriers, which has been suggested to be a model for human obsessive-compulsive disorder (OCD). A web-based questionnaire was administered to owners to elicit clinical and environmental features, with direct examination by a veterinarian occurred in a subset of cases. TC cases and normal controls were compared using a 200K Illumina genome-wide array. Genetic analyses were performed using PLINK. To date we have collected 154 Standard Bull Terriers (92 cases) and 57 Miniature Bull Terriers (22 cases). In more severe cases additional behaviours were commonly observed including aggression, “freezing” and staring episodes. Early onset was associated with increased frequency of TC, whereas improved diet (use of supplements) was associated with decreased severity. Our preliminary genome-wide association study (GWAS) of 24 TC dogs and 24 controls did not result in any genome-wide significant findings. In conclusion, TC is a behavioural syndrome commonly seen in bull terriers with distinct environmental and clinical correlates. Larger samples will be needed to identify genetic risk factors using GWAS. Genetic findings in TC may provide important clues to the genetic basis of human disorders characterized by complex repetitive behaviours, such as OCD and autism.

2718/F

Typical schizophrenia MRI brain volumetric reductions in 22q.11DS adults. *A.S. Bassett[1, 2], A. Ho[2], A. Crawley[3], C. Wei[3], D.J. Mikulis[3], E. Chow[1,2].* 1) Dept of Psychiatry, University of Toronto, Toronto, ON, Canada; 2) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, ON, Canada; 3) Dept of Medical Imaging, Toronto Western Hospital, University of Toronto, Toronto, ON, Canada.

Background: Individuals with 22q11.2 deletion syndrome (22q11DS) are at high risk of developing schizophrenia. Imaging studies are inconclusive as to whether specific regional brain volume reductions are associated with expression of schizophrenia in 22q11DS. Methods: Using the largest sample of adults with 22q11DS studied to date (n=63), magnetic resonance brain images from 29 subjects with schizophrenia and 34 with no history of psychosis (NP) were analyzed using a voxel-based morphometry (VBM) method that also yielded volumes for region of interest (ROI) analyses. We compared gray matter (GM), white matter (WM), and cerebrospinal fluid (CSF) measures between the groups using an analysis of covariance model with total intracranial volume, age, sex, IQ and history of congenital cardiac defects as covariates, and a false discovery rate threshold of $p<0.05$ for VBM results. Results: VBM analyses identified significant GM reductions in the left superior temporal gyrus in the 22q11DS-schizophrenia group ($p=0.029$). There were no significant between-group differences in WM or CSF. ROI analyses of temporal lobe GM showed significant volume reductions in bilateral temporal lobes and superior temporal gyri in the 22q11DS-schizophrenia group. Conclusions: These structural brain findings in a 22q11DS form of schizophrenia are consistent with those from previous studies involving schizophrenia in the general population and provide further support for 22q11DS as a genetic subtype and useful neurodevelopmental model for schizophrenia.

2719/F

Partial *SPAST* and *DPY30* deletions in autosomal dominant hereditary spastic paraplegia. *S. Miura[1, 2], H. Shibata[2], H. Kida[1], K. Noda[1], A. Iwaki[2], M. Ayabe[1], H. Aizawa[1], T. Taniwaki[1], Y. Fukumaki[2].* 1) Department of Respirology, Neurology and Rheumatology, Department of Medicine, Kurume University School of Medicine, Kurume City, Fukuoka Prefecture, Japan; 2) Division of Molecular Population Genetics, Department of Molecular Genetics, Medical Institute of Bioregulation, Kyushu University.

Hereditary spastic paraplegia (HSP) is a genetically heterogenous neurodegenerative disorder characterized by progressive weakness and spasticity in the lower extremities. Spastic paraplegia type 4 (SPG4) is the most common HSP caused by mutations in *SPAST*. We studied a four-generation Japanese pedigree with autosomal dominant HSP both clinically and genetically. Eleven available family members (10 affected; 1 non-affected) and three spouses participated in this study after providing informed consent. Patients in most cases showed hyperreflexia both upper and lower extremities, spasticity of the lower limbs. Four (40%) had urinary dysfunctions and eight (80%) showed a decrease in vibration sense in the lower limbs. In seven patients (70%), gait disturbance was noticed before age 2. All four female patients experienced multiple miscarriages. Nerve conduction studies were performed in three patients. Sural nerve action potentials were below the detectable level in two. In the Wechsler Adult Intelligence Scale-Third Edition (WAIS-III), impaired cognitive function was observed in all three studied patients (Full Scale IQ were 65, 75 and 77). Tau levels in cerebrospinal fluid were mildly increased in two of the three patients. Linkage analysis of chromosome 2 using 26 fluorescent-labeled microsatellite markers spaced at intervals of approximately 13 Mb with the GENEHUNTER program revealed the highest multipoint logarithm of odds (LOD) score of 2.643 at 2p23-p21 where *SPAST* is located. Although we extensively scanned the entire exonic sequences of SPAST by direct sequencing, there is no mutation detected. Real-time quantitative polymerase chain reaction of all exons in *SPAST* using SYBR Green I dye demonstrated a heterozygous deletion of exons 1 to 4 of *SPAST*. Breakpoint analysis revealed a large deletion with the size of 63,851 bp of which the telomeric breakpoint is located in intron 3 of *DPY30* resulting in a deletion of exons 1 to 3 of *DPY30*. To our knowledge, this is the first report on SPG4 associated with partial deletions of both *SPAST* and *DPY30*. Since *DPY30* is known to be an essential component of the dosage compensation machinery, the partial heterozygous deletion of *DPY30* might modify phenotypic expression of SPG4 in the patients of this pedigree. This study was approved by the Ethics Committees of Kurume University School of Medicine and Kyushu University, Faculty of Medicine.

The effects of parental age on the risk for neuropsychiatric disorders. *J.E. Buizer-Voskamp[1,2], W. Laan[3], W.G. Staal[4], E.A.M. Hennekam[5], S.A.J. de With[4], M.F. Aukes[1,3], R.S. Kahn[1], M.P.M. Boks[1,3], R.A. Ophoff[2,6].* 1) Rudolf Magnus Institute of Neuroscience, Department of Psychiatry, University Medical Center Utrecht, Utrecht, The Netherlands; 2) Complex Genetics Section, Department of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 3) Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, Utrecht, The Netherlands; 4) Department of Child and Adolescent Psychiatry, University Medical Center Utrecht, Utrecht, The Netherlands; 5) Department of Clinical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 6) UCLA Center for Neurobehavioral Genetics, University of California, Los Angeles, California, United States.

High parental age may be a risk factor for developing psychiatric disorders. In this study parental age and the risk for developing schizophrenia, autism spectrum disorder (ASD), depressive disorders, and bipolar disorder were measured in the Dutch population. Additionally, effects of parental age on type of DSM-IV(TR) classification (Autism, Asperger Syndrome, Pervasive Developmental Disorder, not otherwise specified (PDD-NOS)) were tested in two ASD samples. Patients were collected through a patient registry. Date of birth of their parents was retrieved from the database of Statistics Netherlands (CBS) together with a fourfold number of matched controls. The ASD patient samples were recruited from two Dutch University hospitals with high expertise in ASD. In total, data on 2,627 schizophrenic, 2,329 autistic, 8,634 depression, and 1,133 bipolar disorder patients was available from the population-based registry. When analyzed as a continuous measure, the paternal age of autistic individuals was significantly higher compared to controls ($p=0.001$). When analyzed as a categorical measure, the age effect becomes even more pronounced: fathers <20 years of age have the lowest risk of having a child with autism (OR=0.37, 95%CI: 0.11-1.19), fathers >40 years of age have a significantly higher risk (OR=1.23, 95%CI: 1.01-1.50). For the clinical samples, data on 461 autistic individuals was analyzed. A greater difference in age between the parents increased the likelihood of a diagnosis of autism instead of Asperger syndrome or PDD-NOS ($p=0.038$). For schizophrenia and depressive disorders, only the categorical analysis showed significant paternal age effects. For schizophrenia, fathers aged >35 years appear to have significantly higher risk (OR=1.27, 95%CI: 1.05-1.53). For depressive disorders, there is a U-shaped effect. For bipolar disorder no parental age effects were found. This study shows that higher paternal age is associated with higher risk for autism. Additionally, greater difference in age between parents increases the odds of a diagnosis of core autism and not PDD-NOS or Asperger syndrome. Secondly, parental age effects were found in schizophrenia and depressive disorders, but not in bipolar disorder. As far as we are aware, this is the first large-scale population-based study examining the effects of parental age in the four major psychiatric disorders simultaneously.

2721/F

Genomewide linkage scans for loci predisposing to dependence on multiple substances. *BZ. Yang[1,4], S. Han[1], HR. Kranzler[5], L. Farrer[6], J. Gelernter[1,2,3,4].* 1) Psychiatry, Yale Univ Sch Med, New Haven, CT; 2) Genetics, Yale Univ Sch Med, New Haven, CT; 3) Neurobiology, Yale Univ Sch Med, New Haven, CT; 4) VA CT Healthcare Center, West Haven, CT; 5) Univ CT Health Center, Farmington, CT; 6) Boston Univ School Med, Boston, MA.

Dependence on multiple substances (MSD), including alcohol and a variety of drugs of abuse is common. MSD patients are often severely affected clinically. Genetic risk factors may play an important role in the development of MSD. With increasing evidence of a role for rare variants and copy number variation (CNV) in complex diseases, genetic linkage studies are still recognized as useful tools for gene discovery. An adequately powered linkage study design has the advantage of detecting diverse genetic effects that segregate in families, including common variants, multiple rare variants within one locus, and CNV. In this study, we hypothesized that different substance dependence (SD) traits share genetic liability. Linkage analysis of MSD could increase power to detect shared risk loci due to severe affection compared to analysis of an individual SD disorder. We genotyped 6,008 single nucleotide polymorphism makers for 952 individuals from 384 African American (AA) families and 806 individuals from 355 European American (EA) families ascertained on the basis of affected sib-pairs with cocaine and/or opioid dependence. We conducted a fuzzy clustering analysis on the SD traits including alcohol, cannabis, cocaine, opioid, and nicotine dependence for AAs and EAs separately, and performed genomewide linkage scans for the resultant membership coefficients from the fuzzy clustering analysis for each individual using Merlin-regression. In AAs, two linkage peaks with suggestive linkage were observed on chromosome 10 with a peak LOD = 2.66 at 96.7 cM and a peak LOD = 3.02 at 147.6 cM; these surround our previous linkage peak near 117.2 cM for alcohol dependence in AA. In addition, two other suggestive linkage regions were identified on chromosome 3 with a peak LOD = 2.81 at 145.5 cM and on chromosome 9 with a peak LOD = 1.93 at 146.8 cM. In EAs, we detected a genome-wide significant linkage signal on chromosome 4 with a peak LOD = 3.31 at 68.3 cM (point-wise p = 0.00005, empirical genome-wide p = 0.038). A suggestive linkage signal on chromosome 21 was also observed with a peak LOD = 2.37 at 19.4 cM. This evidence of genomewide linkage for MSD in the two major US population groups based on a dense SNP map can provide useful information in the search for genes that influence this phenotype.

2722/F

Targeted Next Generation Sequencing for Rare Variant Detection in Patients with Early Onset Parkinson Disease. *G. Bademci[1], Y. Edwards[2], A. Mehta[2], S. Zuchner[2], A. Torres[2], W.K. Scott[1], D. Hedges[1], J.M. Vance[1].* 1) Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, Fl.

Parkinson disease (PD) is a complex, progressive neurodegenerative disorder. Rare variants (RV) are variants with a population frequency usually less than 2% in the human genome. They have been postulated to be a potential source of genetic variation in which some RV contribute to increasing an individual's risk to complex diseases like PD. For the first time Next-generation sequencing (NGS) allows the search for RV to be performed in complex diseases. We recently reported a joint PD GWAS analysis (Edwards et al. 2010), and have also completed a pathway-based meta-analysis of PD GWAS and gene expression. The pathway analysis identified calcium signaling and focal adhesion as two of the top over-represented pathways. As part of an initial pilot project comparing 3 different capture technologies, we evaluated 13 early-onset patients (£30 years) diagnosed with PD for RV in known PD genes, genes within identified pathways and genes with strong PD-risk association. The following genes were targeted for capture: Calcium signaling pathway (DRD1, NOS1A, NOS2A, CALM1, CD38, RYR1, CACNA1E), Focal adhesion (CAV2), Tyrosine metabolism (TH, MAOB, COMT) and MAPK signaling (MAPT). We also captured the following known PD genes and risk-associated genes: PARKIN, SNCA, NPAS3, GFPT2, ATP13A2, DBC1, USP24, RIT2, DGKQ and ELAVL4. NGS was performed using the ABI SOLiD 3 and NGS reads were mapped to the human hg18 reference genome. Variants aligned and called using MAQ version 0.7.1. Novel variants were defined as those not found in currently available dbSNP, Human Genome Mutation Database (HGMD) as well as a literature search. SeattleSeq annotation and Polyphen prediction were used for in silico functional analyses. Two patients were discovered with a novel homozygous variation (R366Q) and a previously reported mutation (G430D) in Parkin. Further, novel variants predicted to negatively impact protein function included missense changes in MAPT (G213R), RIT2 (R182H), and ATP13A2 (A1144T), and calcium signaling pathway genes CD38 (L18R) and CACNA1E (R920C). All variants were found in all 3 captures and were confirmed with Sanger sequencing. The number of RV in this small sampling of early-onset patients support the potential of RV contributing to PD and the utility of using NGS to find RV in a large dataset. Furthermore, we provide evidence to support the utility of pathway analysis to prioritize genes for the identification of RV in complex disease.

2723/F

Quantitative genetics of language measures in families selected for both autism and specific language impairment. *L. Hou[1], J.F. Flax[2], S. Buyske[2,3], A. Hare[2], Z. Fermano[2], C.W. Bartlett[1], L.M. Brzustowicz[2].* 1) The Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital and Department of Pediatrics, The Ohio State University, Columbus, OH; 2) Department of Genetics, Rutgers University, New Brunswick, NJ; 3) Department of Statistics, Rutgers University, New Brunswick, NJ.

The purpose of this study is to estimate heritability of language and reading abilities in nuclear and extended pedigrees ascertained for autism and specific language impairment (SLI). By estimating the heritability of oral and written language measures in these pedigrees, we explored the shared genetics of the two disorders (autism and SLI) under the hypothesis of such an effect. Heritability was calculated twice; once on the entire sample and once removing the individuals with autism who had language and were able to accept the language and reading measures. We found that removing persons with autism increased the size of the standard errors (often considerably) while heritability estimates were less correlated with the original estimates compared to conditioning on ASD status as a covariate (R^2 from 0.96 to 0.32); both lines of evidence are fully consistent with a reduction in sample size as the cause of the additional variability. Conditioning on ASD status as a covariate, 5 individual measures did show significant changes by likelihood ratio testing versus a model that did not include ASD as a covariate (P<.05). Four of these measures involved higher order or metalingusitc tasks from the Comprehensive Assessment of Spoken Language, showing significant changes in heritability when ASD status was explicitly modeled (from 37%, 58%, 38% and 38% to 46%, 70%, 45% and 43%, respectively). Additionally, global language ability (Clinical Evaluation of Language Fundamentals) significantly increased from 42% to 53%. Increasing heritability when statistically controlling for scores from at least one person per pedigree indicates heritability of these tasks and is not consistent with a simple genetic model of correlation between relatives. These results might suggest 1) these tasks have a genetic threshold that is not being appropriately modeled through standard techniques, 2) evidence of unmodeled environmental interactions or, 3) measurement error. The last interpretation is unlikely since higher order language tasks tap into manipulation, generalization, and abstraction of language; skills that are compromised to non-existent in individuals with language disorders depending on the degree of involvement. Furthermore, persons with autism did not display floor effects or show greater variance than when the sample excluded the individuals with autism.

2724/F

A genomewide ordered-subset linkage analysis for alcohol dependence in African-Americans. *S. Han[1], B.Z. Yang[1,4], H.R. Kranzler[5], J. Gelernter[1,2,3,4].* 1) Dept Psychiatry, Yale Univ, New Haven, CT; 2) Dept Genetics, Yale Univ, New Haven, CT; 3) Dept Neurobiology, Yale Univ, New Haven, CT; 4) VA CT Healthcare Center, West Haven, CT; 5) Univ CT Health Center, Farmington, CT.

Alcohol Dependence (AD) is extremely costly to individuals and to society throughout the world. The etiology of AD is complex; genetic factors are known to be important to its development. With increasing evidence of a role for rare variants and copy number variation (CNV) in complex diseases, linkage analysis remains a useful approach to gene discovery. An adequately powered linkage study can detect diverse genetic effects that segregate in families, including common variants, multiple rare variants within one locus and CNV. Previously, we performed a genomewide linkage scan for AD in African-Americans (AA) (Gelernter 2009). The power of that linkage analysis could theoretically have been reduced by the presence of genetic heterogeneity due to the variation of admixture proportions across families in AA. In the current study, we hypothesized that a sample whose genetic ancestry was more homogeneous would increase power to detect linkage. To test this hypothesis, we first completed a genomewide linkage scan with 6008 single nucleotide polymorphism markers to map loci linked with DSM-IV AD in 384 AA families ascertained on the basis of multiple individuals affected with cocaine and/or opioid dependence. Using the admixture proportion as a covariate, we then applied the ordered subset linkage analysis (OSA) technique to identify a more homogeneous subset of families to determine whether it increased evidence for linkage with AD. Statistically significant increases in Kong-Cox LOD scores were observed on chromosomes 4 (P= 0.0001), 12 (P=0.021), 15 (P=0.026) and 22 (P=0.0069). In a subset of 44 AA families (with African ancestry proportions ranging from 0.858 to0.996), we observed a genomewide significant linkage at 180 cM on chromosome 4 (Kong-Cox LOD=4.1, pointwise P=0.00001, empirical genomewide P= 0.008). *GLRA3*, the gene encoding a subunit of the glycine neurotransmitter receptor, is located in this peak region; thus, it deserves further research attention. A parametric linkage analysis confirmed the significant findings from the non-parametric linkage analysis. Our results show new evidence for linkage and demonstrate that the admixture proportion can be used effectively as a covariate to reduce genetic heterogeneity and enhance the detection of linkage signals in AA using the OSA technique. The current study provides important clues for candidate gene and deep sequencing studies to identity causal variants for AD.

2725/F

Genome-wide linkage analysis of flexibility/insistence-on-sameness in multiplex families with Autism spectrum disorders. *N. Chapman[1], A. Estes[1], J. Munson[1], R. Bernier[1], S.J. Webb[1], J. Rothstein[1], G. Schellenberg[2], G. Dawson[1,3], E. Wijsman[1].* 1) University of Washington, Seattle, WA; 2) University of Pennsylvania School of Medicine, Philadelphia PA; 3) Autism Speaks.

Autism spectrum disorders (ASDs)involve qualitative deficits in social interaction and communication, and restricted interests or repetitive behavior. Genetic factors play an important role in autism susceptibility, and both rare and common alleles have been implicated in autism risk. Linkage signals have proven hard to replicate, likely due to phenotypic or genotypic heterogeneity. In order to meet the challenge of phenotypic heterogeneity, we focus on quantitative traits related to autism.

We examine the restricted interests and repetitive behavior domain of the autism phenotype, using the Flexibility/Range of Interests scale of the Broader Phenotype Autism Symptom Scale (BPF). BPF is the average of three scales addressing flexibility in (i) schedule and routine; (ii) physical environment and (iii) interests. Each scale takes integer values of 1 - 5, with 1 indicating above average flexibility, and 5 indicating well below average flexibility.

We present genetic analyses of BPF in 1253 people in 266 families. Families were ascertained through the existence of at least two children affected with an ASD. The families are mostly nuclear and BPF scores are available on 90% of individuals. MCMC oligogenic segregation analysis (OSA), which allows for simultaneous modeling of multiple loci, was used to explore the evidence for genetic influence on BPF. Analysis of age-adjusted BPF gave strong evidence for one QTL, with recessive inheritance and a broad-sense heritability of 41%.

A genome-scan of 387 multiallelic STRs is available on 247 of these families (1168 individuals, 94% genotyped). Using the model obtained from the OSA, single-marker parametric lod scores were calculated. Chromosomes with interesting lod scores were followed up with a novel multipoint approach: using gl_auto from MORGAN, all markers per chromosome were used to generate samples of inheritance vectors (IVs) compatible with the available genotypes, with the program IBDgraph identifying equivalent IVs. Likelihoods were calculated for each unique IV using the parametric model, and then averaged, with weights, over the sampled IVs. This yields a lod score that uses marker information on the entire chromosome, but models the disease locus separately. Two regions achieved lod scores >2 and will be the subject of further study.

2726/F

Phenotyping for a behavior genetics study. *R. Plaetke, V. Stegall, F. Balbi.* Department of Anthropology, University of Alaska, Fairbanks, AK.

Since the building of genome maps for the domestic dog (*Canis familiaris*) and silver fox (*Vulpes vulpes*), animal models have been developed to investigate the genetics of behavior in these species and transfer results to humans (1-4).

These studies are based on the evolutionary aspect of behavior as already proposed by Darwin. In the same way, as he suggested continuity between humans and other species related to “physical” traits, he discussed this concept related to emotions in his book *“The Expression of the Emotions in Man and Animals.”* He proposed that many of the basic emotions and accompanying facial expressions exist in both, animals and humans.

We investigate an extraversion-temperament component in the Alaskan Husky (sled) dog to determine whether phenotypes (1) can be constructed for its characterization and (2) are heritable; and (3) the dogs can serve as a model to investigate the genetics of this component.

Behavior tests of 63 dogs have been performed and videotaped. Videotapes are analyzed under standardized conditions. To date, 28 characterizations of responses and their intensities have been determined; 6 of those are quantitative variables.

We will present:

(1) Details about the behavioral assay and how it is performed in the field.
(2) How we evaluate validity & reliability of the tests.
(3) Construction of phenotypes and their distributions among the dogs.
(4) Segregation of phenotypes in ascertained pedigrees.
(5) Efficient management of “upside down” pedigree structure consisting of each dog, 2 parents, 4 grandparents, and 8 great-grandparents; the usual format provided by breeders.

Hypoxia in Endothelin-2 (Edn2) null mice is associated with photoreceptor (PR) rescue in multiple models of inherited PR degeneration (IPD). *A.N. Bramall[1,2], M.J. Szego[1,2], L.R. Pacione[1,2], T. Van Veen[4], M. Yanagisawa[5], R.R. McInnes[1,2,3].* 1) Program in Stem Cell and Developmental Biology, Hospital for Sick Children Research Institute, Toronto, Ontario; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario; 3) The Lady Davis Institute, Jewish General Hospital, McGill University, Montreal; 4) Department of Ophthalmology Research, Lund University Hospital, Lund, Sweden; 5) HHMI & the Department of Molecular Genetics, University of Texas Southwestern Medical Center, Dallas.

IPDs are among the leading causes of inherited blindness in humans, affecting about 1/3600 individuals. These disorders are characterized by remarkable genetic heterogeneity, but nevertheless most or all IPDs appear to share at least two common properties: exponential kinetics of PR death (Clarke et al. 2000), and a dramatic increase in the PR expression of the *Endothelin-2* mRNA (Rattner et al. 2005). We previously reported at this meeting that the *Edn2* mRNA was 70-fold ($p< 0.009$) and 72-fold ($p<0.0009$) up-regulated in *Tg(RHO P347S)* and *Rd1*$^{-/-}$ retinas, respectively, and that the increased retinal *Edn2* expression was restricted to the mutant PRs. To determine whether the increased *Edn2* mRNA expression was proapoptotic, we had generated two IPD mouse strains that lacked the *Edn2* gene. We found that the absence of Edn2 expression in both *Tg(RHO P347S);Edn2*$^{-/-}$ mice (at post-natal day 40 (PN40)), and *Rd1*$^{-/-}$*; Edn2*$^{-/-}$ mice (at PN15), led to a 41% and 49% increase in mutant PR survival, respectively. Here we provide evidence suggesting that much, if not all the rescue conferred by deleting the *Edn2* gene results from extraocular mechanisms. *First*, whereas *Rd1*$^{-/-}$ retinal explants displayed PR death at rates comparable to those seen *in vivo*, there was no rescue of PR death in *Edn2*$^{-/-}$*; Rd1*$^{-/-}$ retinal explants ($n= 5;p>0.05$), in contrast to the rescue observed *in vivo*. *Second*, the re-introduction of *Edn2* mRNA expression in *Edn2*$^{-/-}$*; Rd1*$^{-/-}$ retinas (but not in the whole animal) using a subretinally injected AAV5-CBA-*Edn2* vector did not restore PR death ($n=6;p>0.05$) *in vivo*. *Third*, *Edn2*$^{-/-}$ mice have very poor pulmonary alveolarization, leading to systemic hypoxia; EPO was 11-fold up-regulated in *Edn2*$^{-/-}$ animals by ELISA ($n=7;p<0.05$). We propose that the *in vivo* rescue of PR death in *Edn2*$^{-/-}$*; Rd1*$^{-/-}$ retinas is due at least partly to the systemic hypoxia, because i) *Edn2*$^{-/-}$ retinas are hypoxic *in vivo*: VEGF, a major hypoxia response gene, was 4-fold elevated by immunobloting in *Edn2*$^{-/-}$ retinas at PN21 ($n=4;p<0.05$); and ii) in *Rd1*$^{-/-}$ retinal explants cultured in 6% O2 from PN10 to PN17, PR death was reduced by 32% vs. *Rd1*$^{-/-}$ explants in normoxia (17% O2) ($n=5$; $p<0.05$). The protective effect of hypoxia on PR death suggests that elucidation of the molecular mechanisms by which hypoxia exerts its protective effect will identify novel neuroprotective pathways in the retina.

2728/F

Identifying Copy Number Variation Influencing Risk for Alzheimer Disease in the Amish. *O.J. Veatch[1], D.R. Velez Edwards[2,3], W.K. Scott[2], J.R. Gilbert[2], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetic Research, Vanderbilt Med Ctr, Nashville, TN; 2) J.P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 3) Vanderbilt Epidemiology Center, Vanderbilt University Medical School, Nashville, TN.

Numerous studies have shown that Alzheimer disease (AD) has a high degree of heritability suggesting strong genetic components influencing risk for developing the disease. However, the heterogeneous nature of the disease has made it difficult to identify the underlying genetic loci for AD. Current studies of human Copy Number Variations (CNVs) indicate these structural variations contribute significantly to genetic and allelic heterogeneity. CNVs affect gene function in many ways including deletion or amplification of regions containing variable numbers of genes that could influence neuropsychiatric disease susceptibility. Large-scale CNV studies require stringent control for population stratification to avoid false positive associations. To avoid issues arising from population stratification we ascertained subjects from Amish communities located in Indiana and Ohio assuming similar genetic substructure. To assess possible CNVs influencing AD, a total of 903 individuals, age ≥ 65 years, from this population were genotyped on an Affymetrix® SNP 6.0 microarray chip. Samples with quality control issues were removed from analysis and the remaining 846 male and female individuals (113 with AD, 466 cognitively normal, 267 with other cognitive phenotypes) were assessed for CNVs using Partek® Genomics Suite software. Copy number intensities were normalized to a baseline created from the cognitively normal Amish individuals, and variations were detected using a hidden Markov Model. A total of 270 CNV regions across the genome were detected in at least 30 individuals. No statistically significant differences in frequency were observed between affected and unaffected individuals in these preliminary data suggesting no strong relationship of these common CNVs with AD. More detailed statistical analyses are ongoing. We also identified regions of allelic imbalance and loss of heterozygosity utilizing cognitively normal Amish individuals as the baseline for both analyses. We are currently examining putative regions of interest and identifying candidate disease-susceptibility genes located in these regions.

2729/F

Expression QTL analysis of top loci from Psychiatric GWAS Consortium meta analysis reveal additional schizophrenia candidate genes. *S. de Jong[1], M.P.M. Boks[2,3], D.L.W.H. Zeegers[1], K. van Eijk[1], E. Janson[1], E. Strengman[1], J.H. Veldink[4], L.H. van den Berg[4], W. Cahn[2], R.S. Kahn[2], R.A. Ophoff[1,2,5], Psychiatric GWAS Consortium.* 1) Department of Medical Genetics, University Medical Center, Utrecht, Netherlands; 2) Department of Psychiatry, Rudolf Magnus Institute of Neuroscience, University Medical Center, Utrecht, Netherlands; 3) Julius Centre for Health Sciences and Primary Care, University Medical Center, Utrecht, Netherlands; 4) Department of Neurology, Rudolf Magnus Institute of Neuroscience, University Medical Center, Utrecht, Netherlands; 5) Department of Human Genetics, Neuropsychiatric Institute, University of California, Los Angeles, USA.

Schizophrenia is a severe psychiatric disorder characterized by delusions and hallucinations, in addition to negative and cognitive symptoms. The disorder affects up to 1% of the population and the genetic contribution is estimated to be around 80%. Thus far, genome-wide association studies (GWASs) of schizophrenia have had limited success, with the best finding at the HLA locus at chromosome 6p. While only a very small number of loci yield genome-wide significance for association, the vast majority of the genetic contribution to disease susceptibility remains uncovered. It is likely to be overrepresented in non-significant top SNPs of large-scale GWAS results. In order to uncover potential interesting candidates, we selected the top 6,000 single nucleotide polymorphisms (SNPs) with significance threshold at p<0.001 from the international PGC meta-analysis consisting of some 9,000 cases and 12,000 controls and examined their possible involvement in schizophrenia using gene expression data from whole blood. Expression QTLs (eQTLs) were calculated for this selection of SNPs in a large set of healthy controls (n=437). The transcripts significantly regulated by the top SNPs from the GWAS meta-analysis schizophrenia-related SNPs were subsequently tested for differential expression in an independent set of schizophrenia cases and controls (n=200). After correction for multiple testing, eQTL analysis yielded significant cis-acting effects, whereas no trans effects were observed. For seven of these transcripts we observed significant differential expression between cases and controls. Results include target genes of interest both in- and outside the HLA region and contain genes that are known to be expressed in brain. These genes are strong candidates for schizophrenia for which further genetic analysis is warranted.

Huntington's disease in Peru:Spread of cases and Analysis of CAG triplet distribution in Peruvian population. *R. Lovaton Espadin, C. Timana Chavez, G. Torres Alva, M. Cornejo Olivas, M. Marca Ysabel, O. Ortega Davila, C. Cosentino Esquerre, L. Torres Ramirez, P. Mazzetti Soler.* Neurogenetics Laboratory,National Institute of Neurological Sciences (Lima-Peru).

Introduction: Huntington's disease is an autosomal dominant disorder characterized by involuntary movements, cognitive and psychiatric disorders. This neurodegenerative disease is caused by the expansion of a CAG triplet repeat in the first exon of the HD gene on chromosome 4p16.3. Huntington's disease cases have been reported in Peru; however, there is little information about the epidemiological characteristics of this population. The purpose of this work is to show the distribution of Huntington's disease cases and a possible founder's effect in Peru. **Materials and Methods:** The National Institute of Neurological Sciences (Lima-Peru) is the national reference center for neurological and neurogenetical diseases in our country, receiving most of the population with Huntington's disease in our country. From our database, 225 persons with more than 36 CAG repeats, independent from their clinical status, were chosen. Their birth place was obtained from their medical records. Graphics and maps were done in order to show how this population has spread inside our country during the last decades. **Results:** Up to 2010, our distribution of cases in relation to place of birth is as follows: most of them came from the Department of Lima (85%) and Cañete, a province from the Department of Lima, accounts for 27 % of cases. 48% of cases were female and 52 % were male. The age at onset of symptoms was 39.8±10 years. The maximum number of CAG triplet repeats that we found was 70.A map of Peru built with the data available shows cases distributed in 12 departments from Peru. **Discussion and Conclusions:** Huntington's disease population in Peru shows some special characteristics. The maximum number of CAG triplet repeats found is less than other Huntington's disease populations (Venezuela, Europe). Probably our Huntington's disease population is younger, the disease probably arrived to our country recently compared to other locations or there is a genetic determinant that prevents expansion of CAG triplets. Distribution of cases in Peru shows an spread of this disease from a probable origin located in the Department of Lima (Cañete) to other departments. This distribution of cases is not related with the population density in Perú. These findings reveal the importance of genetic counseling in patient's relatives to prevent further expansion of this disease.

2731/F

Association between Tryptophan Hydroxylase II gene and late onset depression. *D. Miranda[1], P. Pereira[1], M. Bicalho[1,2], L. De Marco[1], H. Correa[1], S. Campos[1], E. Moraes[2], K. Torres[1], B. Souza[1], M. Romano-Silva[1].* 1) Mental Heathy, UFMG, Belo Horizonte, Brazil; 2) Centro de Referência do Idoso, Hospital das Clínicas, Universidade Federal de Minas Gerais (UFMG), Brazil.

The aim of this study was to examine the association between polymorphisms in the TPH2 gene and late-onset depression in the Brazilian population. Serotonin is a major neurotransmitter in the central nervous system (CNS), and its role in psychiatric disorders is well documented. Tryptophan hydroxylase 2 (TPH2) catalyzes the rate-limiting step in the synthetic pathway for brain serotonin and is considered key for maintaining normal serotonin transmission in the CNS. TPH2 polymorphisms are associated with major depression and suicide, attention-deficit hyperactivity disorder, and repetitive behaviors in autism, which suggest that the TPH2 gene is involved in the development of many psychiatric disorders. We genotyped 8 tagSNPs in the TPH2 gene in 84 outpatients with diagnosis of late-onset depression and 79 individuals belonging to the comparison group to investigate an association between the TPH2 gene and late-onset depression. Our findings suggested an association between tagSNP rs4565946 heterozygous C/T (p= 0,009; χ2= 6,7) and decreased risk of late-onset depression. The tagSNP rs11179000 ancestral homozygous A/A (p = 0,01, χ2= 7,3) and increase risk of late-onset depression. Allelic association of ancestral allele A and raise risk of late-onset depression was demonstrated (p-value= 0,005, χ2= 7,8). We found the statistically significant association between two tagSNPs and late-onset depression. The limitation of our study includes the small sample size, the population stratification and no information about current or past stress. Our results support the hypothesis that the TPH2 gene is associated with late-onset depression.

Targeted proteomic study of serum from children with autism showing differential expression of complement proteins. *H. Li[1], J.A. Caruso[6], D.C. Chugani[2,3,4,5], P.M. Stemmer[6].* 1) Division of Genetic and Metabolic Disorders, Children's Hospital of Michigan, Detroit, MI. 3901 Beaubien Blvd. Detroit, MI 48201; 2) Autism Center, Children's Hospital of Michigan 3901 Beaubien Blvd. Detroit, MI 48201; 3) Division of Clinical Pharmacology and Toxicology, Children's Hospital of Michigan 3901 Beaubien Blvd. Detroit, MI 48201; 4) Pediatrics Dept, Wayne State University School of Medicine 3901 Beaubien Blvd. Detroit, MI 48201; 5) Radiology Dept, Wayne State University School of Medicine 3901 Beaubien Blvd. Detroit, MI 48201; 6) Institute of Environmental Health Sciences Wayne State University 2105 Scott Hall, 540 E. Canfield, Detroit, MI 48201.

Objectives: To identify proteins that are differentially expressed in young children with autism compared to age matched healthy children for use as candidate plasma biomarkers of autism. Methods: Plasma samples were obtained from children with autism having elevated serotonin 2-6 years of age (n=10) and age and gender matched typically developing children (n= 10). Plasma samples were depleted using an IgY-12LC10 column and then labeled with TMT isobaric tags. TMT-labeled plasmas were pooled in sets of four with each set containing a standard sample to enable normalization of all data. TMT-labeled pooled plasma samples were separated on 8-16% SDS-PAGE gels then each lane was divided into 24 slices that were digested with trypsin. Peptides in the tryptic digests were separated on C-18 reversed phase nano-HPLC columns and analyzed using an LTQ MS system using ETD fragmentation. Protein identification was achieved using the Mascot algorithm and isobaric tags were quantified using Scaffold-Q software. Nineteen proteins selected in this discovery phase were then quantified in all 20 samples using a Selected Reaction Monitoring (SRM) strategy on a TSQ Vantage Triple quadrupole MS system. Experimental design and analysis for the SRM work were accomplished using SkyLine and LCQuan software. Results: We identified 85 proteins in the plasma samples that were quantified using the TMT reporter ions. 19 of those 85 proteins were analyzed in all 20 samples using the SRM strategy. The SRM analysis identified two proteins with significantly higher concentrations in the plasma from the children with autism: Complement factor H related protein (FHR1) and Complement C1q subcomponent subunit C. Conclusion: The requirement for large group sizes in experiments designed to identify plasma biomarkers made analysis using the isobaric tag labeling strategy unnecessarily complex and it was found to lack sensitivity to small changes in protein concentration. The targeted proteomic study using a SRM strategy approved to be more sensitive and to be applicable to large group sizes. Our data replicate a previous study showing higher complement factors in blood samples from individuals with autism. The complement system is involved in the lysis and removal of infectious organisms in blood and may be involved in cellular apoptosis in brain. These results may provide a clue to the etiology of autism and provide support for SRM as a useful strategy for biomarker development.

2733/F

Differences in telomere lengths between identical co-twins who are discordant for a history of childhood sexual abuse. *J. Brumelle[1], T. York[2], C. Jackson-Cook[1,2].* 1) Department of Pathology, Virginia Commonwealth University, Richmond, VA; 2) Human & Molecular Genetics, Virginia Commonwealth University, Richmond, VA, USA.

Chronic stress in adulthood has been associated with telomeric attrition and age-related diseases, but little is known about the long-term, cumulative effects of childhood stress on adults. To address this question we initiated a study of identical (MZ) twins who are discordant for a history of childhood sexual abuse (CSA). Because the DNA of discordant MZ twins differs only for environmentally induced changes, they provide a unique opportunity to study the impact of CSA. To date, lymphocytes have been collected from 36 females (12 complete pairs) ages 36 to 69, who were ascertained because they participated in previous studies that characterized their CSA history and behavioral phenotypes. The biological endpoints that were compared between the MZ co-twins included the: 1) frequency (quantified using a micronucleus [MN] assay) and chromosome-specific pattern (using SKY on MN) of acquired chromosomal instability; and 2) chromosome-specific telomere length (assessed using a Q-FISH assay). MN frequencies (average per 1000 binucleates) ranged from a low of 6.5 (52 yo) to a high of 31.5 (57 yo). While not significantly different, individuals with intercourse exposure (IE) tended to have higher frequencies of MN (20.1 ± 3.5 s.e.) than their unaffected co-twins (17.9 ± 2.4). Overall, a non-random pattern of chromatin was present in MN ($p<0.0001$), with chromosomes X (27.3% of MN) and 12 (7%) observed most often and chromosomes 17 (0.35%) and 21 (0.35%) least often in both co-twin groups. Telomere lengths of females having IE were significantly shorter than their unaffected co-twins ($p<0.001$ to 0.015), with the shortening observed for all telomeres except 4p. Telomere lengths between co-twins discordant for non-IE forms of CSA were not significantly different. In CSA and non-CSA twins, similarity in chromosome-specific length patterns were noted (9q, 2q, 22q and 17p, 1p, 4p had the shortest telomeres in both groups), suggesting that the attrition occurred in a consistent, near-linear manner. In summary, this is the first report of telomeric shortening in adult females having CSA with IE when compared to their unaffected identical co-twins. Given the morbidity and mortality of diseases with a stress-related etiology, this study could provide a foundation for development of a biomarker for stress, which could play an important role in preventative medicine.

Genome wide analysis in twins discordant for bipolar disorder reveals altered DNA methylation of inflammatory and stress response genes. *M.P.M Boks[1], R.S Kahn[2], E.M. Derks[2], F. Colas[3], S. Jong de[4], K. Eijk de[4], R.A. Ophoff[3,4].* 1) Psychiatry and Epidemiology, University Medical Center, Utrecht, Utrecht, Netherlands; 2) Rudolf Magnus Institute of Neuroscience, department psychiatry, University Medical Center Utrecht, Utrecht, The Netherlands; 3) UCLA Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, USA; 4) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands.

Epigenetic silencing by methylation of specific DNA loci throughout the genome is likely to be associated with the vulnerability to bipolar disorder. Studies investigating this are however vulnerable to confounding by genetic variation and medication use of bipolar patients. We therefore investigated DNA methylation differences between affected and non affected members of monozygous twin pairs (N=34) and subsequently compared the unaffected members from the discordant twin pairs to a sample of healthy MZ and DZ twins (N=96). Using DNA extracted from whole blood, we analyzed DNA methylation of over 27,000 loci simultaneous using array based technology. We found significant associations of disease status with DNA methylation levels within the discordant pairs, and identified differences between unaffected twin members and healthy twin pairs. DNA methylation loci associated with bipolar disorder highlighted corticoid pathway genes and include the genes B-cell CLL/lymphoma 2 (BCL2) and guanine nucleotide binding protein (GNAL) previously linked to bipolar disorders. Differential methylation in unaffected twin members was enriched for genes involved in inflammatory response. These findings provide support for altered inflammatory response associated with bipolar disorder susceptibility and fit previous experimental data suggesting that the stress response can be modulation by DNA methylation. This study of DNA methylation profiles in whole blood opens new avenues for genetic studies of neuropsychiatric disorders.

2735/F

Abnormally low serum acylcarnitine levels in narcolepsy patients. *T. Miyagawa[1], H. Miyadera[1], S. Tanaka[2], M. Kawashima[1], M. Shimada[1], Y. Honda[3], K. Tokunaga[1], M. Honda[2,3].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo; 2) The Sleep Disorders Research Project, Tokyo Institute of Psychiatry; 3) Japan Somnology Center, Neuropsychiatric Research Institute.

Genome-wide association study identified a novel narcolepsy related SNP rs5770917, which affects expression level of adjacent *CPT1B* gene. CPT1B conjugates carnitine to long-chain fatty acyl coenzyme A and allows the transport of long-chain fatty acid into mitochondrial matrix for subsequent β-oxidation. We hypothesize the dysregulation of fatty acid β-oxidation in narcolepsy. We measured *CPT1B* gene expression in white blood cell by quantitative RT-PCR and serum carnitine fractions (total, free, and acylcarnitine) by enzymatic cycling method. Blood samples from 38 patients with narcolepsy and 56 healthy control subjects were used for *CPT1B* gene expression analysis, and the same 38 patients and 30 control subjects selected from the above 56 controls were used for carnitine fraction measurement. Stepwise multi-regression analysis showed that the risk allele (C) of SNP rs5770917 was associated with decreased *CPT1B* expression ($P = 1.0 \times 10^{-9}$), and the level of *CPT1B* expression was higher in narcolepsy patients than in control subjects ($P = 0.005$). Although the distribution of serum acylcarnitine level did not show significant difference, acylcarnitine levels in 21% (eight of 38) narcolepsy patients were abnormally low below the established normal range, while those of 30 control subjects were all within normal range, regardless of the SNP rs5570917 genotype. Stepwise multi-regression analysis using the dichotomous variable of acylcarnitine (normal or abnormal) as an objective variable revealed that the diagnosis of narcolepsy was associated with abnormally-low acylcarnitine level ($P = 0.006$) while other variables such as *CPT1B* expression level and BMI were not. Our results indicate the involvement of multiple factors in the regulation of serum acylcarnitine levels. Abnormally-low levels of acylcarnitine observed in narcolepsy suggest the dysfunction in the fatty acid β-oxidation pathway in narcolepsy.

MicroRNA expression profiling in the prefrontal cortex of individuals affected with schizophrenia and bipolar disorders. *A. Kim[1], M. Reimers[2], B. Mahor[1,3], V. Williamson[1,4], O. McMichael[1], J. McClay[5], E. Van den Oord[1,5], B. Riley[1,3], K. Kendler[1,3], V. Vladimirov[1,5].* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Department of Psychiatry, Medical College of Virginia of Virginia Commonwealth University, Richmond, VA; 2) Department of Biostatistics, Virginia Commonwealth Univ, Richmond, VA; 3) Department of Human and Molecular Genetics, Virginia Commonwealth University, Richmond, VA; 4) Department of Integrative Life Sciences, Virginia Commonwealth University, Richmond, VA; 5) Center for Biomarker Research and Personalized Medicine, School of Pharmacy, Medical College of Virginia of Virginia Commonwealth University, Richmond, VA.

MicroRNAs (miRNAs) are a class of small non-coding RNA molecules (~22nt) that primarily function to negatively regulate gene expression. The number of miRNAs identified is growing rapidly and approximately one-third are expressed in the brain where they have been shown to affect neuronal differentiation, synaptosomal complex localization and synapse plasticity, all processes thought to be disrupted in schizophrenia. Here we investigated the expression of 667 miRNAs (miRBase v.13) in the prefrontal cortex of individuals with schizophrenia (SZ, N = 35) and bipolar disorder (BP, N = 35) using a real-time PCR-based Taqman Low Density Array (TLDA). After extensive QC steps, 441 miRNAs were included in the final analyses. At a FDR of 10%, 22 miRNAs were identified as being differentially expressed between cases and controls, 7 dysregulated in SZ and 15 in BP. Using in silico target gene prediction programs, the 22 miRNAs were found to target brain specific genes contained within networks overrepresented for neurodevelopment, behavior, and SZ and BP disease development. Further testing of targets via real-time PCR revealed negative correlations of expression between miRNAs and their predicted gene targets, providing additional support for the in silico predictions.

Affect of elevated reactive oxygen species and decreased antioxidants on the DNA quality of sperms in couples experiencing recurrent spontaneous abortions. *R. Dada[1], D. Pathak[1], K. Kumar[1], M.B. Shamsi[1], S. Venkatesh[1], D. Deka[2].* 1) Laboratory for Molecular Reproduction and Genetics, Department of Anatomy, All India Institute of Medical Sciences, New Delhi, India; 2) Department of Obstetrics and Gynaecology, All India Institute of Medical Sciences, New Delhi, India.

Introduction: Sperm has dynamic and critical role in embryogenesis that extends beyond fertilization. Reactive Oxygen Species (ROS) in pathological concentrations challenge the antioxidant and DNA repair machinery and causes errors in genomic factors contributed to embryo by the sperm by inducing mutations in mitochondrial genome and also by inducing nicks in the nuclear genome. During embryonic development, nucleotide alterations if unrepaired are lethal to the accurate transmission of genetic information and affect the embryonic viability and post natal health. The current study was designed to understand the association of antioxidant and ROS with the mitochondrial mutations and nuclear DNA damage in male partners of women experiencing recurrent spontaneous abortions. **Material and Methods:** Forty seven male partners of women experiencing recurrent spontaneous abortions and 29 fertile controls were included in this study. DNA damage was assessed by Comet assay, ROS by luminol induced chemiluminescence and seminal antioxidants (Superoxide Dismutase- SOD, Catalase- Cat) by biochemical methods. Mitochondrial mutations were analyzed by PCR-sequencing. Semen analysis was done according to WHO 1999 guidelines. Statistical analysis was done using Mann-Whittney test. **Results:** In infertile men with normal sperm parameters (category A; n=19) mean ROS in neat semen was 13 410.76 as compared to infertile men with pathological sperm parameters (category B; n=28) where the mean ROS was 15 219.49 RLU/min/20 million sperms. In category A the mean ROS of washed sperms was 17 416.58 as compared to 20 014.87 RLU/min/20 million sperms in category B. ROS was significantly higher for both the washed and neat semen as compared to fertile controls ($P<0.05$). In category A the mean % DNA in comet head was 27.31 , in category B it was 18.54 as compared to 65.98 in fertile controls. The catalase and SOD levels in both category A and B was significantly lower as compared to controls ($P<0.05$). Novel, synonymous mitochondrial mutations observed in 4 patients are g8011A>G in COII gene, g9030C>T in ATP 6 gene, g10127A>T in ND3 gene and g13407A>G in ND5 gene. **Discussion:** Balance between ROS and antioxidants is critical for fidelity of sperm genome. ROS and DNA integrity are better markers of sperm fertilizing potential as compared to conventional semen analysis so their assessment should be included in the diagnostic workup of men in couples experiencing recurrent spontaneous abortion.

2738/F

Cytogenetic and Yq deletion molecular screening in infertile men opting for IVF/ICSI. *S. Dudeja[1], M.B. Shamsi[1], S. Venkatesh[1], R. Kumar[2], N. Malhotra[3], S. Mittal[3], P. Talwar[4], R. Dada[1].* 1) Laboratory for Molecular Reproduction and Genetics, Department of Anatomy, All India Institute of Medical Sciences, New Delhi, India; 2) Department of Urology, All India Institute of Medical Sciences, New Delhi, India; 3) Department of Obstetrics and Gynaecology, All India Institute of Medical Sciences, New Delhi, India; 4) ART centre, Army Research and Refferal Hospital, New Delhi.

Introduction: Infertilty affects 15 % of couples in the reproductive age group and in 40 % of the cases the male factor is involved. The normal spermatogenesis requires the complete functional integrity of the factors mainly present on the Y chromosome. Due to the haploid nature of the Y chromosome genes and its inability to deploy recombination repair in retrieving lost genetic information, the Y chromosome is particularly susceptible to gene deletions. Assisted conception bypasses the natural mechanisms of selection so there is a high probability of transferring the Yq deletions to the offspring which may be particularly lethal if the conceived child is a male. Aberrant recombination, defective chromatin packaging and oxidative stress (OS) are also involved in the aetiology of DNA damage in the germ line. In this study the large base pair chromosomal aberrations and the Yq microdeletions were analyzed in the male partners of couples opting for IVF/ICSI. **Material and Method:** Forty nine male partners of couples opting for IVF/ICSI and 27 healthy fertile males (controls) were included in the study. Cytogenetic analysis was done using GTG banding of cultured lymphocytes. Microdeletions on long arm of Y chromosome were screened by standard PCR-sequencing technique. **Results:** Out of 49 infertile men screened in this study one had 47, XXY chromosomal complement. 45,XY rob (13q:15q) and 45,XY rob (13q:14q) robertsonian translocation was reported in 2 men. One autosomal translocation was reported 46,XY(70 %) / 46,XY del 3 (q24 ® q 25.2) (30 %). Deletion of AZF a (sY 84) and AZF b (sY 127) regions was reported in 2 different men. Two patients had AZF c (sY 254) deletion. **Discussion:** The correlation between Y-chromosome deletions and infertility, and the relative absence of such deletions in fertile men, suggest a cause-and-effect relation between the deletions and infertility. The clinical findings or even the semen analysis can not predict the Y-chromosome microdeletions. With the increase in assisted conceptions, the chances for passing on these defects to offspring are high and should be considered when infertile couples are counseled about this procedure.

2739/F

Trends of the incidence of twin births in Japan. *K. Kurosawa[1], K. Enomoto[1], N. Furuya[1], M. Masuno[2], Y. Kuroki[2].* 1) Kanagawa Children's Med Ctr, Yokohama, Japan; 2) Kawasaki University of Medical Welfare, Kurashiki, Okayama, Japan.

Assisted reproductive technology (ART) is more likely to provide multiple births. Multiple births are associated with increased risk for mothers and infants, including higher rates of caesarean deliveries, prematurity, low birth weight, birth defects, and infant disability. About 30% of deliveries following ART in USA and Europe are twins, compared with approximately 1% following spontaneous conceptions. The increased rate of multiple births from the age of 1980s in many Western countries is clearly contributed by advance and prevalence of ART. However, recent data from population-based epidemiological study presented the decreased number of multiple pregnancies in Japan. To elucidate the causes and the ratios of mono- vs di-zygosity of twin births, we analyzed the incidence of twin births from the data of population-based birth defects motoring system in Kanagawa Prefecture (KAMP), Japan. KAMP has been operated since 1981 as the first population-based monitoring system in Japan, which covers about half of total births in Kanagawa Prefecture, that is, 40,000 births annually. All malformed cases as well as multiple births are registered with two consecutive normal control infants. The zygosity of twins was estimated according to Weinberg's differential rule zygosity estimation methods. From the start of KAMP at 1981, the total births of twins increased consistently from 60 to 100 per 10,000 deliveries, which is consistent with those of Western countries. However, after the peak at 2003, the dramatic decrease in the rate of twin births was observed in KAMP. During the last 20 years, though the incidence of monozygotic twins is stable as 40 per 10,000 deliveries, the incidence of dizigotic twins presented dramatic variation. To our knowledge, this is the first epidemiological report on the trends of decreased rate of twin births. We discussed the causes and backgrounds of the trends observed in KAMP, Japan.

2740/F

Compromised DNA integrity in spermatozoa of infertile men - assessed by sperm chromatin structure assay (SCSA). *S. Venkatesh[1], A. Singh[2], MB. Shamsi[1], R. Kumar[3], NP. Gupta[3], DN. Mitra[2], R. Dada[1].* 1) Anatomy, Lab Molec Reproduction & Gen, New Delhi, India; 2) Dept. of Urology, AIIMS; 3) Dept. of Transplant Immunology.

Introduction:Spermatozoa with good chromatin is prerequisite for not only its physiological function but also for embryogenesis and fetal development. However, conventional semen analysis provides no clue about sperm chromatin structure, which is essential in such men opting for assisted procreation. Aim:To analyze 42 primary infertile men and 18 fertile controls for sperm DNA integrity by sperm chromatin structure assay (SCSA) and to find out the cut-off value to discriminate infertile and fertile men based on their sperm DNA fragmentation index (DFI) in Indian population Methods:Semen analysis were performed as per WHO, 1999 guidelines. Sperm DNA fragmentation index (DFI) was calculated by SCSA. Receiver operating curve (ROC) analysis was performed to find the cut-off value to predict the diseased subject. Mann-Whitney test was used compare semen parameters between infertile and control men. Results:Out of 42 infertile men evaluated for SCSA, the average mean DFI in infertile men was found to be 40.85±37; which is 1.59 fold higher than of control men (25.62±37;). DFI median (interquartile range) of infertile men was significantly ($p<0.0001$) higher compared to control population [(41.5 (34.28, 46.96) Vs 25.16 (22.93, 28.65)]. A cut off value of 31.42 with 83.33% sensitivity and 100 percent specificity (95 percent; CI 0.828 to 0.978) was found by ROC analysis. A strong negative correlation was observed between DFI and sperm count ($p<0.001$), sperm motility ($p<0.0001$), and normal sperm morphology ($p<0.05$) when in the study population, however no such correlation was found in the infertile men. However, men with longer duration of infertility (DI) were found to have increased DFI ($r=-0.330$, $p<0.05$) Conclusion:Impaired sperm DNA quality is the rationale behind male infertility in most of the idiopathic cases. Couples delaying in achieving parenthood have increased risk for getting pregnancy. DFI=31.42 is a valuable cut off point in our population, nearly similar to other studies above which couple may find difficulties in achieving pregnancy. SCSA is a reliable tool applicable beside conventional semen analysis and may be very useful in selecting couples for different ART procedures.

2741/F

Seminal oxidative stress, mitochondrial DNA mutations and nuclear DNA damage in men experiencing recurrent IVF/ICSI failure. *M.B. Shamsi[1], V. Sundararjan[1], R. Kumar[2], N. Malhotra[3], S. Mittal[3], P. Talwar[4], R. Dada[1].* 1) Laboratory for Molecular Reproduction and Genetics, Department of Anatomy, All India Institute of Medical Sciences, New Delhi, India; 2) Department of Urology, All India Institute of Medical Sciences, New Delhi, India; 3) Department of Obstetrics and Gynaecology, All India Institute of Medical Sciences, New Delhi, India; 4) ART centre, Army Research and Refferal Hospital, New Delhi.

Background: Oxidative stress (OS) occurs due to excessive reactive oxygen species (ROS)generation beyond the scavenging capacity of antioxidant defenses. OS damages sperm DNA, thus may transfer defective paternal DNA to conceptus. The damage may be in mitochondrial (mt) genome or nuclear genome. Basic repair mechanism, absence of introns, and vicinity to site of ROS production increases the susceptibility for mt mutation. Presence of unrepaired single or double stranded DNA breaks in nuclear genome of sperm impairs the early and late post fertilization events which influence the pregnancy outcome. **Material and Method:** Thirty two idiopathic infertile men experiencing recurrent IVF/ICSI failure and 21 proven fertile controls were included. ROS in PBS washed sperm was quantified by chemiluminescence. Seminal total antioxidant capacity (TAC) was assayed by commercially available kit. Mt DNA and all exons of p53 gene were analyzed by PCR-sequencing and nuclear DNA damage was assessed by comet assay. Mann-whitney test applied for statistics and was $p<0.05$ considered significant. **Result:** The mean of ROS in infertile men was 1 75 000 as compared to 987 RLU/min/20 million in controls. The mean TAC was 2.78 as compared to 4.55 mM in controls. The DNA damage in infertile men was higher in infertile men as evident from low percent of DNA in sperm comet head in infertile men 18.43 as compared to 54.97 in controls.ROS and DNA damage was significantly higher while TAC was significantly lower in infertile men Two nucleotide variations in ATPase 6, four in ATPase 8 and 1 in COX II gene were observed in patients. Hetroplasmy at g.7572518C>A, g.7572540C>A were observed in P53 gene in 2 patients. **Discussion:** Association of sperm DNA damage and sperm-derived ROS suggests that DNA damage is due to defect in DNA repair mechanism and the antioxidant machinery. Mutations of P53 and an array of other DNA repair genes involved in repair may be responsible for DNA damaged sperms in the ejaculate. The inefficient antioxidant mechanism or the excessive generation of ROS produces mt mutations which manifests as abnormal sperm parameters affecting the fertilizing capacity of the sperm. Considering the spectrum of factors associated with OS, it is essential that males who are opting for assisted conception and experiencing recurrent IVF/ICSI failure be screened at the molecular level and a defined protocol for such assessment be included in the diagnostic workup of such men.

2742/F

Screening for microdeletions on the Y chromosome using array CGH in 72 Japanese patients with non-obstructive azoospermia. *T. Cui, H. Nakaoka, K. Akiyama, A. Tajima, I. Inoue.* School of Medicine, Tokai University, Isehara, Kanagawa, Japan.

Microdeletions of azoospermia factor (AZF) locus are considered to be the main genetic cause of infertility in men with idiopathic azoospermia and sever oligozoospermia. However, it is difficult to identify the infertility casing gene owing to the lack of multiple genes in the observed deletion region. By using array CGH, technology it becomes possible to increase the resolution in a target genomic region of interest, and to detect gene-specific small deletions that may contribute to the identification of a disease-causing gene. Here we have developed a high-resolution array CGH (Agilent, 44k) for Y chromosome, and carried out microdeletion screening in 72 Japanese patients with non-obstructive azoospermia (NOA). Microdeletions at different AZF regions were found in 8/72 patients with NOA (11.11%): one case in AZFa, two cases in AZFb, three cases in AZFa+b+c and two cases in AZFa+b+c+Yp. In addition, four small deletions (SDs) ranging from 5 kb to 125 kb in size were identified in AZF region and their interval. Interestingly, two SDs are located in region involving in intron 26 of ubiquitously transcribed tetratricopeptide repeat gene on Y chromosome (UTY) and BCL6 co-repressor-like 2 (Bcorl2), a noncoding gene respectively. We determined the mRNA expressions by real-time quantitative reverse transcription (RT) polymerase chain reaction (PCR) and found the enhanced testicular expression level of UTY in patient with SD compared to patients without SD of UTY, suggesting the putative association in the spermatogenesis. We showed for the first time the AZF deletion pattern using array CGH, and represented UTY and Bcorl2 gene-specific deletion.

2743/F

Micronuclei frequency and sperm DNA damage In Male Infertility. *V. DURGA RAO[1,3], A. RADHA RAMA DEVI[2,3].* 1) SCHOOL OF BIOTECHNOLOGY, MGNIRSA , HYDERABAD, Andhra Pradesh, India; 2) SANDOR PROTEOMICS, HYDERABAD, INDIA; 3) MOLECULAR DIAGNOSTICS,Center for DNA Fingerprinting and Diagnostics (CDFD). Hyderabad , Andhra Pradesh,India.

Presence of micronuclei is a marker for chromosomal damage and higher frequency of micronuclei is an indicator of chromosome instability causing male infertility. The presence of chromosome instability was studied through micronucleus assay in peripheral blood lymphocytes. Sperm DNA damage was studied in the ejaculated sperm of infertile men and controls by Single Cell Gel Electrophoresis (Comet assay). Micronuclei (MN) assay was carried out in 44 male infertile patients (mean age of 31.23 ± 6.08) and a control group of 28 men (mean age of 31.14± 2.59) that revealed a high frequency of MN in patients (28.62 ± 10.26) compared to controls (13.29 ± 4.02). No effect of age was found on the micronuclei frequencies in both the groups. . The mean comet tail length for the DNA damage in infertile patients was found to be 71.48± 5.1μm, while the controls showed a mean tail length of 54.18± 7.22 μm. In conclusion, the present study demonstrates that there is significant sperm DNA damage in male infertility.

Detection of a New Unbalanced Rearrangement leading to a partial Monosomy Xq and a partial 18q Trisomy associated with Diminished Ovarian Reserve (DOR). *M. Paciolla[1,2], F. Fusco[1], M.B. Lioi[2], X. Li[3], R. Genesio[4], A. Conti[4], L. Poeta[1,2], D. Drongitis[1], E. Chen[5], M.V. Ursini[1], M.G. Miano[1].* 1) Institute of Genetics and Biophysics “Adriano Buzzati Traverso” CNR, Naples, Italy; 2) University of Basilicata, Potenza, Italy; 3) Department of Genetics, Kaiser Permanent Medical Center, San Jose, CA, USA; 4) Dipartiment of Biology and Cellular and Molecular Pathology, University of Naples “Federico II”, Naples, Italy; 5) Department of Genetics, Kaiser Permanente Medical Center, San Francisco, CA, USA.

Diminished Ovarian Reserve (DOR) is a heterogeneous disorder belonging to the gonad failure spectrum, characterized by low numbers of remaining oocytes in the ovaries, usually accompanied by high follicle stimulating hormone (FSH) level. Such diminished ovarian reserve is thought to reflect both a decreased number of eggs and a decrease in egg quality. DOR aetiology factors are multiple and different, such as genetic factors, aging, autoimmune disorders, adrenal gland impairment, iatrogenic, e.g., due to radiation or chemotherapy. At present the exact genetic cause of DOR is still unknown, although DOR with a severe reduction of reproductive performance was reported with a significant high incidence (44.4%) in females carrying X chromosome mosaicisms (45,X/46,XX; 46,XX/47,XXX) without balanced autosomal rearrangements. We report the first unbalanced translocation with segmental loss and gain of genomic fragments associated with DOR. Array CGH and FISH studies revealed a partial Xq monosomy and a partial 18q trisomy resulting from an unbalanced t(X;18) translocation. Real time experiments showed a Xq27 monosomy starting at position 141,2 Mb and a 18q22 duplication starting at position 64,5 Mb. Sequence inspection revealed the presence of a genomic context of LINE-1 (L1) clusters, at both the Xq27 and the 18q22 breakpoints. This structure might increase the likelihood of mispairing, unusual crossover and therefore, gain or loss of genomic materials. To further characterize the outcome of DOR rearrangement, the status of X chromosome inactivation was investigated. Androgen Receptor assay and late-replication DNA analysis revealed a preferential inactivation of rearranged X:18 chromosome, therefore completely skewed inactivation and late replication might mask the outcome of the 18 trisomy as well as of the X monosomy. Our patient has only DOR and no other unusual clinical features. This finding is in agreement with other reports that demonstrated that in X:autosome unbalanced translocation, inactivation signals of X-inactivation centre spread across the X:autosome boundary therefore, resulting in various attenuated phenotypes. Our data include DOR condition among the gonad failure spectrum of diseases linked to X-chromosome abnormalities, and confirm the feature of the Xq27-28 as a region of high genome instability. The hypothesis that the DOR phenotype occurs as a result of faulty meiotic pairing and recombination will be discussed.

Incidence of Yq deletion in infertile males of Gujarat state. *S.S. Chettiar[1], S. Trivedi[2], D.D. Jhala[1,2], D. Chandel[1,2], M.V. Rao[1,2].* 1) GenDiCe, Zoology Dept, Gujarat Univ, Ahmedabad, India; 2) Human Genetics Unit, Department of Zoology, Gujarat University, Ahmedabad, India.

Infertility affects around 2-15% couples attempting for pregnancy, with 50% of cases due to male infertility and the causes are due to identifiable severe defects in sperm production, which are classified as azoospermia, oligospermia and abnormal motility/morphology. Genes on Y-chromosome (Yq11) (AZFa, AZFb, AZFc) are vital for spermatogenesis and Y-chromosome micordeletions are found exclusively in males with azoospermia, severe oligospermia or other spermatogenic defects. In order to define recurrently deleted regions of Yq, (II) determine the incidence of microdeletions among azoo-and oligozoospermic men; (iii) correlate the size and position of the deletions with the infertile phenotype, We have studied 58 infertile men from the Gujarat State, in the Western part of India with azoospermic, oligospermic, teratospermic and asthenospermic. All patients were excluded for cytogenetically detectable microdeletions of the euchromatic region of the Y-chromosome. DNA samples were PCR amplified using different sets of STS markers to assay for deletions in AZFa, AZFb and AZFc regions. Three infertile men (5.17%) were found with microdeletions of Y-chromosome. Fourteen had azoospermia or severe oligospermia, 21 had oligospermia, 18 of the incorporated patients were reported to be teratospermic and 5 had asthenospermia. The present data indicates that a small proportion of men with infertility had Y-chromosome microdeletions, but the size and position of the deletions correlate poorly with the severity of spermatogenic failure, and the deletion does not preclude the presence of viable sperm and possible conception.

2746/F

Cytogenetic and Molecular Causes of Male Infertility. *S.E. Hofherr[1,2], A.E. Wiktor[1,3], B.R. Kipp[1,4], D.B. Dawson[1,4], D.L. Van Dyke[1,3].* 1) Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 2) Clinical Biochemical Genetics; 3) Clinical Cytogenetics; 4) Clinical Molecular Genetics.

10-15% of couples attempting to conceive are infertile. According to the WHO, male infertility accounts for ≥50% of infertility among couples. Up to 25% of males with non-obstructive infertility have chromosomal abnormalities and/or microdeletions of the long arm of the Y-chromosome. These are detected by conventional chromosome and Y-microdeletion analysis. Following IRB approval, we reviewed the results of testing performed in the Mayo Clinic Cytogenetics and Molecular Genetics Laboratories and compared our findings with previously published reports. This study includes 2288 chromosome studies from males ≥18 years of age referred for infertility between 1989 and 2000 and 2749 Y-deletion molecular studies performed between 2002 and 2009. This study did not take into account the cause (obstructive, non-obstructive), or severity (azoospermia, oligospermia) of the infertility. A chromosome abnormality was detected in 333/2288 (15%) males. Of those, 294 (88%) were sex chromosome abnormalities. A 47,XXY or variant karyotype consistent with Klinefelter Syndrome (KS) was observed in 261 males (11%), and accounted for 78% of all abnormal results. This is consistent with previous studies suggesting that KS is the most common chromosome abnormality in the general male population (0.15%) and is associated with infertility. The remaining abnormalities were less common and included 12 Y-rearrangements (inversion, deletion, ring/deletion), ten 47,XYY, seven 46,XX males, two 48,XXYY, and two 48,XXXY. Balanced rearrangements were detected in 32 patients, 7 of which were Robertsonian translocations. An additional 7 specimens represented unbalanced rearrangements. Of the 2749 males tested for Y-microdeletion, 100 (4%) were identified with a deletion of at least one of the azoospermia factor regions (AZFa, AZFb, AZFc). We detected 64 patients with AZFc deletions, 5 with deletion of AZFa and 5 with deletion of the AZFb. Larger deletions encompassing both AZFb and AZFc regions were identified in 17 patients and 9 had deletion of all three AZF regions (AZFa,AZFb,AZFc). The most frequent Y-deletion spanned the AZFc region including DAZ (deleted in azoospermia), which is hypothesized as the cause of infertility in males with a Y-microdeletion. However, 10 patients had deletions of AZFa or AZFb but retained the entire AZFc region including DAZ. These results underscore the value of both chromosome studies and Y microdeletion studies in males with non-obstructive infertility.

2747/F

A retrospective study of preterm birth rate in China: 90,359 (5.4%) preterm births were identified from 1,686,224 newborns. *X.L. Zhao[1], N. Zhong[1,2].* 1) Peking University Center of Medical Genetics, Beijing, China; 2) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Preterm birth (PTB) indicates the delivery occurs before 37 weeks of gestation. The PTB has been widely recognized as one of the leading impact in the neonatal health. In the recent twenty years, a trend of increase in the PTB has been reported. In order to determine the rate of PTB in China and to initiate a campaign of prevention and intervention of preterm births we have conducted a retrospective hospital-based survey on the PTB. One hundreds and eleven hospitals in 23 provinces of China mainland were included in our survey. Hospitals' newborn registry from year 2005-2009 was retrieved. The week of gestation at birth was reviewed. A total of 1,686,224 newborns was included in our data, in which, 90,359 preterm births were recorded, which gave rise to an overall 5.36% of national rate of preterm births. The annual national rate grew from 4.86% of year 2005 to 5.90% of year 2009. The provincial rates are highly varied in the range between 2% to 10%, although most provinces had rates around the overall national rate. When considering the level of hospitals, Tier-1 (the primary healthcare) and Tier-3 (the tertiary healthcare) hospitals showed higher preterm birth rates of 11.98% and 8%. In comparison, the rate of Tier-2 hospitals is 3.97%. The result clearly showed that the preterm rate of costal region (5.02%) is lower than it of inland region (6.35%). The difference is statistically significant ($p<0.01$). This difference in rates of costal and inland regions was correlated with average income of each region. With our knowledge, this survey is the first study to investigate the national PTB rate of China, which may contribute to the international epidemiology of PTB.

2748/F

Genetic Variation in NAT1 Interacts with Cadmium Exposure to Influence Pregnancy Outcomes in non-Hispanic Black (NHB) Women. *A.E. Ashley-Koch[1], G.K. Swamy[2], M.E. Garrett[1], K.S. Quinn[1], A. Buskwofie[1], M.L. Miranda[3].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Obstetrics and Gynecology, Duke University Medical Center, Durham, NC; 3) Nicholas School of the Environment, Duke University, Durham NC.

OBJECTIVE: To examine the contribution of the N-acetyltransferase genes (NAT1, NAT2) and cadmium exposure to the occurrence of maternal and infant pregnancy outcomes. **METHODS:** Healthy Pregnancy, Healthy Baby is a prospective cohort of pregnant women aimed at identifying genetic, social, and environmental contributors to racial disparities in pregnancy outcomes. English-literate women >18 yrs with a normal singleton pregnancy residing within Durham County, NC were enrolled prior to 28 weeks gestation. 594 NHB women were examined for the outcomes of maternal preeclampsia (BP>140/90 and proteinuria) and infant birthweight (BWT) in this analysis. Maternal samples collected during inpatient admission for delivery were analyzed for cotinine and cadmium. Haplotype tagging single nucleotide polymorphisms (htSNPs) were genotyped for NAT1 (n=19) and NAT2 (n=13) using Taqman assays. None of the htSNPs were in linkage disequilibrium. Logistic regression was used to examine the relationship between htSNPs and maternal preeclampsia, adjusting for maternal chronic hypertension, parity, infant sex, age, education, insurance, and cotinine exposure. Linear regression was used to examine the relationship between htSNPs and infant BWT, using the same covariates except chronic hypertension. We also examined potential interactions between NAT htSNPs and cadmium exposure. **RESULTS:** 121 participants (20%) were diagnosed with preeclampsia. Mean infant BWT was 3018 g (sd=663 g). Of the 32 htSNPs examined, 3 in NAT1 were nominally associated with preeclampsia (rs2410545, p=0.02; rs13278990, p=0.006; rs11777998, p=0.007). Three different NAT1 htSNPs were nominally associated with BWT (rs10107390, p=0.01; rs9325827, p=0.02; rs4921880, p=0.001 and met multiple testing correction). Two NAT1 htSNPs provided evidence for interactions with cadmium exposure predicting preeclampsia (rs7003890, p=0.03; rs8190845, p=0.009). Two htSNPs in NAT1 (rs17126345, p=0.01; rs4921879, p=0.01) and one in NAT2 (rs1799930, p=0.04) provided evidence for interactions with cadmium exposure predicting BWT. **CONCLUSION:** NAT1 may influence development of preeclampsia and infant BWT among NHB women, particularly in the context of cadmium exposure. Although evidence for association with NAT2 was limited, rs1799930 represents a slow acetylator form of NAT2 (Vatsis et al, 1991). NAT1 and NAT2 are involved in the metabolism of xenobiotics and are excellent candidates for gene*environment interactions.

2749/F

Genome-wide study of age at menarche in 1,704 US Latinas. *L. Fejerman[1], S. Huntsman[1], C. Eng[1], E.M. John[2,4], M.C. Stern[3], S.A. Ingles[3], E. Gonzalez Burchard[1,6], E. Ziv[1,5].* 1) Dept Med, Univ California, San Francisco, San Francisco, CA; 2) Cancer Prevention Institute of California, Fremont, CA; 3) Keck School of Medicine, University of Southern California, Los Angeles, CA; 4) Stanford Cancer Center, Palo Alto, CA; 5) Helen Diller Family Comprehensive Cancer Center, Univ California, San Francisco, CA; 6) Dept of Biopharmaceutical Sciences, Univ California, San Francisco, CA.

Age at menarche is a complex genetic trait related to breast cancer risk and osteoporosis. Several loci associated with age at menarche have been identified from genome-wide association studies in women of European and East Asian ancestry. Here we report results from the first genome-wide study of age at menarche in a sample of 1,704 US women of Latin American origin. We identified two new loci that showed a suggestive association with age at menarche. The US Latina samples are from the San Francisco Bay Area Breast Cancer Study and the Breast Cancer Family Registry and include both breast cancer cases and healthy controls ages 35 to 79. Genotypes were obtained using the Affymetrix 6.0 platform (~900,000 SNPs). We used imputation to define genotypes for SNPs not included in the Affymetrix chip, using HapMap phase 2 samples (Chinese, Japanese, Africans and Europeans) as references. Our final analysis included ~2,700,000 SNPs. SNPs with low MAF (<1%) were excluded from analysis. We used linear regression models to test the association between each of the SNPs (coded as counts of minor alleles) and age at menarche (defined as a continuous variable). To correct for potential confounding by population stratification, we adjusted for the top principal component of genetic variation which was a proxy for the European/Native American ancestry proportions in the study samples. The strongest associated SNPs were in chromosome 18. One is within the growth regulation by estrogen in breast cancer-like gene (GREB1L, rs9964746, p=1.6e-07) and the other is on 18q22 (rs4891982, p=3.4e-07). These loci are different from those described in East Asians and Europeans. Further investigation of the possible causative variants will shed light into the biological mechanisms that determine age at menarche and that differ between populations.

Genome-wide association study of endometriosis in a Japanese population. *S. Adachi[1], A. Tajima[2], K. Yoshihara[1], T. Yahata[1], I. Inoue[2], K. Tanaka[1].* 1) Niigata University Graduate School of Medical Sciences, Niigata, Japan; 2) Tokai University School of Medicine, Isehara, Japan.

Endometriosis is a complex disease characterized by dysmenorrhea, dyspareunia, noncyclic pelvic pain, and infertility. To identify novel genetic contributors associated with endometriosis in Japanese women, we conducted genome-wide association (GWA) studies using two Japanese cohorts genotyped with the Affymetrix Mapping 500K Array or Genome-Wide Human SNP Array 6.0, respectively. A total of 696 Japanese endometriosis patients and 825 controls were passed our quality-control (QC) criteria based on genotyping quality, cryptic relatedness and population outliers. After applying SNP QC filters to individual chip-cohorts separately, we selected 330,753 SNPs (500K array) and 557,299 SNPs (6.0 array) for the GWA analysis. We performed a meta-analysis of the two GWA studies using the DerSimonian-Laird random-effects model to test for association between each QC-passed SNP and endometriosis. As a result, we identified five SNPs with p-value < 10^{-5}, 22 SNPs with p-value < 10^{-4} and 246 SNPs with p-value < 10^{-3} in the combined dataset. Four of the five SNPs with p-value < 10^{-5} were in high linkage disequilibrium each other and located in and around *IL1A* (interleukin 1 alpha) on 2q13. Further studies with large, independent samples are required to verify the association results.

Ultrastructural analysis of spermatozoa in asthenozoospermic men. *S.Sh. Hayat[1], E.E. Bragina[1,2], L.F. Kurilo[1].* 1) Laboratory of Genetics of Reproductive Disorders, Research Centre for Medical Genetics, Russian Academy of Medical Sciences (RAMS) 115478, Moscow, Moskvorechie str. 1, Russian Federation; 2) Belozersky Institute, Moscow State University,Leninskie Gory 1,Bldg. 40, Russian Federation.

Introduction: Sperm motility is one of the major determinants of male fertility. Semen samples from 8150 men of different fertility status were obtained in Research Centre for Medical Genetics, RAMS. Cohort of asthenozoospermic men were examined for ultrastructural changes. Materials and Methods: 8150 semen samples were analyzed according to World Health Organization criteria. Electron microscopic studies in cohort of 98 infertile men with asthenozoospermia (a<25% or a+ b<50% (WHO 2010) were carried out. Results: Semen analysis showed that reduced sperm motility is the most common alteration in male infertility (88%). In 70% of cases low sperm motility is associated with abnormal sperm morphology. Electron microscopic studies revealed acrosome abnormalities (knobbed, ruffled and incomplete), head defects (abnormal chromatin condensation, decapitated), tail structural defects (peri-axonemal and axonemal abnormalities, lacking dynein arms), etc. Conclusion: Our study results suggest that reduced sperm motility concerns more complicated interactions involved in control of spermatogenesis, either directly or indirectly. The approach will next be identified by further investigations.

Effect of smoking, alcohol, BMI and ROS on sperm chromatin structure in infertile men. *K. Kumar[1], J. Thilagavathi[1], S. Venkatesh[1], MB. Shamsi[1], R. Kumar[2], NP. Gupta[2], R. Dada[1].* 1) Lab for Molecular Reproduction and Genetcis, Dept. of Anatomy, AIIMS, New Delhi, India; 2) Dept. of Urology, AIIMS, New Delhi-29.

Introduction: Nicotine and alcohol are the most addictive substance widely used by human population all over the world, especially in large numbers of men at reproductive age. Body mass index (BMI) is an important criterion for any human to be fit and alteration in BMI may affect the quality of life. Effect of reactive oxygen species (ROS) and the above factors are suspected are important factors that affect men at reproductive age **Aim**: The current study was aimed to find the effect of smoking, alcohol, BMI and ROS levels on sperm DNA integrity by sperm chromatin structure assay (SCSA) in infertile men. **Methods**: 40 infertile men and 20 controls were included in the study. Semen analysis was performed as per WHO, 1999 guidelines. Flow cytometry based sperm chromatin structure assay using acridine orange dye was used to find sperm DNA fragmentation index (DFI). Smoking and alcohol consumption were ranked according to self designed scale. Height and weight were recorded and BMI was calculated. ROS level in the raw semen was measured by luminol-chemiluminescence assay. **Results**: Median (interquartile range) DFI was significantly (P<0.001) higher in infertile men compared to controls. Similarly, sperm count, motility and normal morphology were significantly lower in infertile men compared to controls. No correlation between smoking (r=0.031), alcohol consumption (r=-0.019), BMI (r=0.063) was observed. However ROS level in the neat semen showed a weak negative correlation(r= -0.125) with DFI in the study population. **Conclusion**: Various endogenous and exogenous factors affect sperm DNA integrity. However, suspected factors such as smoking, alcohol consumption, body mass index and seminal ROS levels have no profound effect on sperm DNA integrity. Therefore it is necessary to elucidate the unknown factors associated with the impaired sperm DNA integrity in this population.

2753/F

Nucleotide variations in mitochondrial DNA and supra-physiological ROS levels in cytogenetically normal cases of premature ovarian insufficiency. *M. Kumar[1], D. Pathak[1], A. Kriplani[2], A.C. Ammini[3], P. Talwar[4], R. Dada[1].* 1) Laboratory for Molecular Reproduction and Genetics, Department of Anatomy, All India Institute of Medical Sciences; 2) Department of Obstetrics and Gynaecology, All India Institute of Medical Sciences; 3) Department of Endocrinology & Metabolism, All India Institute of Medical Sciences; 4) Assisted Reproduction Technology Centre, Army Hospital Research & Referral, Delhi Cantonment, Delhi, INDIA.

Premature Ovarian insufficiency (POI) is defined as the cessation of ovarian function under the age of 40 years and is characterized by amenorrhea, hypoestrogenism and elevated serum gonadotrophin concentration (FSH). It is a heterogeneous disorder with a multicausal pathogenesis, however majority of cases are idiopathic. In idiopathic POI, involvement of unknown mechanisms may increase rate of oocyte apoptosis. Studies have shown that elevated oxidative stress (Reactive Oxygen Species) affects the quality of gametes. Mitochondrial mutations in different complexes of electron transport chain have been reported to disrupt the electron flow which leads to formation of more superoxide ions or increased levels of ROS. This study was aimed to screen the mitochondrial genome for variations in idiopathic POI (n=25) and occult ovarian insufficiency (OI) (n=5) patients. 30 diagnosed patients with POI and occult OI were enrolled in this study. Blood samples were collected from the patients and controls. DNA was extracted using phenol chloroform method. A total of 102 nucleotide variations were observed in patients as compared to 58 nucleotide variations in controls. 24% variations were found to be non-synonymous and 76% were synonymous. It was found that 48% variations were in complex I, 8% in complex III, 24% in complex IV and 20% were in complex V of electron transport chain. We found most of the non-synonymous mitochondrial variations in complex I (48%) of the respiratory chain which is the largest of enzyme complex and is associated with oxidative stress. Some non-synonymous pathogenic alterations (p.M31T, p.W239C, p.L128Q) and non pathogenic alterations (ATPase6:p.T53I, ATPase6:p.L190F, ATPase6:p.L199L) were found to be significantly higher in cases as compared to controls. The preliminary data suggest that the mitochondrial mutations and subsequent decline in ATP levels may accelerate follicular atresia and lead to premature ovarian insufficiency. The results of this preliminary study highlight the need to extend this study by analyzing large number of samples in different ethnic populations and analyze for ROS levels and mitochondrial mutations in oocytes as they are of different embryonic origin and develop in a different microenvironment.

2754/F

Genetic Variation in the Inflammatory Pathway Contributes to Preeclampsia in non-Hispanic Black (NHB) Women. *A. Buskwofie[1], G.K. Swamy[2], M.E. Garrett[1], K.S. Quinn[1], M.L. Miranda[3], A.E. Ashley-Koch[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Obstetrics and Gynecology, Duke University Medical Center, Durham, NC; 3) Nicholas School of the Environment, Duke University, Durham NC.

OBJECTIVE: To examine the contribution of genetic variation in the inflammatory pathway to the occurrence of preeclampsia. **METHODS:** Healthy Pregnancy, Healthy Baby is a prospective cohort of pregnant women aimed at identifying genetic, social, and environmental contributors to disparities in pregnancy outcomes. English-literate women >18 yrs with a normal singleton pregnancy <28 wks, residing within Durham County, NC were enrolled. Data were available for 594 NHB women. Preeclampsia was defined as BP>140/90 with proteinuria and chronic hypertension (CHTN) was defined as BP>140/90 before 20 wks. A total of 73 haplotype tagging single nucleotide polymorphisms (htSNPs) were examined in the following genes: IL1A (n=7), IL1B (n=3), IL1RN (n=9), IL2 (n=3), IL4 (n=8), IL5 (n=1), IL6 (n=4), IL8 (n=2), IL10 (n=5), IL12A (n=3), L12B (n=13), IL13 (n=5), CRP (n=3), IFNG (n=2), and TNFA/LTA cluster (n=5). Genotyping was performed using Taqman assays from Applied Biosystems Incorporated. Logistic regression was used to examine the relationship between maternal genotype and preeclampsia, adjusting for CHTN, parity, infant sex, age, education, insurance, and tobacco use (as measured by cotinine levels in maternal blood). **RESULTS:** 121 participants (20.4%) were diagnosed with preeclampsia. Two htSNPs in IL1A (rs2856838, p=0.01 and rs1894399, p=0.02) and one htSNP each in IL1RN (rs2071459, p=0.04), IL12B (rs1003199, p=0.008) and LTA (rs2229094, p=0.002) were nominally significant. The two htSNPs in IL1A which were associated with preeclampsia were not in linkage disequilibrium. **CONCLUSION:** The association of IL1A and IL1RN with preeclampsia is interesting as these genes regulate opposing inflammatory effects and are located in a cluster on chromosome 2 with IL1B which was not associated in our data set. These genes have been previously implicated in the occurrence of preeclampsia (Goddard et al., 2007), suggesting that homeostasis of this part of the inflammatory cascade is important in the development of preeclampsia. The association with rs2229094 in LTA is also interesting, as this SNP is a missense mutation and LTA has been implicated in maternal-fetal genotype incompatibility as it relates to risk for preeclampsia (Parimi et al., 2008). These data add to the body of literature implicating the inflammatory pathway as being an important contributor to preeclampsia.

2755/F

Preimplantation Genetic Diagnosis (PGD) for germ line mosaicism. *G. Altarescu, T. Eldar-Geva, B. Brooks, E.J. Margalioth, E. Levy-Lahad, P. Renbaum.* Zohar PGD Lab & IVF Unit, Shaare Zedek Medical Ctr, Jerusalem, Israel.

Introduction: Single cell diagnosis for PGD requires simultaneous analysis of multiple linked polymorphic markers (in addition to the mutation) and building family haplotypes spanning at least two generations. In cases of germline mosaicism the wild type haplotype may be observed in both affected and unaffected children making the diagnosis more complex. Aims: To discriminate between wild type and mutant alleles in two families: family #1 has two children affected with severe myoclonic epilepsy (SCNA1A del exons1-22); and family #2 with 2 children with Tuberous Sclerosis (TSC1 C1327T) along with two healthy children. In both families, analysis of DNA extracted from peripheral blood lymphocytes and buccal cells was negative for the mutation, in both parents. Material and Methods: Twelve informative microsatellite markers flanking the SCNA1A gene and 12 markers flanking the TSC1 gene along with the identified mutations were used to construct haplotypes using genomic DNA. Single sperm analysis was performed using a multiplex assay that included the 12 markers and the TSC1 C1327T mutation. Results: Neither mutation was detected in genomic DNA derived from blood or buccal cells from either parent. In family #1 the deletion was demonstrated to be of maternal origin. In family #2 both affected children shared the same paternal allele but had different maternal alleles. However, one of the two healthy children also shared this same paternal allele. I In order to confirm paternal transmission we performed single sperm analysis for the mutation along with the 12 informative markers. Of 44 single sperm analyzed, 4 bared the mutant T allele, allowing linkage between the mutation and the genetic markers. Conclusions: Germline mosaicism complicates allele assignment when constructing haplotypes for PGD. Sperm or polar body analyses are useful tools for verifying allelic linkage.

Clinical results on single cells from 470 embryos using 23-chromosome single nucleotide polymorphism (SNP) microarray preimplantation genetic screening (PGS) from 45 patients. *A. Benner[1], A.S. Gabriel[2], C. Chipko[1], D.K. Griffin[2], W.G. Kearns[1,3].* 1) Shady Grove Center for Preimplantation Genetics, Rockville, MD; 2) Dept of Biosciences, University of Kent, Canterbury, UK; 3) Dept of Gynecology/Obstetrics, The Johns Hopkins University School of Medicine, Baltimore, MD.

Objective: To amplify DNA from single blastomeres or trophectoderm cells and perform SNP microarray genetic analyses for the incidence and origin of aneuploidy. **Design:** Prospective study **Materials and Methods:** PGS patients between 12/1/09 and 4/25/10 were analyzed. 45 patients underwent embryo biopsy by laser and SNP microarray PGS primarily due to > 2 spontaneous miscarriages. 3 of these patients were tested for translocation abnormalities and aneuploidy. The maternal ages ranged from 34 to 44yrs. 398 embryos from 37 patients underwent day-3 biopsies, whereas 72 embryos from 8 patients underwent blastocyst trophectoderm biopsies. We amplified the DNA using a modified whole genome amplification (WGA) protocol. We used the Illumina Cyto-12 microarray to determine chromosome aberrations and to obtain genotype data for 300K SNPs. A high-resolution copy-number profile was used to identify copy number variations (CNVs). Parental DNA was simultaneously analyzed with embryo DNA for CNVs and heritability correlations. All aneuploidies will be classified as meiotic I, meiotic II or mitotic errors. Data was analyzed with Illumina GenomeStudio software and Bespoke software to examine informative SNPs and corresponding heterozygosity in and around the centromeric regions to determine the parent and phase of aneuploidy. **Results:** 45 families and 470 embryos were tested. 37 patients undergoing a day-3 biopsy were considered for embryo transfer along with 1 patient undergoing a blastocyst biopsy. All embryos from an additional 7 patients undergoing blastocyst biopsies and PGS were frozen. 59% (277/470) of the embryos were abnormal. Many embryos with CNVs were considered normal because of parental CNV analysis. 3.1 euploid embryos were identified per patient/cycle. The overall clinical pregnancy rate was 62%. The clinical pregnancy rate for women < 35 was 56% (5/9), for women 35-37 it was 63% (5/8), for women 38-40 the clinical pregnancy rate was 75% (9/12) and for women > 40 it was 44% (4/9). The blastocyst biopsy transferred patient is pregnant. All families are currently undergoing analysis for meiotic I, meiotic II or mitotic errors. **Conclusions:** 23-chromosome SNP microarray PGS is a valuable technology in an effort to optimize the transfer of euploid embryos and to increase the delivery rates of couples undergoing in vitro fertilization (IVF) due to repeat miscarriages.

2757/F

Validation and Clinical Application of Karyomapping for PGD Combined with 24 Chromosome Aneuploidy Screening. *G. Harton[1], A. Handyside[2], A. Gabriel[3], D. Griffin[3], R. Prates[1], S. Tormasi[1], D. Wells[4], S. Munne[1].* 1) Reprogenetics LLC, Livingston, NJ, USA; 2) London Bridge Fertility, Gynaecology and Genetics Centre, UK; 3) School of Biosciences, University of Kent, Canterbury, UK; 4) Institute of Reproductive Sciences, Oxford, UK.

Aim: To validate genome-wide SNP genotyping followed by analysis using Karyomapping and apply clinically to test embryos for a single gene defect and screen for 24 chromosome aneuploidy simultaneously. Method: Extensive in-house validation using cell lines known to be affected with, or carriers of, a specific monogenic disorder and/or known to be aneuploid was undertaken using the Illumina HumanCytoSNP-12 beadchip and Karyomapping (Handyside et al. 2009). Following these validation experiments, clinical PGD for single gene defects was performed to diagnose embryos from in vitro fertilization (IVF) cycles from fertility centers around the United States. Prior to clinical testing, DNA from various family members was collected and tested using the same SNP chip. Patients then underwent ovarian stimulation at the ART center, followed by egg collection, insemination, embryo growth and biopsy. The individual biopsied cell or trophectoderm samples were washed and placed into sterile tubes in lysis buffer for shipment to the reference PGD laboratory. Upon receipt of the sample, the embryo sample was lysed, subjected to whole genome amplification (SurePlex or REPLI-g) and finally analysed on the Illumina genotyping platform. Following SNP analysis, Karyomapping software was used to analyze the inheritance patterns of each embryo as compared to the family members. Simultaneous detection of single gene defect status was carried out along with aneuploidy screening prior to decision making on individual embryo transfer. Results: Karyomap analysis was able to detect genetic disease (carrier, affected and unaffected embryos were diagnosed) and aneuploidy status as expected. Multiple chromosome aneuploidies were detected in the embryos including both maternal (trisomy 15, monosomy 10, 20, 21 and 22) and paternal aneuploidies (monosomy 2 and 16). All Karyomap results were confirmed with arrayCGH and direct mutation testing by polymerase chain reaction (PCR). Discussion: Karyomapping combines accurate analysis of single gene defects as well as the incidence and origin of chromosome abnormalities. Partial deletions or duplications can be detected as well as whole chromosome aneuploidies and their parental and phase of origin revealed. The prevalence of chromosomal abnormalities in the patient's embryos underlines the importance of combined gene and chromosome analysis for PGD.

Evaluation of early embryonic development and gene expression in a mouse model for Down syndrome. *M. Johnson[1], A. Pennington[1], L. Reinholdt[2], M. Davisson[2], G. Smith[1].* 1) Obstetrics and Gynecology, University of Michigan, Ann Arbor, MI; 2) The Jackson Laboratory, Bar Harbor, ME.

Despite more than 75% of human preimplantation embryos containing cells with aneuploidies and/or segmental aneusomies, little is understood about the biological effects of genomic imbalances at this early developmental stage. This study evaluated how a complex segmental trisomy affects development and gene expression of preimplantation mouse embryos. Embryos were produced in vitro using oocytes from females carrying the Rb(12.Ts171665Dn)2Cje derivative chromosome that results in triplication of ~7 mb of MMU17 and ~13 mb of MMU16, a segment syntenic with a region of HSA21 that includes the Down syndrome critical region. Embryos were monitored for development up to blastocyst stage (120 hours postfertilization) and genotyped by performing FISH on trophectodermal biopsies. The remainder of the blastocyst was lysed and frozen. Genotypic analysis of 140 blastocysts revealed 37% trisomic, 42% disomic, 12% trisomic/disomic mosaic and 2 % triploid, consistent with 50% transmission of the derivative chromosome. Review of developmental progression found no differences between genotypic classes. Lysates from 10 blastocysts of the same genotype were pooled (3 pools each, trisomic and disomic), total RNA was isolated, transcripts were amplified and gene expression was assessed using Illumina MouseWG-6 v2.0 expression beadchips. Expression data, analyzed with Illumina's BeadStudio software and the R Lumi and Limma packages, showed similar numbers of genes to be expressed in all 6 data sets (12,419 ± 752 with detection p-value £ 0.05). Within the triplicated regions, MMU16qC3.3:term and MMU17cen:qA1, respectively, 44 ± 6 of 86 and 19 ± 3 of 48 genes were expressed. Overall, gene expression profiles were very similar, with r values between 0.97 and 0.98 for each array pair. While 185 genes showed ≥1.5-fold differential expression between disomic and trisomic data sets, after FDR correction for multiple hypothesis testing, no gene was significantly differentially expressed. Of note, none of the ≥ 1.5-fold changes mapped to the triplicated regions. Studies are ongoing to validate expression of select genes from disomic and trisomic regions. These preliminary data suggest that genomic imbalances may not lead to gross disturbances in developmental progression or gene expression profiles during the preimplantation period. These findings have implications for gene expression or phenotype-based approaches for identifying preimplantation embryos with genomic imbalances.

Single-cell, genome-wide aneuploidy, CNV, SNP and mutation profiling using microarrays and NGS for pre-implantation genetic screening, and cancer research and diagnostics. *J. Langmore, V. Makarov, E. Kamberov, T. Kurihara, J. M'Mwirichia.* Rubicon Genomics, Inc, Ann Arbor, MI.

Accurate single-cell analysis (SCA) of mutations and aneuploidies of polar bodies and blastomeres are critical for successful pre-implantation genetic diagnosis and screening (PGD/PGS). Previously, PCR and FISH SCA have been used for PGD/PGS, however advances in whole genome amplification (WGA) might enable array and NGS SCA. However WGA has never been proven to have low enough background and high enough reproducibility for array or NGS-based embryo selection. We present qPCR, array and NGS results showing that PicoPlex™ WGA enables reproducible profiling of single-gene disorders and mutations, as well as genotyping and copy number variation in single human cells. These results are also applicable to analysis of lineage of cancer tissue and circulating tumor cells (CTC).

Single RWPE cells (SV40-transformed normal prostate epithelial cells) in PBS were flow-sorted, lysed and amplified 1 million fold using PicoPlex WGA according to directions. 50 ng aliquots of amplified tumor DNA were evaluated to quantify the stochastic and systematic bias of PicoPlex. The representation and repeatability of PicoPlex WGA were tested using 48 human qPCR assays representing a large range of GC-content. Agarose gels showed a broad peak from 250 to 850 bp. About 50% of the loci were as accurately represented in aDNA as in unamplified DNA. The remaining loci were reproducibly under- or over-represented. Non-human aDNA was less than 30% of the total aDNA.

In testing by third-party reference labs, single-cell qPCR and microarray analysis was possible with >95% of the single embryo and cancer cells tested using BlueGnome, Perkin Elmer, Agilent, OGT, NimbleGen, and Illumina aCGH and SNP arrays, as well as NGS. Aneuploidy of blastomeres, polar bodies, sperm, and cancer cells were accurately tested. Deletions £75 kb were reproducibly detected. Although Illumina SNP call rates were only 50-60%, LOH was less than 10%, showing that the SNPs were accurately called. PCR-based SNP and mutation analyses were 95% accurate.

These results translate into increased accuracy and reproducibility of single-cell PGD/PGS testing using PCR, microarrays and NGS, and open the doors to successful genetic profiling of cancer and stem cells for research and diagnostics.

Preimplantation Genetic Diagnosis for GM1-Gangliosidosis, Type I with Linked Polymorphic Markers. *E. Pomerantseva, D. Pauling, O. Verlinsky, S. Rechitsky.* RGI, Chicago, IL.

GM1-Gangliosidosis (MIM #230500) is an autosomal recessive lysosomal storage disease characterized by the accumulation of ganglioside substrates in lysosomes. GM1-Gangliosidosis is caused by the deficiency of beta-galactosidase-1, which is coded for by the GLB1 gene located in gene map locus 3p21.33. Clinically, patients show variable degrees of neurodegeneration and skeletal abnormalities. There are 3 main clinical variants categorized by severity and variable residual beta-galactosidase activity. Type I, or infantile form, shows rapid psychomotor deterioration beginning within 6 months of birth, generalized central nervous system involvement, hepatosplenomegaly, facial dysmorphism, macular cherry-red spots, skeletal dysplasia, and results in early death. A preimplantation genetic diagnosis (PGD) cycle was performed for a family which lost one child to GM1-Gangliosidosis and had to terminate another pregnancy after a CVS diagnosis revealed the fetus to be affected with the same disease. There are two different mutations of GLB1 gene in this family. The partner is heterozygous for H281Y and the patient is heterozygous for c.1310delA. Their only surviving child carries the paternal mutation. Linkage was established by analysis of family members including DNA from the recent affected pregnancy. Nested and hemi-nested multiplex PCR protocol was developed for both mutations and tightly linked Short Tandem Repeats (STRs). The final protocol included the following polymorphic markers: STR1, STR2, STR3, D3S4525, D3S1619, D3S3512, D3S1768, D3S1277, along with the mutations. The mutations were studied by restriction endonuclease digestion followed by gel electrophoresis, while polymorphic markers were analyzed by fluorescent fragment analysis. The family underwent one cycle of IVF. PGD was performed on single blastomeres. Out of 19 embryos 5 were found to be normal non-carriers, 6 were normal carriers, 6 were predicted to be affected and 2 embryos were abnormal due to aneuploidy for chromosome 3. Overall 11 embryos were cleared for transfer, of which 6 were frozen and 2 transferred, resulting in a singleton pregnancy. Amniocentesis, performed by an independent laboratory, confirmed our PGD results, and a healthy non-carrier female child was born.

2761/F

First experience of preimplantation genetic diagnosis (PGD) for de-novo mutations. *S. Rechitsky, K. Pamerantseva, T. Pakchalchuk, D. Pauling, O. Verlinsky, A. Kuliev.* Reproductive Genetics Inst, Chicago, IL.

PGD is currently performed for inherited conditions with known parents' mutations, detected by direct mutation analysis or haplotyping in oocytes or embryos. However, this cannot be applied when parent(s) or affected children have a de-novo mutation, as neither origin, nor relevant haplotypes are available for testing in single cells. We developed the PGD strategy for a total of 102 families with 38 different genetic disorders, determined by 33 dominant, 3 recessive and 2 X-linked de novo mutations. 97 families were with dominant mutations, of which 40 were of paternal origin, including 2 cases of gonadal mosaicism, 50 of maternal origin, including 1 with gonadal mosaicism, and 7 detected for the first time only in the affected child. PGD design for the following dominant de-novo mutations were developed: atypical Rett syndrome, brachidactily, brain tumor SMARC B1, corneal dystrophy, Darier disease, Diamond-Blackfan anemia, Emery-Dreifus disease, facioscapulohumeral muscular dystrophy, hereditary multiple exostoses, familial adematous polyposis, incontinentia pigmenti, osteogenesis imperfecta 1, retinoblastoma, spinocerebral ataxia 6, metaphyseal dysplasia, MEN 1, MEN 2B, NF1, NF2, optical atriophy 1, tuberous sclerosis type 1 and 2, Marfan, Gorlin, Kalman, Crouson, Peutz-Jeghers, Pfieffer, Loes-Dietz, Treacher Collins, Sotos, Strickler and Von Hippel-Lindau syndromes. All 3 PGD cases for de-novo recessive disorders were of paternal origin, including cystic fibrosis, SMA and Fanconi anemia. PGD for 2 X-linked de-novo mutations included PGD for chronic granulomatosys and incontinentia pigmenti. The development of specific PGD strategy for each of the couples involved an extensive DNA analysis of the parents and affected children prior to PGD, including the mutation verification, polymorphic marker evaluation in blood, whole and single sperm, and polar body analysis in order to establish the normal and mutant haplotypes. Overall, 152 PGD cycles have been performed for 82 of 102 families under study, for which a specific PGD design has been established, resulting in preselection and transfer of 240 (1.83 per cycle) mutation free embryos in 131 (86%) cycles, yielding 62 (54.1%) unaffected pregnancies and birth of 55 healthy children, confirmed to be free of the de-novo mutations tested. The data show feasibility of PGD for de-novo mutations, which may now be routinely performed with the accuracy of over 99%, using the established PGD strategy.

Direct evaluation of CVS: Impact of switching from karyotypes analysis to FISH. *R. Schreck, L. Freilich.* Medical Genetics Institute & Pathology & Lab Med, Cedars-Sinai Med Ctr, Los Angeles, CA.

The purpose of chromosome analysis in prenatal diagnosis is to detect chromosome abnormalities responsible for abnormal development in time for intervention, if desired, and to relieve parental anxiety. Thus both accuracy and timeliness are key components of the process. To address the time factor, many laboratories are offering a rapid, preliminary screen of amniocytes, either by FISH or PCR. Chorionic villus sampling (CVS) which occurs during the first trimester and addresses the time issue, is complicated by the presence of chromosome abnormalities that are restricted to the extra-embryonic tissues or confined placental mosaicism (CPM) in about 1-2% of studies. In addition, the not infrequent discrepancies between results obtained from "direct" preparations and cultured cells, often lead to additional prenatal testing by amniocentesis. We have looked at the use of FISH with probes for chromosomes 13, 18, 21, X and Y and its effects on the levels of accuracy and identification of CPM in CVS studies, both by retrospective analysis of studies using chromosome analysis of spontaneously dividing cells, and by comparing the abnormality rates in this population with a matched population in which only FISH was employed for direct analysis. Evaluation of 8739 CVS analyses in which direct chromosome analysis was done yielded 441 abnormal results (5%) of which 51 (0.58% of all studies) would have been missed by FISH. However, of the "missed" abnormalities where follow-up studies were available less than half (40%) were confirmed by amniocentesis or termination tissue. This suggests that the majority of abnormalities missed by the FISH approach to rapid CVS results represent CPM which raises parental anxiety but is not indicative of an actual chromosome abnormality in the fetus. The rare true abnormalities (2/1000 procedures) missed by the FISH approach were all detected by analysis of the CVS culture. Thus FISH is actually preferable to chromosome analysis as a rapid screen in CVS, as it can reduce the need for second invasive procedures in normal pregnancies.

Genetic factors in the spermatogenesis of infertile males. *M.S. Juchniuk de Vozzi[1], C.S. Pereira[1], S.A. Santos[1], L. Pola[1], P.A. Vozzi[1], M.A.C. Vasconcelos[2], A.C.J.S. Rosa-e-Silva[2], P.A. Navarro[2], L. Martelli[1].* 1) Dept of Genetics, School of Medicine of Ribeirão Preto, University of São Paulo, Brazil; 2) Dept of Gynecology and Obstetrics, School of Medicine of Ribeirão Preto, University of São Paulo, Brazil.

Male infertility is responsible for 50% of in vitro fertilization procedures. Semen analysis to assess the male factor is the first step for infertility investigation. Additionally, genetic analysis of sperm provides information about numerical and structural chromosomal aberrations which were able to finish meiosis without being detected by meiotic checkpoints. Apoptosis is a type of cell death involved in different steps of spermatogenesis, first at puberty, at the beginning of spermatogenesis and subsequently in adult gonads, controlling the normal spermatogenesis. Several studies have shown that the deregulation of apoptosis in germ cells can result in male infertility. The objective of this study is to evaluate the meiotic segregation of gametes and the frequence of apoptotic germ cells of oligozoospermic men with a diagnosis of infertility. We have studied semen samples of fifteen infertile men (group I) and seven male normal controls with proven fertility (group II). Cytogenetic studies of peripheral blood were also carried out for both groups. The fluorescent in situ hybridization (FISH) technique was used for evaluation of the meiotic segregation of chromosomes 3, 13, 21, 22, X and Y in the gametes. The presence of apoptosis was detected by externalization of phosphatidylserine using annexin V-labeled fluorescein. We have detected heteromorphism of chromosome 9 in 13.3% of the infertile man karyotypes and one patient had a marker chromosome. The frequency of total aneuploidies of chromosomes was 6, 88% in infertile men and 3.98% in the control group. The frequencies of disomies of chromosome 3, 13, 21, 22, XY, XX and YY respectively was 0.34%, 0.51%, 0.77%, 0.65%, 0.68%, 0, 19% and 0.20% in infertile patients. Infertile men and controls showed significant differences ($p<0.05$) in the frequencies of aneuploidies of chromosomes 13, 21, 22 and XY disomy. The differences between the groups could be explained by failure in meiotic recombination, interfering with the correct process of segregation. Our results revealed a significant difference between the incidence of apoptotic cells in infertile men and controls ($p<0.05$). The increased frequencies of apoptotic gametes in infertile men could be explained by the process called abortive apoptosis. The possible relationship between total disomies and sperm morphology suggests that the selection of gametes would be strictly controlled in spermatogenesis, being unregulated in oligozoospermic patients.

BCL2 Anti-apoptotic Gene Alterations in Repeated Pregnancy Loss. *S.M. Seyedhassani[1,2], M. Houshmand[1], A. Aflatoonian[2], S.M. Kalantar[2], G. Modabber[1].* 1) Med Gen, National Inst Gen, Tehran, Iran; 2) Research and Clinical center for Infertility, Yazd, Iran.

Introduction: Recurrent pregnancy loss (RPL) is a critical medical problem in about 0.5-2% of women. Molecular genetics background for spontaneous abortion is being understood more and more, and some polymorphisms have been reported so far. This study investigates the alterations of BCL2 gene as an anti-apoptotic gene in women with idiopathic RPL. Material and methods: The frequency of mutations in BCL2 gene of 96 idiopathic RPL women was studied here in comparison to a sample of 96 healthy women. The promoter and the entire coding regions were amplified using a polymerase chain reaction (PCR). The PCR products were documented by 2% agarose gel electrophoresis, and were verified by an automated DNA sequencing method. The result of DNA sequence analysis was compared with the NCBI database using the Clustal X program. Results: The mean age of the women with RPL at the time of blood sampling has been 28.73 and the mean gestational age at the time of miscarriages has been 10.35. The mean age of control group has been 30.20 while they had 2- 4 children. Sequencing of BCL2 gene showed G66C variation in the exon 1 of all RPL and control women and A735G variation in exon 2 of both groups. In A735G variation, there were AA, AG and GG genotypes in 41(42.7%), 40(41.7%) and 15(15.6%) of the RPL and 31(31.3%), 46(47.9%) and 19(19.8%) of the control women respectively. This difference was not significant (P= 0.32) and both of them encode amino acid threonine. There was not a significant association between A and G alleles at nucleotide 735 and the occurrence of RPL (P= 0.14). Discussion: Our result does not indicate any significant variant in BCL2 gene which affects apoptotic process in RPL women. However, the decreased expression of BCL2 is reported in aborted chorionic villi and the importance of BCL2/BAX ratio is shown in different stages of fetal growth and development. The study of post transcriptional and post translational modifications is recommended to clarify the possible role of BCL2 gene in RPL especially on aborted material.

RNA-based genetic study of teratozoospermia; *ZPBP1* mutations associated with abnormal semen morphology in infertile men. *A. Yatsenko[1,2], D. O'Neil[1], A. Roy[1], P. Arias-Mendoza[1], R. Chen[1], L.J. Murthy[3], D.J. Lamb[3,4], M.M. Matzuk[1,2,4].* 1) Pathology, Baylor College of Medicine, Houston, TX; 2) MH Genetics, Baylor College of Medicine, Houston, TX; 3) Urology, Baylor College of Medicine, Houston, TX; 4) Molecular and Cell Biology, Baylor College of Medicine, Houston, TX.

Male infertility is a global health problem of multifactorial etiology, affecting nearly 7% men. It is estimated that genetic factors account for at least 50% of cases of male infertility. Teratozoospermia is a common semen abnormality condition associated with male infertility. It is defined as an abnormal morphology with less than 4% of the normal spermatozoal content. However, genetic defects that cause teratozoospermia are mainly unknown in the majority of patients. In the present study, we investigated the role of zona pellucida binding protein, ZPBP1, in teratozoospermia in humans. Previous studies demonstrated that male mice with the disrupted ZPBP protein were unable to fertilize oocytes due to abnormal spermatozoal morphology and forward sperm motility. Electronic microscopy of spermatozoa showed abnormal ultrastructure, round headed, globozoospermia-like morphology. The ZPBP is a structural protein, predominantly expressed in spermatozoal acrosome, and plays important role in acrosome reaction, binding to oocyte zona pellucida, and ultimately in oocyte penetration. Therefore, it was suggested that abnormal morphology affects acrosome compaction and oocyte penetration that results in inability to fertilize oocytes. To study association between *ZPBP1* mutations and teratozoospermia, we selected 192 cDNA samples from infertile males with abnormal semen morphology and 100 normozoospermic controls. Following RT-PCR, DNA and cDNA sequencing have been performed with patients and control samples. Preliminary, we identified several novel heterozygous missense and splicing alterations in mRNA from teratozoospermic semen samples. The observed cDNA defects were confirmed in the genomic DNA. Analysis of 100 controls did not identify these alterations. In addition, none of these nucleotide changes are listed as known polymorphisms in the dbSNP database. Our preliminary data suggest that mutations in *ZPBP1* may contribute to a significant fraction of teratozoospermia in infertile men. Further genetic studies are in progress. This study was supported in part by the National Institutes of Health Infertility Center (P01HD36289) and U54 the Specialized Cooperative Centers Program in Reproduction and Infertility Research to DJL and MMM.

Rare allele tagged SNPs can identify the Tay Sachs 1278insTATC allele for a universal Preimplantation Genetic Diagnostic assay. *P. Renbaum[1], S. Katz[1,3], S. Zeligson[1], S. Perlberg[1], T. Eldar-Geva[2,3], E.J. Margalioth[2,3], E. Levy-Lahad[1,3], G. Altarescu[1,3].* 1) ZOHAR PGD Unit and Genetics Institute, Shaare Zedek Medical Center, Jerusalem, Israel; 2) IVF Unit, Shaare Zedek Medical Center, Jerusalem, Israel; 3) Hebrew University Medical School, Jerusalem, Israel.

Background: Preimplantation Genetic Diagnosis (PGD) relies on genetic information obtained from a single cell. In addition to mutation detection, accurate diagnosis includes identification of the affected allele by linkage using multiple informative markers. Routinely in PGD, families are first haplotyped using fluorescently labeled Short Tandem Repeat (STR) markers, and a specific multiplex assay is constructed for each case and then used on single cells (polar bodies or blastomeres) for PGD. While STRs are highly variable, they are limited in number, and in some instances it is difficult to find sufficient informative assays flanking the mutation. SNP markers have only two variants (A and B) and as such make the distinction of specific alleles in blastomeres difficult; however, they are present at a much higher frequency throughout the genome. Aims: To examine the use of SNP markers as a tool for PGD diagnosis, and the identification of a universal set of SNP tags which specifically and differentially detect the Tay Sachs (TS) HEXA 1278insTATC Ashkenazi Jewish (AJ) founder allele. Materials and Methods: We genotyped sixteen unrelated carriers of the TS 1278insTATC mutation using Affymetrix 250k Nsp arrays. A region of +/- 2Mb, including 221 SNPs surrounding the HEXA gene, was compared to 40 non-Tay Sachs, unrelated, AJ controls. Results: Heterozygote frequencies of eleven specific SNPs were 5-8 times higher in TS carriers than in AJ controls, suggesting that the 1278insTATC founder mutation occurred on a rare allele. This set of 11 SNPs, represent a rare allele tag and can be used to identify the TS 1278insTATC allele in any carrier. Conclusions: Since this TS allele is very rare, the corresponding wild type allele from either parent can be easily distinguished in blastomeres using a TS universal 11 SNP assay in any carrier couple, without the need to prepare family specific assays. When founder mutations occur on uncommon alleles, a similar strategy can be used to identify a set of rare allele tagged SNPs (RATS) for the establishment of specific universal PGD assays for other disorders.

Aggregating information across loci when testing the genome for associations. *N. Cardin, J. Witte.* Human genetics, Epidemiology and Biostatistics, UCSF, San Francisco, CA.

There is much current interest in elucidating the role of rare genetic variation in common human disease. However the analysis of rare variants is complicated by the inherent lack of power that one can achieve with sparse data. In order to address this challenge it has become common to combine the effects of multiple rare SNPs [1,2,3], for example within regions or pathways. In effect this approach assumes that all combined variants have the same effect and tests the genes or pathways themselves for an association with disease. However, there is no agreement on how to aggregate these variants and most current approaches fail to jointly utilize the evidence from common variants. A common approach taken [1,2] is to choose a frequency threshold, below which variants are aggregated whilst above this threshold variants are analyzed individually. However there is no optimal cut off for such a procedure and in principle we can gain power by combining signals of association across common and rare variants. One approach to this is to use a multi-SNP regression model, under which each variant has its own effect size. However, because of sparse data and correlations induced by LD, this can lead to instability in results and very large confidence intervals for effect size estimates. We propose to take a fully Bayesian approach where effects are sampled from the joint posterior allowing the evidence for association across a set of SNPs (eg. within a gene) to be more robustly examined. It is not yet known to what extent causative variants cluster, eg. within genes or pathways, or to what degree certain classes of SNPs may be enriched amongst causative loci, eg. non synonymous SNPs or variants which interrupt protein function. Even if estimates are taken from the literature these effects may vary from disease to disease. We place a hierarchical prior on the distribution of disease effects which allows the data to inform the degree of clustering of causative loci within a variety of structures. If the literature does provide relevant information then this is also a natural structure within which to make use of it. To demonstrate the utility of the method we provide results from simulated data where we investigate the power of the method under various scenarios and the stability of the results compared to maximum likelihood inference. Using treelets to smooth complicated pedigrees. *A. Crossett[1], N. Melhem[2], FA. Middleton[6], L. Klei[2], S. Tiobech[3], C. Otto[3], AB. Lee[1], B. Devlin[2], W. Byerley[5], M. Myles-Worsley[4], K. Roeder[1].* 1) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA; 2) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA; 3) Belau National Hospital, Korror, Palau; 4) Department of Psychiatry, University of Utah, Salt Lake City, UT; 5) Department of Psychiatry, University of California, Irvine, CA; 6) Department of Neuroscience and Physiology, College of Medicine, State University of New York, Syracuse, NY.

Beyond a few degrees of relationship pedigrees are rarely known with absolute certainty. This uncertainty is often elevated in population isolates, in which all extant individuals trace their ancestry to a limited number of founders. As noted by Choi et al. (Genet Epidemiol, 33:668-78, 2009) this cryptic relatedness can have a detrimental impact on nominal false positive rates for genetic association tests. Choi and colleagues develop an algorithm overcoming this problem: first they estimate the relatedness of all pairs of individuals assessed for association; then they adjust a chi-square test for association on the basis of relatedness. It is important to recognize that using genotype information to estimate relationships between pairs of individuals can be very noisy.

Treelets are an adaptive approach to dealing with noisy, high-dimensional and unordered data. Treelets simultaneously construct a hierarchical tree and an orthonormal basis that represent the internal structure of the data. We propose to use treelets on estimated relationship data by examining each individual's relationship to everyone else. Noise is removed by identifying the most important features of the basis and then reconstructing the data. We apply these techniques to data from Palau, an Oceanic nation of relatively recent origin in human history. These data are part of an ongoing project to understand the genetic basis of schizophrenia.

Mixed Model Coexpression (MMC): calculating gene coexpression under the presence of systematic confounding. *N. Furlotte[1], H.M. Kang[4], C. Ye[3], E. Eskin[1,2].* 1) Department of Computer Science University of California Los Angeles, CA; 2) Department of Human Genetics University of California Los Angeles, CA; 3) Department of Computer Science University of California San Diego, CA; 4) Department of Biostatistics, University of Michigan, Ann Arbor, Michigan.

The analysis of gene coexpression patterns is at the core of many types of genetic analysis. The coexpression between two genes can be easily calculated using a simple Pearson's correlation coefficient. However, technical confounding, such as batch effects, may cause inflation of the Pearson's correlation so that uncorrelated genes appear to be highly correlated. Many methods have been suggested which aim to correct gene expression data for confounding effects. Methods such as COMBAT are applied in order to correct gene expression data for known batch effects. Another method, Surrogate Variable Analysis (SVA), does not depend on a priori knowledge of confounding effects, but rather incorporates the observed correlation structure of the gene expression data into the correction procedure. SVA uses the observed inter-array correlation in order to estimate a discrete number of "surrogate variables", which represent the contribution to the measured gene expression by a set of unknown confounding factors. These factors can be regressed out in order to obtain a corrected dataset. Both COMBAT and SVA have their drawbacks. Namely, they both rely on the assumption that the effects of confounding can be estimated with a discrete number of factors and it is unlikely that this assumption will hold as the patterns of confounding increase in complexity. In this paper, we present a statistical model for calculating gene coexpression called Mixed Model Coexpression (MMC). Our MMC method models coexpression using a mixed model framework, in which technical confounding effects are represented as a random variable in a statistical model for coexpression. Our method assumes that technical confounding effects can be modeled with a random component and that this random component has variance proportional to the inter-array correlation matrix. The key intuition is that technical confounding effects cause the overall array expression patterns to be similar, causing arrays to appear highly correlated. This increased inter-array correlation induces correlation between genes. By utilizing the observed inter-array correlations, we are able to inform our calculation of coexpression, and effectively remove many of the spurious gene correlations. We apply our method to human and yeast datasets and show it is better able to effectively prioritize strong coexpressions when compared with a standard Pearson's correlation and a Pearson's correlation applied to data corrected with SVA.

Composite likelihood-based meta-analysis of breast cancer genome-wide association data. *I. Politopoulos[1], W. Tapper[1], J. Gibson[1], S. Ennis[1], D. Eccles[1,2], A. Collins[1].* 1) Genetic Epidemiology & Bioinformatics Group, Human Genetics Research Division, School of Medicine, University of Southampton, Southampton, Hampshire, United Kingdom; 2) Cancer Sciences Division, School of Medicine, University of Southampton, Southampton, Hampshire, United Kingdom.

We have implemented a model which tests association with disease in genomic regions defined on a linkage disequilibrium unit (LDU) map. This approach has the advantages of evaluating the evidence for association in fixed regions describing comparable levels of linkage disequilibrium, combining the evidence for association from multiple single nucleotide polymorphisms (SNPs) and requiring a substantially reduced correction for the number of statistical tests, compared to single SNP-based analysis. The composite likelihood model provides a point estimate of location which becomes more precise as sample sizes are increased through meta-analysis and information weights facilitate combination of evidence and increase power (*Tapper et al, BMC proceedings 2007 1:S18*). Power is further enhanced by imputation of missing genotypes to increase SNP coverage in each region. P-values from each sample are combined through a weighted Z-transform test (*Whitlock, J Evol Biol 18, 2005, 1368-1373*). As a demonstration of the approach we combined association evidence from 1,143 breast cancer cases and 1,139 controls from the Cancer Genetic Markers of Susceptibility (CGEMS) study (with 498,786 SNPs genotyped and 488,991 imputed) and 280 early onset breast cancer cases from the Prospective Study of Outcomes in Sporadic versus Hereditary breast cancer (POSH) and 5,200 Wellcome Trust Case Control Consortium (WTCCC) Phase 2 controls (with 506,610 SNPs genotyped and 472,799 imputed). Evidence was combined across ~14,000 genomic regions each spanning four LDUs. The point estimate with the strongest association signal in the combined sample is within FGFR2 on chromosome 10 (chi-square of 24.51). Other high ranking signals were identified in the FBN1 gene (chromosome 15, chi-square 14.47) and NTSR1 (chromosome 20, chi-square 12.93). We anticipate extension to include additional breast cancer genome-wide association data sets, including further samples from the POSH consortium, which will increase the understanding of underlying genetic risk factors involved in early onset breast cancer.

A gene-based test of association. *C.S. Tang, M.A. Ferreira.* Genetic Epidemiology, Queensland Institute of Medical Research, Brisbane, Australia.

Results from recent genome-wide association studies indicate that multiple independent risk loci may be present in the same region, suggesting that association methods that can test multiple SNPs simultaneously may have improved power to identify genes with weak effects on disease risk. To address this possibility, we extended our recently developed multivariate test of association that is based on canonical correlation, to test the strength of association between a set of SNPs and a phenotype. This approach is applicable to both continuous or discrete traits measured in unrelated individuals. Simulations show that this test has improved power when compared to standard single-locus analyses when there are multiple independent risk loci in a region. We illustrate the applicability of this novel approach by analysing data from a genome-wide association study of asthma.

A novel genome-information content-based statistic for genome-wide gene-gene co-association analysis designed for next-generation sequencing data. *M. Xiong, L. Luo, Y. Zhu.* Dept Biostatistics, Univ Texas Hlth Sci, Houston, TX.

The current popular methods for testing association of multiple loci are designed for common alleles. The critical barrier in multi-locus analysis for rare variants is as follows. First, multiple rare variants that jointly have significant risk effects, but individually make only a small contribution. In the presence of allelic heterogeneity, the power of current variant-by-variant tests for interaction between rare variants will vanish. Second, new sequence technologies are highly error prone. Due to their large genotyping errors and low frequencies, the signal of rare alleles may be compatible with genotyping errors. Unless genotyping errors are properly taken into account, many multi-locus tests will be invalidated. The great challenges for successful association studies incorporating interaction are (1) lack of deep understanding measure of interaction and statistics with high power to detect interaction or to test for the association taking interaction into account , (2) lack of concepts, methods and tools for detection of interactions for rare variants, (3) severe multiple testing problems, and (4) heavy computations. To meet these challenges, we propose a novel concept of gene-gene co-association in which a gene is taken as a unit of association analysis and shift the paradigm of association studies from discrete loci to continuous genome regions, which allows us to extend association test from common alleles to both common and rare alleles and provide a unified framework for association analysis of both common and rare alleles. We validated the null distribution and the type I error rates of the new statistic through intensive simulations. To evaluate its performance for gene-gene co-association analysis , the proposed test statistic was applied to two independent GWAS datasets of psoriasis. The first dataset included 955 individuals with psoriasis and 693 controls with typed 443,018 SNPs, and the second dataset included 466 individuals with psoriasis and 732 controls with typed 439,201 SNPs. We found that In total, 20 pairs of genes showed significant evidence of co-association in two independent studies. These 20 pairs of genes included 27 distinct genes located in immunology, inflammatory, cytokines-chemokines and cell signaling pathways.

Detection of Disease-related recent common ancestral haplotypes. *D.G. Ying[1], W.L. Yang[2], L. Zhang[2], P.S. Sham[1], Y.L. Lau[2].* 1) Department of Psychiatry, The University of Hong Kong, Hong Kong; 2) Department of Paediatrics, The University of Hong Kong, Hong Kong.

Genome-wide association studies (GWAS) are usually followed by selection a number of SNPs with significant disease association P value. Genetic variants with high penetrance can be effectively detected by GWAS but remains the variants with low penetrance. Haplotype allele with these variants can be inherited from a recent disease ancestor and shared by a small portion of disease population. We have developed a program that can detect the haplotype allele shared by several case individuals with unknown relationship out of disease population using normal Plink format genotype data. Thousands of simulated cases with different haplotype age and number of shared individual are performed for the testing while The results shows well for detecting the age of the haplotype from 10 to 50 generations for at least 4 individuals. Those haplotype alleles with high rank usually have rare block combinations and are highly suspicious to have disease related variants and worth to do further analysis. The time and space requirement for the program is linearly related to number of overall SNPs and square of the number of population size.

Genome-Wide Association Study of Specific Language Impairment using a gene-based approach. *P. Evans[1], E. Gamazon[1], K. Kelsey[2], J. Tomblin[2], D. Nicolae[1], N. Cox[1].* 1) Gen Med, Univ Chicago, Chicago, IL; 2) Speech Pathology and Audiology, Iowa City, IA.

Specific language impairment is a highly heritable disorder characterized by deficits in language development in a child despite normal overall intelligence. We performed a genome-wide association study on 429 genetically European individuals on the Affymetrix 6.0 genotyping chip for two different phenotypes: lcompf (change these phenotype names) and ldiagf. A third phenotype ppcompf, was analyzed in 258 genetically European individuals for which we had data on this phenotype. LCOMPF is a measure of language ability. LDIAGF is a dichotomous trait based on LCOMPF, with LCOMPF scores less than -1.1 (roughly 10%) leading to an affected status for LDIAGF. The PPCOMPF phenotype represents a measure of phonological memory and awareness thought to be impaired in individuals with SLI. The genome-wide association results using the HapMap imputed SNPs for each phenotype were used to perform a functional genome-wide association study. Nonsynonymous SNPs and eQTLs are included in a gene-based analysis. This allows us to look at the functional SNPs for each gene and combine p-values of those SNPs to give an overall gene-based score. The gene NRN1, is the top gene for the lcompf phenotype with and without the parental education as a covariate. NRN1 is involved in postmitotic-differentiating neurons of the developing nervous system and is also involved in the development of neuronal structures involved in plasticity in adults. In vitro assays have shown that this gene promotes neurite outgrowth. The function of the most significant genes for other phenotypes have functions that are not as clear for how they would cause SLI. The top genes using the ldiagf phenotype are OCIAD1, C6orf108, ALDH3B2, DPY19L2P1, LIPI, and IFNGR2. OCIAD1 is thought to be a cell adhesion protein overexpressed in ovarian cancer. ALDH3B2 is involved in alchohol metabolism and lipid peroxidation. DPY19L2P1 is a pseudogene of a membrane protein. LIPI is a membrane associate phospholipidase. and IFNGR2 is interferon gamma receptor and is involved in susceptibility to mycobacterial infection. The top genes for ppcompf are PXMP4, and ALDH3B2. PXMP4 is a peroxisomal membrane protein, and ALDH3B2 is also seen in LDIAGF.

2775/W

A framework for assessing association between gene and disease by evaluating component SNPs. *B.A. Goldstein[1], A.E. Hubbard[1], E.C. Polley[1], L.F. Barcellos[2], IMSGC.* 1) Division of Biostatistics, Univ California, Berkeley, Berkeley, CA; 2) Division of Epidemiology, Univ California, Berkeley, Berkeley, CA.

The primary goal of large SNP association studies is to identify genes that are associated with disease. However, most methods involve analyzing variation only at the level of the SNP. This approach ignores composite properties of variation within a gene that may be more explanatory of function. Currently available methods that attempt to examine a particular gene as a unit (e.g. haplotype analysis, rare variant analysis) are limited by their assumptions and applications. We propose a method to define a functional form for the effect of multiple SNPs within a gene on an outcome, providing a means to better understand the gene-disease relationship. The function for each gene is derived using the Super Learner algorithm, an ensemble learner that makes no assumptions about the underlying causal mechanism. A novel wald-like test of association is performed between the gene's derived function and the chosen outcome, to detect genes of interest. A summary measure is also reported based on the area under the curve (AUC). Theoretic and simulation results show this method maintains perfect Type I error control when the null is true. Moreover, it is able to detect true associations that would otherwise be missed based on marginal testing. We apply this method to a large candidate gene study in multiple sclerosis, comprised of more than 2,000 genes with 27,000 SNPs and ~3,000 individuals. Using FDR for Type 1 error control, our procedure identifies 76 genes across 10 chromosomes (10 located outside the MHC on chromosome 6). Typical univariate testing identifies 70 genes across 7 chromosomes (8 located outside the MHC). This procedure provides a new approach for considering SNP data, with an emphasis on the gene, rather than individual polymorphism(s).

Association between SLC2A9 transporter gene variants and the serum uric acid phenotype reveals within-gene differences between persons of European and African ancestry. *S.T. Turner[1], A.D. Rule[1], M.E. Matsumoto[2], T.H. Mosley[3], S.L.R. Kardia[4], M. de Andrade[2].* 1) Div Nephrology & Hypertension, Mayo Clinic, Rochester, MN; 2) Div Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 3) Dept Geriatric Medicine, University of Mississippi Medical Center, Jackson, MS; 4) Dept Epidemiology, University of Michigan, Ann Arbor, MI.

It is well known that increased uric acid levels lead to gout, kidney stones, hypertension, and cardiovascular disease. Uric acid is filtered, reabsorbed, and secreted in the kidney under regulation by the SLC2A9 transporter in renal tubules. Genetic variation in the SLC2A9 gene has an established association with serum uric acid in European ancestry populations. The Genetic Epidemiology Network of Arteriopathy family-based cohorts underwent study visits between 2001 to 2005 that included a blood draw and a spot urine collection. Genotype was obtained using the Affymetrix Genome-Wide Human SNP Array 6.0. The associations between SNPs in the SLC2A9 transporter gene and each phenotype were assessed using a linear mixed effects model taking into account the family relationship. Analyses were adjusted for age, sex, diuretic use, body mass index, homocysteine, and triglycerides in a parsimonious model after considering 30 covariates with known associations with uric acid. A gene-level Bonferroni corrected p-value <0.01 was considered statistically significant. We identified SLC2A9 gene variants showing association with serum uric acid in 1155 subjects of African ancestry (53 SNPs) and 1132 subjects of European ancestry (63 SNPs). SNPs in the first half of the gene showed weakly significant association in subjects of African ancestry but not in subjects of European ancestry. SNPs in the latter half of the gene were the most statistically significant SNPs for both cohorts, and generally were more significant in subjects of European ancestry than African ancestry. The most statistically significant SNP was in the latter half of the gene and explained 2.77% and 2.71% of the variation in serum uric acid in subjects of European and African ancestry, respectively. After adjustment for the most statistically significant SNP, 0.86% of the variation in serum uric acid in subjects of African ancestry was explained by a SNP in the first half of the gene. These SNPs were not associated with differences in fractional excretion of urate or urine urate to creatinine ratio. These findings show that SLC2A9 transporter variants associate with serum uric acid levels in subjects of African and European ancestry, but there are race-differences in the specific gene regions that most affect serum uric acid levels.

A Genome-wide Association and Imputation Software Pipeline for The Identification of Shared Susceptibility Loci. *D. Ellinghaus[1], M. Nothnagel[2], S. Schreiber[1,3], A. Franke[1].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University, Schittenhelmstr. 12, 24105 Kiel, Germany; 2) PopGen Biobank, Christian-Albrechts-University, 24105 Kiel, Germany; 3) First Medical Department, University Clinic S.-H., Campus Kiel, Germany.

Genome-wide association studies (GWAS) and subsequent meta-analysis projects have been successful in identifying novel genetic susceptibility factors for several autoimmune and inflammatory diseases. Although many examples exist that different disorders share common genetic risk loci (e.g. IL23R in Crohn's disease, ulcerative colitis and psoriasis; NOD2 in Crohn's disease and sarcoidosis), systematic and genome-wide approaches are scarce. We therefore developed a fast and flexible genome wide association and imputation software pipeline for an automated processing of genome-wide association data. Different and complementary analysis strategies are currently developed to identify common disease loci and to prioritize associated loci for follow-up studies: GWAS datasets will be combined via confirmed-marker-, joint-, ranking-, meta- and difference-analyses. The software pipeline is implemented in Python and R in an object-oriented style, makes use of the open source PLINK library and the BEAGLE software package, and runs on a Linux compute cluster with a batch processing system. Nearly all parameters, options and datasets can be combined in a flexible way and can be read from configuration files. An attached comprehensive and fully automated plotting pipeline facilitates a fast evaluation of candidate loci (regional association plots) or summary statistics (IBS-, Manhattan-, and QQ-plots). We have recently completed GWAS for various complex diseases. More than 8,000 controls and 16,000 cases for 15 distinct diseases were genotyped on Affymetrix or Illumina SNP arrays and were prepared for combined analyses. The project takes a systematic, genome-wide approach by studying an overlay of GWAS data sets from different diseases in clinically relevant combinations. A large-scale replication of the identified loci as well as subsequent resequencing of replicated disease loci will identify the broad spectrum of variation and will yield lists of potentially causative variants that are relevant for more than one disease. Association analysis results for both the individual analyses and the combined analyses will be made publicly available through a UCSC custom track. The current status of the project will be presented at the conference and the software will be publicly released.

Increasing power for family-based association in the presence of locus heterogeneity using a mixture TDT. *D. Gordon, D. Londono, S. Buyske.* Dept Gen, Rutgers, State Univ NJ, Piscataway, NJ.

Background: Locus heterogeneity can significantly reduce statistical power to detect association in both case-control and trio designs. Recent work by Zhou and Pan uses a mixture model to allow for locus heterogeneity in a case-control design.

Methods: We extend the work of Zhou and Pan to the TDT statistic for trios. We specify that in the presence of locus heterogeneity, each set of trios is a mixture of associated and non-associated trios. We perform simulations to determine the empirical type I error rate and power of the mixture TDT in the presence of locus heterogeneity.

Results: Our simulations suggest that the mixture TDT maitains the correct empirical type I error rate when there is no disease locus. Also, power gains in the presence of locus heterogeneity may be substantial.

Conclusions: It is possible to address locus heterogeneity in association testing as well as linkage analysis. We have software to perform our analyses.

A simple method for tightening the confidence limits reported in a genetic epidemiological study. *W.-Y. Lin, W.-C. Lee.* Graduate Institute of Epidemiology, National Taiwan University, Taipei, Taiwan.

In this paper, we develop a simple method to improve the efficiency of a genetic epidemiological study. The effects of single-nucleotide polymorphisms (SNPs) in a study are assumed to arise from an unspecified prior distribution with an unknown mean and an unknown variance. We use the observed log odds ratios (logORs) and their variances to estimate the prior mean and the prior variance. And the posterior distribution will be asymptotically normally distributed regardless of the prior distribution of these effects. Based on these, we proposed a simple formula to tighten the confidence limits of the many logORs reported in a study. We evaluate the performances of our method by simulation studies. We found that the proposed method can indeed booster efficiency while maintaining the average coverage probability at a desired level. The larger the ratio of the prior variance to the average variances of logORs, the smaller the total number of logORs is needed to guarantee the coverage probability. For example, when the ratio of the prior variance to the average variances of logORs is 2, the efficiency of our method relative to the traditional confidence interval method is 1.5, and roughly 50 logORs (or 50 SNPs) can guarantee the coverage probability. We further apply our method to a genetic epidemiological study on age-related macular degeneration to demonstrate the tightening of the confidence limits. Our method is easy to implement and is to be recommended for improving the efficiency of a genetic epidemiological study.

2780/W

Genetic variants within chromosome 4q28.3 are not reproducibly associated with Age-related Macular Degeneration (AMD). *J. Gibson[1], H. Griffiths[2], A. Collins[1], JRW. Yates[3], JC. Folk[4], JS. East[4], AJ. Lotery[2,5], S. Ennis[1].* 1) Human Genetics Division, School of Medicine, University of Southampton, UK; 2) Clinical Neurosciences Division, School of Medicine, University of Southampton, UK; 3) Institute of Ophthalmology, University College London, UK; 4) Department of Ophthalmology and Visual SciencesThe University of Iowa Carver College of Medicine, Iowa City, Iowa, USA; 5) Southampton Eye Unit, Southampton General Hospital, Southampton, UK.

Age-related Macular Degeneration (AMD) is a major cause of vision loss and several genes have been associated with AMD susceptibility. A meta-analysis combining data from six linkage genome scans identified regions of interest on seven chromosomes(1). The most significant regions were subsequently found to harbour the susceptibility loci, LOC387715/ARMS2, HTRA1 and CFH. The aim of this study was to assess next most significant region on chromosome 4q28.2-4q32.3 for association with AMD in a UK sample (470cases,470controls). Following an initial scan of 501 SNPs we found one significant SNP (rs4863760,p=6.96E-05) and carried out higher density screening of 51 SNPs around this SNP (138.6-138.8Mb,UCSC Mar06). Standard quality control filters were applied. A further two SNPs were associated, rs4391086 and rs4554127 (corrected p=0.003,0.007). LD is almost complete between these three SNPs; allele frequencies and odds ratios are also very similar suggesting these SNPs represent the same association signal. Haplotypes were inferred across seven haplotype blocks. The haplotype CGC (rs12645301,rs10021969,rs9996605) was the most significant (permutation-corrected p=0.002) and marginally more significant than any of the three significant SNPs. The haplotype GTTGAAATCGGTTC-GAA in the adjacent block, containing all three significant SNPs, is also significant (corrected p=0.014). It is possible that these blocks represent a larger block, in which haplotypes are frequently inherited together. Significant results were interrogated in two further independent samples. In a US sample, of 331 cases and 332 controls, two of the three most significant SNPs (rs4391086,rs4863760) were genotyped along with the two haplotype tagging SNPs (rs12645301,rs9996605). To test a possible population-specific effect, two SNPs were analysed in a second UK sample of 969 cases and 5038 controls. No association was detected. To-date one gene has been identified in this region, although complement factor I is located distantly (27.8Mb) from our significant SNP. This study reports three nominally significant SNPs, but which were not replicated in two independent samples suggesting a false positive result. An alternative explanation is that the power to replicate is limited due to reliance on a broad phenotype. Analyses in larger samples, with careful characterisation of sub-phenotypes, may further elucidate the role of this region in AMD. (1)Fisher,S.A.et al.(2005) Hum.Mol.Genet.14,2257-2264.

2781/W

Using publically available control data for GWAS - a simple strategy for genetic matching. *C.C. Teerlink[1], J.M. Farnham[1], K. Allen-Brady[1], B.D. Horne[2], N.J. Camp[1], L.A. Cannon-Albright[1,3].* 1) Dept of Internal Medicine, University of Utah, Salt Lake City, UT; 2) Dept of Cardiology, Intermountain Healthcare, Salt Lake City, UT; 3) George E. Wallen Department of Veterans Affairs Medical Center, Salt Lake City, UT.

Publicly available genotyped control subjects are a valuable contribution to genetics in the form of providing control genotype data at little to no cost. They may also increase statistical power for genomewide association studies (GWAS) through many-to-one matching to cases. However, to appropriately utilize these controls care must be taken to remove population stratification due to admixture that may still be present even after matching cases and controls on stated ethnicity. We present a method to identify a set of genetically matched controls from within a set of self-identified ethnically matched controls from a publicly available genotype dataset. The method uses multi-dimensional scaling (MDS) to select controls based on their genetic distance from the case set. We demonstrate the fitness of controls selected by this method through a small GWAS case-study for a common cancer (n = 70 subjects). We compare the Genomic Inflation Factor (λ) for the controls selected by our method to that obtained from two sets of locally ascertained controls. In this case study, our proposed method was able to identify a large, genetically representative set of controls that provide sufficient power for genome-wide significance, despite the small number of cases analyzed. We recommend the use of this method applied to publicly available controls as a powerful and cost efficient method for GWAS of varying size.

2782/W

Effect Of Population Stratification On Quantitative Trait Association Analyses. *S. Ghosh, T. Haldar.* Human Genetics Unit, Indian Statistical Inst, Kolkata, India.

It is now well established that population stratification can result in spurious association findings in genetic case-control studies. However, very few studies have addressed similar issues for mapping quantitative traits. Since quantitative phenotypes are often precursors of clinical end-point traits and carry more information on within-genotype trait variability, it is being argued that studying these quantitative traits may be a more powerful strategy to map genes than the binary clinical end-points. Thus, it is of interest to evaluate the adverse effects of population stratification on the analyses of quantitative traits. The two popular statistical tests of association for quantitative traits using population level data are ANOVA and Kruskal-Wallis. We have theoretically shown that neither genetic heterogeneity nor phenotypic heterogeneity alone can affect the false positive rate of either of the tests. However, if the data comprise subpopulations with different allele frequencies at the marker locus of interest as well as different phenotypic means or distributions, the rate of false positives will be elevated. We have also carried out extensive simulations under different genetic models and probability distributions of quantitative traits to assess the extent of increase in the rate of false positives in the presence of population stratification. We find that the rate of false positives increases at a very fast rate with increase in differences in the standardized phenotypic means and marker allele frequencies in the subpopulations.

2783/W

A Simple Path Model for Assessmet of Pleiotropic Associations for a Dichotomous Trait and a Related Quantitative Trait. *R.L. Hanson, C.C. Mason, W.C. Knowler.* Diabetes Epidemiology Clin Res, NIDDK, Phoenix, AZ.

Genetic studies are often designed to examine determinants of a quantitative trait related to a disease in addition to the disease itself (e.g, global transcription studies). We have developed a simple path model to assess joint associations between genotype, disease and a quantitative trait. Logistic regression models are used to assess association between quantitative trait and disease, between genotype and quantitative trait and between genotype and disease (assuming an additive polytomous model). In path model analyses, the odds ratios from these models are transformed using Yule's Q method and analyzed as correlations. A "pleiotropic" path model is used to estimate the effect of genotype on disease (b_D), effect of genotype on the quantitative trait (b_Q) and the residual correlation. The pleiotropic path ($b_D b_Q$) quantifies the extent to which genotype may influence both traits and its standard error is calculated from the "correlation" matrix. We conducted a simulation study to assess the properties of this pleiotropic test statistic (χ^2_{PL}) and to compare it with tests for association of genotype with the quantitative trait (χ^2_Q), disease trait (χ^2_D) and the 2 df joint test for association with both phenotypes (χ^2_B). Simulations were performed for 1500 individuals with prevalence of disease 0.2. Different models were run with different amounts of variance explained by genotype for the quantitative trait and disease (h^2_Q, h^2_D). Area under the receiver operating characteristic curve (aROC) was used to examine the ability to distinguish data generated under the hypothesis of a pleiotropic association from that generated under the null. Three null hypotheses were assessed: 1.) no association with either trait; 2.) association with disease but not the quantitative trait; 3.): association with the quantitative trait but not disease. For replicates simulated under each of the three null hypotheses, the type I error of χ^2_{PL} was generally at or below nominal values. Power of χ^2_{PL} was generally similar to the less powerful of χ^2_D or χ^2_Q. The aROC was consistently higher for χ^2_{PL} than for χ^2_D, χ^2_Q or χ^2_B. For example, for distinguishing a model with h^2_Q=0.10 and h^2_D=0.01 from similar models in the absence of pleiotropy, the aROC was 0.96 for χ^2_{PL}, compared with 0.86 for χ^2_B, 0.84 for χ^2_Q and 0.79 for χ^2_D. The high aROC suggests that χ^2_{PL} may be useful in screening large numbers of genotypic-phenotypic associations with disease.

Association mapping of quantitative traits in samples with related individuals. *J. Jakobsdottir[1], M.S. McPeek[1,2].* 1) Dept Statistics, Univ Chicago, Chicago, IL; 2) Dept Human Genetics, Univ Chicago, Chicago, IL.

Association studies commonly use samples of unrelated individuals with no known familial relationships. When data on related individuals are available, power can be gained by including all individuals in the analysis, while properly accounting for the dependence among them. We propose an association test for quantitative traits, the MQLSQ test, that is valid when some sampled individuals are related with known relationships. The MQLSQ is an extension of the MQLS case-control association testing method of Thornton and McPeek from binary to quantitative traits. We treat the genotype data as random, and condition on the phenotype data and any covariates. The analysis makes use of estimated polygenic and environmental components of variance of the phenotype. The MQLSQ test is valid even when the phenotype model is misspecified and with either random or phenotype-based ascertainment. The genotype of a given individual receives a weight that depends not only on the phenotype and covariate information of that individual but also on the phenotypes and covariate information of the relatives of the individual. As a result, individuals with missing genotype information but available phenotype and covariate information will contribute to the genotype-specific weight of their relatives and, thus, indirectly increase the effective sample size when testing for association of the marker. We show theoretically that this weighting scheme should have positive impact on power as it does in the case-control setting. The MQLSQ is a quasi-likelihood score test for association between marker and phenotype. Advantages of our quasi-likelihood score test approach include: (1) computational feasibility; (2) no need to specify the null joint distribution of phenotypes for related individuals; (3) asymptotic optimality properties; (4) robustness to misspecified trait model; (5) incorporation of covariates and polygenic components of variance; (6) applicability to completely general combinations of family and case-control designs. We perform simulation studies to confirm correct type I error of the method and to evaluate power and robustness of the MQLSQ in comparison to a previously proposed method, GTAM.

Natural Selection and Efficient Phenotype Association in Exome Resequencing Studies. *C.R. King[1], P.J. Rathouz[1], D.L. Nicolae[2].* 1) Health Studies, Univeristy of Chicago, Chicago, IL; 2) Statistics, University of Chicago, Chicago, IL.

Projects to determine the impact of rare genetic variation on human disease with base-pair by base-pair resequencing of many participants are underway. Recent authors have recognized the importance of using population genetics to inform the hypothesized causal model, particularly with respect to the role of rare variation. We present a generalized linear mixed model which uses population genetic theory to suggest a pooling strategy for all information within a gene for efficient testing. We demonstrate analysis of whole exome sequencing of a case-control study. In simulation we show power improvements over alternative methods in scenarios of interest. We show how to incorporate additional prior information on SNP effects from mutation type, location and phylogenetics. Our method produces easily interpreted parameter estimates and model summaries.

Lupus nephritis is among the most severe clinical manifestations of Systemic lupus erythematosus (SLE), a disease that affects African Americans (AA) three times more than European Americans (EA). Genetic determinants of SLE susceptibility and specific SLE manifestations are supported by high twin concordance rates, linkage and association study findings and the identification of variants associated with disease. Given a threefold increased risk of lupus nephritis in certain populations, we investigated a recently identified gene for non-diabetic end stage renal disease, MYH9 (Myosin, heavy Chain 9), shown to be associated in AA. Genetic association tests were performed within MYH9 region in 6 different populations of SLE cases shown to have American College of Rheumatology classification criterion for renal disease. We investigated MYH9 in independent cases and controls, respectively, from 6 population groups: AA (635/1734),EA (1119/3546), Asian (531/1270), Native American (111/193), Hispanic (548/619) and Gullah (70/122). Controls were defined as either SLE cases without renal involvement or unaffected individuals. Results were similar, thus only those using unaffected individuals were presented. Seventy-three single nucleotide polymorphisms (SNPs) in moderate linkage disequilibrium (LD) ($r^2 > 0.80$) were selected. We then performed single SNP tests for association with renal disease status using logistic regression adjusted for global African, European and Asian ancestry and sex assuming additive/dominant genetic model. In EA, the association peak centered around 35,040,000 base pairs with multiple SNPs showing association. We identified three SNPs rs5750250, rs2413396 and rs4820232 within MYH9 that were strongly associated with renal disease ($1 \times 10^{-4} \pounds p \pounds 9 \times 10^{-4}$) with high LD ($D' \geq 0.99$).The best associated SNP was rs5750250 ($P=2.32 \times 10^{-4}$). In the Gullah, significant association centered at 22q35.05. No statistically significant associations were detected in populations of other ancestral backgrounds. While we did not replicate previous findings in AA, a significant association in the Gullah population, despite a sample size of only 192, confirms the elevated risk of SLE renal disease in populations of African ancestry. The presence of our strongest effect in EA is a novel finding and suggests the role of MYH9 in lupus nephritis in diverse populations.

Bayesian Variable Selection for Survival Regression in Genetics. *I. Tachmazidou[1], M. Johnson[2], M. De Iorio[3].* 1) MRC Biostatistics Unit, Cambridge, United Kingdom; 2) Division of Experimental Medicine, Imperial College London, United Kingdom; 3) Department of Epidemiology and Biostatistics, Imperial College London, United Kingdom.

Variable selection in regression with very big numbers of variables is challenging both in terms of model specification and computation. We focus on genetic studies in the field of survival, and we present a Bayesian-inspired penalized maximum likelihood approach appropriate for high-dimensional problems. In particular, we employ a simple, efficient algorithm that seeks maximum a posteriori (MAP) estimates of regression coefficients. The latter are assigned a Laplace prior with a sharp mode at zero, and non-zero posterior mode estimates correspond to significant single nucleotide polymorphisms (SNPs). Using the Laplace prior reflects a prior belief that only a small proportion of the SNPs significantly influence the response. The method is fast and can handle datasets arising from imputation or resequencing. We demonstrate the localization performance, power and false positive rates of our method in large simulation studies of dense-SNP datasets and sequence data, and we compare the performance of our method to the univariate Cox regression and to a recently proposed stochastic search approach. In general, we find that our approach improves localization and power slightly, while the biggest advantage is in false positive counts and computing times. We also apply our method to a real prospective study, and we observe potential association between candidate ABC transporter genes and epilepsy treatment outcomes.

Genetic association test for a longitudinally-measured trait in samples with related individuals. *X. Wu[1], M.S. McPeek[1,2].* 1) Department of Statistics, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL.

Although there are many successful applications of GWAS in identifying complex disease susceptibility loci, few published studies have investigated the contribution of genetic variants to disease susceptibility over time. For analysis of a longitudinally-measured trait, it is important to account for the time-dependence among observations for a given individual. When the sample includes related individuals, there is dependence across individuals as well, due to the effects of genetics as well as possible environmental effects. We develop a statistical method for genetic analysis of a longitudinally-measured trait in samples with related individuals. We propose quasi-likelihood score tests for genotypes conditional on longitudinal phenotype measurements and covariates. The conditional model for genotypes is derived from a phenotype model that includes components of variance for polygenic effects, inter-individual variation caused by non-genetic effects, time-varying correlation of observations within individuals and measurement errors. An advantage of analyzing genotype conditional on phenotype is that one can still obtain a valid test even when some important aspects of the trait model are not correctly specified. We perform simulation studies to verify that the type 1 error of the proposed approach is correct, and to demonstrate the power advantage and robustness to model misspecification of the proposed approach. The method is applied to analysis of longitudinal blood pressure measurements from the Framingham SHARe data.

Power of genome-wide search strategies for binary trait loci. *Z. Wu[1], H. Zhao[2].* 1) Mathematical Sciences, WPI, Worcester, MA; 2) Epidemiology and Public Health, Yale, New Haven, CT.

For more fruitful discoveries of genetic variants associated with diseases in the genome-wide association studies, it is important to know whether joint analysis of multiple markers is more powerful than the commonly used single-marker analysis. We provide analytical power calculations for various methods to detect binary trait loci: the marginal search, the exhaustive search, the forward search, and a two-stage screening search. In the context of binary traits, we define genetic models based on disease odds for joint genotypes and derive asymptotic distributions of score tests in logistic model fitting. Our statistical framework takes into account linkage disequilibrium, random genotypes, and correlations among test statistics. We derive the analytical results under two power definitions: the power of finding all the associated markers and the power of finding at least one associated marker, and two types of error controls: the discovery number control and the Bonferroni type I error rate control. After demonstrating the accuracy of our analytical results by simulations, we apply them in a broad genetic space to investigate the relative performances of different search methods under different power and error control definitions. The relative performances for binary trait have both similarities and differences from those in quantitative trait study. Our analytical study provides rapid computation as well as insights into the statistical mechanism of capturing genetic signals. We have implemented our method in the R package markerSearchPower which provides researchers a convenient tool to find proper sample size in experimental design, to decide suitable strategies in data analysis, and to increase chance for true findings. Our statistical approach can also be used to address model selection problems of binary responses with general random predictor settings in other application areas.

Comparing methods for association test of low-frequency variants using GWAS data with family relatedness. *Q. Zhang, I. Borecki, M. Province.* Division of Statistical Genomics, Washington University School of Medicine, St. Louis, MO.

Due to sparse distribution plus genetic relatedness between samples, association test for low-frequency variants in GWAS data from many different pedigrees is more prone to produce biased p-values, which usually increases false positives. Under the generalized frame of linear model, we summarize (and propose) multiple possible methods that could be utilized to deal with this problem, and investigate the statistical performance of these methods by comparing p-value distributions under the null hypothesis. We include bootstrapping, permutation and mixed model based methods for comparison, and generate the data under the null by semi-simulation based on a real GWAS data set of 2700 subjects from 508 pedigrees. We focus on quantitative traits with different heritabilities and investigate the inflation rate of p-values for variants with different frequencies. Our findings and conclusions may provide a useful guide for association scan of low-frequency variants in GWAS.

HIERARCHICAL GENERALIZED LINEAR MODELS FOR DETECTING RARE VARIANTS WITH DISPARATE EFFECTS IN ASSOCIATION STUDIES. *D. Zhi, N. Yi.* Department of Biostatistics, University of Alabama at Birmingham, Birmingham, AL.

Rare genetic variants are believed to be responsible for part of the missing heritability overlooked by common variants-based genome-wide association studies. However, existing association tests for common variants do not offer a sufficient power for rare variant association. Therefore, collapsing methods, which test the combined effects of multiple variants in a functional unit, typically a gene, have been proposed to test the combined effect of multiple rare variants. However, collapsing methods only achieve high power when the effects of individual variants in the combination are of the same direction (i.e., all disease-causing or all protective). In reality often variants with disparate effects coexist. In this work we developed hierarchical generalized linear models for the identification of multiple groups of rare variants. Our model allows that each group contains variants with similar effects while different groups having disparate effects. In simulation, we show that our method can detect associations missed by existing methods.

Adjustment of Local Ancestry in Family-based Genetic Association Analysis of Admixed Populations. *X. Wang[1], X. Zhu[2], M. Li[1].* 1) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104; 2) Department of Epidemiology and Biostatistics, School of Medicine, Case Western Reserve University, Cleveland, Ohio 44106.

Family-based study design is commonly used in gene mapping studies of complex human diseases. Most family-based studies use the transmission of alleles to assess the evidence of genetic association. It is generally believed that the transmission disequilibrium test (TDT) is robust again spurious association due to population stratification or admixture. While this is true when population stratification is due to discrete population structure with non-admixed populations, one should use the TDT-type methods with caution when they are applied to admixed populations. As described in the original TDT paper (Spielman et al., 1993), the TDT statistic depends on the difference of transmitted and non-transmitted alleles, which is a function of the linkage disequilibrium (LD) coefficient between the marker and disease loci in the parental generation. Ewens and Spielman (1995) further showed that for a recently admixed population such as African American and Hispanic Americans, the LD coefficient between the marker and disease loci in the parental generation (which is also admixed) contains a spurious component from the admixture process. Due to this reason, for admixed populations, the TDT can only be used as a test of linkage, but it cannot distinguish between “spurious association” and “true association”. To our knowledge, currently there are no family-based testing procedures that distinguish between spurious and true associations for admixed populations. Here we propose a retrospective likelihood framework that solves this problem. Unlike the TDT and other family-based tests of association, our method does not rely on transmission disequilibrium. Indeed it models the conditional distribution of a test SNP given disease status of the child and genotypes of ancestry informative markers surrounding the test SNP in a parents-offspring trio. This retrospective likelihood allows us to explicitly model local ancestry difference between study trios and thus eliminates the effect of population stratification at the test SNP. Our preliminary simulation studies show that our method can control type I errors under a wide range of population stratification mechanisms. We will conduct thorough simulations to evaluate the power of our method.

2793/W

A sequential Bonferroni procedure using smoothed weights for genome-wide association studies. *G. Gao.* Dept Biostatistics, Virginia Commonwealth Univ, Richmoned, VA.

In genome-wide association studies (GWAS) with a case-control design, the Cochran-Armitage trend test (CATT) assuming the additive disease model and the two degree of freedom genotype association test (GAT) using a chi-square statistic have been widely used for detecting disease-susceptibility markers. The CATT usually has higher power than the GAT under additive and multiplicative disease models, but has lower power than GAT under dominant and recessive disease models. In addition, both tests have relatively low power for dominant and recessive disease models. To generate a method that is statistically powerful for the four commonly used disease models (additive, multiplicative, dominant, and recessive) in GWAS, we apply the generalized sequential Bonferroni (GSB) procedure of Holm to GWAS using the CATT. We estimate a weight for each marker as reciprocal of the p-value from a HWD test using cases only. The HWD test can provide useful information for detecting marker-disease association under dominant and recessive disease models, but have almost no power for additive and multiplicative disease models. Furthermore, we smooth the weights in the GSB procedure to decrease the negative influence of those weights which do not provide useful information. The GSB procedure using smoothed weights is referred to as smoothed-GSB procedure. Simulation studies showed that in GWAS the smoothed-GSB procedure has higher power than the CATT and GAT under the four models except that it has power comparable to the CATT under additive and multiplicative models. We have applied the smoothed-GSB procedure to GWAS of the coronary artery disease dataset from the Wellcome Trust Case-Control Consortium.

A generalized Kruskal-Wallis test for association analysis of imputed SNPs. *E. Acar[1], L. Sun[1,2].* 1) Department of Statistics, University of Toronto, Toronto, Ontario, Canada; 2) Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada.

Research on imputation-based genetic association studies has mostly focused on evaluation and improvement of genotype imputation accuracy. However, while many algorithms have been developed, few statistical testing strategies have been proposed in this domain. The popular dosage approach, using the expected number of copies of the risk allele to define the genotype variable, and the best-guess approach, identifying the genotype with the highest posterior imputation probability, both have drawbacks. The former imposes a restrictive additive model on the association analyses, and the latter fails to incorporate imputation uncertainty in the testing procedure.

A robust, powerful association test statistic is developed by generalizing the Kruskal-Wallis test to account for imputation uncertainty. Using the posterior probability of each genotype group, we construct a nonparametric test statistic and derive its asymptotic null distribution. The extended statistic uses all available information and requires no assumption on the data distribution.

Simulation and application studies show that the proposed test outperforms its parametric predecessors. Depending on the specific model assumptions, the gain of the power could be over 50%, while the loss of power is negligible when the simulated data are tailored for a best-guess or dosage model. With its ease of implementation, this generalized Kruskal-Wallis test could shed new light on current genetic association studies of imputed SNPs or other studies with group uncertainties.

Meta-analysis vs GWAS in lung cancer studies. *K. Ahn, C.J. Gallagher, J.E. Muscat.* Dept Public Health Sciences, Penn State Col Med, Hershey, PA.

The sequencing of the human genome has made it possible to identify an informative set of more than one million single nucleotide polymorphisms (SNPs). Genome Wide Association Studies (GWAS) have now become a standard method for the discovery and replication of new candidate loci or genes. Since GWAS use tag SNPS, they cannot be directly compared to previous candidate genes. In addition, many associations with candidate genes have not been replicated. This study compared the results from a GWAS study of lung cancer to candidate genes that have been analyzed in meta-analysis. The goals were to determine the consistency of findings across all study designs. We studied the population of white Caucasian drawn from a European GWAS of lung cancer. We included SNPs in Linkage Disequilibrium with 10 candidate genes that were part of meta-analysis (MA). Finally, we have 14 SNPs in MA and 23 SNPs in the GWAS. We found that 5 SNPs from 4 genes in MA are significant statistically and 3 SNPs from one gene in the GWAS are. The mixed results indicate that GWAS findings are sometimes inconsistent with the results from MA. These differences may be due to the quality of studies, appropriate control of covariates and other factors. The findings indicate that for certain genes, their role in the development of lung cancer is unclear and that GWAS findings are possibly not the gold standard in etiologic research.

A General Statistical Framework for Genome-wide Association Studies (GWAS) Based on Bayesian Graphical Modeling. *L. Briollais[1], H. Massam[2], A. Dobra[3], J. Liu[1].* 1) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada; 2) Dept. of Stat. and Math., York University, Toronto, Canada; 3) Dept. of Stat., University of Washington, Seattle, USA.

The actual paradigm to analyze GWAS is to perform an exhausting testing of all single SNP associations with the response variable with the major drawback that the selected subset of SNPs has in general a very low predictive value. As a shift to the usual approach, we propose here a general statistical framework for GWAS based on Bayesian graphical modeling and able to: 1) Assess the joint effect of multiple SNPs (linked or unlinked); 2) Explore the model space efficiently using the Mode Oriented Stochastic Search (MOSS) algorithm of Dobra and Massam (2009); 3) Incorporate expert prior knowledge in the model search in particular to enhance the detection of rare functional genetic variants. We illustrate our new methodology through an application to the CGEM breast cancer data. Our algorithm selected several SNPs embedded in multi-locus models with high posterior probabilities. Most of the selected SNPs have a biological interest. Interestingly, several of them would not have been detected in the single-SNP testing approach. Finally, we discuss the impact of informative priors in this statistical framework through simulations.

Population-based linkage in GWAS bipolar data. *S.R. Browning[1], B.L. Browning[2].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Medical Genetics, University of Washington, Seattle, WA.

We performed population-based linkage analysis in the Wellcome Trust Case Control Consortium bipolar disorder study using a novel algorithm for detecting haplotype-cluster identity by state (HC-IBS). Our method detects "recent" identity by descent due to shared ancestry within the past 20 generations, while accounting for haplotype phase uncertainty and linkage disequilibrium. We found a significant excess of HC-IBS in case-case pairs compared to control-control and case-control pairs, indicating increased relatedness within cases. In contrast, the estimated kinship coefficients are similar between case-case pairs and control-control pairs, because the kinship coefficient in unrelated pairs of individuals is primarily influenced by ancient identity by descent which is more prevalent than recent identity by descent. Much of the increased HC-IBS in case-case pairs is due to pairs of individuals who share at least 0.1% of their genome in the HC-IBS analysis (no pair of individuals in this study shares more than 6%), suggesting that the excess in shared ancestry is primarily due to common ancestors within the past 10 generations. The excess HC-IBS in case-case pairs is distributed across the whole genome, which is consistent with a polygenic component to this disorder. Our HC-IBS analysis identified two loci with strong signals for population linkage after correcting for the overall increase in HC-IBS in case-case pairs. One of these loci is located in a region that has been repeatedly linked with bipolar disorder in family-based linkage studies. A replication analysis using GAIN bipolar disorder data is in progress.

Haplotype and Dosage-based Tests for Rare Variant Association. *A. Byrnes[1], M. Li[2], Y. Li[1].* 1) Department of Biostatistics, Department of Genetics, University of North Carolina, Chapel Hill, NC 27599; 2) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Empirical evidence suggests that both common and rare variants contribute to complex disease etiology. Although the effects of common variants have been thoroughly assessed in the most recent wave of genome-wide association studies (GWAS), our knowledge on the impact of rare variants remains limited. A number of methods have been proposed to test for rare variants association in sequencing-based studies, a study design that may become predominant in the imminent future. On the contrary, few methods are available to detect rare variants in GWAS data we have in the current era. There are good reasons for the lack of methods targeting GWAS data: commercial panels for GWAS studies were designed to cover most of the common variants and have poor coverage of rare variants in our genome and tests proposed for common variants are underpowered for rare variants. Now that public sequencing data from the 1000 Genomes Project are being rapidly generated and released, an attempt to detect rare variants with GWAS data holds promise before large investment is made for resequencing. Here we propose two methods for rare variant analysis: a haplotype based approach and an imputation dosage based approach that maximally extract information for rare variants within a pre-specified region. Although directly applicable to resequencing data, our methods are designed for data in the current era and manifest their advantages most with GWAS or candidate gene genotyping data where more accurate information on a larger number of rare variants is inferred through haplotyping or imputation with the aid of external sequencing data. Using real GWAS data and a reference sample of 60 individuals, we showed that rare variants (allele frequency 1-5%) can be reasonably inferred with an overall accuracy of 99.2% . The accuracy increases to 99.8%, when we have a reference sample of 500 individuals, a sample size aimed in the 1000 Genomes Project for each major continental group. Given reasonably well-inferred less common variants, we have shown our methods improve power for rare variants association with GWAS data in extensive simulation studies as well as in the WTCCC data for type-1 diabetes in the IFIH1 region. Permutation p-values generated by our methods for WTCCC IFIH1 region are in the order of 10-3 while the best p-value using existing tests for rare variants is greater than 0.2.

2799/W

An efficient, hierarchical Bayes approach to simultaneous analysis of SNPs in genome-wide association studies. *P.S. Carbonetto, M. Stephens.* Dept. of Human Genetics University of Chicago Chicago, IL.

Simultaneous analysis of all SNPs in a genome-wide association study offers a number of advantages, in principle, over standard SNP-by-SNP analyses. Significantly, simultaneous analysis allows one to control for the most strongly associated variants when examining more borderline associations, and to improve power to distinguish false positive associations from true positives. Multi-SNP analyses also lend themselves more naturally to useful extensions, such as the discovery of interacting genetic risk factors, or gene-environment interactions. Two well-studied approaches to performing such genome-wide analyses are penalized regression (e.g. LASSO), and Bayesian variable selection regression (BVSR). A key advantage of the latter is that it reports levels of confidence in individual findings. However, the former is substantially more computationally tractable, since exact algorithms are available (BVSR relies on Markov chain Monte Carlo methods that can take weeks of computer time). We address this problem by developing a more efficient approach to inference for BVSR using variational approximation techniques. We demonstrate, through simulation, that our proposed method recovers results on par with those from extensive MCMC computation, and at a fraction of the computational expense. We illustrate the use of our method on data from the Pharmacogenomics and Risk of Cardiovascular Disease (PARC) study, a large, multiple-phase analysis with > 500,000 SNPs from Illumina SNP chips for ascertaining genetic factors relating to C-reactive protein. We contrast our results with standard single-SNP analyses, and illustrate how our method provides more easily interpretable measures of the strength of evidence for association at each SNP.

A generalized estimating equations strategy for genome-wide association studies of dichotomous outcomes in general pedigrees. *MH. Chen[1,3], X. Liu[2], M.G. Larson[3,4], V. Ramachandran[5,3], Q. Yang[2,3].* 1) Department of Neurology, Boston University School of Medicine, Boston, MA; 2) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 3) The NHLBI's Framingham Heart Study, Framingham, MA; 4) Department of Mathematics and Statistics, Boston University, Boston, MA; 5) Preventive Medicine and Epidemiology, Boston University School of Medicine, Boston, MA.

Genome-wide association studies (GWAS) have been frequently conducted on general or isolated populations with related individuals. However strategies for analyzing dichotomous phenotypes obtained on general pedigrees are not well developed. We propose a generalized estimating equations (GEE) strategy that uses a robust variance estimator with independence working correlation structure to account for multiple level of relatedness in a general pedigree. For low minor allele frequency (MAF) genetic variants, low prevalent disease, or small sample size, we propose using a one-step jackknife variance estimator that has better control of type I error than the robust variance estimator. We compare our proposed strategies with another popular method, generalized linear mixed model (GLMM), and with different working correlation structure choices in GEE through simulation studies. Our proposed strategy has better power than GLMM for low prevalence traits and is more computationally efficient. We also showed that for GEE, using independence structure performs similarly to using kinship coefficient matrix as working correlation structure in robust variance estimators. We apply our proposed strategy and alternative strategies to GWAS of gout in the Framingham Heart Study.

Power and sample size calculations for case-control genome-wide association studies considering rare variants by high-throughput sequencing. *F. De La Vega[1], C. Barbacioru[1], D. Gordon[2].* 1) Genetic Systems R&D, Life Technologies, Foster City, CA; 2) Department of Genetics, Rutgers University, Piscataway, NJ.

Genome-wide association studies (GWAS) have been successful in identifying common genetic variation reproducibly associated with disease. However, most associated variants confer very small risk and after meta-analysis of large cohorts a large fraction of expected heritability still remains unexplained. A possible explanation is that rare variants currently undetected by GWAS with SNP arrays could contribute a large fraction of risk when present in cases. This concept has spurred great interest in exploring the role of rare variation in disease. As the cost of sequencing continue to plummet, it is becoming feasible to directly sequence case-control samples for testing disease association including rare variants. When designing a GWAS by sequencing trade-offs need to be made in terms of sample size and depth of sequence coverage to achieve a desired statistical power. We have developed a test statistic that allows for association testing among cases and controls using sequence reads. In addition, our method allows for random errors in sequence reads. We determine the probability of a true sequence read based on the observed sequence reads using the EM algorithm. Using classical statistical methodology, it is straightforward to create a statistic that tests for association among cases and controls. In addition, we derive the non-centrality parameter for this statistic, so that we can compute power and sample size calculations for any specified input parameters. We document the validity of our method through simulations. Under fixed cost, increasing sample size at the expense of sequence coverage depth improved poser. However, sequencing platform accuracy is a critical factor in achieving power with low pass sequencing coverage.

2802/W

Family Enrichment Improves Power for Finding the Missing Heritability. *P. Du[1], A. Rossi[1], H. Jafri[1], F. Kuo[2,3], C. Huang[2,3], L. Michelson[1], S. Diehl[2,3].* 1) High Performance and Research Computing, UMDNJ, Newark, NJ; 2) Center for Pharmacogenomics and Complex Disease Research, UMDNJ-New Jersey Dental School, Newark, NJ; 3) Health Informatics, UMDNJ-School of Health Related Professions, Newark, NJ.

The missing heritability problem refers to the fact that genome-wide association studies (GWAS) have failed to find most of the genes that underlie complex diseases. The common gene-common disease model has been questioned and an alternative based on many rare, higher risk genes has been proposed. Traditional case-control designs have very low power to detect rare genes. It has been suggested that using multiplex families may help to address this problem by enriching for rare higher risk susceptibility genes. However, no one has systematically evaluated this in models that include both common genes (detectable by GWAS) together with rare higher risk variants. In this study, we used high performance computing to assess power of 36,000 two gene models. Prevalence ranged from 10-35%, allele frequencies from 0.001-0.35, and genotype relative risks for the common gene ranged from 1-1.9 and 1-5.0 for the rare gene. SIMPED was used to simulate two (unlinked) disease genes and penetrance functions assigned affection status based on model parameters. Enrichment criteria focused exclusively on siblings. Only one case or one control was sampled from a family for association tests. Enriched cases were defined as coming from families with at least half of the siblings affected and enriched controls had no siblings affected. We also sampled cases and controls (ignoring family history) for tests of the traditional case control design. The Armitage trend test was used to calculate power for detecting the disease genes. We evaluated power for tests of enriched cases versus traditional controls and for enriched controls versus traditional cases. We found that power of these enrichment strategies often far exceeded that of the traditional case-control design as shown by the following example: 20% prevalence, minor allele frequencies of 0.3 and 0.01 for the common and rare disease genes, and relative risks of 1.45/1.9 and 2.0/3.0, respectively, and sample size 1,000 cases and controls. In the traditional case-control design, the common gene has genome wide significance of 2.37E-09 but the rare gene has expected P-value of 0.006. Using family enrichment, power is greatly improved for the rare gene, with an expected P-value of 5.99E-11, sufficient for genome-wide adjustment. These results demonstrated that family enrichment has the potential to very substantially increase power to detect rare disease-causing genes and help reveal at least part of the missing heritability.

Human genome harbors different kind of structural variations and one of the recent ones are long streces of homozygoze SNP's, also known as Runs of Homozygosity (ROH). It have been shown that this structural variation is common in inbreed cohorts although it is also very common in outbreed populations. We have analyzed ROH patterns in about 5,500 individuals from 17 populations (21 cohorts) genotyped with Illumina high-density arrays for the ROH patterns and added the 11 HapMap3 populations to measure the patterns in different continents, giving total 6,800 samples. Our analyses reveal a huge variety of ROH alleles in every single population and covering the whole genome, although the mean number and length varies by continents. The transmission of ROH alleles was checked both in HapMap3 and Estonian Biobank trios. The Genome-wide ROH association analyzes (GWRA) method was applied on two large case-control cohort of Ulcerative Colitis and Chrohn's Disease to evaluate if ROHs are able to reveal the "missing heritability". We were able to pick up several already known UC and CD loci from the genome. To conclude in addition to SNP's and CNV's, ROH's can be used as genetic markers in WGA studies for finding disease genes.

2804/W

Controlling for undetected cofactor structure in genome-wide association analyses (GWAS). *C. Gao, J. Mezey.* Biological Statistics and Computational Biology, Bornell, ithaca, NY.

The problem of how to account for environmental or population structure in genome-wide association studies (GWAS) is well defined in cases where contributing co-factors are measured or can be inferred. However, it is also well appreciated that undetected co-factors can exist and produce false positives in GWAS and it has been unclear how to correct for such undetected effects. We hereby propose a novel Restricted Factor Analysis (RFA) approach to deal with this problem. Our approach is to include factors without pre-defined loading matrix L or factor effect vector F directly into a linear modeling framework used to analyze genetic marker associations in GWAS. While such models are unidentified with respect to L and F treated separately, these models are identified with respect to LF. We therefore treat this as a nuisance parameter for the purposes of identifying genetic marker associations. We analyze marker associations with our undetected factor model using an Expectation-Maximization (EM) algorithm. We demonstrate with a simulation analysis that for cases where a set of traits m are affected by both allelic variation at several loci and by a undetected factor F that our method is able to account for the effects of the factor. We find that our method outperforms approaches that ignore the possibility of undetected factors for identifying false positives, increasing power in the detection of associations, and in the estimation of effect sizes of associate markers. We also demonstrate that our method can account for the effects of cryptic population structure on the phenotypes, without directly inferring population structure from genotype data, and that when we account for structure that is not orthogonal to the associated markers, our method can reduce false positives significantly. We applied our method to analyze genome-wide gene expression data collected for the immortalized lymphoblastoid cell lines produced from the Hapmap phase II individuals. By accounting for hidden factor structure in these data when analyzing within each population, we are able to identify more eQTLs compared to standard methods that ignore the undetected structure.

Multi-SNP Analysis of Lipid Traits in The Woman's Genome Health Study. *Y. Guan[1,2], M. Barber[1], R. Krauss[3], P. Ridker[4], D. Chasman[4,5], M. Stephens[1,2,5].* 1) Dept. of Human Genetics, Univ Chicago, Chicago, IL; 2) Dept. of Statistics, Univ Chicago, Chicago, IL; 3) Children's Hospital Oakland Research Institute, Oakland, CA; 4) Division of Preventive Medicine, Brigham and Women's Hospital, Boston, MA; 5) These authors jointly direct this project.

Almost all ongoing Genome-wide association studies have limited their initial analysis to simple single SNP tests. Once a genetic association has been identified in a region, attention naturally turns to better understanding and characterizing that association: for example, understanding which SNPs, and how many SNPs, may be independently influencing outcome. Here we use Bayesian multi-SNP analyses to examine this issue for lipid traits in a large study of approximately 23,000 individuals: the Women's Genome Health Study (WGHS). Our aim is to provide a comprehensive picture of the patterns of associations in regions previously identified through single-SNP meta-analysis, and to provide a global assessment of the extent to which such regions are likely to harbor multiple functional SNPs. We performed comprehensive multi-SNP association analysis in the WGHS samples, focusing on approximately 100 genomic regions. For each region we assess both the overall strength of evidence for an association in the WGHS data, and the evidence for multiple SNPs independently affecting phenotype. We also attempt to narrow down the most plausible functional candidate SNPs, among genotyped and imputed SNPs, based on relative strengths of association. We also use simulation to assess whether individual untyped functional SNPs may be partly responsible for apparent multi-SNP signals. Of the 49 regions showing moderate to strong overall evidence for association in the WGHS data, 12 showed strong evidence for multiple SNPs affecting phenotypes. Simulations suggest that the majority of these multi-SNP signals are due to the regions genuinely harboring multiple functional SNPs, rather than due to untyped variants that are correlated with combinations of typed SNPs. Furthermore, several of these regions (eg. APOB, APOC-APOE, ABCA1, and CETP) show strong evidence for three or more independent SNPs affecting phenotypes. For these regions, using multi-SNP analysis we estimate the proportion of variance in relevant phenotypes explained by each locus to be substantially greater than that explained by any individual SNP. We also attempt to identify the most plausible candidate functional SNPs in each region, and investigate possible interactions among independent functional SNPs. Our work illustrate the potential helpfulness of these kinds of analysis, both for improving power to detect associations and, more importantly, for providing fuller explanations for observed associations.

Increasing power of meta-analysis when effects are present in a subset of the studies. *B. Han[1], E. Eskin[1,2].* 1) Computer Science, University of California, Los Angeles, Los Angeles, CA; 2) Human Genetics, University of California, Los Angeles, Los Angeles, CA.

In genetic association studies, meta-analysis is becoming a popular tool for pooling information from multiple studies. One important issue in meta-analyses is the heterogeneity between studies. We focus on a specific type of heterogeneity that the genetic effect of a variant is present in only a subset of the studies because of hidden factors masking the effect of the variant. In this case, the current approaches of fixed effects model (FE) and random effects model (RE) have relatively low power. We introduce a new model called randomly-present fixed effects model that models the possible absence of effects. We propose a statistical testing procedure under this model using an Expectation-Maximization algorithm and develop an importance sampling procedure that efficiently estimates p-values. In simulations, our method shows higher power than FE and RE if the effects are absent in one or more studies and comparable power if the effects are present in all studies. This shows that our method can bring the variants to attention as genome-wide significant that are only moderately significant in current approaches because of the masking of the effects. Besides introducing the new approach, we also show the relationship between the two widely used statistics based on FE: the weighted sum of z-scores and the inverse-variance-weighted effect size. It follows that the optimal weights of z-scores are function of allele frequency as well as sample size in contrast to the current weighting scheme which weights only by the square-root of the sample size.

A powerful and efficient variable selection method for genome-wide association studies. *Q. He, D.Y. Lin.* Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel hill, NC.

Genome-wide association studies (GWAS) involving half a million or more single nucleotide polymorphisms (SNPs) allow genetic dissection of complex diseases in a holistic manner. The common practice of analyzing one SNP at a time does not fully realize the potential of GWAS to identify multiple causal variants and to predict risk of disease. Existing methods for joint analysis of GWAS data tend to miss causal SNPs that are marginally uncorrelated with disease and have high false discovery rates (FDRs). We introduce GWASelect, a statistically powerful and computationally efficient variable selection method designed to tackle the unique challenges of GWAS data. This method searches iteratively over the potential SNPs conditional on previously selected SNPs and is thus capable of capturing causal SNPs that are marginally correlated with disease as well as those that are marginally uncorrelated with disease. A special resampling mechanism is built into the method to reduce false-positive findings. Simulation studies demonstrate that the GWASelect can be substantially more powerful than existing methods in capturing causal variants while having a lower FDR. In addition, the regression models based on the GWASelect tend to yield more accurate prediction of disease risk than existing methods. The advantages of the GWASelect are illustrated with the Wellcome Trust Case-Control Consortium (WTCCC) data.

Analysis of Secondary Phenotypes in Case-Control Genetic Association Studies: A Gaussian Copula Approach. *J. He, H. Li, M. Li.* Dept Biostatistics, Univ Pennsylvania, Philadelphia, PA.

In many case-control genetic association studies, a set of correlated secondary phenotypes that may share common genetic factors with the disease status are collected. Examination of these secondary phenotypes can yield valuable insights about the disease etiology. The standard regression-based analysis by assessing the effect of a test SNP using cases only, controls only, or combined samples of cases and controls is appropriate only when the test SNP is not associated with the disease. Otherwise, the aforementioned methods will yield inflated type I errors and biased parameter estimates, due to the unequal sampling probabilities between cases and controls. To solve this issue, we developed a Gaussian copula based approach that efficiently combines information on disease status and correlated secondary phenotypes. Our method can incorporate a single secondary phenotype as well as several correlated secondary phenotypes. To evaluate the performance of our method, we conducted extensive simulations under various settings. We considered a single secondary phenotype that is correlated with the disease status. Our simulation results showed that the copula-based approach yields unbiased parameter estimates for the analysis of the secondary phenotype and the type I errors are well controlled at the 1% nominal level under all settings we considered. On the contrary, the regression-based analysis without adjustment of the disease status gives highly inflated type I error of 7% when the secondary phenotype and the disease status are correlated (correlation = 0.5) and the test SNP is moderately associated with the disease (OR = 1.2). We also applied our method to the analysis of LDL-C level in a genome-wide association study on high HDL, where “cases” are defined as those individuals with extremely high HDL-C level and “controls” are defined as those with extremely low HDL-C level. We treated LDL-C as a secondary phenotype and tested for association with SNPs located in CETP, a gene that is well-known to be associated with HDL-C but not LDL-C. Using the copula-based approach, we did not find any evidence of association, but the regression-based analysis without adjustment of “case-control” status identified 13 significantly associated SNPs ($P < 0.01$). Taken together, our results suggest that it is important to appropriately model secondary phenotypes in case-control genetic association studies.

Scalable multiple-locus analysis algorithms with increased power to detect weak associations in genome-wide association studies (GWAS). *G.E. Hoffman[1], J.G Mezey[1,2].* 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 2) Department of Genetic Medicine, Weill Medical College of Cornell University, NY, NY.

All corroborated disease loci that have been discovered in genome-wide association studies (GWAS) were identified by independently analyzing each genetic marker in a study. While the success of individual marker analysis is unequivocal, it is well appreciated that this standard technique suffers from low statistical power to detect weak associations due to small locus effects, weak linkage, or low minor allele frequencies. With the goal of increasing power to detect these weak associations, we apply a class of multiple-locus methods that simultaneously assesses the associations of all genetic markers. We develop a class of algorithms that scale extremely well and overcomes previous computational limitations so that we can perform a GWAS analysis of a thousand samples and one-million markers in less than 24 hours on a standard desktop (with large memory capacity). The class of multiple-locus methods presented here leverages the framework of penalized regression and generalized linear models to provides great versatility for analyzing case/control and continuous phenotypes using a range of popular and theoretically justified penalties such as Lasso and MCP. We have undertaken a simulation study to assess performance and demonstrate that our multiple-locus methods have increased power over individual marker analysis to detect weak associations in large datasets. Through our analysis of available GWAS data from the Wellcome Trust Case Control Consortium, we demonstrate that our algorithms produce a qualitatively different ordering of the top ’hits’ and identifies novel associations and epistatic interactions between markers that were missed by individual marker analysis.

Analysis of Untyped SNPs: Maximum Likelihood and Imputation Methods. *Y. Hu, D. Lin.* Biostatistics Dept, Univ North Carolina, Chapel Hill, NC.

Analysis of untyped SNPs can facilitate localization of disease-causing variants and permit meta-analysis of association studies with different genotyping platforms. We present two approaches for using the linkage disequilibrium structure of an external reference panel to infer the unknown value of an untyped SNP from the observed genotypes of typed SNPs. The maximum likelihood approach integrates prediction of untyped genotypes and estimation of association parameters into a single framework and yields consistent and efficient estimators of genetic effects and gene-environment interactions with proper variance estimators. The imputation approach is a two-stage strategy which first imputes the untyped genotypes by either the most likely genotypes or the expected genotype counts and then uses the imputed values in downstream association analysis. The latter approach has proper control of type I error in single-SNP tests with possible covariate adjustments even when the reference panel is misspecified; however, type I error may not be properly controlled in testing multiple-SNP effects or gene-environment interactions. In general, imputation yields biased estimators of genetic effects and gene-environment interactions, and the variances are underestimated. We conduct extensive simulation studies to compare the bias, type I error, power, and confidence interval coverage between the maximum likelihood and imputation approaches in the analysis of single-SNP effects, multiple-SNP effects and gene-environment interactions under cross-sectional and case-control designs. In addition, we provide an illustration with genomewide data from the Wellcome Trust Case-Control Consortium (WTCCC) [2007].

The Use of Imputed Values in the Meta-Analysis of Genome-Wide Association Studies. *S. Jiao, L. Hsu, C.M. Hutter, U. Peters.* Fred Hutchinson Cancer Research Center, Seattle, WA.

Genome-wide association studies (GWAS) have been proven to be effective in studying the association between common single nucleotide polymorphisms (SNPs) and common complex traits and diseases. To add value from GWAS data, it is common practice to impute the genotypes of untyped SNPs by exploiting the linkage disequilibrium (LD) structure among SNPs. The imputed genotypes not only improve genome coverage, but also make it possible to combine studies which are genotyped on different platforms in meta-analyses. A popular way of employing imputed data is the “expectation-substitution” method, which treats the imputed dosage (expected number of minor alleles) as if it were the true genotype and performs an association test. However, two important questions remain unanswered: 1) Does the expectation-substitution method give unbiased estimates of the effect size (strictly speaking strength of the association)? 2) Does the imputation quality need to be incorporated into the weights in a meta-analysis? We show, both theoretically and numerically, that the estimates given by the expectation-substitution method are approximately unbiased under practical conditions. In addition, we show that the variances of the estimates are proportional to the imputation quality. As a result, the usual inverse variance weighting scheme automatically and adequately incorporates imputation quality in the meta-analysis, and there is no need to further incorporate imputation quality scores.

Analyzing contiguous homozygosity to quantify haplotype structure differences between case and control samples. *T. Johnson[1], T. Tanaka[2], M. Kubo[3], Y. Nakamura[4], T. Tsunoda[1].* 1) Laboratory for Medical Informatics, Center for Genomic Medicine, RIKEN Yokohama Institute, Yokohama, Kanagawa-ken, JAPAN; 2) Laboratory for Cardiovascular Diseases, Center for Genomic Medicine, RIKEN Yokohama Institute, Yokohama, Kanagawa-ken, JAPAN; 3) Research Group for Genotyping, Center for Genomic Medicine, RIKEN Yokohama Institute, Yokohama, Kanagawa-ken, JAPAN; 4) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Minato-ku, Tokyo, Japan.

We describe a method that we term *agglomerative haplotype analysis* (AHA) to supplement single-locus tests of genome-wide association study (GWAS) data by comparing cases and controls for haplotype structure differences. Based on analysis of the structure and extent of contiguous homozygosity, segments of contiguous homozygous genotypes in each individual are first detected and the length of any segments intersecting a particular SNP *i* stored in an intersecting segment length vector (ISLV*i*). For each disease, we then create two ISLVs for each SNP that are specific to the disease's case and control samples and calculate their empirical cumulative distribution functions ECDF*i*:cases and ECDF*i*:controls. We quantify case-control differences using the Cramér-von Mises criterion ω^2 (the integral of the squared difference between the two ECDFs) and determine the statistical significance of each ω^2 value using an adaptive permutation test framework. Due to the high computational load for testing >400k SNPs, we first select a set of the most extreme ω^2 values by using a peak/peak-outlier detection algorithm and perform permutation testing for that reduced set of »2,000 positions. A genome-wide significance level (GWSL) is determined using a minimum p-value based analysis of simulated case-control datasets by creating 100 random sets of case samples and controls, performing AHA for each set, and specifying the GWSL as the 5th percentile of the set of lowest p-values across those analyses. We illustrate this method using myocardial infarction (MI) samples from the Japan BioBank, which preliminary analyses suggested to have a large case-control difference on chromosome 12. Using 1,637 case samples and 7,345 controls matched using principal component analysis based genetic matching, we detected a single region with six peaks exceeding the GWSL. That region lies on chromosome 12 between 110.1-111.7 Mb, a region that contains the BRAP gene, which was previously reported by members of our group to contain SNPs associated with risk for myocardial infarction in Japanese. Comparison of $ECDF_{cases}$ and $ECDF_{controls}$ for the top peak (p<9x10^{-8}) shows cases to have »5% more homozygous segments with length >1cM. Although this positive signal maps to a known causal variant that was detected by standard GWAS approaches, our result supports the ability of AHA to detect genomic regions in which cases and controls have different frequencies for an extended haplotype.

Possible genetic loci associated with Chagas disease in Northeastern Brazil. *C.E.M. Kawamata[1], R.G.M. Ferreira[1], L.M. Garrido[1], L.C. Perreira[1], M.F. Feitosa[2], H. Krieger[1].* 1) Paratology, ICB, São Paulo, São Paulo, Brazil and INAGEMP; 2) Div Statistical Genomics, Washington University School of Medicine, St. Louis, MO.

Chagas disease, also known as American Trypanossomiases caused by the protozoan Trypanosssoma cruzi that is usually transmitted by Triatominae bugs, affects about 10 million people in the American continent. Previous segregation analysis showed evidence of a major gene with a small multifactorial component influencing the predisposition to the T. cruzi infection in 4697 individuals of 886 families from Northeastern Brazilian origin, collected in 1969-1970 in São Paulo, Brazil. In a follow-up study, it was carried out a genome-wide scan analysis in 69 individuals (18 cases and 51 controls). A total of 263K SNPs were genotyped, and after excluding SNPs with sex incompatibility, non-equilibrium Hardy-Weinberg and technical error 261K SNPs were analyzed by using a logistic regression analysis with an additive model. We found strong evidence of association between infection to T. cruzi with rs1746997 (minor allele frequency = 0.1667, adjusted-Bonferroni P = 0.015) on chromosome 10. This finding suggests that the susceptibility to T. cruzi infection is influenced by at least one genetic variant. Linkage studies on 15 large families are in progress in order to validate these findings. (CNPq, FAPESP).

Association analysis of dynamic-traits via temporally-smoothed lasso. *S. Kim[1], J. Howrylak[2], E.P. Xing[1].* 1) School of Computer Science, Carnegie Mellon Univ, Pittsburgh, PA; 2) Harvard Medical School, Boston, MA.

Classical quantitative trait locus (QTL) mapping usually concerns identifying causal genetic variations that underly clinical or molecular traits such as body metrics or gene expression values. In such an analysis, it is standard to assume that the trait values follow a time-invariant distribution. In this paper, we address a new QTL mapping problem, where the trait is a time series, namely, a dynamic trait (or d-trait). Examples of a d-trait include time courses of response to a drug, growth of a tumor, and expression of a gene, which all have a developmental characteristic with a trend over time. We define a QDTL mapping problem as discovering the genetic variations that induce such temporal changes, rather than a one-time genetic effect at a single time point. Causal genetic loci underlying a d-trait are likely to influence the trait dynamics with potentially varying effect sizes over time. To detect such loci, it is important to take into account the temporal correlation in the d-trait measurements during analysis, rather than merely performing a genome-wide association (GWA) at each time point separately as in conventional methods. This problem poses a significant new challenge to current GWA methodology. We propose a new statistical method based on a temporally-smoothed regularized regression that takes advantage of the temporal correlation in a d-trait to discover causal QDTLs. Our approach first learns the temporal correlation information in the d-trait using an autoregressive model, then incorporates this information in a novel regularization function within a regression method to estimate correlated regression coefficients. Our method does not assume any parametric form of the trajectory of d-trait measurements, and has the flexibility of handling any types of stationary and nonstationary trends. We demonstrate our method on both simulated data and clinical data obtained from asthmatic children in the Childhood Asthma Management Program study.

A powerful approach to efficiently combine p-values for gene-based association analysis. *M. Li[1,2], P. Sham[1,2,3], C. Cherny[1,2,3].* 1) Department of Psychiatry, The University of Hong Kong, Hong Kong; 2) The Centre for Reproduction, Development and Growth, The University of Hong Kong, Hong Kong; 3) The State Key Laboratory of Brain and Cognitive Sciences, The University of Hong Kong, Hong Kong.

Shifting from Single-nucleotide polymorphism (SNP)-based association analysis to gene-based analysis may be a promising solution for increasing power of genome-wide association studies (GWAS). Methodology for efficient evaluation of gene-wise association significance is still far from developed and does not suffice for the demand to handle large genome-wide dataset. Available methods resort to time-consuming permutation to account for the gene-size and linkage disequilibrium problems. We proposed a powerful association approach to efficiently combine p-values of SNPs within a gene to produce a gene-based p-value. This method employed the gene as an analysis unit. The p-value is used to evaluate gene-level association significance. We theoretically proved that the gene-based p-value is uniformly distributed U(0,1) under null hypothesis for independent SNPs. More importantly, this method could easily integrate prior weights of SNPs. Through a series of computer simulation, we demonstrated that the gene-based method was more powerful than the original SNP-based test and immune to gene size and linkage disequilibrium between markers. Moreover, our test outperformed three other alternatives including Bonferroni correction, Sidak combination test and Fisher combination test. It was even more powerful than the Logistic regression in some situations. In a test, this method (after implemented) only spent less than 1 minute in performing a genome-wide gene-based scan for 2,543,885 SNPs on an ordinary desktop computer, Intel Core™ 2 CPU 2.66GHz, RAM 1.97GB, and 32-bit Windows XP™ Professional Version 2002. To conceptually assess its performance in real data, we applied it to re-analyze three datasets of published GWAS. Our gene-based association method reported 6 more significant genes than the SNP-level association method did (FDR=0.005) in a GWAS dataset for Crohn's disease. Among the 6 genes, the two were convincingly replicated in independent samples conducted the original studies. It reported 4 more significant genes (FDR=0.01) than the SNP-level association test in GWAS for Psoriasis and Schizophrenia respectively. In conclusion, we provided a powerful method to efficient evaluate the gene-wise association significance. This method is expected to identify more disease susceptibility genes of complex diseases and will also facilitate advanced bioinformatics analysis like pathway and protein-protein interaction network enrichment analyses.

Deep follow up genome-wide association study to identify psoriasis susceptibility genes. *Y. Li, J. Ding, G. Abecasis.* Center of Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI.

ABSTRACT: Psoriasis is a chronic immune-mediated genetic disorder that appears on the skin, affecting about 1% of the human population. Genome-wide association studies have been conducted in an effort of identifying susceptibility loci for psoriasis. In a previous two-stage case-control study, we (Nair, Duffin, Helms and Ding et al. 2009) genotyped 438, 670 SNPs in 1,409 psoriasis cases and 1,436 controls in the first stage and then followed up 21 promising SNPs in 5,048 psoriasis cases and 5,041 controls in the second stage. In total eight replicated gene regions were confirmed to be associated with psoriasis disease. In order to further scan the above genome regions for additional psoriasis susceptibility loci, we now deeply follow up extra 7,978 SNPs in 2,855 independent psoriasis cases and 2,165 controls. Our newly follow up SNPs consist of 8 panels, including critical SNPs from 1000G in those eight replicated regions, top SNPs from a meta-analysis on 1000G imputation, and top SNPs from a meta-analysis on HapMap imputations. Our deep follow up results provide strong support for the eight associated gene regions established in the previous study. In additon, we discover some De novo psoriasis susceptibility loci. With probably the largest number of follow up SNPs in the GWAS literature, our study will help to identify high-risk individuals and shed lights on developing new therapies for psoriasis related auto-immune diseases.

Correcting for Population Stratification in Genome-Wide Association Studies. *D.Y. Lin, D. Zeng.* Dept Biostatistics, CB #7420, Univ North Carolina, Chapel Hill, NC.

Genome-wide association studies are susceptible to the confounding effect of population stratification in that the combination of allele-frequency heterogeneity with disease-risk heterogeneity among different ancestral sub-populations can induce spurious associations between genetic variants and disease. We provide a statistically sound and computationally feasible solution to this important and challenging problem. We estimate the odds ratio of disease with a genetic variant by fitting a semi-parametric logistic regression model which includes an arbitrary function of a propensity score relating the genotype probability to ancestry-informative genomic markers. This approach provides correct control of type I error and unbiased estimates of odds ratios with proper confidence intervals even under severe population stratification. The advantages of the new method over the existing methods are demonstrated through realistic simulation studies. In particular, the new method is shown to perform nearly as well as the logistic regression analysis with known ancestry. An application to the genome-wide association data of the Wellcome Trust Case-Control Consortium (2007, Nature) further illustrates the superior performance of the new method. The relevant software is available at our website.

Testing for Weak Signal. *P. Lipman[1], M. Cho[2], P. Bakke[3,4], A. Gulsvik[3,4], X. Kong[5], S. Pillai[5], E. Silverman[2], C. Lange[1].* 1) Dept of Biostatistics, Harvard University, Boston, MA; 2) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 3) Dept of Thoracic Medicine, Haukeland University Hospital, Bergen, Norway; 4) Institute of Medicine, University of Bergen, Norway; 5) GlaxoSmithKline, Research Triangle Park, NC.

When a statistical analysis involves multiple tests, such as a Genome-Wide Association study (GWAS) that involves upwards of one million SNP-association tests, one must correct the nominal p-values to account for the multiple opportunities to achieve statistical significance. With conservative corrections (such as the widely-used Bonferroni correction), one often fails to reject the null hypothesis when the null hypothesis may in fact be false. Despite the great success of GWAS, the majority of loci remains undiscovered, but can be identified by large-scale follow-up studies. In this communication, we develop an overall statistical test that is applied to the set of most promising association tests from the original study. The overall test will conclude whether there is evidence that the null hypothesis is in fact false in the tested set of association tests, even though no individual test achieves a global significance level. That is, we create a test that examines if one or several (weak) signals exist in the data. The conclusions of the test are used to determine whether a follow-up study on the top hits is recommended. This single test is statistically straight-forward and easily implemented. Using simulations, power is assessed under realistic scenarios of Genome-Wide Association studies. The test can also be modified to help determine the number of top hits which should be further examined in the follow-up study. We illustrate the method with an application to a chronic obstructive pulmonary disease GWAS dataset.

Analysis of Family- and Population-Based Samples in Cohort Genome-Wide Association Studies. *A. Manichaikul[1,2], W.M Chen[1,2], K. Williams[3], Q. Wong[3], J.I. Rotter[4], S.S. Rich[1], J.C. Mychaleckyj[1].* 1) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 2) Department of Public Health Sciences, Division of Biostatistics, University of Virginia, Charlottesville, VA; 3) Collaborative Health Studies Coordinating Center, University of Washington, Seattle, Washington; 4) Medical Genetics Institute, Cedars-Sinai Med Center, Los Angeles, CA.

Cohort studies typically sample unrelated individuals from a target population, although family members of index cases may be also be recruited to investigate shared familial risk factors and to apportion genetic and environmental risk. The recruitment of family members may be incomplete or ancillary to the main cohort study, resulting in a mixed sample of independent family units, including unrelated singletons and multiplex families of 2+ members. There are multiple methods available to perform genome wide association (GWA) analysis of binary or continuous traits in families, but it is unclear whether the methods known to perform well on ascertained pedigrees, sib-ships, or trios are appropriate in analysis of a mixed unrelated cohort and family sample.

The Multi-Ethnic Study of Atherosclerosis (MESA) is an example of a cohort study of unrelated individuals enhanced by an ancillary study to recruit family members specifically for genetic analysis (MESA Family). Approximately 8400 consenting participants recruited by the original MESA cohort and MESA Family and MESA Air ancillary studies have been recently genotyped under the NHLBI SHARe program resulting in 6657 independent families with GWA data, 10.5% of which are multiplex (17.6% in African American families, 20.6% in Hispanic).

We present simulation studies based on MESA pedigree structures to compare performance of several popular methods of GWAS analysis for both quantitative and dichotomous traits in cohort studies. We evaluated approaches suitable for analysis of families, and combined the best performing methods with population-based samples either by meta-analysis, or by pooled analysis of family- and population-based samples (mega-analysis), comparing type 1 error and power. We further assessed practical considerations such as availability of software and ability to incorporate covariates in statistical modeling. Our results suggest that linear modeling approaches which accommodate family-induced phenotypic correlation, e.g. the variance component model of Chen and Abecasis (2007) for quantitative traits or generalized estimating equations as implemented by Chen and Yang (2010) for dichotomous traits, perform best in the context of combined family- and population-based cohort GWAS.

Discovery of novel associations by re-analysis of GWAS using a family of scalable multiple locus algorithms. *J. Mezey[1,2], G. Hoffman[1], B. Logsdon[1], C. Gao[1], L. Omberg[1].* 1) Biological Statistics (BSCB), Cornell Univ, Ithaca, NY; 2) Genetic Medicine, Weill Cornell Medical College, New York, NY.

All replicated associations discovered in genome-wide association studies (GWAS) have been identified by independently analyzing each genetic marker in a study. While such individual marker techniques are straightforward to apply and have been a fruitful approach for identifying associations, it is also well appreciated that other approaches can perform better in the identification of weaker associations. We have developed a highly scalable family of multiple locus algorithms for identifying weaker associations by simultaneous analysis of all markers in a GWAS. The foundation of our family of methods is a penalized generalized linear model (GLM) that we use to analyze both case-control and continuous phenotypes, and a set of established penalties, including standard types (e.g. lasso) and non-standard but theoretically well-justified types (i.e. MC+ and mixtures). With these models, we can implement both likelihood-based model selection, using cyclic coordinate-wise descent techniques, as well as Bayesian model selection where we use approximate variational Bayes techniques to implement fast Bayesian model averaging. We have used our family of algorithms to re-analyze a number of publically available GWAS data sets, including data from studies archived in dbGaP and data collected by the Wellcome Trust Case Control Consortium. With our re-analyses, we have identified a number of novel associations not previously identified in the original studies, including associations that have also been identified in other populations, i.e. we have been able to replicate previously unreplicated associations by re-analyzing existing data. These results demonstrate that there is potentially more association information that can be extracted from existing GWAS data when applying non-standard analysis techniques.

Meta-analysis of sex-specific genome-wide association studies. *A.P. Morris, R. Magi.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Genome-wide association studies (GWAS) have proved to be extremely successful in mapping novel loci contributing effects to complex human traits. However, despite these successes, much of the genetic component of the variance in these traits remains unexplained. One potential source of genetic variation which may contribute to this "missing heritability" is that which has sex-specific or sex-differentiated effects. Such associations could arise, for example, if sex hormones play a role in the regulation of gene expression.

Despite recent confirmed evidence for sex-specific associations with complex traits including schizophrenia and central obesity, males and females are typically analysed together in GWAS. In these "combined-sex" analyses, allelic effects are often adjusted for gender if the trait distribution varies between males and females. However, researchers have been unwilling to undertake male- and female-specific analysis because of a fear of a loss in power because of reduced sample size as a result of stratification by sex.

Here, we review the methodology for sex-specific fixed effects meta-analysis of GWAS. Within this framework, we propose a sex-differentiated test of association, and demonstrate how we can test for heterogeneity of allelic effects between males and females. This methodology can be implemented using the "-sex" option in the freely available, open source GWAMA software (www.well.ox.ac.uk/GWAMA).

We have performed detailed simulations to compare the power of meta-analysis of gender-specific GWAS with that of the "combined-sex" approach of analysing males and females together. Our results highlight only a small loss in power of the sex-differentiated meta-analysis when allelic effects are the same in males and females. However, in the presence of heterogeneity in allelic effects between males and females, sex-differentiated meta-analysis offers substantial gains in power.

The arcOGEN Consortium: stage 1 of a genome-wide association scan for osteoarthritis. *K. Panoutsopoulou on behalf of the arcOGEN Consortium.* Wellcome Trust Sanger Institute, Hinxton, UK.

The genetic architecture of osteoarthritis (OA) has not been characterised yet; as with many common complex traits it appears to be of a highly polygenic nature with multiple risk loci conferring small effects, detection of which necessitates large sample sizes. To enable a well-powered genome-wide association study (GWAS) for OA, we have formed the arcOGEN Consortium, a UK-wide collaboration aiming to carry out a 2-stage GWAS of 8,000 cases and 10,000 controls.

We have completed stage 1 GWAS in 3,177 knee and/or hip OA cases and have compared their genotypes against 4,894 publicly available population-based UK controls from the Wellcome Trust Case Control Consortium 2 study. Of the 514,898 single nucleotide polymorphisms (SNPs) that passed our quality control, 89 SNPs reached p values<10^{-4} (as opposed to 51 expected under the null hypothesis of no association). We took forward 102 independent SNPs with p<10^{-4} to in silico replication in three further OA GWAS (from the deCODE, Framingham and Rotterdam studies) and a subset of 52 SNPs in a UK-based GWAS (TwinsUK) comprising a total of 41,075 individuals. Based on meta-analysis results across the arcOGEN and in silico replication datasets we prioritised 36 SNPs for de novo replication in a further set of 6,255 OA cases and 8,289 controls of European ancestry (from Spain, Greece, USA and the Netherlands). None of the followed-up signals reached genome-wide significance (p<$5x10^{-8}$), but this could be due to low power caused by limited sample size, small effect sizes and phenotype heterogeneity. The strongest signal was observed for rs2277831, which lies within the *MICAL3* gene (odds ratio (OR) for the G allele 1.07 [1.04-1.11], p=$2.85x10^{-5}$).

Our study highlights possible novel OA susceptibility loci, which will require corroboration in sample sets of larger size. Stage 2 of the arcOGEN GWAS in 4,500 OA cases is currently underway. A combined analysis of the 2-stage GWAS will provide us with sufficient power to detect modest effects at common loci at the genome-wide significance level (90% power to detect an allele with frequency 0.20 and allelic OR of 1.2).

Stratification-Score-Based Matching Outperforms Other Matching Approaches when Controlling for Confounding. *G.A. Satten[1], M.P. Epstein[2], R. Duncan[2], K.A. Broadaway[2], A.S. Allen[3].* 1) CDC, Atlanta, GA; 2) Dept of Human Genetics, Emory Univ, Atlanta GA; 3) Dept of Biostatistics and Bioinformatics & Duke Clinical Research Institute, Duke University, Durham NC.

Proper control of confounding due to population stratification is crucial for valid analysis of genetic association studies. Fine matching of cases and controls based on genetic ancestry is a strategy for control of confounding that is increasing in popularity. Information on genetic ancestry can typically be summarized by a relatively small number of genomic variables such as principal components, chosen to be significant predictors of genomic variability. However, it is difficult to match cases to controls using more than one continuous variable. Existing matching approaches therefore define some scalar measure that combines information from all of the significant components, which is then used to form matched sets. However, inclusion of ancestry components that do not predict disease status into a matching criterion can lead to inaccurate matches, and hence to an improper control of confounding. Here we propose that cases and controls be matched on the stratification score, which is the probability of disease given genomic variables [AJHG 80:921-930]. Matching on the stratification score leads to more accurate matches because case participants are matched to control participants who have a similar risk of disease, given genetic ancestry information. Using a genome-wide case-control study of schizophrenia among African-Americans, we show that confounding is resolved by our stratification-score matching approach but not by other existing matching procedures (GEM, spectral-GEM and GSM). We also use simulated data to show the superior performance of our approach. [GEM=GEnetic Matching, Amer J Hum Genet 82:453-463; spectral-GEM, Genet Epidemiol 34:51-59; GSM= Genetic Similarity Score Matching, Genet Epidemiol 33:508-517].

A multivariate genome-wide association analysis of 10 LDL subfractions, and other lipid measures, in 1800 Caucasians. *H. Shim[1], K. Wojnoonski[2], L. Mangravite[2], M. Barber[1], M. Stephens[1,3], R. Krauss[2].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Children's Hospital Oakland Research Institute, Oakland, CA; 3) Department of Statistics, University of Chicago, Chicago, IL.

Levels of plasma lipids and lipoproteins are related to risk of cardiovascular disease, and because of this considerable attention has been devoted to genome-wide association (GWA) analyses of various lipid-related measures, including plasma concentrations of LDL-cholesterol (C), HDL-C, and triglycerides (TG). These measures however fail to identify potentially important subfractions of lipoprotein particles (i.e. those defined by differences in size and density). To better understand, in detail, how genetic variants influence components of lipoprotein metabolic pathways, we performed a GWA analysis of 10 LDL subfractions measured by gradient gel electrophoresis, together with LDL-C, HDL-C, TG, apolipoprotein B, and LDL peak diameter in > 1,800 Caucasian subjects from the Pharmacogenomics and Risk of Cardiovascular Disease study. Unlike most previous analyses of these kinds of data, we analyzed all measurements jointly, rather than one at a time, providing a more detailed picture of the effect each genetic variant has on the entire lipid profile. Specifically, we use a novel Bayesian framework for multivariate association analysis, which simultaneously addresses the twin questions of *which* genetic variants affect components of the lipid system, and *how* they affect the system. We find that measuring LDL subfractions reveals associations not evident from analysis of total LDL-C. For example, rs3764261 in CETP is not significantly associated with LDL-C (Bayes Factor, BF < 1) but extremely strongly associated with the multivariate subfraction data (BF > 10^35). This is because this variant increases some subfractions and decreases others, with the effects approximately canceling one another out. In contrast, genetic variants in other genes show very different patterns: e.g., variants in APOE increase all LDL subfractions, whereas variants in SORT1 affect LDL-III and IV subfractions only. These differences among genes are evident only because of the more refined phenotyping, and point to the potential value of these kinds of analyses to identify novel genetic influences on cardiovascular risk. More generally, they illustrate the potential for detailed phenotypic measurements to enhance the ability to discover biologically meaningful associations from genome-wide analyses.

Genetic Association Analysis of CAOD Using Mixed Models. *N.-H. Son[1], K. Song[2], S.M. Myoung[3], D.-J. Shin[4], Y. Jang[5].* 1) Cardiovascular Genome Center, Yonsei University College of Medicine, Seoul, Korea, MS; 2) Department of Biostatistics, Yonsei University College of Medicine, Seoul, Korea, PhD; 3) Department of Medical Informatics, Jungwon University, Chungbuk, Korea, PhD; 4) Cardiovascular Genome Center, Yonsei University College of Medicine, Seoul, Korea, PhD; 5) Cardiovascular Genome Center, Department of Internalmedicine, Yonsei University College of Medicine, Seoul, Korea, MD, PhD.

In genetic association studies, the complicated interaction among genes and the interaction between environmental factors and genes should be taken into consideration. However, as the number of SNPs increase, the frequently used analysis methods such as logistic regression have analytic limitation to test and interpret this complex relationships. We proposed using the mixed model approach to identify significant genotype groups and the gene-gene interactions. For the purpose of these analyses, we used data from 1,006 individuals(503 individuals who were patients with CAOD and other who were healthy) and 5 SNPs among 32 candidate SNPs examined from Cardiovascular Genome Center, Yonsei University. We defined genotype groups which are groups of individuals with same genotypes. And these observed groups were treated as random effects in a mixed model. We compared the odds of random effects model with that of mixed effect model. We could analyze genotype group-specific effects through the random effects in mixed model, and it was possible to assess the effects of SNP combination. In conclusion, the mixed model approach provided a flexible framework for identifying a significant genetic contributions that may come about through the effects of multi-locus genotypes or through an interaction between the genotype and environmental factors with the variations in diseases.

Using covariates to improve power in genomewide association studies with related individuals. *S.A. Stanhope, M. Abney.* Department of Human Genetics, The University of Chicago, Chicago, IL.

In this paper we introduce GLOGS (Genomewide LOGistic mixed model / Score test), a procedure that simultaneously incorporates both arbitrary kinships between individuals and non-genetic susceptibility risk factors in genomewide association studies (GWASes). Because GLOGS is capable of controlling for a wider range of predictors of disease risks than alternative methods, it yields greater power in detecting associations between genetic markers and phenotypes.

We demonstrate such improvements in two simulation studies based on a dense kinship coefficient matrix, covariates and disease phenotypes observed in previously collected data. First, we examine the performance of GLOGS for cases independent of covariates. We show that GLOGS can yield up to a 4× improvement in power in comparison to FBAT. Next, we show that including non-genetic susceptibility risk factors in GLOGS can provide up to a 2× improvement in power compared to analyses omitting such effects.

To demonstrate the applicability of GLOGS to actual data collections, we perform GWASes of an asthma phenotype in the Hutterite population and an alcoholism phenotype in the GAW14 dataset. From the latter we report several markers associated with alcoholism.

Methodologically, GLOGS models disease risk in a mixed effects logistic regression framework. Kinships are expressed as an unobserved polygene represented as random effects correlated across individuals, and other risk factors are fixed effect covariates. Marker-specific score tests based on a null (no marker effect) model fit are used to evaluate associations. Since GLOGS represents kinships between individuals through a correlation matrix, it is appropriate for use on populations with either known pedigrees or inferred kinship coefficient matrices.

This study contributes to GWAS methodology through the simultaneous, tractable and general handling of both kinships between individuals and other predictors of disease risk. To promote the applied use of GLOGS, its current implementation is available for download.

Increasing power of groupwise association test using aggregated statistic of rare variants. *J. Sul[1], B. Han[1], D. He[1], E. Eskin[1,2].* 1) Computer Science Department, University of California, Los Angeles, CA; 2) Department of Human Genetics, University of California, Los Angeles, CA.

The advent of next generation sequencing technologies allow one to discover nearly all rare variants in a genomic region of interest. This technological development increases the need for an effective statistical method for testing the aggregated effect of rare variants in a gene on disease susceptibility. The idea behind this approach is that if a certain gene is involved in a disease, any rare variants that disrupt the function of the gene are associated with the disease. In this paper, we present Rare variant Weighted Aggregate Statistic (RWAS), a method that groups rare variants and computes a weighted sum of their z-scores. We show that RWAS outperforms previous methods for the groupwise association test such as a weighed sum statistic by Madsen and Browning in the disease-risk model where each variant makes a small contribution to disease-risk. In addition, we can incorporate into RWAS prior information of which variants are likely causal, and we show that prior information can have considerable effects on the power of studies.

2828/W

A Significance Level by Empirical Distribution of the Statistic in Genome-wide Association Study. *A. Takahashi[1], N. Hosono[2], M. Kubo[2], Y. Nakamura[3], N. Kamatani[1].* 1) Laboratory for Statistical Analysis, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 2) Laboratory for Genotyping Development, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 3) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Genome-wide association study(GWAS) were widely performed, and succeeded in the identification of many genes associated with diseases. In GWAS, more than several hundred thousand Single Nucleotide Polymorphisms(SNPs) are usually genotyped, and perform the association test. In this analysis, the small p-values happen by chance because a lot of the statistical tests are performed. It is important to control the family wise error rate to capture the genes truly associated with diseases. Various significance levels in GWAS have been suggested until now. A most simple method to correct the family wise error rate is a Bonferroni's correction. However it is well known that this correction is too conservative. In addition, all SNPs were not independent because of the linkage disequilibrium(LD). The distribution of test statistics such as a trend test in GWAS is not obvious. A significance level depends on SNPs used set and population. One method to determine a significance level is to create the empirical distribution of the statistic. To assess the global type I error rate, we created the empirical distribution of the statistic by permutation test. In the Biobank Japan project, more than 30,000 Japanese people were genotyped by the Illumina Human610-Quad(610K) and the Illumina Human 550v3(550K) Genotyping BeadChips to discover susceptibility genes. At first, the two groups were created by selecting samples from 30,000 people at random. We conducted association test between two groups. The empirical distribution of the statistic under the null hypothesis can be obtained by permuting the samples at random in the two groups. We have shown the global type I error rate under the Illumina 610K/550K BeadChips in Japanese population. If sample size is small, SNPs whose minor allele frequencies are low may be observed as mono-polymorphisms. This fact means the number of effective statistical tests changes. We also have studied a significance level related to sample size.

Testing heterogeneity of quantitative trait variance among genotype classes guides fine mapping of association signals. *F. Takeuchi, N. Kato.* National Ctr for Global Health & Med, Tokyo, Japan.

Purpose. Single nucleotide polymorphisms (SNPs) identified in genome-wide association studies (GWAS) are supposedly markers in linkage disequilibrium (LD) with some causal variant(s), and fine mapping is a current hot topic. For efficient fine mapping, we want to know whether the variant(s) accounting for a GWAS signal is included in the common SNP(s) (minor allele frequency, MAF, ≥5%) showing the strongest association, or will emerge once association testing is extended into low frequency variants (MAF, 0.5-5%). To answer the question, we propose a statistical test that examines if the association of a SNP with a quantitative trait (QT) is due to LD with (possibly unknown) low frequency variants. **Proposed method.** We test the heterogeneity of QT variance (ie, heteroscedasticity) among genotype classes of a SNP, using the Bartlett's test (significance level 0.05), after applying rank-based inverse normal transformation to the QT distribution in the whole study population. **Results.** To quantify the QT variance, we modeled a marker SNP with alleles *A* and *a* and a single causal variant with alleles *B* and *b*, assuming that the QT is normally distributed with the unit variance and the mean equal to 2*d*, *d* or zero within individuals of genotype *B/B*, *B/b* or *b/b*, respectively. If the low frequency allele *B* is always linked to allele *A*, individuals with *A/A* genotype have either of three genotypes, *B/B*, *B/b* or *b/b*, thus show a wide QT distribution; the QT variance inflates proportionally to d^2 and the variance of the causal genotype within the individuals. For SNPs identified in simulated GWAS, heteroscedasticity was detectable (power >0.8) when the SNP is in LD with one primary causal variant that has a frequency lower than the SNP by >8-fold. Finally, we could validate the usefulness of the test by real data for the *APOE* locus associated with LDL-cholesterol level. **Conclusion.** Testing heteroscedasticity can guide fine mapping by suggesting the next step after studying association of common SNPs exhaustively in a locus. If heteroscedasticity is significant for the common SNP(s) showing the strongest association, we recommend extending the study into low frequency variants, which should include the variant causing heteroscedasticity. Alternatively, if heteroscedasticity is not significant (when tested in >5,000 samples), the leading SNP(s) are causal, or there are multiple low frequency causal variants together canceling heteroscedasticity.

A Sequential Test Algorithm for DNA Pooling/Bootstrap-Based Studies. *J.I. Velez Valbuena, M. Arcos-Burgos.* Med Genetics Branch, NHGRI/NIH, Bethesda, MD.

DNA pooling is a practical way to reduce the cost of large-scale association studies to identify susceptibility loci. In contrast to individual genotyping, in DNA pooling we can combine samples from *N* cases and *M* controls into two single pooled sample tests and estimate the allele frequency of hundred of thousand SNPs using high-throughput genotyping technologies. Selection of disease-associated SNPs is performed based on their *P*-value after a statistical test has been run. For the subset of those SNPs determined to be significant, all individuals are then genotyped to corroborate results from the pooled samples.

The strategy described above has been successfully used for years. However, there are situations in which either it is not possible to recruit the number of patients (cases) needed based on power estimations or replication of DNA pools is important. In both situations, the limitation is the availability of DNA samples.

When using sequential testing, formally presented in 1945 as sequential probability ratio test (SPRT), units of interest are sequentially included as they are generated, and a statistical test is run at every stage. In the context of DNA pooling, units would be represented by the pooled samples coming from each group of cases and controls while using a bootstrapping re-sampling strategy.

We have developed a SPRT algorithm for identifying disease-associated SNPs when comparing cases and controls via DNA pooling that is at least as powerful as the strategy previously described, but that needs less DNA samples than the strategy described above. Along with our algorithm, we also provide a way to estimate the number of stages needed, i.e., the number of SNP-chip pairs to stop the algorithm achieving a desired significance and power levels. We illustrate how our approach works using GWAS on Oppositional Conduct Disorder (OCD) and Attention Deficit Hyperactivity Disorder (ADHD).

Covariate Adjustment in Case-Control Studies. *C. Xing.* McDermott Ctr, Univ Texas SW Med Ctr, Dallas, TX.

A conventional wisdom in classic linear regression is that adjusting for covariates associated with the response variable can improve the precision of estimates by reducing the residual variance; however, covariate adjustment in logistic regression models always leads to a loss of precision. Nonetheless, this loss of precision does not always result in a loss of power. When the genetic and risk/preventive environmental factors are independent and do not have interaction effects on the disease, it is always more efficient to adjust for the predictive covariates. Recently, Kuo and Feingold (Genet Epidemiol 2010, 34:246-253) compared the power of three logistic regression models to detect genetic effects, concluded that "the most commonly used approach to handle covariates—modeling covariate main effects but not interaction—is almost never a good idea", and recommended modeling only the genetic factors without covariate adjustment in genome-scanning. A person's genetic background is determined from birth, thus in most cases it is not unreasonable to assume it is independent of his/her subsequent environmental exposure, which has been a key assumption in some study designs to investigate gene-environmental interaction. If we assume that only a small proportion of genetic variants interact with the known environmental factors on disease susceptibility, then, contrary to the conclusion by K&F, we recommend adjusting for predictive covariates at the genome-scanning stage.

Where do true positives rank in GWAS? *D.V. Zaykin.* Dept Biostatistics, NIEHS/NIH, Res Triangle Park, NC.

A standard calculation in the design of GWAS is a sample size determination needed to achieve adequate power at the genome-wide level of significance. An alternative approach is to calculate the probability that a true positive will rank among a specific number of best results, when they are sorted by an association statistic. The rank-based approach allows one to find the number of most significant results to follow up on, as determined by the desired probability of capturing a true association. The rank-based approach is appealing, since it provides guidance for the number of SNPs needed in a replication study. Unlike the power-based approach, it does not require specification of a particular significance level. The usual evaluation of ranking probabilities is via simulations and non-standard numerical methods. I give a very simple but highly accurate approximation for computing ranking probabilities. The approximation allows for linkage disequilibrium and is applicable to multiple associated SNPs. Further, I describe a straightforward relation of ranking probabilities to power at the GWAS level.

eQTL mapping in peripheral blood CD4+ lymphocytes identifies replicable, novel asthma susceptibility loci, augmenting standard genome-wide association testing. *S. Sharma, A. Murphy, V. Carey, B. Himes, J. Howrylak, B. Raby.* Dept Respiratory Epidemiology, Channing Laboratory, Boston, MA.

Rationale: Genome-wide association studies (GWAS) have yet to identify the majority of genetic variants involved in the pathogenesis of complex diseases like asthma, perhaps in part due to lack of meaningful data to guide functional prioritization of the large number of markers tested. Expression quantitative trait loci (eQTL) mapping should enable such prioritization by identifying those variants that impact phenotypic diversity in transcript abundance. Using asthma as a model, we sought to evaluate this possibility by testing the cis-acting regulatory variants identified from an eQTL mapping study of peripheral blood CD4+ lymphocytes (a cell-type implicated in the pathobiology of asthma) for association with asthma susceptibility in two well-characterized populations. **Methods**: The eQTL study was performed in a subset of 200 non-Hispanic white subjects with mild-moderate persistent asthma participating in the Childhood Asthma Management Program (CAMP), for whom GWAS genotype data (Illumina HumanHap 550k chip) were available. CD4+ lymphocyte gene expression profiles were generated using the Illumina HumanRef8 v2 array. eQTL testing was restricted to those variants mapping within 50kb of transcript, resulting in identification of 6,977 cis-acting regulatory variants in 1,8311 genes (FDR<0.05). We then tested these variants for association with asthma susceptibility in 403 parent-child trios participating in CAMP using family-based association tests in PBAT. Significant associations were then tested for replication in 600 parent-child trios participating in the Genetics of Asthma in Costa Rica Cohort. **Results**: Cis-acting regulatory polymorphisms demonstrated reproducible association with asthma in both cohorts. We first confirmed the previously-reported association of chromosome 17q regulatory variants (i.e. the ZPBP2/GSDMB/ORMDL3 locus) with asthma susceptibility (CAMP p=0.0007, Costa Rica p=0.000003, fisher's combined p=4.4 x10-8). However, additional variants in other biologically plausible candidates were also observed including FADS2 (Fisher's combined p=0.0002) and TNFSF12 (Fisher's combined p=0.005). These represent novel asthma susceptibility targets warranting validation in independent cohorts. **Conclusions**: Our results suggest that eQTL mapping of regulatory variation is a powerful method for identifying disease-susceptibility loci. Using this method, we have identified two novel asthma susceptibility loci.

Model-Based Multifactor Dimensionality Reduction for detecting gene-gene interactions in case-control data in the absence and presence of noise. *K. Van Steen[1,2], T. Cattaert[1,2], M.L. Calle[3], S.M. Dudek[4], J.M. Mahachie John[1,2], F. Van Lishout[1,2], V. Urrea[3], M.D. Ritchie[4].* 1) Systems and Modeling Unit, Montefiore Institute, University of Liege, Grande Traverse 10, 4000 Liège, Belgium; 2) Bioinformatics and Modeling, GIGA-R, University of Liege, Avenue de l'Hôpital 1, 4000 Liège, Belgium; 3) Department of Systems Biology, University of Vic, Carrer de la Sagrada Família 7, 08500 Vic, Spain; 4) Ritchielab, Center for Human Genetics Research, Vanderbilt University, 519 Light Hall, 2215 Garland Avenue, Nashville, TN 37232-0700, USA.

Analyzing the combined effects of genes and/or environmental factors on the development of complex diseases is a great challenge from both the statistical and computational perspective, even using a relatively small number of genetic and non-genetic exposures. Several data mining methods have been proposed for interaction analysis, among them, the Multifactor Dimensionality Reduction Method (MDR), which has proven its utility in a variety of theoretical and practical settings. Model-Based Multifactor Dimensionality Reduction (MB-MDR), a relatively new MDR-based technique that is able to unify the best of both non-parametric and parametric worlds, was developed to address some of the remaining concerns that go along with an MDR-analysis. Whereas the true value of MB-MDR can only be revealed via extensive applications of the method in a variety of real-life scenarios, here we investigate the empirical power of MB-MDR to detect gene-gene interactions in the absence of any noise and in the presence of genotyping error, missing data, phenocopies and genetic heterogeneity. For the considered simulation settings, we show that the power is generally higher for MB-MDR than for MDR, in particular in the presence of genetic heterogeneity, phenocopies and epistasis models involving markers with low minor allele frequencies.

Contingency table test for multiple-categories with arbitrary weights on the cells. *R. Yamada, T. Kawaguchi.* Statistical Genetics, HGC, Kyoto University, Kyoto, Japan.

Test of independence between two factors is one of the most basic tests for many fields. In genetics, it has been in regular use for genotype-phenotype correlation. The simplest case of genotype-phenotype correlation handles two categorical phenotypes (cases vs. controls) and three diplotypes of diallelic genetic variants, ie., 2x3 table test. Even for this simple table, multiple tests, Pearson's test with two degrees of freedom (df), genetic mode-specific tests with 1 df (dominant test, recessive test , additive test). Sometimes MAX3 test or MAX test, which is consisted of the three mode-specific tests, is also used. All of these tests analyze the same table and they output different result because they weighi cells of the table differently.

In the recent genetic epidemiology studies, the phenotypes can be multi-categorical with disease stages or grades and combinations of multiple conditions of diseasee criteria, and the number of categories of genotypes can be more than three. Therefore it is beneficial to handle NxM tables in the same way with the genetic mode-specific tests for 2x3 tables.

When we generalized the idea for 2x3 tables to NxM tables, we evaluated the structure of tests geometicly.In the case of 2x3 tables, Pearson's test of 2 df and other tests of 1 df were in the relation where Pearson's test's statistics drew elliptic contour lines in 2-dimensional space and the others did straight lines.We generalized two-dimension to df-dimension for NxM tables, where df = (N-1)x(M-1) and gave the method to calculate statistics for NxM tables with arbitrary weights on the celles.

Bayesian Analysis of Rare Variants in Genetic Association Studies. *N. Yi, D. Zhi.* Dept Biostatistics, Univ Alabama, Birmingham, AL.

Recent advances in next-generation sequencing technologies facilitate the detection of rare variants, making it possible to uncover the roles of rare variants in complex diseases. As any single rare variants contain little variation, association analysis of rare variants requires statistical methods that can effectively combine the information across variants and test their overall effect. We here propose a novel Bayesian generalized linear model for analyzing multiple rare variants within a gene or genomic region in genetic association studies. Our model can deal with complicated situations that have not been fully addressed by existing methods, including issues of disparate effects and non-functional variants. Our method jointly models the overall effect and the weights of multiple rare variants and estimates them from the data. This approach could produce different weights to different variants based on their contributions to the phenotype, yielding an effective summary of the information across variants. We evaluate the proposed method and compare its performance to existing methods on extensive simulated data. The results show that the proposed method performs well under all situations and is uniformly more powerful than existing approaches.

Stability selection analysis of GWAS uncovers importance of second messenger signalling pathways in genetic predisposition to rheumatoid arthritis. *H. Eleftherohorinou[1,2], C. Hoggart[1], V. Wright[2], M. Levin[2], L. Coin[1].* 1) Department of Epidemiology and Biostatistics, Imperial College London, St Mary's Campus London, United Kingdom; 2) Department of Paediatrics, Division of Medicine, Imperial College London, St Mary's Campus London, United Kingdom.

Background: Genome-wide association studies (GWAS) have largely identified genes associated with disease on the basis of single-SNP *P* values. Meta-analysis of multiple GWAS has been applied the last couple of years to increase the sample size and therefore the power of discovery, but in essence it follows the same concept as the single-SNP approach and as such it suffers from the same limitations. Aim: We recast the question of how to associate genes with disease as a variable selection problem. We introduce a stability selection procedure in a pathway-based setting to identify functionally relevant genes which are robustly selected in predictive models of case-control outcome in two rheumatoid arthritis (RA) studies. Methods: We examined 700 pathways assembled from public databases and we used the cumulative trend statistic (CTT)[1] to assess their evidence of association with the disease. We collected the genes within associated pathways and we applied Hlasso[2], a logistic regression and variable selection algorithm, under subsampling and constant tuning of the regularization parameters, shape λ and penalty f'. Selection probabilities, over 1000 subsamples and 100 parameter sets, were calculated for genes blocks as a means to address for large gene size and LD structure. The procedure is called stability selection[3]. It is based on the principle that while tuning the amount of regularization, the truly relevant variables exhibit higher and stable selection probabilities. Subsampling is used to control the finite sample familywise type I error rate. Results: We identified 45 genes from the Wellcome Trust Case Control Consortium RA study and 54 genes from the North American Rheumatoid Arthritis Consortium (NARAC) study. 30 of these genes were selected in both studies ($P_{overlap\_by\_chance}<10^{-6}$), of which 21 are novel associations with RA. The novel associations implicate genetic variation in second messenger signalling pathways through cyclic AMP, inositol phosphate and calcium in RA susceptibility. Conclusion:The marriage of the biologically driven pathway information with a robust variable selection methodology yields markedly improved and consistent results across two independent datasets of RA. Concurrency of findings is achieved both at the pathway and at the gene level. HLA Associations with Birth Date and Age and Applications to Disease Association Studies. *L. Gragert[1], M. Maiers[1], W. Klitz[2].* 1) Bioinformatics, National Marrow Donor Program, Minneapolis, MN; 2) Public Health, University of California, Berkeley, CA.

In order to test for HLA disparities based on birth date and age, we split a control sample of European-American donors recruited by the NMDP between 1997 and 2002 into two parts and ran HLA association studies. Comparing the HLA of donors under 50 with those over 50, we found several significant HLA associations. The HLA haplotype most associated with older age was A*02-B*18-DR*04 with an odds ratio of 0.582 and a P-value of 0.0006 after Bonferroni correction. We also found a B-DR haplotype associated with younger age, B*35-DR*02 with an odds ratio of 1.25 and a P-value of 0.013. When comparing donors born before 1950 with those born after 1950, we also detected several significant associations, some of which were distinct from the age association analysis. HLA differences based on age may come about from protective and/or predisposing effects of HLA for disease, results in older subjects having a different HLA makeup than younger subjects. HLA differences based on birth date may reflect demographic changes in populations over time, a result of new immigration or higher levels of admixture in younger subjects. Further investigation is needed to test hypotheses for the causes of these HLA disparities. We have previously described significant HLA associations within self-identified race/ethnic (SIRE) categories for geography, gender, and population substructure. Matching controls for all of these factors when conducting HLA disease association studies and must be considered part of the research protocol to avoid erroneous conclusions.

Shared Loci for Leprosy and Crohn's Disease: Clues to Inflammation and Immunity? *F.O. Vannberg[1], H.S. Wong[1], S. Gochait[2], D. Malhotra[2], S.O. Sow[3], R.M. Pitchappan[4], R.N.K. Bamezai[2], A.V.S. Hill[1].* 1) Wellcome Trust Human Genetics, Univ Oxford, Oxford, United Kingdom; 2) National Centre of Applied Human Genetics, School of Life Sciences, Jawaharlal Nehru University, New Delhi 110067, India; 3) Institut Marchoux, Bamako, Mali, West Africa; 4) Centre for Excellence in Genomic Sciences, Madurai Kamaraj University, Madurai 625021, India.

Our group have identified novel mycobacterial susceptibility loci using genome-wide approaches. A subset of the leprosy susceptibility loci overlap with those of Crohn's disease, including the 13q14.11 locus. This locus contains the gene *C13orf31* (rs3764147, P=6.1x10-8, OR= 1.59, 95%CI 1.34-1.89), and this SNP was found to consistently replicate in leprosy case control populations from New Delhi (India), Kolkotta (India) and from the west African country of Mali. The MHC locus near HLA-DRB1 associates with leprosy (rs1071630, P=4.9x10-14, OR=0.43, 95%CI 0.35-0.54), and lies within 10 kb of the MHC association signal for ulcerative colitis, another form of inflammatory bowel disease. We did not replicate the previous leprosy association with *NOD2*, although we did find that another innate immune receptor did associate with leprosy (*TLR1*, rs5743618, I602S, P=5.7x10-8, OR=0.31, 95%CI 0.20-0.48). We further go on to perform genetic association analysis between our genome-wide association study of leprosy and that of the Wellcome Trust Case Control Consortium Crohn's disease study. This formalized analysis identifies overlapping genetic susceptibility loci between these diseases to better define molecular pathways involved in immunity to intracellular pathogens and to the excessive inflammation which defines Crohn's disease.

Gene-based analysis identifies novel loci shared by Crohn's disease and ulcerative colitis. *K.I. Morley[1,2], L. Jostins[1], D.G. Clayton[3], J.C. Barrett[1], UK IBD Genetics Consortium.* 1) Human Genetics, Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Cambridge, United Kingdom; 2) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, School of Population Health, The University of Melbourne, Melbourne, Australia; 3) Cambridge Institute for Medical Research, Medical Genetics, Wellcome Trust/MRC Building, Addenbrooke's Hospital, Cambridge, CB2 0XY, United Kingdom.

Genome-wide association (GWA) studies of Crohn's disease (CD) and ulcerative colitis (UC) have identified over 50 associated genomic regions. This research has provided insight into how irregularities in the innate and adaptive immune systems predispose to these conditions, and has also demonstrated that there are both common and independent biological mechanisms contributing to each disease. Joint association analysis of CD and UC may improve power to detect loci shared between them, but must allow for the fact that different variants within a gene region may show a different degree of association to each trait. We used a recently developed variable selection method, an extension of the elastic net, to conduct genome-wide gene-based analysis of a data set combining 1,748 CD cases (WTCCC), 2,361 UC cases (WTCCC2), and 5,417 controls. We replicated many of the known loci for CD and UC (such as *IL23R*, *NOD2*, and *NKX2-3*), and also identified a number of novel loci exceeding a genome-wide gene-based significance threshold of $3x10^{-6}$. These novel loci include a region on chromosome 11q13.1, where *CTSW* (cathepsin W, $p = 8x10^{-12}$) is located, expression of which is regulated by *IL-2* and occurs primarily in cytotoxic lymphocytes. We also identified a locus at chromosome 16p13 that encompasses *DEXI* ($p = 2x10^{-7}$), a gene transcribed in response to the powerful anti-inflammatory drug dexamethasone and *CIITA* ($p = 2x10^{-8}$), which regulates transcription of class II major histocompatibility complex genes. Replication of these findings is ongoing in an independent collection of 5,000 inflammatory bowel disease cases. These results demonstrate the utility of our gene-based approach to joint association of related diseases, a method that can be extended to include additional related diseases, or applied to non-autoimmune disease phenotypes.

Identifying phenotypes of interest from noisy measurements: Mood responses to a single dose of amphetamine. *B. Engelhardt[3], A. Hart[2], M. Stephens[1,2], H. de Wit[4], A. Palmer[2,4].* 1) Department of Statistics, Univ Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) Department of Computer Science, University of Chicago, Chicago, IL; 4) Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL.

Phenotypes of interest can be difficult to measure and quantify. Complex phenotype information is often summarized in such a way as to maximize the possibility of detecting meaningful genetic associations, but the phenotypic interpretation of the summarization is not always clear. We present our approach to complex phenotype summarization within the scope of a genome-wide association study involving response to amphetamine in humans. Propensity to drug addiction may be linked to the mood-altering response to a drug, but drug response is a difficult phenotype to quantify. In this study, we sought to find genetic markers that influence response to d-amphetamine, which is known to be a heritable trait. Healthy young adults participated in three sessions in which they received, in randomized order, placebo, 10mg, and 20mg of d-amphetamine. The participants then completed self-reported mood questionnaires, and their physiological reactions were assessed, every 30 minutes for a three-hour period. Because of the variability inherent in these complex data, no single question or measurement simply quantified the reaction to the drug across all individuals. To identify a stronger signal of drug response, we smoothed the data by summarizing the time points in various ways, then we applied a method for sparse factor analysis (SFA) to these data. SFA is a statistical model that identifies a small set of factors that, through a weighted linear combination, approximate the survey responses of each individual. Each survey question may or may not contribute weight to a particular factor. By looking at questions that contribute substantial weight to a factor, we can identify the phenotype captured by that factor. Previously, principal components analysis with rotations was applied in lieu of SFA, but we have found that SFA produces factors with a higher level of sparsity, leading to greater interpretability in the factors. On these data, SFA found a set of factors that are individually identifiable as drug response or other phenotypes of interest. Furthermore, when we analyzed association between these factors and the available genotypes in a Bayesian framework, we identified a number of possible associations near genes of interest. This study shows the promise of using SFA on complex data to extract meaningful signals of phenotype, which were substantiated by the quality of the associations we identified.

Scan Statistics for Pathway-based Genome-wide Association Study. *T. Nishiyama[1, 2], K. Takahashi[3], T. Tango[3], S. Takami[4], H. Kishino[4].* 1) Doctor of Public Health Program in Biostatistics, National Institute of Public Health, Wako, Japan; 2) Clinical Trial Management Center, Nagoya City University Hospital, Nagoya, Japan; 3) Department of Technology Assessment and Biostatistics, National Institute of Public Health, Wako, Japan; 4) Laboratory of Biometry and Bioinformatics, Graduate School of Agriculture and Life Sciences, University of Tokyo, Tokyo, Japan.

Despite great success of genome-wide association studies (GWAS) in identification of genes underlying complex diseases, the current GWAS have focused only on examining significance on a SNP-by-SNP basis. One of the biggest challenges facing GWAS is a lack of sufficient power to detect small effects as significant. To overcome this limitation, gene set analysis (GSA) methods of analyzing SNP data in GWAS have recently been proposed. However, GSA methods of GWAS do not use gene-pathway structure information, represented by gene products as graph nodes and graph edges between these nodes. Instead of focusing only on the SNPs that are grouped as gene-sets, we propose genome-wide association analysis that incorporates pathway structure information. As a proof of concept, we performed GWAS on a set of 868 cases and 1194 controls genotyped for almost 545080 SNPs, based on pathway structure information on Pathway Commons. To detect clustering of significantly associated SNPs on Pathway Commons pathway, scan statistics were applied with a variable window size. We treated the smallest P values as our statistic of interest and determined its overall significance level. We applied this method based on existing statistics used for GSA methods, such as Gene Set Enrichment Analysis (GSEA). The results demonstrated that this new method for GWAS was able to identify biologically meaningful sub-pathways associated with the trait examined. The performance of our scan-statistics approach is extensively compared with GSA methods.

Novel methods for detecting associations between continuous trait and rare variants: Application to the 1000 genome project. *M. Ladouceur[1,2], C. Greenwood[1,2], Y. Aulchenko[3], B. Richards[1,2].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Divison of Clinical Epidemiology, Montreal Jewish General Hospital, Montreal, Quebec, Canada; 3) Erasmus Medical Center, Rotterdam, Holland.

For many complex traits, common variants describe a small proportion of the genetically determined variance. Recent evidence suggests that multiple rare variants may account for a larger proportion of this susceptibility. However, these variants are hard to identify using conventional single nucleotide-based association methodology unless extremely large samples are available. Therefore new methodologies are required to dissect the contribution of rare base pair variants to common disease susceptibility. We are developing novel methods to identify the contribution of rare variants to continuous phenotypes, using exome sequencing data from the 1000 genomes project. We simulate various continuous trait based on the genotypic information of each individual, to reflect different plausible scenarios. The phenotypes are simulated using several sets of exclusive assumptions: 1) the effects of the rare variants on the traits are deleterious 2) the effects of the rare variants are distributed following a gamma distribution, and finally 3) that the effects of the rare variants can be mostly deleterious but some will have a protective effect. Several methods are tested to find the association between gene and trait. We test the genetic association using a random effect model, where the genotypic information is used as a method to cluster groups of individuals. Another approach allows inclusion of gene-based genomic kinship information in a random effect model. Finally, different models where each variant receives a specific weight will be computed. A genetic score per individual will be calculated as the sum of rare alleles across the genetic loci of interest of the number of minor allele found at a particular SNP divided by its weights. The genetic score per individual is regressed against the value of their phenotype. To assess the p-value of that score, we use a permutation test. Comparison with standard approach will be perform.

Assessing statistical significance in PLINK segmental sharing test. *J. Kwan, S. Cherny, P. Sham.* HKU, Hong Kong, Hong Kong, Hong Kong.

Genome-wide association studies (GWAS) have been used for identifying the genetic causes of many complex traits like Alzheimer's disease, schizophrenia, as well as various cancers. Given that nearly a million genotypes are generated for each individual in a typical case-control GWAS, it is natural to ask how the GWAS data could be fully utilized. Traditionally, GWAS are known to be suffered from the weak detection of rare risk variants. Resequencing of candidate loci or entire genome can certainly uncover such alleles, but this would require additional genotyping resources. Imputation of genotypes at loci untyped in the study but typed in the HapMap project does provide some extra information, but not necessary for the discovery of rare variants. Purcell et al. (2007) introduced a segmental sharing analysis between pairs of unrelated individuals using GWAS data. Their idea is based on family-based linkage analysis in which one would like to know if any chromosomal region is shared more among affected members than among affected and unaffected members within pedigrees, and the segmental test can be regarded as its extension when these familial relationships become distant and varied. If one can trace back to the infinite past, every case or control in a GWAS should actually belong to one of the many descendants of a remote common ancestry. In other words, all individuals within a GWAS should be considered related members within one large pedigree rather than totally unrelated. The PLINK approach of segmental sharing analysis is to compute a (linkage) test statistic S for each independent locus (i.e., in approximate linkage equilibrium with other tested loci) across the genome, asking whether there is a higher rate of case/case sharing than expected at each position, and to look for extended regions with statistic S significantly deviated from the expectation. However, whether the statistic S observed is significant remains a crucial question. One standard approach is to generate an empirical distribution of the statistic S under the null hypothesis via permutation. An alternative approach is to derive a SNP-wise p-value threshold characteristic to the sample of interest to balance the possibility of getting excessive false positive or false negative results. Here, we derived and proposed a threshold for the PLINK segmental sharing analysis by extending the theoretical framework of Lander and Kruglyak (1995) for family-based linkage analysis.

Empirical-Bayesian Testing for Association in Family-based Association Study. *T. Wang, C.Y. Lin, K. Pradhan, K. Ye.* Department of Epidemiology and Population Health, Albert Einstein Col Medicine, Bronx, NY.

With availability of new genotyping technology, in particular SNP arrays as well as the coming next-generation sequencing, efforts of mapping genes of human diseases/traits have been focusing on genetic association study. Family-based and population-based studies are two commonly-used designs of genetic association study. In contrast to population-based study, family-based study is robust to bias due to population stratification. However, family-based study is often less powerful than population-based study because part of association information (information between families) is not used due to its susceptibility to the bias of population stratification. To improve power, a two-stage algorithm has been proposed to fully make use of association information in genome-wide association studies. This algorithm can keep good control of the global type-I error rate, but p-values of individual loci are still subject to population stratification in that loci with substantial population stratification tend to have smaller p-values than loci without population stratification. This makes difficult to explain the association results for individual loci, because individual p-values are no longer comparable. To overcome limitations of current approaches, we propose a new Empirical-Bayesian test for combining association information within and between families. In this test, the population stratification parameter is not canceled out by conditioning on parental genotypes, but it is estimated from data, and then a shrinkage parameter is defined by this population stratification parameter so that the amount of shrinkage to the statistic based on information within families is estimated from data. By simulations, we showed this test can substantially improve the power, while it keeps good control of type I error rate in presence of subtle local population stratification.

Inference Techniques for Large Samples: An Unbiased Estimator Without Using Likelihood. *Y.E. Maruvka[1], N.M. Shnerb[1], D.A. Kessler[1], J. Wakeley[2], Y. Bar-Yam[3], S. Solomon[4], G. Yaari[5].* 1) Physics, Bar-Ilan University, Ramat Gan, Israel; 2) 2Department of Organismic & Evolutionary Biology, Harvard University, Cambridge, MA 02138, USA; 3) New England Complex Systems Institute, Cambridge, MA 02138, USA; 4) 4Racah Institute of Physics, Hebrew University of Jerusalem, Jerusalem 91904, Israel; 5) 5Department of Ecology and Evolutionary Biology, Yale University, New Haven, Connecticut 06520, USA.

Progress in genetic sequencing techniques challenge scientists analysing genetic polymorphism. The current methods based on maximal likelihood are geared towards small samples, and thus have conceptual and technical problems in dealing with large samples. Here we present a paradigmatically new approach to analysing large samples inspired by mean-field theory of statistical mechanics. The key behind our approach is to find some quantity (summary statistic - SS) that behaves almost deterministically, despite the randomness of the entire genetic tree. By comparing the measured quantity to the expected value for this quantity, one may infer the demographic parameters. We used various SS to infer a range of parameters. We used the number of haplotypes (NOH) (i.e. distinct genetic sequences) in the genetic sample as our SS. We derived an expression for the NOH in the genetic sample, which is an almost deterministic quantity. However, from this single number it's not possible to infer the two parameters of a growing population: the current population size and growth rate. We solved this by defining the NOH for subsets of the whole genetic sequence. Due to the independence of the mutations along the genome, using a shorter genetic sequence is parallel to reducing the mutation rate. Thus, we obtained a function F(l) of the NOH vs. the mutation rate (sequence length). By fitting this measured function to our formula for the NOH, we were able to infer the current population size and growth rate, with small error bars, and as opposed the current methods, without bias in the growth rate. For real cases, where repeated mutations occur, we developed a simulation-obtained function to replace the analytical one. We applied our method to Chinese HVR1 sequences of the mtDNA and retrieved the demographic and mutational parameters. Another almost deterministic quantity that we used is the number of lineages as a function of time (NLFT). Looking backward in time, genetic lineages coalesce stochastically, but still the average NLFT is an almost deterministic quantity (in large samples only). Therefore, by comparing the average NLFT of some real sequences to the NLFT expected by the formula that we derived, one can infer the demographic parameters. We applied our method both to simulated and real datasets, and demonstrated that in comparison to the common methods, our method is faster, has smaller error estimations, and most significantly, has an unbiased estimator.

Capitalizing on Admixture in Genome-wide Association Studies: A Two-stage Testing Procedure and Application to Height in African-Americans. *G. Kang[1], G. Gao[1], S. Shete[2], D. Redden[1], B. Chang[3], T. Rebbeck[3], J. Barnholtz-Sloan[4], N. Pajewski[1], D. Allison[1].* 1) The University of Alabama at Birmingham, Birmingham, AL; 2) M. D. Anderson Cancer Center, University of Texas, Houston, TX; 3) School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Case Comprehensive Cancer Center, Case Western Reserve University, Cleveland, Ohio.

As genome-wide association studies expand beyond populations of European ancestry, the role of admixture will become increasingly important in the continued discovery and fine-mapping of variation influencing complex traits. Though admixture is commonly viewed as a confounding influence in association studies, approaches such as admixture mapping have demonstrated its ability to highlight disease susceptibility regions of the genome. In this study, we illustrate a powerful two-stage testing strategy designed to uncover trait-associated single nucleotide polymorphism in the presence of ancestral allele frequency differentiation. In the first stage, we conduct an association scan using predicted genotypic values based on regional admixture estimates. We then select a subset of promising markers for inclusion in a second-stage analysis, where association is tested between the observed genotype and the phenotype conditional on the predicted genotype. We prove that, under the null hypothesis, the test statistics used in each stage are orthogonal and asymptotically independent. Using simulated data designed to mimic African-American populations in the case of a quantitative trait, we show that our two-stage procedure maintains appropriate control of the family-wise type I error rate (FWER), and has higher power under realistic effect sizes than the one-stage testing procedure in which all markers are tested for association simultaneously with control of admixture. We apply the proposed procedure to a study of height in 201 African-Americans genotyped at 108 ancestry informative markers. The two-stage procedure identified two statistically significant markers rs1985080 (PTHB1/BBS9) and rs952718 (ABCA12). PTHB1/BBS9 is downregulated by parathyroid hormone in osteoblastic cells, and is thought to be involved in parathyroid hormone action in bones and may play a role in height. ABCA12 is a member of the superfamily of ATP-binding cassette (ABC) transporters and its potential involvement in height is not clear.

Association Analyses of Mitochondrial Genes Polymorphisms with Femoral Neck Compression Strength Index. *N. Yu[1], T. Xu[1,4], Y. Cheng[1,4], Y. Pei[3], L. Zhang[3], J. Chen[1,2], H. Liu[1], J. Li[1], R. Kirk[1], Q. Tian[1], P. Yu[1], J. Hamilton[1], Y. Liu[1], H. Deng[1].* 1) University of Missouri - Kansas City, kansas city, MO; 2) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan, P.R. China; 3) Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, P.R. China; 4) Institute of Clinical Pharmacology, Central South University, Changsha, Hunan, P.R.China.

Introduction: Femoral neck compression strength index (CSI) is a novel parameter that integrates bone density, bone size, and body size [CSI = (BMD×FNW)/Weight]. It may have the potential to improve hip fracture risk assessment. However, the genetic factors underlying variations in CSI remain unknown. Recent studies found that mitochondrial dysfunction was associated with ageing-related phenotypes such as osteoporosis, suggesting potential role of mitochondrial genes on bone metabolism.

Materials and Methods: We performed association analyses for CSI in a sample of 2,258 unrelated US Caucasians (1728 females and 558 males) genotyped for Affymetrix genome-wide human SNP array 6.0. We focused our analyses on 20,131 mitochondrial SNPs due to the important role of mitochondria on bone metabolism. Association statistical analyses were carried out using PLINK software package (version 1.07).

Results: We identified four SNPs, (rs6782625, rs1842033, rs17020648 and rs17020592) that were significantly associated with CSI in males only (p = 2.35×10^{-6}, 2.40×10^{-6}, $2.40\times10^{-6}$and 2.45×10^{-6}, respectively). These four SNPs are located at the CMC1 (COX assembly mitochondrial protein homolog) gene. Importantly, the SNP rs17020592 was replicated in a Chinese sample including males sample (combined p = 2.21×10^{-6}). Interestingly, none of the SNPs in the CMC1 gene was associated with hip BMD in Caucasians or Chinese.

Conclusions: In this focused study of mitochondrial SNPs, we found that the CMC1 gene was consistently associated with CSI in US Caucasians and Chinese, independent of BMD. The CMC1 gene may affect bone metabolism by regulating the mitochondrial Cu-Zn superoxide dismutase activity. Our findings may provide new insights into pathogenesis of osteoporosis.

Key words: osteoporosis, CMC1, compression strength index, hip fracture, mitochondria.

Delineation of plausible sets of causative SNPs in GWAS associated regions. *M. Reppell, C. Ma, M. Boehnke, L.J. Scott.* Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Current GWAS show clear evidence of association in multiple regions throughout the genome. Each associated region will likely have a single SNP with the strongest evidence for association, but multiple additional strongly associated SNPs are often present. For a given region our goal is to identify the most plausible set of causal SNPs based on the evidence for association, with the assumption that the causal variant is among the analyzed variants. Biological follow-up experiments can be time consuming and costly and thus, in the absence of variants annotated as functional, for each signal we would like to quantitate the trade-off between number of SNPs selected for follow-up and probability of including the causal SNP within the selected set. We have taken a simulation based approach, initially using data from the *MMAB* region on chromosome 12, recently identified in large scale meta-analyses of high density lipoprotein cholesterol (HDL-C) concentrations. Using an additive model and data for ~2500 Finnish subjects from the FUSION study, we chose an effect size and randomly generated quantitative traits for each of the 459 SNPs in the *MMAB* region, assuming each SNP in turn was causal. We then tested all SNPs for association with each simulated quantitative trait. We compared the difference in association strength between the simulated causal SNP and the most strongly associated SNP; simulation runs where no SNP achieved genome wide significance (p-value < $5x10^{-8}$) were excluded from further analysis. Our results showed that when 0.25% of the trait variance was explained by the causative SNP, this SNP's p-value was among the best 10 p-values in 55% (43/78) of our simulations and within one $\log_{10}$ unit of the most strongly associated SNP in 69.2% (54/78) of simulations. For 2.5% of trait variance explained, these numbers increased to 74.4% (31513/42356) and 97.0% (41085/42356), respectively. This work shows that as effect size increases so does our ability to select smaller sets of SNPs that are likely to contain the causal variant for biological follow-up. We currently are analyzing other GWAS associated regions to determine more general rules for selection of a plausible set of causal SNPs based primarily on regional patterns of linkage disequilibrium and accounting for imputation quality.

Describing and automating best-practices for pathway analysis in genome-wide association studies. *N. Tintle[1], A. Bekmetjev[1], R. Pruim[2].* 1) Math Dept, Hope College, Holland, MI; 2) Math and Stat Dept, Calvin College, Grand Rapids, MI.

Pathway (gene set) analysis is an increasingly popular method for the analysis of data from case-control genome-wide association studies (GWAS). In contrast to traditional approaches which seek to evaluate phenotype association for each SNP individually, pathway analysis is used to establish the significance of biologically related sets of SNPs (e.g. all the SNPs related to genes in a particular biological pathway). While many different implementations of pathway analysis have been proposed, little practical advice on best practices for pathway analysis is available. Additionally, there is a noticeable lack of software tools available which automate the multi-step pathway analysis process. In this presentation we present results of theoretical, simulated and real data analyses comparing a variety of approaches to pathway analysis yielding a set of best-practices. Additionally, we describe a series of freely available R scripts we have written that provide a semi-automated pathway analysis environment for case-control GWAS data.

2851/W

Detecting Rare Variants: Bayesian Group Risk Index. *M. Wilson, D. Thomas, D. Conti.* Department of Preventative Medicine, University of Southern California, Los Angeles, CA.

We are interested in investigating the involvement of multiple rare variants within a given group (i.e. gene or region) by conducting analyses of individual groups with two goals: (1) to first determine if the group of rare variants is associated with risk; and (2) conditional upon the group being associated we wish to identify specific genetic markers within the group that are driving the association. In particular, we seek a formal integrated analysis that achieves both of our goals. For rare variants with minor allele frequency (MAF) less than .05 there is very little power to statistically test the divergence of observed counts between cases and controls for each variant. Thus, genetic association studies are often limited to detecting association within a subset of only the common genetic markers. However, it is very likely that some associations exist in the rare variants themselves that many not necessarily be represented in the set of common markers. Our framework aims at developing a risk index based on multiple rare variants in a group or region and in turn detecting associated regions based on the indices. Our analytical strategy is novel in that we use a Bayesian approach to incorporate model uncertainty in the selection of which variants to include in the index as well as if the variant is involved as a protective or risk contributing factor. Addiitonally, the approach allows for inference at both the group and variant specific levels. Using a set of study-based simulations, we show that our methodology has added power over the more commonly used weighted sum indices to detect risk groups and to identify the specific markers driving the association.

Do VEGF and eNOS gene haplotypes influence the development of retinopathy of prematurity in premature infants? *K. Yanamandra[1], S.A. Ursin[1], H. Chen[1], A. Pramanik[1], J.A. Bocchini Jr.[1], R. Dhanireddy[2].* 1) Dept Pediatrics, LSU Med Ctr, Shreveport, LA; 2) Dept. Pediatrics, UT Health Science Ctr, Memphis, TN.

Retinopathy of prematurity (ROP) is a multifactorial disease with multiple genes and environment playing a major role in the etiology of the disease. Early gestations and low birth weights are risk factors in the development of the disease. Ventilated very low birth weight infants have immature retina and are susceptible to ROP. The immature vasculature leads to retinal detachment in extreme cases. Vascular endothelial growth factor (VEGF), being a major mediator of angiogenesis, and Nitric oxide (NO), being an upstream and downstream regulator of VEGF mediated angiogenesis, have been suggested to play a role in the development of diabetic retinopathy. Our laboratory has been studying the etiology of ROP in ventilated very low birth weight infants since 2003. Presently we have been investigating the role of VEGF and endothelial nitric oxide synthase (eNOS) gene polymorphisms in the development of ROP. We genotyped 360 premature infants (56 infants with ROP and 304 infants without) for the presence of single nucleotide polymorphisms (SNPs) using PCR-RFLP methods: T-460C in the promoter region of VEGF gene, T-786C in the promoter region of eNOS gene and G894T in exon 7 of the coding region. Our results revealed a significant increase of variant haplotype (VEGF-460T/eNOS-786C/eNOS 894T) frequency over the other haplotype (-460C/-786T/894G) in premature infants with ROP compared to those infants without ROP (odds ratio 2.5, 95% CI 1.7-3.7, p=<0.000001). Our data reveal a strong association of variant haplotype of VEGF/eNOS genes suggesting that these genes are playing a significant role in the etiology of ROP in these premature infants. Data and statistics on the individual genotypes and their associations with the disease will be presented.

Augmented variable selection of GWAS findings for genetic associations of hypertension by a composite test incorporating marker information content. *J. Zhou[1], J. Chu[1], S. Wang[1], W. Yang[1], CC. Gu[1,2].* 1) Division of Biostatistics, Washington University, St Louis, MO 63108; 2) Department of Genetics, Washington University, St Louis, MO 63108.

Backgrounds: GWAS studies employing case-control designs typically focus on individual SNPs that are most different in allelic or genotypic frequencies between the two groups. We hypothesize that cases chromosomes are originated from different subpopulations than those in controls and the differences in fine LD structures between the 2 groups contain disease-related location information that could be used to improve detection of disease variants. Methods: The method of marker ambiguity score (MAS) was developed to measure the information content that a genetic marker possesses in discriminating fine local LD structures (Gu et al., 2006). It quantifies disagreement between SNP memberships in LD blocks derived in different subpopulations. We present here a composite test (CT) combining conventional single-SNP test (SST) result and MAS score for each individual SNP for more informative selection of important SNPs. Permutation (1000 iterations) then followed to obtain empirical p-values. We applied the method to a GWAS study of hypertension in 9315 Caucasian samples and compare the results with those by SST. Results: We report results on Chr5 (168082 SNPs) and Chr2 (220741 SNPs), with most and least number of significant SNPs by SST at 10-5, respectively. We considered a lower significance thresholds to examine the method's ability to prevent premature exclusion of potentially important SNPs. Briefly, (1) at a significance level of 0.01, on Chr2, we had 2568 significant SNPs by CT and 2693 by SST with 1879 only detected by CT; on Chr5, there were 1862 and 1740 significant SNPs by CT and SST respectively, with 1762 only by CT; (2) on both chromosomes, significant SNPs detected by CT were more likely associated with know genes, with most pronounced change On Chr5, where number of SNPs associated with a known gene increased from 79 SNPs to 765 by CT; (3) among the "novel" findings by CT, 12 synonymous and 9 missense SNPs were found on Chr5 while 4 synonymous and 3 missense SNPs were on Chr2; (4) among the "novel" ones detected by CT only, many were associated with genes with promising roles in HT including ALK (transmembrane receptor protein kinase activity pathway), which was detected in an independent CA sample (n=592) of GWAS analysis of HT. Conclusion: Our analyses provide interesting evidence that incorporating marker information content in GWAS analysis will improve selection of potentially important variants in GWAS studies of hypertension.

GREAT.stanford.edu: From low input and high throughput to concrete functional hypotheses output. *G. Bejerano[1], C. McLean[2], D. Bristor[1], M. Hiller[3], S. Clarke[4], B. Schaar[3], C. Lowe[5], A. Wenger[2].* 1) Dev Biol/Computer Sci, Stanford Univ, Stanford, CA; 2) Computer Science, Stanford University, Stanford, CA; 3) Developmental Biology, Stanford University, Stanford, CA; 4) Genetics, Stanford University, Stanford, CA; 5) Biomolecular Science and Engineering, UC Santa Cruz, Santa Cruz, CA.

Recent technological advances in DNA sequencing provide an unprecedented view of the regulatory genome in action. We can now sequence all binding events of transcription factors and complexes, examine the dynamics of chromatin marks, assay for open chromatin modifications between healthy and disease samples, human vs. chimp samples, and more. High throughput technologies also enable genome wide association studies for different human traits and diseases, and the inference of recent evolutionary events including population specific selective sweeps and human-specific changes in functional non-coding DNA content. Once a set of genomic regions of interest is defined, attempts to interpret this data must currently resort to the use of computational tools developed for microarray analysis. However the one-probe-per-gene methodology is a poor proxy for the rich regulatory landscape of the human genome. More often than not these analyses fall short, forcing researchers to manually scrutinize but a handful of their copious data. Our lab has recently published (McLean et al, Nat. Biotechnol., May 2010) the Genomic Regions Enrichment of Annotations Tool (GREAT), providing the first computational tool that properly models whole genome cis-regulatory data. Our published work focused on successfully applying GREAT to reinterpret ChIP-Seq datasets of multiple transcription-associated factors in different developmental contexts. Here we significantly extend the same methodology, demonstrating how to analyze high throughput datasets of particular interest to Human Geneticists: Genome Wide Association studies (GWAS), epigenetic markers and key transcription factors from human cancer cell lines, as well as evolutionary datasets such as Human Accelerated Regions (HARs), and genomic sweeps in different human populations inferred from HapMap data. For each of these, GREAT recovers many known functions that are missed by microarray-based tools, as well as generates novel testable hypotheses. Many of these datasets are rich in genomic regions putatively regulating components of particular pathways and cellular processes, some known, others novel. Some cancer related datasets show interesting similarities to target sets of different drugs. GREAT incorporates rich biological annotations from 20 ontologies and is available to the Human Genetics community as an intuitive web tool at http://great.stanford.edu/. Direct submission is also available from the UCSC Genome Browser.

A novel method for estimating the overlap of eQTLs between two tissues, with application to skin and lymphoblastoid cells. *J. Ding, G.R. Abecasis.* Biostatistics, Univ Michigan, Ann Arbor, MI.

Gene transcript levels can serve as an intermediate phenotype that bridges genotypes and more complex organismal phenotypes, including common diseases. Genome-wide association studies of gene expression in several human tissues have identified thousands of genetic loci impacting the expression of specific transcripts. Each of these loci is called an expression quantitative trait locus (eQTL). Although it is expected that many eQTLs will be tissue specific, the exact proportion of eQTLs that are tissue specific or shared between tissues remains unknown.

A simple measure of the tissue specificity of eQTLs can be obtained by examining the overlap of eQTL lists from two different tissues. Unfortunately, this naïve approach will likely underestimate the true proportion of overlapping signals. We have developed a more accurate method. Our multi-step procedure first generates a list of potential eQTLs and then uses unbiased estimates for eQTL effect sizes to estimate the expected number of replicating eQTLs for a specific sample size. The proportion of overlapping eQTLs can then be interpreted in this context. When applied to compare cis-eQTLs detected in an analysis of 57 skin biopsies and in a panel of ~400 lymphoblastoid cell lines, our method shows that 70-80% of eQTL are shared between tissues, a much larger proportion than the naïve estimate of 30-40%.

Our results provide guidance to researchers contrasting eQTL results across tissues and a specific means to accurately estimate the proportion of overlapping eQTLs between tissues.

A Hierarchical Model Approach to Map Population/Tissue Specific eQTLs. *X. Wen[1], M. Stephens[1,2].* 1) Dept Statistics, Univ Chicago, Chicago, IL; 2) Dept Human Genetics, Univ Chicago, Chicago, IL.

Recent studies have shown that the correlation between genetic variant and gene expression may behave in a population-specific or tissue-specific manner. To investigate the population/tissue specificity of eQTLs, we propose a hierarchical mixture model approach. Our model not only can efficiently map tissue/population specific eQTLs, but also has the ability to assess the probability of the tissue/population specificity of all eQTLs. More importantly, the proposed model allows researchers to investigate biological features that are potentially causal to eQTL specificity. We demonstrate our method by both simulation and real data application (e.g. Stranger's data for population specific eQTL mapping).

Association of Gene-Gene Interactions with Venous Thromboembolism (VTE): A Pathway-Directed Candidate-Gene Case-Control Study. *J.A. Heit[1], S.M. Armasu[2], T.M. Petterson[2], D.N. Rider[2], J.M. Cunningham[3], M. de Andrade[2].* 1) Internal Med/Hematology Res, Mayo Clinic, Rochester, MN; 2) Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 3) Experimental Pathology, Mayo Clinic, Rochester,MN.

While bivariate interactions between Factor V Leiden, prothrombin G20201A and hereditary deficiency of antithrombin, protein C and protein S compound VTE risk, whether other gene-gene interactions are associated with VTE is largely unknown. Thus, our goal is to test gene-gene interactions for an association with VTE. Cases (n=1486) were Mayo Clinic European-American patients of non-Hispanic ancestry with objectively-diagnosed VTE in the absence of active cancer, venous catheter or antiphospholipid antibodies. Controls (n=1439) were Mayo Clinic outpatients without VTE who were frequency-matched on case age, gender, race, MI/stroke status and state of residence. We selected candidate genes relevant to the anticoagulant, procoagulant, fibrinolytic and innate immunity pathways. For these genes (n=754), we selected all non-synonymous coding SNPs with minor allele frequency ≥ 0.005; the remaining SNPs were selected using an LD tagging algorithm (Carlson et al, AJHG 2004); 500 successful ancestry-informative markers were also included. Leukocyte genomic DNA was genotyped using a custom Illumina Infinium iSelect chemistry and platform, including appropriate controls. For these analyses, all pairwise SNP-SNP interactions for 12,497 SNPs were tested as well as SNPs uncovered using a 2-stage procedure. In addition, we tested all Factor V Leiden -, prothrombin G20210A - and ABO non-O blood group - SNP interactions. The mean ± SD case and control ages were 54.7± 6.3 and 55.5±15.7 years, respectively, and 1504 were female. Analysis of ancestry-informative markers gave no evidence of population stratification. Among almost 72 million pairwise interactions tested, 7018 could be evaluated for the 2nd stage ($p < E-4$). Of these, 516, 50 and 5 SNP-SNP interactions reached p-values £ 1E-5, 1E-6, and 1E-7 respectively; 373 reached the Bonferroni statistical significance threshold (£ 7.1E-6). The gene-gene pairwise interaction with p-value £ 1E-8 was: Arachidonate 5-lipoxygenase-activating protein (ALOX5AP) - Angiotensin I converting enzyme 1 (ACE 1). Gene-gene pairwise interactions with the lowest p-value for Factor V Leiden and ABO non-group O were Lymphocyte membrane glycoprotein (CD44) (7.4E-5), and Phospholipid scramblase 1 (PLSCR1) (5.3E-5), respectively. Our pairwise gene-gene interaction analyses suggest potential associations between VTE and novel genes and gene pathways for future testing in replication studies.

A direct approach to surrogate variable analysis for high dimensional data. *S. Lee[1], W. Sun[1,2], F.A. Wright[1,2], F. Zou[1,2].* 1) Biostatistics, University of North Carolina, Chapel Hill, NC; 2) Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC.

In modern high dimensional datasets, such as genome-wide gene-expression measured by microarray or RNA-seq, unobserved environmental, demographic, and technical factors can have a negative effect on estimating and testing the effects of experimental design variables (i.e. observed variables). These hidden factors are a source of systematic variation and can induce dependence among observations which can prevent proper estimation and valid type I error control. Recently, "surrogate variable analysis" (SVA) has been proposed to tackle this problem. To estimate hidden factors which are possibly correlated with observed variables, a current version of SVA either conducts PCA on a subset of measurements, or performs a weighted PCA based on presumed associations of measurements with hidden factors vs. associations with the variables of interest. This method, however, has limited usage if signals of observed variables are spread across all measurements. Furthermore, the steps of finding subsets or computing weights add variability to estimation, and prevent efficient adjustment and elucidation of the theoretical properties of this approach. We propose a simple and direct SVA approach which skips the additional step of SVA and uses all measurements simultaneously. We first show that the hidden factors can be successfully reconstructed from naïve estimates of observed variables and residuals from the linear model where only observed variables are included. Extensive simulation and real data analysis will then be used to demonstrate the advantages of the proposed method over the existing SVA approach.

Large-scale time series LC-MS/MS analysis of monocyte proteome from patients with severe traumatic injury. *H. Gao[1,4], A. Kaushal[1,4], W. Qian[2,4], D. Camp[2,4], W. Xu[1,4], J. Seok[1,4], R. Davis[1,4], R. Tompkins[3,4], W. Xiao[1,3,4].* 1) Stanford Genome Technology Center and Biochemistry Department, Stanford Univ, Stanford, CA; 2) Pacific Northwest National Laboratory, Richland, WA; 3) Massachusetts General Hospital, Harvard Medical School, Shriners Hospital for Children, Boston, MA; 4) Inflammation and Host Response to Injury Program.

Severe traumatic injury has long been a significant health care burden due to complications. To date, little is known about the underlying molecular mechanism responsible for the development of complications. Here we explore the monocyte proteome (including 13,095 peptide features) from 100 patients with severe injury collected at 12 hours, 1, 4, 7, 14, 21, and 28 days after injury using dual channel liquid chromatography coupled with tandem mass spectrometry technique, in order to identify proteomic profiles of those developing complications and to predict clinical outcomes early. We integrate the time series linear mixed model with a binary probit regression approach to identify proteomic features with significant differential expression across time or between clinical outcomes. After demonstrating its superior performance using both simulation and spike-in experiments, we apply our approach to this large-scale data set and detect 569 proteins with differential expression over time at 1% false discovery level. We compare them with the results from genome-wide expression analysis of those samples and discover that while a fraction of genes have distinctive trends between gene expression and protein expression, more than 60% show the similar variation pattern across time. Pathway analysis reveals that those genes are mainly related to integrin signaling, ILK signaling, Fcy receptor-mediated phagocytosis, and virus entry via endocytic pathways.

Allelic Expression Imbalance to Detect the Cis-acting Regulatory SNPs. *R. Xiao[1], M. Boehnke[2], L. Scott[2].* 1) Dept of Biostatistics and Epidemiology, Univ of Pennsylvania, Philadelphia, PA; 2) Dept of Biostatistics, Center of Statistical Genetics, University of Michigan, Ann Arbor, MI.

Testing for association between gene expression and SNPs identified by genomewide association studies (GWAS) can help understand the relationship between these SNPs and the trait of interest and identify the gene(s) most likely to influence the trait. Allelic expression imbalance (AEI) between the two alleles of a gene can be used to detect cis-acting regulatory SNPs (rSNP) in individuals heterozygous for a transcribed SNP (tSNP). The use of AEI is complementary to testing for SNP-gene expression association and has the advantage of testing both alleles within the same environment in each individual. Analysis of the AEI data depends on linkage disequilibrium (LD) between the rSNP and tSNP and whether we know linkage phase. In this study, we propose five tests to detect the association between the potential rSNP and the AEI when LD between the rSNP and tSNP is incomplete (D' < 1) and there is no phase information between them. We show that the relative power of the tests depends strongly on the magnitude of the LD between the rSNP and tSNP, and whether the two SNPs have similar allele frequencies, and less strongly on the AEI effect size of the rSNP and the number of tSNP heterozygotes. We further demonstrate that the impact of a second ungenotyped rSNP on the relative power of these tests depends on the LD structure of the three SNPs, but almost never invalidates the proposed tests nor substantially changes the rankings of the tests.

Identification of SNP-gene expression associations with adaptive methods. *A. Ziegler[1], T. Zeller[2], A. Schillert[1], S. Blankenberg[2], S. Szymczak[1].* 1) Inst Med Biometry & Statistics, Univ Lübeck, Lübeck, Germany; 2) Department of Medicine II Cardiology, Johannes Gutenberg University, Mainz, Germany.

Single nucleotide polymorphism-gene expression association studies (SNP-eQTL analysis) are performed to clarify the molecular function of genetic variants identified in genome-wide association (GWA) studies. The aim of these studies is to detect differences in gene expressions given genotype. Standard statistical approaches such as the analysis of variance (ANOVA) or the Kruskal-Wallis test can lead to false positive associations since model assumptions are often violated in SNP-eQTL studies. In fact, the empirical type I error level can be up to 99% when the nominal error level is 5%. A promising alternative for controlling the type I error are adaptive statistical methods. Here, characteristics of the distributions are estimated in the first step. These information about skewness and tail weights are then used to select an appropriate test statistic in the second. We propose a new adaptive test for the analysis of SNP-eQTL associations and demonstrate its validity in Monte-Carlo simulation studies. Using CADomics, a GWA study of coronary artery disease with 2000 cases and 3000 controls in combination with global monocyte transcriptome data (n=1500), we identified several biologically promising SNP-eQTL associations.

A simple scalable association hypothesis test combining gene-wide evidence from multiple polymorphisms. *D. Vaidya, R. Mathias, L. Becker, D. Becker.* Medicine, Johns Hopkins University, Baltimore, MD.

Introduction: In high-density single-nucleotide polymorphism (SNP) scans, tests of SNP-phenotype association hypotheses are reported, however there is biological interpretation only for genes that span multiple SNPs. The current practice of using Bonferroni-corrected significance thresholds is overly conservative and yet only polymorphism-specific, not gene-wide. We demonstrate and validate a method of combining gene-wide evidence using data for high-density lipoprotein cholesterol (HDLC).

Methods and Results: In a family based study (N=1782 from 482 families), we used 1000 phenotype-permuted datasets to determine the correlation of z-test statistics for 592 SNP-HDLC association tests comprising 14 genes previously reported to be associated with HDLC. We generated gene-wide p-values using the distribution of the sum of correlated z-statistics. Of the 14 genes, CETP was significant ($p=4.0*10^{-5}$ <0.05/14), while PLTP was significant at the borderline ($p=6.7*10^{-3}$ <0.1/14). Gene-wide p-values that were more significant than Bonferroni-corrected p-value for the most significant SNP in the 11 of 14 genes (p=0.023). Gene-wide p-values calculated from SNP correlations derived for 20 simulated normally distributed phenotypes reproduced those derived from the 1000 phenotype-permuted datasets (Spearman correlation = 1.00).

Conclusion: We have validated a simple scalable method to combine polymorphism-level evidence into gene-wide statistical evidence. High-throughput gene-wide hypothesis tests may be used in biologically interpretable genomewide association scans. Gene-wide association tests may be used to meaningfully replicate findings in populations with different linkage disequilibrium structure, when SNP-level replication is not expected.

Integration of sequence and array data in a population and haplotype-based model of SNPs and CNVs. *L.JM. Coin.* Epidemiology and Biostatistics, Imperial College, London, Greater London, United Kingdom.

Read depth analysis has been proposed as a method for detecting copy number variants from second generation sequence data. However, the resolution of this approach strongly depends on coverage. In particular, the resolution of current single-sample methods may be limited on low-coverage population sequencing projects such as the 1000 genomes project. To overcome this, we extended our previously published algorithm, cnvHap, which learns the local CNV haplotype structure in the entire population, to low-coverage sequence data. We used dense array CGH data collected on Hapmap samples to demonstrate the improvement in resolution available from this approach. We have previously quantified the improvement in CNV genotyping accuracy from integrating multiple genotyping and CGH platforms in a single probabilistic model (cnvHap). In order to investigate whether existing array data can improve CNV genotyping accuracy from low coverage sequence data, we also integrated array and sequence data in our model, and ascertained improvements in CNV genotyping accuracy.

A New Multi-Phenotype Approach on Genome-Wide Association Studies (GWAS) to Identify Novel Pleiotropic Genes that Affected Multiple Quantitative Traits: Bone Metabolism and Glucose Homeostasis, in Caucasian Populations. *Y. Hsu[1,2], X. Chen[3], D. Karasik[1], LA. Cupples[4], J. Meigs[5], DP. Kiel[1].* 1) Hebrew SeniorLife Inst Aging Res and Harvard Medical School, Boston, MA; 2) Integrative Molecular and Physiological Sciences Program, Harvard School of Public Health, Boston, MA; 3) Department of Environmental Health, Harvard School of Public Health, Boston, MA; 4) Department of Biostatistics, Boston University School of Public health, Boston, MA; 5) Massachusetts General Hospital, Boston, MA.

Pleiotropy occurs when gene codes for a product has a signaling function on various targets. Previous studies have proposed to simply look-up on the overlaps of association signals among univariate GWAS across multiple traits to identify pleiotropic genetic effects. However, the correlation among traits may also lead to overlap in false positive/negative signals. In addition, due to moderate genetic effects, it is inefficient to detect pleiotropy by univariate analytical framework. Adopting multivariate methods may overcome these disadvantages of univariate GWAS and improve statistical power. We propose here a new approach to test for pleiotropy on GWAS using a two-stage strategy: in the first stage, we performed a multi-phenotype GWAS by modeling traits simultaneously using our newly developed method, empirical-weighted linear-combined test statistics (eLC); and then, we tested the pleiotropy using a simplified structure equation modeling on selected SNPs from the first stage. eLC is to directly combine correlated test-statistics with a weighted sum of univariate statistics to maximize the heritability of the overall association tests. Using GWA16 simulated dataset, our eLC approach has outperformed the simple look-up on the overlaps among univariate GWAS and traditional multivariate methods (such as MANOVA, GEE and PCA). A recent rodent study showed that bone biomarker, osteocalcin, was involved in endocrine regulation of glucose homeostasis, which provided directly evidence linking the skeleton to the pathogenesis of diabetic complications. Significantly genetic correlations for bone mineral density (BMD) with fasting glucose and insulin in the Framingham Study indicates that shared genetic determinants may regulate both bone and energy metabolism. We applied our approach to data from the Genetic Effects for Osteoporosis (n=32,000) and Meta-analysis of Glucose and Insulin traits (n=36,610) consortia to identify pleiotropy on both BMD and glycemic phenotypes. Several pleiotropic effects were found, i.e. SNPs in or near NPSR1, TNFRSF11B and TGFBI genes. In conclusion, we proposed a powerful approach to identify pleiotropy from GWAS meta-analysis and our results reveal novel pleiotropic genes to further elucidate the link between the skeleton and energy metabolism.

2865/T

The winner's curse in meta-analysis of genome-wide association studies. *H. Nakaoka, H. Miura, I. Inoue.* Division of Molecular Life Science, School of Medicine, Tokai University, Isehara, Kanagawa, Japan.

Meta-analysis is a useful tool to enhance the statistical power to detect gene-disease associations by combining results from the original and subsequent replication studies. Recently, consortium-based meta-analyses of several genome-wide association (GWA) datasets have discovered new susceptibility genes of common diseases. Assessing consistency or heterogeneity of the associations across studies is an important aim of meta-analysis. There are two commonly used procedures for combining results from independent studies: fixed effects model (FEM) meta-analysis assumes that effect sizes are homogeneous across studies and all differences are due to chance and random effects model (REM) meta-analysis can incorporate between-study heterogeneity. We illustrated properties of test for and measures of between-study heterogeneity and effect of between-study heterogeneity on conclusions of meta-analyses via simulation study.

Our simulation shows that the use of FEM could increase the type I error rate even to the extent that the between-study heterogeneity could not be fully identified by Cochran's *Q* test and two measures (I^2 and H_M^2). We should note that the power of REM meta-analysis of GWA datasets (assuming that five to 20 GWA studies are combined and the total case-control sample size ranges from 5,000 to 20,000) to detect a small genetic effect (odds ratio [OR] = 1.4 under dominant model) decreases as between-study heterogeneity increases and then the mean of OR of the simulated meta-analyses passing the genome-wide significance threshold would be upwardly biased (referred to as "winner's curse" phenomenon). The estimates of mean OR were upwardly biased especially in simulation scenarios whose powers of detecting gene-disease associations were low. Additionally, we examined approaches to overcome and adjust the biases due to the winner's curse phenomenon.

The implication from the results of this simulation study is: i) the use of REM rather than FEM would be preferable to control false positive rate; ii) a study design of consortium-based meta-analysis of GWA datasets considering the presence of between-study heterogeneity would be constructed; and iii) further data accumulation after initial findings from GWA meta-analyses is needed to estimate unbiased effect sizes of the discovered gene-disease associations.

The PhenX Toolkit: Facilitating the use of common measures in genomics research. *H. Pan[1], D. Jackman[1], V. Bakalov[1], K. Chang[1], A. Flynn[1], W. Huggins[1], J. Levy[1], D. Nettles[1], Y. Qin[1], H. Ray[1], P. Schad[1], N. Whitehead[1], M. Zmuda[1], H. Junkins[2], E. Ramos[2], L. Strader[1], C. Hamilton[1].* 1) Research Computing Division, RTI International, Research Triangle Park, NC; 2) National Human Genome Research Institute, Bethesda, MD.

To facilitate cross-study comparisons, PhenX (consensus measures for Phenotypes and eXposures) created a Toolkit of common measures for researchers to use when designing genomics-based studies. The PhenX Toolkit provides the user with a web-based interface for searching, browsing and selecting PhenX Measures and protocols. For each PhenX Measure, the Toolkit provides the user with a brief description of the measure, the rationale for selecting the measure, protocol(s) for collecting the measure, and supporting documentation. The Toolkit contains over 200 measures (15 research domains). Measures for the six remaining domains will be included in the Toolkit by the end of 2010. To expand its utility, the PhenX Toolkit has extended its browse and search capabilities and its collaborative efforts. The “Smart Query Tool” provides the option to use either a high-specificity search through measure and protocol names, synonyms and keywords or a full-text search. The “Data Collection Worksheet” will enable Toolkit users to integrate PhenX measures into their studies more easily while the Data Dictionary provides users with variable names, identifiers and many attributes in several formats. Mapping PhenX measures and variables to related research efforts will facilitate data interoperability, thus helping Toolkit users combine and/or harmonize data. To demonstrate its utility, PhenX has mapped PhenX measures, protocols and/or variables to studies in dbGaP, the Public Population Project in Genomics’s (P3G) Data Schema and Harmonization Platform for Epidemiological Research (DataSHaPER), and electronic Medical Records and Genomics (eMERGE), and the results of mapping will be presented. PhenX measures are accessible using the caBIG CDE browser. Logical Observation Identifiers Names and Codes (LOINC) is developing LOINC codes for PhenX measures. These codes will make enable identification of PhenX variables in electronic medical records (EMRs), clinical data repositories and other resources, thus facilitating cross-study analysis. The PhenX Toolkit provides the research community with freely available, well-established, low-burden, high quality measures, and the bioinformatics support to use them effectively. Broad acceptance and use of PhenX Measures can facilitate identification of genes associated with common diseases, as well as gene-gene and gene-environment interactions. Supported by: NHGRI, Award No. U01 HG004597.

Elucidating the molecular etiology of asthma using genome-wide association study pathway analysis. *J.R. Huyghe[1], G. Van Camp[1], K. Van Steen[2].* 1) Department of Biomedical Sciences, University of Antwerp, Belgium; 2) Department of Electrical Engineering and Computer Science (Montefiore Institute), University of Liège, Belgium.

Genome-wide association studies (GWAS) have resulted in new insights in the biology of a substantial number of complex phenotypes. However, for most of the investigated phenotypes, the identified common SNPs cumulatively explain just a fraction of the total heritability. Yet, evidence exists that hundreds of common variants with very small effects account for a large portion of the missing heritability [1]. Their identification would require impossibly large sample sizes and by performing single SNP analysis these variants will be missed. In addition, gene-gene and gene-environment interactions, together with genetic and allelic heterogeneity may dilute power. Therefore, several investigators advocate GWAS Pathway Analysis (GWASPA) as a potentially more powerful complementary analysis to single SNP analysis [2,3]. In a GWASPA, pathway database information and, possibly, prior information regarding disease biology, is harnessed to statistically combine signals across sets of related genes. This study aims to carry out a GWASPA on the data from SHARP, the SHARe (SNP Health Association Resource) Asthma Resource Project, a large GWAS for asthma based on case-parent trios as well as independent cases [4]. Several different strategies for GWASPA have been proposed [2,3]. For any GWASPA, a number of important choices need to be made that affect the outcome of the analysis: i) How to define pathways? Which pathway database resource to use? Should prior information regarding pathways involved be used, or should an “agnostic” approach be used in which all pathways are considered? ii) How to map SNPs to genes? iii) How to score the pathways and to formally assess statistical significance? Moreover, several hurdles need to be taken, including adequately handling varying numbers of genes per pathway, varying numbers of SNPs per gene, varying SNP densities across the genome, linkage disequilibrium, multiple independent signals in one gene, and multiple testing. Special attention will be given to the multiple testing problem. In particular, strategies will be explored to reduce the computational burden of permutation tests. Methods to assess significance for case-parent trio data will be explored as well. We will present and motivate our analytic strategies. [1] Purcell, S.M. et al. (2009), Nature 460: 748-752; [2] Wang, K. et al. (2009), Am. J. Hum. Gen. 84: 399-405; [3] Holmans, P. et al. (2009), Am. J. Hum. Gen. 85: 13-24; [4] dbGaP accession number phs000166.v2.p1.

Multiethnic genetic association studies improve power for locus discovery. *S.L. Pulit[1,2], B.F. Voight[2], P.I.W. de Bakker[1,2,3,4].* 1) Division of Genetics, Department of Medicine, Brigham and Women’s Hospital, Harvard Medical School, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 3) Department of Medical Genetics, University Medical Center Utrecht, The Netherlands; 4) Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, The Netherlands.

To date, genome-wide association studies (GWAS) have focused predominantly on populations of European ancestry. The limitation of focusing on strictly European samples is exemplified by an association to type II diabetes recently discovered in East Asian samples. The association (in the *KCNQ1* locus) had little power to be detected in European samples (where the polymorphism had a minor allele frequency of ~5%), but had improved power to be discovered ($p < 5x10^{-8}$) in East Asian samples (at MAF ~40%) and replicated at a more liberal threshold in a European cohort. An approach for future GWAS would be to focus further efforts on cohorts of multiple ethnicities. This approach leverages the idea that population genetic drift may have elevated some variants to higher allele frequency in different populations, boosting statistical power to detect an association. Based on empirical allele frequency distributions from eleven worldwide populations represented in the new HapMap Phase 3 resource as well as pilot data from the 1000 Genomes Project, we simulate a range of genetic models to quantify the power of association studies in multiple ethnicities relative to studies that exclusively focus on samples of European descent. In each of these simulations, we perform a first phase of GWAS in strictly European samples (to mimic the first wave of GWAS already completed in samples of European ancestry) followed by a second GWAS phase in any one of the populations represented in HapMap 3 or the 1000 Genomes Project, as well as multiethnic population panels. We find that nontrivial power gains can be achieved by conducting future whole-genome studies in worldwide populations, where, in particular, African populations and multiethnic cohorts contribute the largest relative power gains for low-frequency alleles (<5%) of moderate effect that suffer from low power in samples of European descent. Our results emphasize the importance of broadening an imminent second wave of genetic studies to worldwide populations to ensure efficient discovery of genetic loci contributing to phenotypic trait variability, especially for those traits for which large numbers of samples of European ancestry have already been collected and tested.

2869/T

The use of abdominal adipose tissue gene expression and genotype data to identify novel genetic pathways involved in metabolic syndrome. *J.L. Min[1], R.X. Menezes[2], M. van Iterson[1], L. Parts[3], P.A.C. 't Hoen[1], G.J.B. van Ommen[1], J.T den Dunnen[1], J.M. Boer[1].* 1) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Epidemiology and Biostatistics, VU Medical Centre, Amsterdam, The Netherlands; 3) Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

Genome-wide association studies of complex traits have identified reproducible associations with modest effect sizes, with often unknown functional basis. The integrated analysis of genotypic and expression data for association with complex traits could identify novel genetic pathways involved in complex traits. However, linkage disequilibrium between SNPs, the abundance of eQTLs and confounding variation in gene expression data may decrease power to detect eQTL associations. Power to find eQTL associations can be greatly improved by accounting for global variation using factor analysis, and by analysing groups of genes rather than individual genes. Menezes (2009) *et al*. analysed DNA copy number and gene expression data from the HapMap individuals and detected additional associations using genesets. On abdominal fat gene expression data from 52 individuals kindly provided by the MolPAGE consortium, we re-analysed the genotype (Illumina 317k arrays) and expression data (Affymetrix hgu133plus2 arrays) by modelling genotype as a function of factor-analysis corrected gene expression levels using genesets. These genesets comprise expression levels of genes that are i) within a 1Mb interval of the SNP or ii) that belong to the same pathway or gene ontology class. Preliminary results showed 308 (uncorrected) and 434 (factor-corrected) significant SNP-geneset associations (FDR P < 0.01) whereas the gene-by gene model detected 650 (uncorrected) and 831 factor-corrected significant SNPs (FDR P < 0.01). The geneset model found 20 (31 SNPs) and 47 (68 SNPs) independent SNP-geneset associations (r^2 < 0.5) in addition to the gene-by-gene model. Of these, 25 and 37 SNPs were associated with multiple expression probesets. In addition, we tested 205 genesets that were grouped by KEGG pathway. Of these, 13 genesets were significantly associated with 13 SNPs (4 loci) that were in *cis* with at least one of the probesets in the geneset. These loci were overlapping with the 1 Mb window geneset or gene-by-gene eQTL associations suggesting the influence of a single expression probe in *cis* and a lack of pathway effects in *trans*. Our results strongly support *cis*-regulatory variation in abdominal fat extending over multiple genes that can be detected using genesets. Additional eQTL associations were found in the factor-corrected expression data. Using a similar approach, we will explore whether a group of SNPs - belonging to the same pathway - influences gene expression variation.

Novel statistical methods for combining genome-wide linkage and association analyses provide evidence of different genetic architecture for autism in the presence or absence of intellectual disability. *V. Vieland[1], J. Hallmayer[2], Y. Huang[1], A. Pagnamenta[3], D. Pinto[4], H. Khan[4], A.P. Monaco[3], A.D. Paterson[4], S.W. Scherer[4], J.S. Sutcliffe[5], P. Szatmari[6], Autism Genome Project.* 1) Battelle Ctr Math Med, Res Inst Nationwide Child Hosp, Columbus, OH; 2) Dept of Psychiatry, Division of Child and Adolescent Psychiatry and Child Development, Stanford Univ School of Medicine, Stanford, CA; 3) Wellcome Trust Centre for Human Genetics, Univ of Oxford, Oxford UK; 4) The Centre for Applied Genomics and Program in Genetics and Genomic Biology, The Hospital for Sick Children and Dept of Molecular Genetics, Univ of Toronto, ON; 5) Department of Molecular Physiology and Biophysics, Vanderbilt Kennedy Center, and Centers for Human Genetics Research and Molecular Neuroscience, Vanderbilt Univ, Nashville, TN; 6) Department of Psychiatry and Behavioural Neurosciences, McMaster Univ, Hamilton, ON.

Using novel adaptations of the PPL (posterior probability of linkage) framework to simulaneously analyze genome-wide linkage data on 1,069 multiplex autism families (with 10K genotypes) together with 1,129 autism trios (with 1M genotypes), we set out to identify genes involved in autism spectrum disorders (ASD), with a particular focus on whether different genes might be involved in causing ASD in the presence or absence of lower IQ (LIQ). We found multiple linked loci, and because the PPL can accumulate evidence against linkage as well as in favor of linkage, we were able to divide loci into those linked in LIQ families but unlinked in normal IQ (NIQ) families or vice versa. The LIQ group showed stronger and more numerous linkage peaks, suggesting more major gene effects. We then conducted genome-wide association analysis based on the posterior probability of trait-marker disequilibrium (PPLD), using PPLs from the multiplex families as prior linkage information going into PPLD analyses in the trios. PPLD-based evidence implicating specific genes was low even under the linkage peaks, however, overall the NIQ group yielded more loci with PPLD's > 10%, suggesting the possibility of greater contributions from multiple genes of smaller individual effect. In aggregate our results suggest that both the specific genes involved and also the genetic architecture of ASD may differ between the LIQ and NIQ families. Sequencing of particular candidate genes (CDH8, PTCHD1) implicated in these analyses and supported by independent evidence is ongoing.

Integration of genome-wide SNP and expression profiling data to identify candidate genes for brain arteriovenous malformation hemorrhage. *S.M. Weinsheimer[1], L. Pawlikowska[1], H. Xu[2], A.S. Achrol[1,3], B. Stamova[2], P.Y. Kwok[4,5], S. Sidney[6], J. Zaroff[6], C.E. McCulloch[7], F.R. Sharp[2], W.L. Young[1,8], H. Kim[1,7].* 1) Center for Cerebrovascular Research, Department of Anesthesia and Perioperative Care, University of California, San Francisco, San Francisco, CA; 2) Department of Neurology and MIND Institute, University of California, Davis, Sacramento, CA; 3) Department of Neurosurgery, Stanford University, Palo Alto, CA; 4) Cardiovascular Research Institute, University of California, San Francisco, San Francisco, CA; 5) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 6) Division of Research, Kaiser Permanente Northern California, Oakland, CA; 7) Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA; 8) Departments of Neurology and Neurological Surgery, University of California, San Francisco, San Francisco, CA.

Background: Brain arteriovenous malformations (BAVMs) occur throughout life, but are an especially important cause of intracranial hemorrhage (ICH) in young adults. To identify candidate genes associated with ICH presentation in BAVM patients, we have performed a genome-wide association study (GWAS) and a global profiling of blood gene expression in BAVM patients. Integrating data from these two genomic approaches may more accurately identify functional genes and expression quantitative trait loci (eQTLs) relevant for BAVM hemorrhage. **Methods:** We compared results from our GWAS study (with 127 ICH and 211 non-ICH patients) and blood gene expression profiling study (with 20 ICH and 20 non-ICH patients) to determine whether the genes and gene pathways identified in each study were similar. Pathway analysis was performed using WebGestalt software to provide a functional interpretation of the genes. We tested for significant overlap in genes identified between the two studies, and searched for eQTLs using linear regression in the subset of 12 patients (3 ICH, 9 non-ICH) with both genotype and expression data available. **Results:** Our GWAS identified 582 SNPs associated with ICH presentation (*P*<0.001). Of these, 372 (64%) SNPs mapped to +/- 100kb of 349 genes. Blood gene expression profiling identified 493 genes associated with ICH presentation (false discovery rate £0.1, fold-change≥1.2). Twelve genes (3.4% of 349) overlapped in the two approaches, although this number is not greater than expected by chance (*P*=0.23). However, all 12 genes are expressed in normal brain tissue, and 10 of these genes were also significantly decreased in the blood of hemorrhagic BAVM patients compared to unruptured patients. Although the majority of genes did not overlap between the two studies, they belong to similar functional pathways including Wnt signaling, MAPK signaling, T cell receptor signaling, and Natural killer cell mediated cytotoxicity pathways. eQTL analysis for the 12 overlapping genes resulted in 1 significant trans eQTL (Beta=0.74; *P*=2.25E-08) for the *LARGE* gene, and 2 marginally significant trans eQTLs (Beta=0.44; *P*=9.6E-08) for the *CLTA* gene. **Conclusions:** Comparison of results from GWAS and blood gene expression profiling studies revealed several candidate genes and pathways for BAVM hemorrhage. Integration of genotype and gene expression datasets may be a powerful tool to identify novel eQTLs that influence the expression of genes involved in BAVM hemorrhage.

A rigorous statistical framework for integrating multiple heterogeneous existing data sets. *J. Bukszár[1], A.N. Khachane[1], K. Åberg[1], Y. Liu[2], J.L. McClay[1], P.F. Sullivan[2], E.J. van den Oord[1]*. 1) Virginia Commonwealth Univ, Richmond, VA; 2) University of North Carolina, Chapel Hill, NC.

During the past decade, databases related to the genetic basis of complex diseases have grown exponentially. Examples are meta-analyses of genome linkage scans, published candidate gene studies, disease-specific biochemical pathways, and genome-wide association studies. Integrating these existing data into novel data collection studies has huge potential to increase the likelihood of identifying the genes affecting susceptibility to common diseases. This is because these data provide a freely available independent source of information and the convergence of evidence from data generated by different technologies reduces the risk of false discoveries. Because of the volume and heterogeneity of existing databases, there have been several efforts towards developing systematic data integration methods. A limitation of many of the proposed methods is that they lack a solid statistical basis. This hampers the optimal use of existing data in empirical research. For example, most approaches produce a prioritization score that indicates the disease relevance of a gene. However, it is typically very hard to assess the quality of that score, there are no tools to check whether the assumptions made to calculate the scores are accurate, and methods specifying how to optimally integrate these scores into novel data collections are lacking. Here, we propose a rigorous statistical framework for integrating multiple heterogeneous existing data sets into novel studies. Our framework can handle existing data and novel data collections generated by any kind of technology/activity and providing information about genetic units at any level (e.g., SNPs, genes, regions). Furthermore, it can be used in the case of a small number of relatively large genetic effects as well as scenarios involving a very large number of small effects. The end product of the data integration process is the compound local true discovery rate (ceTDR) that can be interpreted as the probability that a genetic marker is associated with the disease after taking all existing and novel data into account. Because it is formalized in a mathematical way, we can prove that our framework has numerous desirable properties. We demonstrate our framework using a large meta-analysis of schizophrenia GWAS. Results show that several of the external data sets were informative and that after integrating these data, SNPs that were likely to have effects were much more reliably separated from those without effect.

The extent and nature of epistasis among expression quantitative trait loci (eQTLs). *W. Bush, S. Turner.* Ctr Human Gen, Vanderbilt Univ, Nashville, TN.

Epistasis is often proposed as an important part of complex disease architecture, but the detection and confirmation of epistasis has proven difficult. An often cited rationale for examining epistasis is that combinations of genetic variants may influence gene expression in complex dynamic systems. Recent studies have explored and identified single nucleotide polymorphisms that alter the expression of genes in lymphoblastoid cell lines isolated from multiple human subpopulations -- so called eQTLs. Often, multiple SNPs near a gene of interest are identified, some of which likely represent independent genetic effects. In this work, we analyze the degree and extent to which there is non-linear interaction among eQTL SNPs for the genes they regulate. We identified genes with more than one eQTL SNP with ANOVA p-values < 5e-3 from the work of Veyrieras et al. eQTL SNPs were pruned so that no two SNPs have an r-squared > 0.1 to minimize haplotype effects. We then fit multi-locus association models for each gene, and statistically test the influence of SNP-SNP interactions using R^2 difference tests. From this analysis, we assess the role that regional (or cis) epistasis plays in altering expression of human genes, which could ultimately lead to testable multi-locus models for studies of human phenotypes.

2874/T

Non-independence and transmission bias of pathway-based allele combinations. *J. Haines, W. Bush.* Ctr Human Genetics, Vanderbilt Univ Medical Ctr, Nashville, TN.

Epistasis is thought to be a pervasive part of complex phenotypes due to the dynamics and complexity of biological systems, and a further understanding of epistasis in the context of biological pathways may provide insight into the etiology of complex disease. The International HapMap Project characterizes the structural dependencies between alleles of the human genome in multiple human populations. In this study, we use genotype data from the HapMap project to characterize potential dependencies between alleles of genes that have related biological functions. Using a collection of KEGG pathways, we performed chi-square tests to identify non-independence between the genotypes of SNP pairs from functionally related genes within parental Caucasian and Yoruba samples. We further refine this list of SNP pairs by testing for the over- or under-transmission of pseudo-haplotypes to offspring in the sample using a haplotype-based TDT test. From these analyses, we identify pathways enriched for non-independent genotypes in both Caucasian and Yoruba populations. We also identify a set of 863 SNP pairs (representing 453 gene pairs) with consistent non-independence of genotypes and consistent transmission distortion (by TDT) of the same pseudo-haplotype in both Caucasian and Yoruba populations. These results represent allele pairs with strong evidence of epistasis within the context of a biological function, potentially due to co-selection of alleles in response to the environment.

Initialization Parameter Sweep in ATHENA: Optimizing Neural Networks for Detecting Gene-Gene Interactions in Simple and Complex Disease Models. *E. Holzinger, C. Buchanan, S. Turner, E. Torstenson, S. Dudek, M. Ritchie.* Ctr Human Gen Res, Vanderbilt Univ, Nashville, TN.

Recent advances in genotyping technology have led to the generation of an enormous quantity of genetic data. Traditional methods of statistical analysis have proved insufficient in extracting all of the information about the genetic components of common, complex human diseases. A contributing factor to the problem of analysis is that amongst the small main effects of each single gene on disease susceptibility, there are non-linear, gene-gene interactions that can be difficult for traditional, parametric analyses to detect. In addition, exhaustively searching all multi-locus combinations has proved computationally impractical. Novel strategies for analysis have been developed to address these issues. The Analysis Tool for Heritable and Environmental Network Associations (ATHENA) is an analytical tool that incorporates grammatical evolution neural networks (GENN) to detect interactions among genetic factors. Initial parameters define how the evolutionary process will be implemented. This research addresses how different parameter settings affect detection of disease models involving interactions. In the current study, we iterate over multiple parameter values to determine which combinations appear optimal for detecting interactions in simulated data for both a simple two-locus model, as well as a more complex three-locus model.

Detection of SNP-SNP interactions in case-parent trios, with applications to a study of oral clefts. *H. Schwender[1,2], S.-C. Jin[3], T. Wu[3,4], R.A. Redett[5], G. Raymond[5], Y.H. Wu-Chou[6], H. Wang[5], X. Ye[7,8], S. Huang[9], V. Yeow[10], S.S. Chong[11], S.H. Jee[12], J.B. Hetmanski[3], K.Y. Liang[2], T.H. Beaty[3], K. Ickstadt[1], I. Ruczinski[2].* 1) Department of Statistics, TU Dortmund University, Dortmund, Germany; 2) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA; 3) Department of Epidemiology, Bloomberg School of Public Health, John Hopkins University, Baltimore, MD, USA; 4) Peking University Health Science Center, Beijing, China; 5) School of Medicine, Johns Hopkins University, Baltimore, Maryland, USA; 6) Chang Gung Memorial Hospital, Taoyuan, Taiwan; 7) Mt. Sinai Medical School, New York, New York, USA; 8) Wuhan University, Wuhan, China; 9) Peking Union Medical College, Beijing, China; 10) KK Women's and Children's Hospital, Singapore; 11) National University of Singapore, Singapore; 12) Epidemiology and Health Promotion, Yonsei University, Seoul, Korea.

Numerous methods have been proposed for the detection of interactions between genetic markers, particularly SNPs, in population-based association studies. However, only a few such procedures have been devised for case-parent trio data. One of these exceptions is an extension of the genotypic transmission disequilibrium test (gTDT) to two-way epistatic interactions. Another example is trio logic regression, an adaptation of logic regression originally developed for population-based designs, which makes it possible to detect higher-order SNP-SNP interactions.

In this presentation, we first show how a permutation-based gTDT procedure can be employed to identify the most significant two-way interactions in genotype data from a case-parent study concerned with cleft lip with or without cleft palate. We then investigate potential higher-order interactions using trio logic regression, and propose a resampling method that applies trio logic regression to several subsets of the data, and summarizes the results over the different applications. This approach stabilizes the results of trio logic regression, and quantifies the contribution of the detected interactions to overall disease risk. We demonstrate via a simulation study that this approach has the capability to identify disease-associated SNP-SNP interactions, even if their actual effect size is modest. This procedure is also applied to a set of SNPs from 10 candidate genes in the case-parent trio study concerned with oral clefts. In this application, an interaction of 3 SNPs from the FGF10 gene is identified that yields an odds ratio of about 6.1 and a p-value of $9.68 * 10^{12}$.

A comparison of multifactor dimensionality reduction and L1-penalized regression to identify gene-gene interactions in genetic association studies. *S.J. Winham[1], A.A. Motsinger-Reif[1,2].* 1) Department of Statistics, North Carolina State University, Raleigh, NC; 2) Bioinformatics Research Center, North Carolina State University, Raleigh, NC.

In recent years, research in the area of genetic epidemiology has exploded, creating a wealth of high-dimensional data and new analytical challenges. In addition, much evidence suggests that common, complex diseases may be due to complex etiologies such as gene-gene and gene-environment interactions, and these types of interactions are difficult to identify in high-dimensional data using traditional statistical approaches. Therefore data-mining approaches designed to sift through large amounts of data are gaining popularity for association studies, performing variable selection and statistical modeling simultaneously. One of the most commonly used data-mining approaches to evaluate potential gene-gene interactions is Multifactor Dimensionality Reduction (MDR), designed specifically to address this problem. However, variable selection is a hot topic in the field of statistics, and a number of penalized regression techniques have emerged, like the Least Absolute Shrinkage and Selection Operator (Lasso). Lasso has exploded in popularity within the statistical community, and is now being applied for variable selection in human genetics, including extensions for interactions in GWA studies. In this study we compare the performance of both MDR and Lasso to detect gene-gene interactions. We consider two different Lasso approaches, the traditional (ungrouped) L1 penalty (TL1) and the group L1 penalty for categorical data (GL1). Through simulation, we compare the performance of MDR, GL1, and TL1 in regards to power to identify gene-gene interactions, the number of identified loci, and true and false positive rates under a wide range of genetic models and effect sizes. Unsurprisingly, we find that each method has both advantages and disadvantages, and our results are context dependent. GL1 is frequently superior to TL1, which tends to over-fit, identifying false positive as well as true positive loci. MDR has higher power to detect interactions for models which also exhibit independent main effects; for both types of Lasso the main effects tend to dominate and the interaction effects are missed. When the model is purely epistatic, GL1 outperforms MDR and TL1 for lower minor allele frequencies, whereas MDR outperforms GL1 and TL1 for higher frequencies. The results of these simulations provide general recommendations of when each of the three approaches might be best suited for detecting and characterizing interactions with different mechanisms.

Dose Genetic Regulation of IgE Begin In-Utero - Evidence from T_H1/T_H2 Gene Polymorphisms and Cord Blood Total IgE. *H.-J. Tsai[1,3], X. Hong[1,2], X. Liu[1,2], L. Arguelles[2], R. Kumar[4], G. Wang[2], N. Kuptsova-Clarkson[2], C. Pearson[5], K. Ortiz[5], A. Bonzagni[5], S. Apollon[5], L. Fu[2], J. Pongracic[4], R. Schleimer[6], P. Holt[7], H. Bauchner[5], X. Wang[1,2].* 1) Dept Pediatrics, Northwestern Univ Sch Med, Chicago, IL; 2) The Mary Ann and J. Milburn Smith Child Health Research Program, Children's Memorial Hospital and Children's Memorial Research Center, Chicago, IL; 3) Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan; 4) Division of Allergy and Immunology, Children's Memorial Hospital,Chicago, IL; 5) Department of Pediatrics, Boston University School of Medicine and Boston Medical Center, Boston, MA; 6) Division of Allergy-Immunology, Northwestern Feinberg School of Medicine, Chicago, IL; 7) Division of Cell Biology, Telethon Institute for Child Health Research, West Perth 6872, Western Australia.

Background: Elucidation of early life factors is critical to understand the development of allergic diseases which mostly manifest in the first few years of life. In contrast to numerous genetic studies of blood total IgE, few studies were conducted to identify genetic determinants of cord blood IgE (CBIgE). Objective: To test associations between genes involved in the T_H1/T_H2 pathway and CBIgE obtained at birth in a large U.S. inner-city birth cohort. Methods: CBIgE, was measured by Phadia ImmnunoCAP. It was analyzed as a continuous outcome (log_{10}-transformed CBIgE) and a binary outcome (detectable CBIgE $\geq$ 0.1kU/L). The association of each SNP with the two outcomes was tested using multiple tobit regression and logistic regression models, respectively, with adjustment of pertinent covariates, ancestry proportion, and multiple testing. Ethnic heterogeneity and gene-gene (GxG) interactions were also explored. Results: Three SNPs (rs1800925, rs2069743 and rs1295686) in IL13 gene were significantly associated with CBIgE levels (p £$6x10^{-4}$, pFDR<0.05). These SNPs jointly influenced CBIgE level in a dose-response manner (ptrend=$9.4x10^{-8}$). Significant associations were observed for the SNPs in IL13RA1 (rs5956080) and STAT6 (rs11172106) genes. Ethnicity-specific effects were observed for SNPs in IL5 (rs4143832) and GATA3 (rs570613) genes. Several statistically significant GxG interactions were detected (i.e. IL13 and IL4R, IL13 and STAT6, IL13RA1 and JAK2, STAT3 and JAK1) in relation to the two CBIgE outcomes. Conclusion: Our data demonstrated that multiple SNPs were individually and jointly associated with CBIgE, with evidence of gene-gene interactions and ethnic heterogeneity. Our finding suggests genetic regulation of IgE may begin in-utero.

Accelerating Detection of Genetic Interactions in Genome-wide Association Studies using Graphics Processing Units. *S. Chikkagoudar[1], K. Wang[2], M. Li[1].* 1) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Most of the published Genome-wide association studies (GWAS) report results from single marker based analysis in which each SNP is analyzed individually. There is growing evidence that gene-gene interactions are important contributors to genetic variation in complex human diseases. However, detecting gene-gene interactions in whole-genome level remains a challenge due to the lack of powerful and computationally efficient methods. The most commonly used method for studying such interactions is to use a regression framework in which a pair of markers and their interaction terms are included as predictors. However, such analysis is computationally intensive when a large number of markers are available for testing, such as when analyzing typical GWAS datasets. It is infeasible to test for all pairwise interactions using traditional CPU computing even with small-scale computing clusters. However, gene-gene interaction analysis is parallelizable in nature. Parallel computing until recently meant using a computing cluster having multiple nodes or CPUs. The costs of building and using a computing cluster may run in hundreds of thousands of dollars. An emerging economical scientific computing paradigm is to use Graphics Processing Units (GPUs) that are present in graphic cards of most desktop computers for general purpose computing. A GPU is a processor that was traditionally used for accelerating graphical operations. A typical graphics card has several processors as well as its own dedicated memory. The computing power offered by the latest graphic cards is comparable to that of a computing cluster with hundreds of core processors, but the GPU programming approach for parallel computing is much cheaper. Our software package analyzes gene-gene interaction using the power of GPU computing to analyze several SNP pairs in parallel. The algorithm is scalable and can handle large datasets. First, the dataset is split into several fragments of a fixed size, where each fragment contains a different set of SNPs. Second, all the SNP pairs within each fragment are analyzed in parallel, and then the SNP pairs between fragments are analyzed in parallel. Finally, we report the results for those SNP pairs that meet a certain p-value threshold. We used a NVIDIA Geforce 9800GT card that costs $120 to test the algorithm. Our algorithm achieves a speed up of 5.8 times over its CPU implementation for a test dataset containing one fragment of 224 SNPs and 1077 individuals.

Scott[2].* 1) Dept Epidemiology, Johns Hopkins Univ,Sch Pub Hlth, Baltimore, MD; 2) Johns Hopkins Univ, Sch of Medicine, Baltimore MD; 3) University of Iowa, Dept of Pediatrics, Iowa City IA; 4) University of Pittsburgh, Sch Dental Medicine, Pittsburgh PA; 5) Utah State University, Logan UT; 6) NIEHS/NIH, Durham NC; 7) University of Bergen, Bergen Norway; 8) Mount Sinai Medical Sch, New York NY; 9) Chang Gung Memorial Hospital, Taoyuan Taiwan; 10) Peking University Health Sciences Center, Sch Pub Hlth, Beijing PRC; 11) Wuhan University, Wuhan PRC; 12) Peking Union Medical College, Beijing PRC; 13) KK Womens and Childrens Hospital, Singapore, Singapore; 14) National University of Singapore, Singapore, Singapore; 15) Yonsei University, Seoul, Korea; 16) Sichuan University, West China Sch of Stomatology, Chengdu, PRC; 17) University of Southern Denmark, Odense, Denmark; 18) Center of Inherited Disease Research, Johns Hopkins Univ. Baltimore MD.

Cleft palate (CP) is a complex and heterogeneous birth defect which shows strong evidence of genetic control, although multiple causal genes are likely and several environmental risk factors (generally maternal exposures) may interact with such genes. We conducted a genome wide association study (GWAS) using 550 case-parent trios drawn from an international consortium to screen for genetic risk factors while testing for gene-environment (GxE) interaction with 3 common maternal exposures: smoking, alcohol consumption during the peri-conceptual period and multivitamin supplementation during pregnancy. Conventional transmission disequilibrium tests (TDT) for all autosomal and X-linked SNPs showed none achieving genome wide significance in this sample of 550 trios when maternal exposures were ignored. We used PBAT to screen all autosomal markers for GxE interaction with (1) a 2 df test for gene effects (G) and GxE interaction considered together, and (2) a 1 df test for GxE interaction alone. Markers in 16 different genes/regions showed substantial increases in statistical significance, giving p-values$<10^{-6}$ in either the 2 df or the 1 df test. Conditional logistic regression models were then used to estimate the odds ratio for SNP effects with and without exposure [i.e. OR(CP|G no E) and OR(CP|G and E)], where the target allele was fixed as the apparent high-risk allele. Five genes showed compelling evidence of GxE interaction with maternal exposures: MLLT3 and SMC2 with maternal alcohol consumption; and OBSCN, TBK1 and ZNF236 with maternal smoking. ACOXL and BAALC also showed suggestive evidence of GxE interaction with maternal vitamin supplementation. While most of these genes appeared to represent “pure interaction” where both the high-risk allele and the maternal exposure were necessary to see any increase in OR(CP|G and E), OBSCN seems to represent “quantitative interaction” where OR(CP|G no E) was statistically significant and exposure enhanced the effect of these markers.

Study of a Polynesian genetic isolate underscores gene environment interaction in biliary atresia. *A. Henrion Caude[1], M. Girard[1], A.L. Leutenegger[2], M. Besnard[3], A.S. Jannot[1], D. Vernerey[1], M. Sahbatou[2], P. Chune[4], C. Tetaria[4], A. Munnich[1], O. Bernard[5], S. Lyonnet[1], E. Jacquemin[5].* 1) Inserm U781, Department of Genetics, Hôpital Necker-Enfants Malades, Université René Descartes, Paris, FRANCE; 2) Fondation Jean DAUSSET - C.E.P.H. - Paris, FRANCE; 3) Centre Hospitalier territorial, Papeete, Tahiti, POLYNESIE FRANCAISE; 4) Banque d’ADN de Polynésie, Papeete, Tahiti, POLYNESIE FRANCAISE; 5) Department of Pediatric Hepatology, Hôpital Bicêtre, Kremlin-Bicêtre, FRANCE.

Despites a century-old characterization of biliary atresia (BA), nothing is commonly assumed about heritability of this disease, its onset, its susceptibility factors nor its physiopathology. In this study, we provide the clues to thoroughly revisit BA as a dynamic complex disease, related to genetic ancestry. Among the 152,866 children born in French Polynesia between 1979 and 2009, 40 had biliary atresia accounting for an incidence of 26.1/100,000 live births, which is the highest incidence worldwide. Epidemiologic data and follow-up study over 30 years period reveal statistically significant two-dimensional influence of environment. We further identified that temporality of BA significantly fitted a sinusoidal model. In all 40 patients, we also studied genealogic and clinical data. Genome-wide analyses of 250,000 SNPs in 24 patients and their parents were performed. Genetic isolate was evidenced by genealogy, inbreeding coefficient calculation (F=0.045) and principal component analysis. Contribution of environmental factors was integrated into an original statistical modeling. While homozygosity mapping revealed no significantly shared region, suggestive linkage to chromosome 2q13.1 was identified in patients with environmental constraint. Transmission disequilibrium test analysis further identified suggestive association with SNPs from 14 loci. Using bioinformatics, we could identify that the majority of genes that were encompassed in those loci were involved in the same highly significant morphogenetic pathway, specific of liver. Our findings provide a novel view of a complex genetic make-up in an isolate population underlying BA. As such, our design unveils an approach to study the contribution of both ethnic and environmental factors in a rare disease with a complex genetic background.

Empirical tests for compositional epistasis. *T.J. VanderWeele.* Department of Epidemiology, Harvard School of Public Health, Boston, MA.

The term “epistasis” is sometimes used to describe some form of statistical interaction between genetic factors and is alternatively sometimes used to describe instances in which the effect of a particular genetic variant is masked by a variant at another locus. The latter use of the term is sometimes referred to as “compositional epistasis.” In general statistical tests for interaction are of limited use in detecting compositional epistasis. It is, however, shown that there are relations between empirical data patterns and compositional epistasis that have not been previously noted. These relations can sometimes be exploited to empirically test for compositional epistasis in the sense of the masking of the effect of a particular genetic variant by a variant at another locus. The methods are illustrated by an example concerning possible epistatic interaction between HLA-DRB1 and R620W PTPN22 polymorphisms on anti-CCP-Positive rheumatoid arthritis.

Epistatic relations between MAP2K4 and PTPN22 in development of rheumatoid arthritis. *K. Shchetynsky[1], M. Ronninger[1], B. Ding[2], L. Klareskog[1], L. Alfredsson[2], L. Padyukov[1].* 1) Rheumatology Unit, Department of Medicine, Karolinska Institutet/Karolinska University Hospital Stockholm, Sweden; 2) Institute for Environmental Medicine, Karolinska Institutet, Stockholm, Sweden.

HLA-DRB1 shared epitope (SE) alleles and PTPN22 alleles have been established as the two major genetic risk factors for autoantibody-positive rheumatoid arthritis (RA). Recently, MAP2K4 locus has been identified as being in statistical interaction with HLA-DRB1 in RA patients with anti-citrullinated protein antibody (ACPA). MAP2K4 encodes a dual specificity protein kinase (MKK4) that has been earlier demonstrated to promote JNK activation in rheumatic diseases. The aim of this study was to address possible epistasis between MAP2K4 and PTPN22 genes. This study was based on genome-wide association study data for 1921 RA cases and 1079 healthy controls included in the Swedish Epidemiological Investigation of Rheumatoid Arthritis (EIRA) study population. The analysis was performed on 22 SNPs from MAP2K4 locus and rs2476601 from PTPN22. To assess genetic interaction, the attributable proportion due to interaction (AP) was calculated. AP was interpreted as the proportion of RA cases that can be attributed to the interaction *per se* in specified combinations of alleles. We performed separate analyses according to ACPA status among the cases as well as according to presence of SE alleles in the cohort. In our analysis, SNPs rs8078439, rs9895159, rs2013868, rs2169161, rs7212043 from MAP2K4 gene, when combined with rs2476601 from PTPN22 provided a more than additive increase in risk of ACPA-positive RA (AP 0.33 [95% CI 0.08-0.57], AP 0.49 [95% CI 0.19-0.79], AP 0.47 [95% CI 0.25-0.69], AP 0.46 [95% CI 0.24-0.68], AP 0.5 [95% CI 0.3-0.71], respectively). Additionally, rs9895159, rs2013868, rs2169161, rs7212043 demonstrated significant interaction with rs2476601 regarding ACPA-positive RA in absence of SE alleles (AP 0.61 [95% CI 0.16-1.05], AP 0.5 [95% CI 0.12-0.88], AP 0.46 [95% CI 0.05-0.87], AP 0.54 [95% CI 0.19-0.89], respectively). However, none of these interactions could be observed for ACPA-negative RA. This study implies that combinations of polymorphisms in MAP2K4 and PTPN22 may characterize a novel genetic risk factor for autoantibody-positive RA. These epistatic relations may also point at a signalling pathway important in RA development.

Gene-by-Environment Interaction in Studies Based on Nuclear Families. *M. Shi, DM. Umbach, CR. Weinberg.* Biostatistics Br, NIEHS, Res Triangle Park, NC.

Several proposed methods for examining haplotype-exposure interactions use data from affected individuals and their parents. Unfortunately, that design cannot assess the effects of exposure, limiting the interpretability of identified interactions. Motivated by the Two Sister Study, an ongoing study of families affected by young-onset breast cancer, we consider a design that supplements the case-parents design with an unaffected sibling who is not genotyped but provides exposure data. If, in the population at large, inheritance is Mendelian and haplotypes do not influence propensity for exposure, then this tetrad structure permits the study of genetic effects, exposure effects, and gene-by-exposure interactions. In the presence of exposure-related population stratification, the traditional gene-by-environment analysis of data from the case-parent design may be biased, a phenomenon not well recognized by investigators. We document this bias and then show that it can be ameliorated by careful adjustment using the tetrad design. When some genotypes or some family members are missing, one can use available software to infer the list of possible diplotypes for family members and then use multiple imputation to estimate parameters and perform statistical tests. We present findings from simulation studies to compare the performance of the tetrad design with that of the case-parents and the discordant sib-pairs designs in testing gene-by-exposure interaction. We compare both type I error rates and power under a range of scenarios. We also identify circumstances under which one can improve efficiency by additionally studying one or more unaffected offspring.

A likelihood approach to testing for and estimating additive gene-environment interaction in case-control studies. *S. Wang[1], L. Sheppard[1,2], B. Weir[1,3].* 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Department of Environmental and Occupational Health Sciences, University of Washington, Seattle, WA; 3) Department of Genome Sciences, University of Washington, Seattle WA.

The recent development of genome-wide genotyping technology has provided new opportunities in finding major genetic factors that contribute to the risk of complex diseases and also spawned numerous studies of gene-environment interaction (G X E). However, to date there are relatively few examples of replicated and biologically plausible G X E findings in the literature. One possible reason for this phenomenon is the lack of adequate statistical power in many studies. Another possible reason is that many G X E studies have been limited to testing for multiplicative interaction due in part to the fact that multiplicative models are more accessible than additive models. Despite the lack of studies, additive interaction is considered to be more biologically relevant than multiplicative interaction. We propose a likelihood ratio test (LRT) for statistical additive interaction between genetic and environmental factors in case-control studies. This proposed LRT is useful not only for detecting additive gene-environment interaction, it also produces a maximum likelihood estimate (MLE) of interaction contrast ratio (ICR, a measure of additive interaction) and provides confidence intervals (CIs) for the ICR estimate based on profile likelihood. To illustrate this method we apply it to the data set obtained from a case-control study of venous thromboembolism in relation to factor V Leiden allele and oral contraceptive (OC) use (Botto and Khoury 2001 and reference therein). Our proposed LRT finds no evidence of statistical additive interaction between factor V Leiden allele and OC use at a significance level of 0.05. The MLE of ICR obtained from our proposed likelihood approach equals to that obtained from odds ratios. The profile likelihood-based 95 percent CI for this ICR estimate is skewed to the left and contains the value zero. We also conduct simulation studies to compare the performance of the profile likelihood-based CI resulting from our proposed LRT with that obtained from the best method currently available for estimating CIs of additive interaction estimates. The results of these simulation studies show that our proposed method and this available method perform equally well for estimating CIs of ICR estimates. However, as our proposed method is oriented for hypothesis testing, it can be used more conveniently for screening a large number of combinations of SNPs and environmental exposures to detect interactions in genome-wide association studies.

Gene-gene associations in the apoptosis pathway and breast cancer risk. *R. Abo[1], A. Cox[2], MWR. Reed[2], M. Parry[2], S. Rigas[2], N. Camp[1].* 1) Univ Utah, Salt Lake City, UT; 2) University of Sheffield, Sheffield, UK.

Missing heritability in common diseases may be due to rare variants and gene-gene effects. Haplotype analyses provide more power for rare variants and joint analyses across genes can address multi-gene effects. The recent CASP8 variant (Cox et al. 2007) and haplotype (Shephard et al. 2009) associations with breast cancer provide CASP8 as a candidate for potential gene-gene effects with other apoptosis genes. Here we present a gene-gene data-mining analysis based on three genes that encode proteins that interact in the extrinsic apoptosis pathway: CASP8, TNFRSF10B and TNFRSF10A. Breast cancer cases and controls were from Sheffield, UK (n=1843). The method for analysis is an extension of our haplotype-mining software, and allows construction of multi-locus SNP sets at two genes and tests joint gene-gene effects and interactions between single variants or haplotype combinations. A Monte Carlo framework is used to provide statistical significance assessment of the joint and interaction statistics. All three gene pairs were analyzed using the gene-gene mining approach based on 100,000 simulations for assessment of empirical p-values. For all three gene pairs, several results reached the most significance possible empirical p-value with 100,000 simulations (P<1.0 x 10-5). All of the top results consisted of a two-locus haplotype at one gene interacting with a single variant in the other gene. For CASP8-TNFRSF10A, four interactions were suggested: three identified with interaction odds ratios statistics (IOR=5.86, 4.72, 3.45 with corresponding P<1.0 x 10-5 for the first two and P=8.0 x 10-5); the fourth was identified with the correlation statistic (P=4.0 x 10-5). The CASP8-TNFRSF10B analysis also produced four interactions with the IOR statistic (IOR=3.27-7.40, all P < 1.0 x 10-5). Five interactions were suggested in the TNFRSF10A-TNFRSF10B analysis, four with IOR and one with the correlation statistic. Two of these findings suggested a positive epistatic effect in disease risk (IOR=3.97, 4.53, both P < 1.0 x 10-5), while the other two findings suggested a negative effect (IOR=0.255, 0.217, both P < 1.0 x 10-5). The correlation statistic achieved P=7.0 x 10-5. These results illustrate the potential of our gene-gene approach to identify statistical interactions between biologically relevant genes that may be responsible for contributing to breast cancer risk. Assessment of construction-wide significance is now required to interpret these findings.

Gene-environment interactions in genome-wide association studies: A comparative study of tests applied to empirical studies of type 2 diabetes. *M.C Cornelis[1], E.J Tchetgen[2,3], L. Liang[2,3], L. Qi[1], N. Chatterjee[4], F.B Hu[1,2], P. Kraft[2,3].* 1) Nutrition, Harvard School of Public Health, Boston, MA; 2) Epidemiology, Harvard School of Public Health, Boston, MA; 3) Biostatistics, Harvard School of Public Health, Boston, MA; 4) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health and Human Services, Rockville, MD.

The most effective statistical approach to investigating gene-environment (GXE) interactions in the context of genome-wide association studies (GWAS) remains unresolved. Using two case-control GWAS of type 2 diabetes (T2D), we present a comparative study of five tests for interactions: (i) standard logistic-regression-based case-control; (ii) case-only; (iii) semi-parametric maximum-likelihood estimation (semiMLE) (iv) an empirical-Bayes (EB) shrinkage estimator; and (v) a two-stage test. We also compared two joint tests of genetic main effects and GXE interaction: (i)joint and ii) semiMLE joint tests. Elevated body mass index (BMI) was the exposure of interest and modeled as a binary trait based on our findings of inflated Type I error in tests of interaction when the environmental main effect is misspecified. Single nucleotide polymorphisms (SNPs) with the most significant GXE interactions using the standard test were also strongly correlated with the exposure among controls. A similar, but less dramatic, pattern was observed for the EB and two-stage tests, while the case-only and semiMLE interaction tests were not correlated with tests of G-E independence among controls. Both joint tests detected markers with known marginal effects, and yielded similar or markedly smaller P values for SNPs in TCF7L2 (marginal P=3.4E-7 and 1.5E-4 versus joint P<8.3E-7 and 2.3E-7 in men and women, respectively). However, a marginal effect model adjusted for BMI produced similar results to those of the joint tests. In summary, our findings suggest that statistical methods which exploit G-E independence are efficient and robust options to investigating GXE interactions in GWAS. In contrast, tests that incorporate the standard GXE interaction parameter are liable to detect markers that are associated with the exposure by chance and should be interpreted with caution. Finally, joint tests of genetic main effects and GXE interaction can be powerful approaches to enhancing the detection of disease loci.

Gene-Gene Interaction between ROBO1 and RORA in Neovascular Age-related Macular Degeneration. *G. Jun[1,2,3], M. Nicolaou[1], M.A. Morrison[4], I.K. Kim[4], D.A. Schaumberg[5], M.G. Kotoula[6], E.E. Tsironi[6], F. Zacharaki[6], G.S. Hageman[7], L.A. Farrer[1,2,3,8,9], M.M. DeAngelis[4].* 1) Medicine, Boston University School of Medicine, Boston, MA; 2) Ophthalmology, Boston University School of Medicine, Boston, MA; 3) Biostatistics, Boston University School of Public Health, Boston, MA; 4) Ophthalmology, Massachusetts Eye & Ear Infirmary, Boston, MA; 5) Division of Preventive Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 6) Medicine, University of Thessaly, Larissa, Greece; 7) Ophthalmology & Visual Sciences, John A. Moran Eye Center, Salt Lake, UT; 8) Neurology, Boston University School of Medicine, Boston, MA; 9) Epidemiology, Boston University School of Public Health, Boston, MA.

ROBO1 is a strong candidate gene for neovascular age-related macular degeneration (AMD) based upon its location under a linkage peak on chromosome 3p12, its expression pattern, and its purported function in a pathway that includes RORA, a gene previously associated with neovascular AMD risk. Previously, we observed that expression of ROBO1 and RORA was down-regulated among neovascular AMD cases, as compared to unaffected siblings. Thus, we hypothesized that AMD risk is increased by an interaction of these two genes. Using Taqman and Sequenom assays, we genotyped 31 single nucleotide polymorphisms (SNPs) in ROBO1 and tested association for neovascular AMD (unaffected = normal, AREDS category 2, or AREDS category 3; affected = neovascular AMD) in two cohorts including 226 discordant and 87 concordantly affected sibpairs from New England and 261 unrelated subjects from central Greece (139 affected and 121 unaffected). We selected 5 SNPs (rs730754, rs8034864, rs12900948, rs17237514, rs4335725) in RORA that previously showed association with neovascular AMD in three diverse cohorts and 16 SNPs in ROBO1 that were moderately significant in the family cohort ($P < 0.05$) to test gene-gene interaction. Tests of all models including one of the 16 ROBO1 SNPs, one of the 5 RORA SNPs and an interaction term in the two cohorts analyzed separately using the program UNPHASED revealed significant interaction between 9 SNPs in ROBO1 and rs8034864 in RORA after adjustment for multiple testing (meta $P < 6 \times 10^{-4}$). No other SNPs in RORA showed significant interaction with ROBO1 SNPs at the permuted significance threshold of $P < 0.001$. These findings suggest that the effects of the ROBO1 and RORA genes on neovascular AMD risk are not independent and that further functional studies of these genes are warranted.

A machine learning approach for genome-wide interaction analysis. *U. Masao, T. Gen.* Yamagata University, Yamagata, Japan.

Nowadays genome-wide association studies (GWAS) using single nucleotide polymorphisms (SNPs) to identify human diseases-susceptible genes have been popularly employed. However, geneticists come to recognize that gene-gene (epistatic) interactions should be considered rather than single-locus weak effects (Cordell 2009, Nat Rev Genet). It may be inevitable that, without allowing for the gene-gene interaction, we will miss a large proportion of genetic component contributing to heritability for human complex common diseases. Direct application of commonly used methods for the recent GWAS, such as the Bonferroni's correction, to gene-gene interactions analysis incurs several problems. Among them, computational burden and difficulty in setting overall p-value for testing are extremely serious. The former restricts the algorithm to be much simple, whereas the latter is a theoretical problem that no efficient and universal approach is proposed so far. The main reason is that the number of SNPs is too large (typically 300k-1,000k SNPs should be handled) and, hence, that of the interactions between SNPs turns out to be ultra huge, indicating that Bonferroni's correction can be undesirably conservative. Instead of conventional hypothesis testing, we developed a new software implementing a logistic regression-based machine learning approach, which allows to complete an exhaustive search for SNP by SNP interaction in non-filtered large GWAS data within several days under common computing environments and to avoid multicollinearity due to these highly-correlated SNPs. Our fast program was applied to find some novel genetic components in the WTCCC (Wellcome Trust Case-Control Consortium) data.

GxG interactions potentially account for the blood pressure linkage peak on chromosome 2 in the Old Order Amish. *M. Montasser, Y. Chang, Y. Wang, J. O'Connell, A. Shuldiner, B. Mitchell, N. Steinle.* Endocrinology Diabetes & Nutri, Univ Maryland Sch Med, Baltimore, MD.

Blood pressure is a complex trait regulated by environmental and genetic components, as well as the interaction between them.While the environmental components are very well established, the genetic components remain largely unknown. We previously identified significant evidence for linkage of a QTL on chromosome 2q31-34 to diastolic blood pressure (DBP) in 660 Old Order Amish (OOA) with a LOD score of 3.36; this locus was repeatedly identified by several other groups. To fine map this QTL, we genotyped 3,052 SNPs within the 40Mb linkage region in 762 OOA individuals and performed variance component association analysis. All analyses were adjusted for the effect of age, age2, sex, and excluded those who are taking hypertension medication. Single SNP association analysis did not identify any highly significant results after correcting for multiple testing. We then examined interactions between each pair of these SNPs using the generalized multifactor dimensionality reduction (GMDR) method. Several rounds of searching identified 10 pairs involving 19 different SNPs showing evidence for interaction. The best models identified by GMDR were then tested using regression models implemented under the variance component method to allow incorporation of the linkage and family components. In conditional linkage analysis, each of these pairs individually accounted for up to 6% of the variability of DBP, and reduced the LOD score by up to 34%. A combination of 6 of the 10 pairs accounted for 18% of the total variation in DBP and reduced the LOD score by 85%. These SNPs have relatively high minor allele frequencies (>0.15) and are located in intergenic regions, introns of known genes (in PARD3B, ABI2 , CREB1, FAM126B, LOC729245, MARCH4, MPP4, and SPAG16), and in coding exons (SLC4A3 and BARD1). Cross examination of eQTLs or loci that are associated with expression levels showed that 15 of the 19 SNPs are either eQTLS themselves or are in high LD with other SNPs that are known eQTLs that influenced expression of at least one gene. These results, if replicated in other populations, suggest that accounting for gene by gene interactions is an under-explored approach in searching for genes involved in complex traits and may explain at least some of the missing "heritable" component of complex traits, such as blood pressure and hypertension.

2891/T

Evidence for interaction is scale dependent: Searching for interaction in genome-wide association data on multiplicative and additive scales. *L. Petukhova[1, 2].* 1) Department of Dermatology, Columbia University, New York, NY; 2) Department of Epidemiology, Columbia University, New York, NY.

The term 'interaction' has a number of connotations within the fields of genetics and epidemiology. In genetics, interaction is most commonly thought of as epistasis, which is traditionally defined as the masking of effects of one locus, by a second locus. In epidemiology, this concept is expressed as 'effect measure modification'. Furthermore, epidemiologists draw a distinction between statistical interaction, a departure from the underlying form of a statistical model, and synergy, which is mechanistic and thus biologically meaningful. Finally, in genetics literature it is common to see tests of interaction performed on a multiplicative scale and rarely is evidence assessed on an additive scale. However, epidemiologists have demonstrated that the choice of statistical model will influence whether or not there is evidence for statistical interaction and may or may not correspond to the underlying causal model. We have recently completed a genome-wide association study in alopecia areata in which we identified at least eight regions in the genome with statistically significant association (p<5x10-7). Two of these regions contain three genes which are each ligands of NKG2D, an activating receptor of natural killer (NK) cells. In order to evaluate statistical interaction, we first identified a set of SNPs that are likely to harbor mechanistic interaction because they share a common biological pathway. Specifically, we identified at set of 51 SNPs with at least nominal association (p<1x10-3) to AA, from within 28 genes in the NK cell mediated cytotoxicity pathway. We then use conditional logistic regression to search for evidence of interaction on both multiplicative and additive scales among the SNPs in this pathway and demonstrate that evidence for statistical interaction is driven by the choice of statistical model.

Pathway-based candidate genes analyses revealed evidence of sex-gene interactions, epistasis, and novel pathways for essential hypertension. *P.B. Shih[1], A. Kamburov[1], J.H. Moore[2], B. Rana[1], M. Mahata[1], S. Mahata[1], T. Ideker[1], D.T. O'Connor[1].* 1) School of Medicine, University of California, San Diego, San Diego, CA; 2) Department of Genetics, Dartmouth Medical School, Lebanon, NH.

Essential hypertension is a highly heritable polygenetic disease of unknown etiology. While the GWAS have uncovered credible genetic loci, together these loci only explained less than 10% of phenotypic variance in common diseases such as hypertension. To address the issue of "missing heritability", we examined the hypertension genetic complexity introduced by effect modifiers such as gene-by-gene (epistasis) and gene-by-sex interactions. We also utilized hypertension differentially expressed microarray data to examine the "interconnectedness" pathway candidates have with these disease reporter genes. Using an extreme-phenotype case-control study design, we assessed gene-by-sex interactions and epistatic relationships of 49 hypertension candidate genes chosen from 4 well-studied hypertension pathways both by non-parametric method (MDR) and parametric models. The MDR analysis revealed a two-locus model of IL6 with CHGA to successfully predict hypertension cases, and significant gene-by-sex interactions for COMT, IL6, and CHGA (permutated p-value <0.001). These associations were confirmed using parametric tests both as categorical and quantitative blood pressure trait. Furthermore, regression models demonstrated the BP residues explained in this study population were increased by 4% of the total variance when accounting for the interaction effects. In cella experiments confirmed the functional nature of epistasis (IL6 and CHGA) , while 2 Y-chromosomal markers verified sex-specific influence on genotype-phenotype correlations. Moreover, hypergeometric analysis of the PPI network and over-representation analysis using the pathway databases demonstrated candidate genes' close connection with hypertension reporter genes, uncovered additional protein partners our pathway candidate genes interact biochemically with, and revealed novel pathways these genes participate in. Together, our data confirmed the important roles epistasis and gene-by-sex interactions play in heritable risk of essential hypertension. The significant interconnectedness between pathway candidate genes and hypertension differentially expressed reporter genes suggested the disease-modulating effects the pathway candidates have beyond their known biochemical pathways. Consideration of epistasis, gene-by-sex interactions, and candidate genes' roles in the global genetic architecture of hypertension susceptibility may be the key to finding the "missing heritability".

2893/T

Robust Detection of Genetic Associations incorporating gene-environment interaction and independence. *E. Tchetgen.* Department of Epidemiology Harvard Sch Pub Healt, 677 Huntington ave, Boston, MA.

We consider the detection and evaluation of genetic effects in the presence of gene-environment interaction and independence. Whereas ordinary logistic regression cannot exploit the fact that the genetic variant and the environmental factor are unrelated in the underlying population of interest, we present a novel approach which makes explicit use of this assumption to improve detection and evaluation accuracy of genetic associations. For a binary genetic variant, our method which uses both cases and controls, entails =85tting a constrained retrospective logistic regression, in which the genetic variant plays the role of the response variable, and both the disease indicator and the environmental exposure are the independent variables. The regression model constrains the parameters corresponding to the environmental exposure odds ratio association with the genetic variant among the controls to be null, thus explicitly encoding the gene-environment independence assumption. The main appeal of the proposed retrospective regression approach is that (i) it is easy to implement with standard software, (ii) it readily accounts for multiple environmental exposures of a polytomous or of a continuous nature, and also allows for any additional observed covariates, (iii) it is more efficient than ordinary logistic regression (iv) unlike ordinary logistic regression, and the pro=85file likelihood approach of Chatterjee and Carroll(2005), our approach does not require a model for the odds ratio association of the environmental exposure with the disease outcome; as a result it is agnostic and thus completely robust to possible model misspeci=85cation which can happen with an exposure of a polytomous or of a continuous nature.

2894/T

Exhaustive search of gene-gene and gene-environment interactions for obesity related traits across three ethnic cohorts of women. *D.R. Velez Edwards[1], A. Naj[2], W. Zheng[1], W. Wen[1], X.O. Shu[1], Y. Gao[3], W. Lu[4], Y.B. Xiang[3], K. Monda[5], K. North[5], M. Neuhouser[8], M. Vitolins[7], J. Manson[6], M. O'Sullivan[5], E. Rampersaud[2], T.L. Edwards[1].* 1) Vanderbilt Epidemiology Center Institute of Medicine and Public Health, Vanderbilt University, Nashville, TN; 2) Hussman Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL, USA; 3) Department of Epidemiology, Shanghai Cancer Institute, Shanghai, 200032, China; 4) Shanghai Center for Disease Prevention and Control, Shanghai Institute of Preventive Medicine, Shanghai, 200336, China; 5) Department of Obstetrics and Gynecology, University of Miami, Miami, FL, USA; 6) Harvard Medical School, Boston, MA; 7) Department of Epidemiology & Prevention, Division of Public Health Sciences, Wake Forest University Health Sciences, Winston-Salem, NC; 8) Fred Hutchinson Cancer Research Center, Seattle, WA.

Genome-wide association studies of BMI and obesity have associated several SNPs, some of which interact with physical activity. However, no large evaluation of gene-gene (GxG) or gene-environment (GxE) interactions has been performed. We conducted a search of GxG and GxE interactions in post-menopausal African-American (AA) and Hispanic (HP) women from the Women's Health Initiative SNP Health Associated Resource GWAS study. GWAS data from Chinese women in the Shanghai Women's Health Study, Breast Cancer Study, Endometrial Cancer Study, and Breast Cancer Survivor Study (N=6932) were used to investigate the top 30 GxG interaction models from HP and AA analyses with interaction term p<9x10-10. Single SNP linear regression on BMI adjusted for MDS-derived axes of ancestry was run in race-stratified data with 871512 SNPs available from AA (N= 8264) and 837668 SNPs from HP (N=3510). 70880 SNPs (MAF>0.1) associated with BMI (p<0.1) in AAs (mean Beta: 1x10-5) and 64494 SNPs in HPs (mean Beta: 3x10-5) and were used for GxG analyses without LD pruning. GxG analysis was run using linear regression for 2.5 billion pairwise SNP combinations in AA and 2 billion in HP, adjusted for ancestry. The most consistent evidence from GxG interaction terms across all ethnic groups was for SNPs in *SLCO1B1* (rs7966613) and *ADCYAP1* (rs1610274)(AA p= 7x10-9; Chinese p=2x10-3). This result was not observed in HP; however, GxG interactions were observed at other SNPs within these genes (p=2x10-3). *SLCO1B1* and *ADCYAP1* are involved in energy homeostasis via thyroid hormone activity from human genetic studies, mouse models, and cell culture. Tests of GxE interaction at all SNPs for physical activity (met-hrs/wk), energy intake (kcal/day), and smoking were run with linear regression in AA and HP adjusted for ancestry, followed by meta-analysis of all GxE interaction terms. The strongest evidence for concordant GxE interactions in AA and HP was for smoking and *CSMD1* (rs10104470; Q statistic p= 0.8, beta=2x10-4, p=3x10-7). *CSMD1* has been associated with metabolic syndrome, methamphetamine dependence, and smoking cessation. The strongest evidence for GxE association within a cohort was in AA for dietary energy and *PFTK1* (rs17479541; SNP beta=-0.02, kcal beta=7x10-6, SNPxkcal beta=1x10-5, p=4x10-7), a gene involved in thyroid hormone pathways and adipogenesis. No results survive Bonferroni correction; however, validation of these results with independent AA and HP cohorts are ongoing.

Incorporating Covariates in Association Mapping Using General Pedigree Data. *Y.-F. Chiu, C.-Y. Lee.* Biostatistics & Bioinformatics, National Hlth Res Inst, Zhunan, Miaoli, Taiwan.

As complex diseases are often involved a number of genetic and environmental factors, incorporating these factors into linkage mapping can improve the power to detect disease loci or the efficiency of estimating disease loci. Moreover, the incorporation of covariates provides information that can be used to characterize disease loci, which is helpful for understanding disease etiologies and mechanisms and for identifying population subgroups that may have particularly high disease risks. Previously, we developed two approaches to incorporate covariates into linkage disequilibrium mapping in the case-parent design. The approaches, including parametric and nonparametric modeling, are robust in that no assumption about the underlying genetic model is required, other than the assumption that there is no more than one disease gene in the chromosomal region. In addition to the estimate of a disease locus, the magnitudes of the associations between the genetic effect at the disease locus and covariates can also be assessed. In practice, data are often available for extended pedigrees with multiple nuclear families or relative pairs, it would be desirable to have the association mapping approaches that can use all potentially informative data. In the present study, we will extend these approaches to general pedigrees to make full use of the data available, so as to improve the efficiency of estimate for a disease locus. By making full use of pedigree data, one can also estimate the relative risks among different relatives, which is informative for uncovering the underlying genetic model of a disease. Our simulation studies evaluated the efficiency in estimating the disease locus when using general pedigrees compared to trios data. The proposed approach was applied to a young-onset hypertension data sample and the relative efficiency of estimating the locus of young-onset hypertension using either trios only or the whole family data was assessed.

Marker-set Analysis for Genetic Main Effects and Gene-environment Interactions via Gene-trait Similarity Regression. *JY. Tzeng[1,2], D. Zhang[1].* 1) Department of Statistics, North Carolina State Univ, Raleigh, NC; 2) Bioinformatics Research Center, North Carolina State Univ, Raleigh, NC.

Modern association studies of complex traits, such as GWAS or sequencing studies, demand statistical tools that are cable to detect small-effect variants, model complex interaction effects, and have convincing speed performance. In this work, we introduce a similarity-based regression method to perform marker-set analysis. The method uses genetic similarity to aggregate information from multiple polymorphic sites (e.g., SNPs or a mixture of different polymorphisms), and regresses trait similarities for pairs of unrelated individuals on their genetic similarities to access the gene-trait association. The association is detected using a score test whose limiting distribution is derived. The proposed method can account for covariates, has the capacity to model both main and interaction effects, and is computationally efficient. We also show that the gene-trait similarity regression does not require phase sequence and that it explicitly models the non-additive effects among markers. These features makes it an ideal tool for evaluating association between phenotype and marker sets defined by haplotypes, genes or pathway in whole-genome analysis.

A powerful two-stage method for genome-wide analysis of gene-gene interactions in case-control data. *Z. Bochdanovits[1], J. Peánka[2], P. Heutink[1], A. van der Vaart[2].* 1) Dept Clinical Genetics, VU Univ Medical Ctr, Amsterdam, Netherlands; 2) Department of Mathematics, Vrije Universiteit, Amsterdam, the Netherlands.

Functional gene x gene interaction (epistasis) is a biologically very plausible explanation for, part of, the "missing heritability" of complex traits. Although this possibility is widely acknowledged, a full screen for epistatic effects on a genome-wide scale is still considered unfeasible because statistical power would be seriously compromised by correcting for multiple testing. Previously we have suggested that a possible way to avoid this problem is to ascertain pairs of variants that are a priori more likely to be involved in functional gene-gene interactions and test only these for association with a complex phenotype. Here we present the formal procedure for detecting genome-wide significant gene x gene interactions based on a pre-test to select pairs of loci that exhibit non-equilibrium two locus genotype frequencies in controls, followed by an adjusted test statistic for interaction that corrects for the correlation between the pre-test and interaction test induced by re-using the controls in the second step. Multiple testing correction is only necessary for the number of test in the second step, while type I error is correctly maintained. We show that the procedure has superior power compared to a related one step interaction test followed by multiple testing correction for all pairs involved provided that the ratio of controls vs. cases is larger than approximately two. The overall power of the method depends on true interactions inducing two-locus disequilibrium between the loci in the controls. We show that realistic interaction effect sizes on disease susceptibility induce sufficient two-locus disequilibrium in controls to be detected in the pre-test, while gene pairs with strong additive effects of either loci are much less likely to pass the pre-test. Because only the chi-square test based pre-test is performed for all pairs of loci, the procedure is computationally feasible and efficient while the reduction of the number of tests in the second step conveys increased overall power making this procedure suitable to analyze genome-wide data.

A Mann-Whitney based whole genome-wide association study finds significant gene-gene interaction for Type 2 diabetes. *Q. Lu[1], C. Wei[1], C. Ye[1], R.C. Elston[2].* 1) Dept of Epidemiology, Michigan State Univ, East Lansing, MI; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

With the merge of large amount data from whole genome-wide studies, interest has been moved towards whole genome-wide search for gene-gene interaction. The importance of gene-gene interaction has long been recognized. However, identifying interactions has been a great challenge, especially when involves millions of genetic markers. Most of the currently used statistical tools are not originally designed for whole genome gene-gene interaction search, and are subject to issues such as multiple testing, computational inefficiency, and incapability of capturing high order interaction. We here proposed a Mann-Whitney based approach for whole genome-wide gene-gene interaction search. It extends traditional univariate Mann-Whitney test to assess the joint association of multiple loci, considering all levels of possible interactions. With only one overall significant test is conducted, it avoids issue of the multiple testing. The approach adopts a computationally efficient algorithm, and thus is feasible to conduct whole genome-wide gene-gene interaction analysis with a reasonable time on a high performance personal computer. We evaluated the approach using both simulation and real data application. By applying the approach on 24 Type 2 diabetes (T2D) susceptibility genes, we identified a four locus model strongly association with T2D in the Wellcome Trust (WT) study (permutation P-value<0.001), and replicated the finding in the Nurses' Health Study/ Health Professionals Follow-up (NHS/HPFU) study (P-value=3.03E-11). Furthermore, we conducted a whole genome-wide gene-gene interaction search on nearly 500K loci. The approach identified four loci joint associated with T2D (P-value=1.29E-5) in WT study. The significance leave of this association reaches 4.01E-6 in the NHS/HPFU study.

A Novel Statistic for Genome-wide Interaction Analysis. *X. Wu[1], H. Dong[3], L. Luo[2], Y. Zhu[2], G. Peng[2], J. Reveille[4], M. Xiong[2].* 1) Deptof epidemiology , Bengbu Medical College at Bengbu, Bengbu, Anhui, China; 2) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030; 3) Laboratory of Theoretical Systems Biology and Center for Evolutionary Biology, State Key Laboratory of Genetic Engineering, School of Life Science and Institute for Biomedical Sciences, Fudan University, Shanghai 200433, China; 4) Division of Rheumatology, Medical School, University of Texas Health Science Center at Houston, Houston, TX 77030.

Although great progress in genome-wide association studies (GWAS) has been made, the significant SNP associations identified by GWAS account for only a few percent of the genetic variance, leading many to question where and how we can find the missing heritability. There is increasing interest in genome-wide interaction analysis as a possible source of finding heritability unexplained by current GWAS. However, the existing statistics for testing interaction are less powerful for genome-wide interaction analysis. To meet challenges raised by genome-wide interactional analysis, we have developed a novel statistic for testing interaction between two loci (either linked or unlinked). The null distribution and the type I error rates of the new statistic for testing interaction are validated using simulations. Extensive power studies show that the developed statistic has much higher power to detect interaction than classical logistic regression. The results identified 44 and 211 pairs of SNPs showing significant evidence of interactions with FDR < 0.001 and 0.001 < FDR < 0.003, respectively, which were seen in two independent studies of psoriasis. These included five of interacted pairs of SNPs in genes LST1/NCR3, CXCR5/BCL9Land GLS2, some of which were located in the target sites of miR-324-3p, miR-433, and miR-382, as well as 15 pairs of interacted SNPs that had nonsynonymous substitutions.

2900/T

A Novel Statistic for Testing Genetic Interactions between Linked Loci. *J. Zhao[1], X. Wu[2], Y. Zhu[2], M. Xiong[2].* 1) Biostatistics & Epidemiology, Univ Oklahoma HSC, Oklahoma City, OK; 2) University of Texas HSC at Houston, Houston, TX.

Despite the success of GWAS in identifying single SNP associations for complex diseases, the positive associations identified so far explained only a small proportion of phenotypic variations in the studied phenotypes. The etiology of human complex disorder, however, involves multiple genes and their interactions. Modeling complex genetic interactions is clearly important to fully explain inter-individual variability in complex disease phenotypes. Up to date, identification of gene × gene interactions at a genome-wide level remains a challenge for human genetic studies, partly because of lack of powerful statistical methodologies. We have previously reported a LD-based test statistic in detecting gene × gene interactions between two unlinked loci. Here we report another novel test statistic for testing genetic interactions between linked loci at a genome-wide level. The statistic defines gene × gene interaction as a stochastic dependence between two interacting loci in leading to disease susceptibility. The performance of the new statistic including null distribution, statistical power and type 1 error rates at different significance levels, were evaluated using extensive simulation studies. The proposed novel statistic was also assessed in comparison with three existing methodologies in testing genetic interactions: logistic regression, the "fast-epistasis" program implemented in PLINK, and the haplotype odds ratio method. Our results showed that the proposed novel test statistic has a higher power in detecting genetic interactions. Finally, we applied the proposed statistic to two GWAS datasets to identify genome-wide genetic interactions for rheumatoid arthritis. Dozens of genetic interactions were identified and replicated in the two independent studies.

2901/T

A Faster Pedigree-Based Generalized Multifactor Dimensionality Reduction Method for Detecting Gene-Gene Interactions. *G.B. Chen[1], J. Zhu[2], X.Y. Lou[1].* 1) Section on Statistical Genetics, Department of Biostatistics, University of Alabama, Birmingham, AL; 2) Institute of Bioinformatics, Zhejiang University, Hangzhou, China.

We proposed a faster pedigree-based generalized multifactor dimensionality reduction algorithm, called PedGMDR II (PII), to detect gene-gene interactions underlying complex traits. Inheriting from our previous framework of PedGMDR (PI), PII is applicable to handle both dichotomous and continuous traits in pedigree-based designs and allows for covariate adjustment. Compared with PI, this faster version can theoretically halve the computing burden and memory requirement. To evaluate the performance of PII, we performed comprehensive simulations across a wide variety of experimental scenarios, in which we considered two study designs, discordant sib pairs and mixed families with varying size, and five common factors that may potentially affect statistical power: minor allele frequency, missing rate of parental genotypes, covariate effect, gene-gene interaction, and scheme to adjust phenotypic outcomes, leading to a total of up to 4096 scenarios. Simulations showed that PII gave a well controlled type I error rates against population admixture. In general, PII had a higher average power than PI in simulations for both dichotomous and continuous traits, and the advantage was more pronounced for continuous traits. Given a magnitude of interaction effect, PII appeared to be less sensitive to changes in other factors. Applied to the Mid-South Tobacco Family study, PII detected a significant interaction with a P-value of 5.4×10^{-5} between two taster genes, *TAS2R16* and *TAS2R38*, responsible for nicotine dependence. In conclusion, PII is a faster supplementary version of our previous PI for detecting multifactor interactions.

Using Biological Knowledge To Discover Higher Order Interactions In Genetic Association Studies. *G. Chen[1], D. Thomas[1], A. Presson[2].* 1) Preventive Medicine, USC, Los Angeles, CA; 2) Biostatistics and Pediatrics, UCLA, Los Angeles, CA.

The recent successes of genome-wide association studies (GWAS) have revealed that many of the replicated findings have explained only a small fraction of the heritability of common diseases. One hypothesis that investigators have suggested is that higher-order interactions between SNPs or SNPs and environmental risk factors may account for some of this missing heritability. Searching for these interactions poses great statistical and computational challenges. We propose a novel method that addresses these challenges by incorporating external biological knowledge into a fully Bayesian analysis. The method is designed to be scalable for high-dimensional search spaces (where it supports interactions of any order) because priors that use such knowledge focus the search in regions that are more biologically plausible and avoid having to enumerate all possible interactions. We provide several examples based on simulated data demonstrating how external information can enhance power, specificity, and effect estimates in comparison to conventional approaches based on maximum likelihood estimates. We also apply the method to data from a GWAS for breast cancer, revealing a set of interactions enriched for the Gene Ontology terms growth, metabolic process, and biological regulation.

2903/T

A Novel and Comprehensive Method To Find Complex Interactions. *S. Prabhu, I. Pe'er.* Computer Sci, Columbia Univ, New York, NY.

Despite considerable success in exposing the genetic basis of many diseases, genome wide association studies have made limited progress in explaining their heritability. One popular hypothesis as to why single locus methods have had limited success in this area speculates that complex interactions between distant loci might be responsible for some of the missing heritability. In such a case, while the marginal effect of any single contributing locus might be statistically insignificant (amid genome-wide testing burden), when seen in combination with its interacting counterparts their effect becomes apparent.

However, designing association studies for complex interactions have hitherto been plagued by problems arising from their combinatorics. Specifically, two fundamental limitations have been:

(a) Computational - the total number of interactions increases exponentially with the number of loci. For datasets of just a million typed SNPs, even testing all low-arity (2-way, 3-way) interactions presents a considerable computational burden. (b) Statistical - testing all interactions independently incurs a multiple testing burden that can be prohibitive. However, we demonstrate that in most realistic scenarios computational infeasibility sets in much earlier than the statistical bound.

We present a novel method that uses Probably Approximately Correct (PAC) learning techniques to search for complex interactions. Our algorithm seeks telltale patterns in randomly chosen groups of cases that are indicative of interaction effects. By repeated random sampling and examination of a few summary statistics for each sample, we are able to uncover any existing interaction in the case cohort with arbitrarily high probability. In other words, without resorting to search space reductions (e.g. shortlisting a few loci based on marginal effect, functional significance, etc.) or brute-force enumeration of all possible combinations of loci, our method comprehensively searches for interactions under various disease models at a very small fraction of the erstwhile computational cost. On synthetic case-control datasets (whole genome sequences with 16M SNPs, or genotypes with 1M SNPs), our method reveals 2-way, 3-way and 4-way interactions when marginal effects of each contributing locus are completely unremarkable ($p<0.4$).

Predicting Patient Outcomes from Clinical and Genome-Wide Data. *M.M. Barmada[1], S. Visweswaran[2], P. Hennings-Yeomans[2], K. Bui[2], G. Cooper[2].* 1) Dept Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA.

Clinical classification and prediction are key components of clinical care. Even modest improvements in classification and predictive performance have the potential to significantly improve patient outcomes and reduce healthcare costs. Traditional clinical data are becoming increasingly available in electronic form. In addition, in the foreseeable future genome-wide patient-specific data are likely to become available as part of the electronic health record to inform clinical care. Both sources of data provide significant opportunities for using statistical and machine-learning methods to improve classification and prediction over what is currently possible. However, the sheer magnitude of the number of variables in these data (in the hundreds of thousands or millions) presents formidable computational and modeling challenges. It is therefore important to explore new ways to use traditional clinical data and genome-wide data together to improve clinical classification and prediction. We propose a new approach for using both types of data to perform clinical classification and prediction. The new method builds on our previous work in Bayesian outcome prediction, which has yielded positive results when applied using just traditional clinical data. That previously developed method, however, is not able to handle computationally the huge number of variables introduced by genome-wide data. The new Bayesian method is computationally tractable, yet still able to model important interactions among the predictor variables. Using data from the Framingham SHARe resource, we examine how clinical and genome-wide data can be used to predict the onset of major cardiovascular events and death from all causes. We compare the new Bayesian method to a set of traditional prediction methods with regard to computational tractability and predictive performance in terms of discrimination and calibration.

2905/T

Gene-smoking interactions on chromosomes 5 and 18 in age-related macular degeneration revealed through genome-wide environmental interaction analysis. *W.K. Scott[1], A.C. Naj[1], W.H. Cade[1], P.J. Gallins[1], P.L. Whitehead[1], I. Konidari[1], M.D. Courtenay[1], L.M. Olson[2], K.L. Spencer[2], N.C. Schnetz-Boutoud[2], S.G. Schwartz[3], J.L. Kovach[3], A. Agarwal[4], G. Wang[1], J.L. Haines[3], M.A. Pericak-Vance[1].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 3) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Naples, FL; 4) Vanderbilt Eye Institute, Vanderbilt University Medical Center, Nashville, TN.

Age-related macular degeneration (AMD) is the most common cause of irreversible vision loss in older adults in developed countries. AMD has a complex etiology comprising several genetic (*CFH, ARMS2, CFB/C2, CFI, TIMP3*) and environmental (cigarette smoking, estrogen use, diet) risk factors. The major genetic factors have been identified using linkage analysis and association mapping (*CFH* and *ARMS2*), candidate gene testing (*CFB/C2*, *CFI*), and genome-wide association screening (*TIMP3*). While these factors explain a substantial portion of the risk of AMD, additional factors (including gene-gene and gene-environment interactions) remain to be discovered. To this end, we conducted a genome-wide association and gene-environment interaction study of 1013 white AMD cases and 601 white unaffected controls using the Affymetrix Genome-Wide SNP Array 6.0. Environmental risk factor information was collected on 830 cases and 486 controls by self-administered questionnaire. After quality control checks, 671,524 SNPs were retained for analysis. Main effects analysis using logistic regression and an additive genotype model (adjusting for age and sex) detected genome-wide significant associations ($p<5x10^{-8}$) at 3 known loci: *CFH* ($p=1.3x10^{-24}$), *ARMS2* ($p=2.8x10^{-20}$), and *CFB/C2* ($p=8.8x10^{-9}$). Gene-environment interaction was tested by including pairwise interaction terms between genotype and smoking history (ever/never) in the logistic regression models. No interactions were genome-wide significant, but the strongest interactions were detected in an intergenic three-SNP block on chromosome 18 ($p=5.3x10^{-7}$ at rs1707364) and an intergenic three-SNP block on chromosome 5 ($p=5.4x10^{-6}$ at rs4865735). Unfolding these interactions by stratification on smoking history revealed significant, opposite effects at each locus: the minor alleles at the chromosome 18 locus increase risk of AMD in ever smokers (OR=1.4, 95% CI: [1.1-1.8]) but decrease risk in never smokers (OR=0.55, 95% CI: [0.42-0.73]. A similar pattern was observed at chromosome 5: the minor alleles increase risk in non-smokers (OR=2.1, 95% CI: [1.3-3.3] but decrease risk in ever smokers (OR= 0.53, 95% CI: [0.37-0.75]. These results suggest that gene-environment interactions with no detectable main genetic effects may explain some risk of AMD. Additional studies to replicate and extend these findings are needed to establish the biological mechanisms underlying the interactions.

Copy number haplotype inference with Hidden Markov Model and localized haplotype clustering. *Y. Lin[1], S. Hsu[2], C. Tang[1], W. Hsieh[2].* 1) computer science, National Tsing Hua University , Hsinchu, Taiwan; 2) Statistics, National Tsing Hua University , Hsinchu, Taiwan.

Copy number polymorphisms and aberrations can now be studied at high resolution using genome-wide SNP arrays. Most of the tools detect the copy number alteration regions by either segmentation approach or a dynamic Hidden Markov Model. The total copy number or allele specific copy number is inferred based on the probe intensities designed to measure the quantity of either allele. Hidden Markov Model based approaches can only provide discrete states and are not accurate for somatic mutations since the sample is a mixture of heterogeneous cells. On the other hand, HMM is perfectly suitable for integrating Linkage Disequilibrium information, which is the major source of haplotype inference. We present a method based on Hidden Markov Model to detect parent specific copy number variation with fractional copy number estimation. Two haplotype trees are constructed for the two chromosomes and the states inferred are the copy numbers of the two alleles under consideration. Each allele is modeled with three states, the normal, plus and minus copy numbers. The transition of states helps to construct the haplotype for either chromosome as well as the copy number status. The CNV regions thus inferred will be pooled together to make the copy number estimation. The enormous computation load can be greatly reduced with the help of localized haplotype clustering proposed by Browning et al. (2006 AJHG). A few iterations are required to reach the convergence. The proposed method is evaluated on the known regions of copy number variation on 270 HapMap individuals as well as an oral cancer cohort of 112 samples. We also compare the other four popular methods including PenCNV, genoCN, COKGEN, and QuantiSNP. Although they do not provide parent specific haplotypes, we compare the overlapping rates of the detected regions, and consistency of the copy number estimation. Our observation found that PenCNV gives the best overlapping rates of the known detection regions and is the most efficient package with the shortest running time. Our method is more sensitive to short regions while the long regions can also be correctly detected.

2907/T

Towards a genetic screening test for dyslexia allowing functional regeneration: A strategy for identification and analysis of genetic risk factors. *H. Kirsten[1,2], A. Wilcke[1,2], P. Ahnert[3], J. Boltze[2].* 1) University Leipzig TRM, Leipzig, Germany; 2) IZI Fraunhofer Leipzig, Leipzig, Germany; 3) University Leipzig , IMISE; Leipzig, Germany.

Our aim is to develop a genetic screening test for dyslexia, a severe disorder of reading and frequently of writing, affecting approx. 4 % of all schoolchildren. A significant problem is late diagnosis resulting in a decreased chance of functional regeneration. Our solution is an early genetic test that will initiate existing early training programs. Genetic dyslexia markers necessary for this test are identified in a micro array based fine screen supplemented by polymorphisms of highly relevant candidate genes. Validation of these markers is done by A) genotyping an independent cohort; B) by characterising markers in functional magnet resonance imaging (fMRI) and electroencephalography (EEG); and C) by characterising markers in allele specific mRNA-expression analysis or allele-specific chromatin immunoprecipitation (ChIP). The final test will neither include fMRI/EEG nor expression analysis. It translates genetic findings into a clinical assay. This test would allow early identification of children at risk, enabling early support resulting in functional regeneration.

2908/T

A sex-specific association between a 15q25 variant and upper-aerodigestive tract cancers. *D. Chen, T. Truong, V. Gaborieau, P. Brennan, JD. McKay on behalf of the INHANCE consortium.* International Agency for Research on Cancer, Lyon, France.

Sequence variants located at 15q25 have been associated with lung cancer and propensity to smoke. We recently reported a modest association between rs16969968 and risk of upper aerodigestive tract (UADT) cancers (oral cavity, oropharynx, hypopharynx, larynx and esophagus)(Odds Ratio (OR)=1.08), particularly in women (OR=1.24). We sought to replicate these findings in an additional 4,604 cases and 6,239 controls from 10 independent UADT cancer case-control studies participating in the International Head and Neck Cancer Epidemiology (INHANCE) consortium. The rs16969968 variant was genotyped using the TaqMan genotyping platform. We observed a similar association in the replication series (OR=1.07, 95% confidence interval (CI)=1.00-1.13, *P*=0.03) as well as the sex difference (*P*-heterogeneity=0.01).To further evaluate this genetic effect, we combined the individual level data from the UADT cancer studies in the initial study and the 10 independent studies presented here, making for a total of 8,572 UADT cancer cases and 11,558 controls from 14 studies. In the combined analysis, the association was observed almost uniquely in females (OR=1.22, 95% CI=1.12-1.34, $P=7\times10^{-6}$) but not males (OR=1.02, 95%CI=0.97-1.08, *P*= 0.35) (*P*-heterogeneity=6×10^{-4}). In women the association of rs16969968 with UADT cancer risk was relatively consistent among subgroups stratified by smoking status, cigarettes smoked per day (CPD), alcohol consumption, ever/never smoking-drinking status and age. In contrast, among men there was little evidence for association between rs16969968 and UADT cancer in any stratum. The rs16969968 variant has been consistently associated with propensity to smoke cigarettes (particularly CPD), we therefore examined whether rs16969968 was associated with number of CPD among 11,991 ever smokers included in the combined initial and replication data sets. rs16969968 minor allele was associated with propensity to smoke (*P*= 1×10^{-6}), however, there was little evidence for a sex difference in the effect of the rs16969968 variant on propensity to smoke, with male and female variant carriers smoking approximately the same amount more (male and female rare homozygotes smoked 1.79 and 1.29 cigarettes more than common homozygotes, respectively) (*P*-heterogeneity=0.86). No association was noted with age of smoking initiation or cessation in males or females. Further research is warranted to elucidate the mechanisms underlying these observations.

2909/T

Association Mapping Across the Major Histocompatibility Complex Region in the Risk of Childhood Acute Lymphoblastic Leukemia. *K.Y. Urayama[1,5], A.P. Chokkalingam[1], C. Metayer[1], J.L. Wiemels[2], J.K. Wiencke[2], E. Trachtenberg[3], G.M. Taylor[4], P. Brennan[5], H. Hansen[2], S. May[1], L.F. Barcellos[1], P.A. Buffler[1].* 1) School of Public Health, University of California, Berkeley, CA; 2) Laboratory for Neuro and Molecular Epidemiology, University of California, San Francisco, CA; 3) Children's Hospital and Research Center, Oakland, CA; 4) University of Manchester, Manchester, United Kingdom; 5) Genetic Epidemiology Group, International Agency for Research on Cancer, Lyon, France.

Given the accumulating support for a role of immunologic factors in the etiology of childhood leukemia, the major histocompatibility complex (MHC) is an important candidate region for genetic studies of this disease. The MHC is a gene-dense region populated by a large number of genes that play a role in immune function and response, including the highly polymorphic human leukocyte antigen (HLA) genes involved in antigen presentation to T lymphocytes. We conducted association mapping across an approximately 4 megabase region of the MHC using the Illumina MHC Mapping Panel of single nucleotide polymorphisms (SNP) and specific allelic typing of the previously associated *HLA-DPB1* locus among 634 acute lymphoblastic leukemia (ALL) cases aged 0-14 years and 902 population controls enrolled in the Northern California Childhood Leukemia Study. Single-marker logistic regression analyses assuming log-additive and dominant genetic models of 1,143 SNPs and adjusted for age, sex, and Hispanic ethnicity indicated several potentially associated regions. These include regions tagged by SNPs rs7747023 (*OR2W1*, p=0.002) and rs1233388 (*OR2H2*, p=0.003) of the extended class I region, rs3130785 (p=0.006) of the classical class I region, rs9296068 (*HLA-DOA*, p=0.002) of the classical class II region, and rs213203 (*VPS52*, p=0.0004) of the extended class II region. Separate analysis of five common alleles of the *HLA-DPB1* gene, located adjacent to *HLA-DOA*, did not show associations with childhood ALL risk. However, a sliding window haplotype analysis containing *HLA-DPB1* alleles and nearby SNPs identified an associated 4-marker haplotype comprised of rs399604 (*HLA-DOA*), rs9296068 (*HLA-DOA*), *DPB1*, and rs3762013 (*COL11A2*) (global $p=4.1\times10^{-4}$). A specific haplotypic effect of the common haplotype G-A-DPB1*0401-G was observed ($p=7.2\times10^{-6}$). As the first MHC-wide high resolution SNP association study in childhood ALL, we provide preliminary evidence suggesting that genetic variation within specific regions of the MHC may be involved in genetic susceptibility to this disease. The regions identified in this study warrant further evaluation through confirmation in other populations and subsequent fine-mapping of replicated regions.

Host Genetic Factors and Vaccine-Induced Immunity to Salmonella typhi and Streptococcus pneumoniae. *B.J. Hennig[1], L. Ashton[2], D. Goldblatt[2], A.M. Prentice[1,3], A.A. Richards[1,3], S.C. Szu[4], S.E. Moore[1,3].* 1) MRC Int Nutrition Group, London School of Hygiene & Tropical Medicine, London, London, United Kingdom; 2) Institute of Child Health, London, UK; 3) MRC Keneba, Medical Research Council Laboratories, Fajara, The Gambia; 4) National Institutes of Health, Maryland, USA.

Background: Little is known about the role of host genetic variation on vaccine-induced immunity. We assessed the genetics of vaccine responses to *S.typhi* and *S.pneumoniae* immunization using data available from two projects from The Gambia (West Africa): Firstly, antibody responses to two polysaccharide vaccines from a study of early life predictors of immunity (Moore SE *et al* in preparation) and secondly, genotype data from a study on HBV vaccine-induced immunity (Hennig BJ *et al* PLoS ONE. 2008 Mar 26;3(3):e1898). Methods: The combined dataset comprised 130 individuals of Mandinka ethnicity (mean age of 18.0 ±2.3 years), vaccinated with a single dose of a S.tyhpi Vi and a 23-valent capsular polysaccharide pneumococcal vaccine (Typhim Vi and Pneumo23, both Sanofi Pasteur). Anti-Vi antibody and antibodies against pneumococcal serotypes 1, 5, 14 and 23f were measured by ELISA at baseline and 14 days post-vaccination. Genotype data on 715 SNP across 133 genes (typed on Illumina BeadArray platform) were employed. Multiple linear regression models with single SNPs as exposure and post-vaccination geometric mean antibody titre (GMT) as outcome were applied, whilst adjusting for pre-vaccination antibody level, age, sex, village and relatedness (clustering by sibship), but not multiple comparisons. Results: Pre-vaccination antibody level had a strongly affected post-vaccination antibody level ($P<1.0 \times 10^{-5}$), but no effect was seen for age, sex and marginal effects of village. SNPs associated with antibody responses to one or more pneumococcal serotype or S.typhi reaching the cut-off of a ratio of GMT of <0.6 or >1.5 and a P-value of $<1.0 \times 10^{-4}$ are: IL19 (rs3950619, rs2056225, rs2243158, rs2243174); IL1RL1 (rs4988956, rs10192157); CTLA4 (rs3087243); IL7R (rs10213865, rs3194051); HLA-DQA1 (rs9272775); NFKBIL2 (rs4082353); FAS (rs3218614); MS4A1 (rs1051756); AICDA (rs2580876); IRAK3 (rs1152918); IL26 (rs3782554); ITGAL (rs2230433); and MAP2K4 (rs2108496). Discussion: These data should be interpreted with caution due to the small sample size and require replication; nevertheless, the observed effect sizes are large (>1.5-fold in/decrease in GMT of vaccine-induced antibody) and the p-values small. Genetic variants shown to associate with immunity induced by *S.typhi* and *S.pneumoniae* vaccination here do not appear to have been reported previously. These data will help understand the mechanisms underlying vaccine-induced immunity and thus to improve future vaccines.

Pathway analysis of height, genetic variants and adult systolic blood pressure in the Northern Finland Birth Cohort 1966. *M. Kaakinen[1,2], U. Sovio[3,4], A-L. Hartikainen[1], A. Pouta[5], J. Laitinen[6], M. Savolainen[1,2], K-H. Herzig[1,2], T. Lajunen[1,2], M. Perola[7], N. Freimer[8], B. De Stavola[4], E. Läärä[1], M-R. Järvelin[1,2,3,5].* 1) University of Oulu, Oulu, Finland; 2) Biocenter Oulu, Oulu, Finland; 3) Imperial College London, London, UK; 4) London School of Hygiene and Tropical Medicine, London, UK; 5) National Institute for Health and Welfare, Oulu, Finland; 6) Finnish Institute of Occupational Health, Oulu, Finland; 7) National Institute for Health and Welfare, Helsinki, Finland; 8) Neurobehavioral Genetics and Semel Institute for Neuroscience and Human Behavior, UCLA, Los Angeles, CA.

Height is positively associated with hypertension but the underlying mechanisms behind the phenomenon are unclear. We investigated how birth length (BL), accelerated height growth in infancy, which is often observed in children born small and is a known risk factor for adverse metabolic profile in adulthood, adult height and four candidate single-nucleotide polymorphisms (SNPs) associate with adult systolic blood pressure (SBP). In addition, we studied if these genetic variants associate with height. The study population consisted of 5851 singletons belonging to the Northern Finland Birth Cohort 1966. We used pathway analysis to estimate the associations between BL, peak height velocity (PHV) in infancy and height and SBP at age 31 years. Four SNPs identified via genome-wide association studies and meta-analysis for SBP were included into the model. The analysis also accounted for gender, gestational age, maternal height, age, smoking, parity, socioeconomic status (SES) and subject's own smoking, drinking, SES and BMI at 31 years. Frequent height measurements at 0-2 years were used to estimate individual height curves, and PHV was derived as the maximum value of the growth velocity curve, typically occurring soon after birth. An inverse association between BL and SBP was observed (beta=-0.40 mmHg/cm, SE=0.09, p<0.001) after controlling for all the assumed relationships. Low BL was also associated with increased PHV in infancy (p<0.001), which in turn was associated with increased adult height (p<0.001) but not with SBP adjusted for adult height (p=0.47). Mediation of the BL association on SBP was observed via PHV and height at 31 years (total indirect effects beta=0.23 mmHg/cm, SE=0.04, p<0.001). The sum of the direct and indirect effects, i.e. the total effect of BL on SBP, remained negative (beta=-0.17 mmHg/cm, SE=0.08, p=0.03). SNP rs1378942 in *CSK* associated negatively with SBP (beta=-0.64 mmHg/each copy of A-allele, SE=0.25, p=0.009) and also showed a negative borderline-significant association with PHV (p=0.05). SNP rs932764 in *PLCE1* (for SBP beta=-0.73 mmHg/each copy of A-allele, SE=0.25, p=0.004) showed weak evidence for negative association with adult height (p=0.09). About third of the low BL effect on high adult SBP was mediated via increased PHV in infancy and current height. The weak associations of two of the SBP-associated SNPs with height suggest a possible underlying shared genetic component; however, replication studies are needed.

Risk of tuberculosis among close contacts to TB patients: the role of Vitamin D receptor gene polymorphisms. *C. Luo[1], M. Reichler[1], B. Chen[1], E. Sigman[1], F. Maruri[2], T. Sterling[3].* 1) CDC, Atlanta, GA; 2) Tenn. Dept. of Health, Nashville, TN; 3) Vanderbilt Univ., Nashville, TN.

Background: Single nucleotide polymorphisms (SNPs) in the Vitamin D receptor (VDR) gene have been implicated in susceptibility to TB among persons of Black race/ethnicity, but the contribution of VDR gene SNPs to TB susceptibility among persons of other race/ethnicities has not been well characterized. **Methods:** We enrolled U.S.-born contacts with latent TB infection or active TB disease with >180 hours of exposure to smear+ TB patients at 9 sites. Blood was collected and genotyped for VDR gene SNPs BSM1and FOK1 and epidemiologic data collected by contact interview. Pairwise analysis was conducted using χ^2 tests with homozygous wild genotype as the referent group. This analysis is limited to contacts of white (n=69), Hispanic (n=39), and American Indian (n=22) race/ethnicity. **Results:** Among 130 contacts, 9 had active TB and 121 had a positive tuberculin skin test (TST+) but not active disease. Compared with TST+ contacts, contacts with active TB of Hispanic race/ethnicity were more likely to have the homozygous mutant genotype for VDR BSM1 (OR=undefined, P<.001). There was no association for VDR BSM1 among contacts of white or American Indian race/ethnicity, and no association for VDR FOK among contacts of any of the three race/ethnicities. **Conclusions:** In this U.S. population, active TB among Hispanic contacts after exposure to *M. tuberculosis* was associated with homozygous mutant genotype for VDR BSM1. This finding strengthens the association between VDR BSM and TB susceptibility (previously observed for contacts of Black race/ethnicity) by demonstrating the association in a second race/ethnicity. **Funding:** Centers for Disease Control.

Evaluating 20 Autoimmune Disease Associated Loci with Rheumatoid Arthritis in a Colombian Population: Evidence for Replication and Gene-Gene Interaction. *A.K. Maiti[1], H. Deshmukh[1], X. Kim-Howard[1], P. Viswanathan[1], A. Rojas-Villarraga[2], J.M. Guthridge1[1], JM. Anaya[2], S.K. Nath[1].* 1) Gen Epidemiology Unit, A&I, OMRF, Oklahoma city, OK; 2) Center for Autoimmune Diseases Research (CREA), Universidad del Rosario-Corporación para Investigaciones Biológicas, Bogota, Colombia.

Objective: Recently, genome-wide and high-density candidate gene association studies have identified multiple SNPs which are associated with rheumatoid arthritis (RA), especially in individuals with European Ancestry. Additionally, many of these associated SNPs are also associated with multiple autoimmune diseases, supporting the hypothesis of shared or general autoimmunity genes/loci. However, due to cultural, nutritional or environmental differences between populations, both ethnic-specific single variant association and gene-gene interaction within these SNPs should also be evaluated. The main objective of this study is to assess and replicate the genotype-phenotype correlation between recently reported associated 20 variants from multiple autoimmune disease and RA genes/loci in an ethnically homogenous non-Caucasian Colombian population from Paisa community. Methods: 20 SNPs from 17 genes/loci were genotyped in 353 RA cases and 368 controls in individuals from Columbia. For each SNP, allelic and genotype based association tests were applied to evaluate genotype-phenotype correlation. Permutation based tests were used to validate the statistical significance. Gene-gene interactions were assessed by logistic regression and multiple testing was adjusted with both Bonferroni corrections and false discovery rate (FDR). To evaluate the veracity of genetic association, we used RA data from GAW16 either from genotypes or by imputation. Results: We replicated the genetic association with rs6822844, (p = 0.008, OR = 0.86) from IL21, rs13277113 (p=0.0009, OR=1.46) and rs2736340 (p= 0.0001, OR=1.63) from C8orf13-BLK, and rs763361 (p=0.03, OR=1.21) from CD226 in the Colombian population. The population attributable risks were estimated as10%, 27%, 34%, and 16% for rs6822844, rs13277113, rs2736340, and rs763361 respectively. We also detected evidence of gene-gene interaction between MMEL1 and C80rf13-BLK (p=0.0002) in Colombian population. 6 of these 20 SNPs were replicated in GAW16 data but no gene-gene interaction is detected. Conclusion: We replicated association with 4 autoimmune predisposing loci in a non-Caucasian population. Contributions of these genes to disease predisposition in RA suggest that there are common disease mechanisms between RA and clinically different autoimmune diseases. Identification of gene-gene interaction in Colombian population is important, and this should be confirmed in another independent homogenous population.

2914/T

Characterization of the *LILR* complex across populations and association analysis of the region with systemic lupus erythematosus. *C.J. Gallant[1], A.M. Delgado-Vega[1], E. Sánchez[2], S. The leukocyte immunoglobulin-like receptors (*LILRS*) are a family of 13 genes on chromosome 19q13 that are mainly expressed on myeloid and lymphoid cells. LILRs function as inhibitory, stimulatory or soluble receptors and interact with FCRγ and HLA class I molecules. To date, different *LILRs* in the region have demonstrated extensive polymorphism (CNVs), population differentiation, evidence for balancing selection and association or linkage with disease susceptibility, including the autoimmune disease systemic lupus erythematosus (SLE). Given their importance in immune regulation, we propose that *LILRs* may contribute to SLE susceptibility and that population-specific polymorphisms may help explain differences in disease severity or susceptibility. To test this hypothesis, we combined dense genotyping, sequencing and quantification of copy number variable regions in European, South American and American Hispanic, Asian and African-American SLE cases and controls. We will present the results of our characterization of the *LILR* region across populations and report the findings of the association analysis between SLE and LILR polymorphisms.

Evidence that Variants in the Clock Gene PER3 Confer Susceptibility to Type 2 Diabetes in Mexican Americans and to Diabetic Complications in Type 1 Diabetics. *J. Below[1], E. Gamazon[2], G. Bell[1], D. Nicolae[3], N. Cox[2], C. Hanis[4].* 1) Dept of Human Gen, Univ Chicago, Chicago, IL; 2) Dept of Genetic Medicine, Univ Chicago, Chicago, IL; 3) Dept of Statistics, Univ Chicago, Chicago, IL; 4) Dept of Human Gen, Univ Texas Health Science Center, Houston, TX.

Results derived from a GWAS (Affymetrix 6.0) in 837 unrelated cases with type 2 diabetes and 781 controls all of whom were Mexican Americans from Starr County, TX, and a GWAS (Affymetrix 5.0) in 1651 subjects of recent European ancestry with type 1 diabetes studied through the Genetics of Kidneys in Diabetes (GoKinD) in whom a variety of complications of diabetes were measured, both identified functional SNPs controlling expression of PER3. Functional Genome Wide Association (FGWA) utilizes a priori functional information for markers combined with set-level analysis to calculate a single p-value at the level of the gene. The gene-level p-value for PER3 approached genome-wide significance at 2.67E-05 (given that we have at least one functional SNP in 13,000 genes) for type 2 diabetes, and was the second most significant gene-based signal observed for the type 2 diabetes study. The gene-level p-value for kidney failure (the primary complication phenotype examined in GoKinD) was 9.5E-04 and was the 13th most significant signal. The GoKinD signal is driven by 3 missense mutations: rs10462020, rs228697, and rs10462021. rs10462021 and rs10462020, also contribute to the significance in Starr County as well as an additional missense mutation: rs2640909. For all of these missense variants, the minor allele was associated with increased risk for type 2 diabetes and kidney failure. PER3 is a key player in the transcriptionaltranslational feedback loop of the circadian system, which is responsible for regulation of numerous physiological and behavioral systems. Recent papers have implicated circadian clock function and metabolic diseases, showing that glucose intolerance is connected to expression of PER3 in humans. Our results support these findings, and are consistent with the hypothesis that missense mutations in PER3 may degrade glucose homeostasis sufficiently to increase risk of type 2 diabetes and lead to increased risk of diabetic kidney failure.

2916/T

Pre-Diabetic Ascertainment and the Relationship between BMI and Diabetes/Glucose Genetic Variants. *J.C. Engert[1,4], S.D. Bailey[1], C. Xie[2], G. Paré[2], A. Montpetit[3], S. Anand[2], The EpiDream investigators.* 1) Dept of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Population Health Research Institute, McMaster University, Hamilton, Ontario, Canada; 3) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 4) Dept of Medicine, Royal Victoria Hospital, McGill Univ, Montreal, PQ, Canada.

Recent genome-wide association studies (GWAS) have convincingly associated several genetic loci with type-2 diabetes (T2D) and obesity. However, there is little overlap in the susceptibility loci identified for both diseases. In fact, only the FTO gene has been identified as contributing to both traits. We tested approximately 2000 inflammatory, metabolic, and cardiovascular candidate genes in 9451 European EpiDREAM participants (individuals screened for the DREAM trial) for an association with body mass index (BMI) and fasting plasma glucose (FPG). As expected, the SNPs most significantly associated with BMI are within the FTO locus (rs7193144, β= 0.63, p=3.30x10-14) and those most significantly associated with FPG are within the TCF7L2 locus (rs7903146, β=0.10, p=4.564x10-10). Interestingly, SNPs within both of these genes were significantly associated with both traits (p<0.05). Previous reports from ascertained populations have identified an association of TCF7L2 SNPs with BMI, but this result has not been replicated in prospective studies. In EpiDREAM, we observed that the TCF7L2 allele that increased BMI lowered FPG (β=-0.38, p=1.591x10-5). A significant number of the SNPs tested (n=175) affect both BMI and FPG (p<0.05) and the direction of the effect for the majority of these SNPs (n= 137) are the same. 38 SNPs, from 26 genes, (including TCF7L2 appeared to have an effect on both traits, but in opposite directions. We created a genotype score of 13 previously reported loci convincingly associated with T2D or glucose-related traits, excluding the FTO locus. We observed a graded relationship between the allele score and BMI in EpiDREAM individuals. Specifically, individuals with a low T2D genetic risk score (£8) had an average BMI that was more than two full points higher than individuals with a high T2D genetic risk score (≥19)(average BMI = 31.1 and 29.0, respectively, p=3.18x10-3). These results can be explained if the sum of T2D and FPG risk alleles, leads to diabetes in an additive model with BMI. Thus, more risk alleles are required on average to cause diabetes in lean individuals than in obese individuals, and a negative correlation between these loci and BMI is observed in a sample ascertained for glucose-related traits such as EpiDREAM. We believe that risk allele associations with BMI may be the result of ascertaining pre-diabetic individuals.

***MTNR1B* is Associated with Glycemia During Pregnancy in Mexican-American Populations.** *M.G. Hayes[1], H. Lee[1], D. Levine[2], C. McHugh[2], L.P. Lowe[1], J. Morrison[3], A. Pluzhnikov[3], M. Urbanek[1], L. Armstrong[1], C. Ackerman[1], D. Mirel[4], A.R. Dyer[1], B.E. Metzger[1], N.J. Cox[3], W.L. Lowe[1] for the HAPO Study Cooperative Research Group.* 1) Northwestern University, Chicago, IL; 2) University of Washington, Seattle, WA; 3) University of Chicago, Chicago, IL; 4) The Broad Institute, Cambridge, MA.

The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study, a multicenter international study, examined the association of maternal glucose levels with fetal growth and outcome in >25,000 pregnant women from multiple ethnic groups. Results showed a continuous relationship between maternal glucose measures and birth size throughout the range of glucose concentrations less than those diagnostic of diabetes. We conducted a genomewide association study in a subset of HAPO populations (European-ancestry, Mexican-American, and Afro-Caribbean) to determine genetic associations with maternal glycemia and insulin secretion (fasting, 1-hr, and 2-hr glucose and fasting and 1-hr C-peptide from the OGTT) at 27.8±1.8 weeks gestation. Genotyping results are currently completed for 840 Mexican-American mothers. Associations were assessed through linear regressions with the single trait/outcome under an additive genetic model adjusting for known confounders (mother's age, BMI, height, and mean arterial pressure at the OGTT; gestational age of the baby at OGTT; parity; and ancestry [the first two principal components of variation calculated from a LD trimmed set of 95K SNPs spanning the genome]). Among our strongest signals was rs10830963, a C>G transversion occurring within an intron of *MTNR1B* on chromosome 11 which encodes the melatonin receptor 1B, which was recently identified in a GWAS meta-analysis as a variant associated with increased fasting glucose levels in non-pregnant women and men of European ancestry. In the HAPO study, this SNP was strongly associated with increased fasting glucose (2.1 mg/dL [95%CI: 1.4-2.8] per maternal minor allele; P=3.4x10-8), as well as associated with 1-hour glucose (5.5 mg/dL [95%CI: 2.0-9.0]; P=0.0024), and 2-hour glucose (3.4 mg/dL [95%CI: 0.9-5.9]; P=0.0086) during the OGTT. This same minor allele was also associated with the new diagnostic criteria for hyperglycemia during pregnancy (OR=1.73 [95%CI: 1.30-2.29]; P=0.0001). These results suggest that genetic variation in *MTNR1B* is not only associated with increased fasting glucose levels in non-pregnant women and men of European ancestry, but also associated with glycemia during pregnancy in Mexican-Americans.

2918/T

Variants in *PFKFB2* are Associated with Body Mass Index and Insulin Secretion in Pima Indians. *Y. Muller, J. Fleming, S. Bhutta, R. Hanson, L. Bian, W.C. Knowler, C. Bogardus, L. Baier.* NIDDK, NIH, Phoenix, AZ.

A prior genome-wide association study (GWAS) in Pima Indians using the Affymetrix 1-million SNP chip identified variants within *PFKFB2* that were associated with quantitative traits that predict obesity. *PFKFB2*, located on chr.1:207226620-207254368bp, encodes 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase, a bifunctional enzyme involved in the synthesis and degradation of fructose 2,6-bisphosphate. PFKFB2 has a role in regulation of insulin secretion in pancreatic β-cells *in vitro*, and high fructose 2,6-bisphosphate levels in transgenic mice result in weight gain. To follow-up on our GWAS findings, the putative promoter, exons and exon-intron boundaries of *PFKFB2* were sequenced in 24 Pima Indians, and 13 single nucleotide polymorphisms (SNPs) were identified. Fourteen SNPs were genotyped in a population based sample of 3501 full heritage Pima Indians informative for body mass index (BMI). A 3'-UTR SNP (rs17258746) with a risk allele frequency of 0.10, was associated with BMI (mean BMI 38.3 kg/m^2 vs. 36.8 kg/m^2, p=0.00007, adjusted for age, sex and family membership). Among 415 non-diabetic Pimas studied for quantitative traits, the obesity risk allele for rs17258746 was associated with higher percent body fat (p= 9.9 x 10^{-9}, adjusted for age, sex and family membership), higher fat mass (p=0.0001, adjusted for age, sex, % body fat and family membership), and higher waist and thigh circumferences (p=0.001, 0.0005, respectively, adjusted for age, sex, % body fat and family membership). Among 268 subjects with normal glucose tolerance, the risk allele of rs17258746 was further associated with lower acute insulin response to an intravenous glucose bolus infusion (p=0.005, adjusted for age, sex, % body fat, family membership and glucose disposal), as well as lower 30-min plasma insulin level during an oral glucose tolerance test (adjusted p=0.0002). These results suggest that PFKFB2 has roles in metabolic pathways that affect acute/early insulin secretion and BMI in humans.

2919/T

A genome-wide search for non-synonymous SNPs affecting rate of progression from proteinuria to end-stage renal disease (ESRD) in patients with type 1 diabetes (T1D). *J. Skupien, G.D. Poznik, A.S. Smiles, M.G. Pezzolesi, J.H. Warram, A.S. Krolewski.* Section on Genetics and Epidemiology, Joslin Diabetes Center, Boston, MA.

Objective: We carried out a genome-wide association analysis to identify non-synonymous genetic variants underlying susceptibility to ESRD in patients with T1D and proteinuria. As a precise indicator of the disease process underlying progression to ESRD, we used the rate of decline in renal function from an estimated glomerular filtration rate (eGFR) of 75 down to 30 ml/min/1.73 m^2, as we have previously demonstrated this decline to be linear. Methods: A cohort of 334 European-descent T1D patients presenting with proteinuria was genotyped with the 500K Affymetrix microarray. Imputation was performed with IMPUTE2 software using reference haplotypes from HapMap Phase 3 and 1,000 Genomes Project to yield data for a total of 16,934 non-synonymous SNPs. Serial measurements of serum creatinine were used to estimate eGFR using the MDRD formula. Subjects were followed for up to 18 years, during which time 153 developed ESRD. We used a random effects model to test the impact of each SNP on the average individual rate of GFR decline within the range of 75-30 ml/min/1.73 m^2. Results from this analysis were compared to Cox proportional hazards models both with and without adjustment for baseline eGFR. Results: We identified 32 non-synonymous SNPs that were significant at a $p<10^{-3}$ level. Only 2 SNPs were confirmed by Cox model at the same significance level. The SNPs meeting genome-wide significance criterion of $p<10^{-6}$ included rs2298624 on chromosome 18 in the *MYO5B* gene (myosin V B, $p=8.5\cdot10^{-8}$) and rs16844152 on chromosome 4 in the *RGS12* gene (regulator of G-protein signaling 12, $p=2.7\cdot10^{-7}$). Only the latter SNP was significant in our Cox model analysis ($p=3.2\cdot10^{-4}$). Survival analysis did not identify any SNPs with genome-wide significance. Conclusions: We analyzed non-synonymous SNPs with a statistical model that uses subject's rate of eGFR decline as a measure of the risk of progression to ESRD. We postulate that this analysis is the most appropriate for studying the genetics of ESRD risk. Time-to-event analysis suffers from biases caused by differing lead-in times before onset of renal function decline, as well as late follow-up entry. Adjusting for baseline eGFR may not properly correct for these. Despite intuitive equivalence between progression rate and time-to-event phenotypes, the results were not concordant. This interesting issue requires further careful research. Our findings will be tested in an independent case-control study.

2920/T

Identification of novel type 2 diabetes loci through systematic evaluation of linked regions 1q21-23 and 20q13 in North Indians. *R. Tabassum[1], A. Mahajan[1], O.P. Dwivedi[1], G. Chauhan[1], V. Sharma[1], S. Ghosh[2], N. Tandon[3], D. Bharawaj[1].* 1) Genomics and Molecular Medicine Unit, Institute of Genomics and Integrative Biology, CSIR, Delhi, India; 2) Human Genetics Unit, Indian Statistical Institute, Kolkata 700 108, India; 3) Department of Endocrinology, All India Institute of Medical Sciences, New Delhi 110 029, India.

The robust replication of 1q21-23 and 20q13 as strongly linked genomic regions in multiple ethnic groups warrants their systematic exploration for the discovery of type 2 diabetes susceptibility genes. Here, we performed gene-centric candidate region analysis to examine association of variants in putative regulatory regions of the genes on 1q21-23 and 20q13 with type 2 diabetes. We genotyped 207 SNPs in 2,115 Indo-European participants (1,073 cases and 1,042 controls) and replicated the associations detected in an independent sample set of 2,079 Indo-European subjects (1,041 cases and 1,038 controls), recruited from North India. Association of 12 SNPs with type 2 diabetes at nominal significance was observed with strongest association at variants in two genes [OR=1.31, P=1.4×10-3 and OR=1.25, P=1.1×10-3] Allele dosage analysis revealed 2.89 fold risk of type 2 diabetes in individuals carrying >10 risk alleles than those having <6 risk alleles [P= 1.4×10-9], with 1.21 times increase in risk with every increase in effective allele score [PTrend=1.5×10-10]. In the replication analysis, we confirmed the association of these variants with type 2 diabetes that was further corroborated through meta-analysis [OR=1.29, P=3.9×10-5 and OR=1.19, P= 1.8×10-4 respectively]. Moreover, we identified chromosomal segments on 1q21-23 and 20q13 influencing type 2 diabetes related traits. Variants of two genes were found to influence the measures of glucose homeostasis [β=2.39 mg/dl, P=3.3×10-4] and obesity (β= -1.13 kg/m2, P=3.4×10-5] respectively. Interestingly, all the four strongly associated genes have probable roles in inflammatory processes. In conclusion, we identified novel genes, both with probable role in inflammation as novel type 2 diabetes susceptibility genes and hence, further reinforced the contribution of inflammation in the development of type 2 diabetes.

2921/T

A large-scale candidate-gene association study of age at menarche and age at natural menopause. *C. He[1,2], P. Kraft[3,4], J.E. Buring[4,5,6], C. Chen[3,4], G. Paré[5,6,7], S.E. Hankinson[4,8], S. Chanock[9], P.M. Ridker[4,5,6,7], D.I. Chasman[5,6,7], D.J. Hunter[3,4,8,10].* 1) Department of Public Health, Indiana University School of Medicine, Indianapolis, IN; 2) Melvin and Bren Simon Cancer Center, Indiana University, Indianapolis, IN; 3) Program of Molecular and Genetic Epidemiology, Harvard School of Public Health, Boston,; 4) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 5) Donald W. Reynolds Center for Cardiovascular Research, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 6) Division of Preventive Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 7) Center for Cardiovascular Disease Prevention, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 8) Channing Laboratory, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 9) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Department of Health and Human Services, Bethesda, MD; 10) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA.

Recent genome-wide association (GWA) studies have identified several novel genetic loci associated with age at menarche and age at natural menopause. However, the stringent significance threshold used in GWA studies potentially lead to false negatives and true associations may have been overlooked. Incorporating biologically relevant information, we examined whether common genetic polymorphisms in candidate genes of 9 groups of biologically plausible pathways and related phenotypes are associated with age at menarche and age at natural menopause. A total of 18,862 genotyped and imputed single nucleotide polymorphisms (SNPs) in 278 genes were assessed for their associations with these two traits among a total of 24,341 women from the Nurses' Health Study (NHS, N=2,287) and the Women's Genome Health Study (WGHS, N=22,054). Linear regression was used to assess the marginal association of each SNP with each phenotype. We adjusted for multiple testing within each gene to identify statistically significant SNP associations at the gene level. To evaluate the overall evidence for an excess of statistically significant gene associations over the proportion expected by chance, we applied a one-sample test of proportion to each group of candidate genes. The steroid-hormone metabolism and biosynthesis pathway was found significantly associated with both age at menarche and age at natural menopause (nominal p=0.040 and 0.011, respectively). Additionally, the group of genes associated with precocious or delayed puberty was found significantly associated with age at menarche (nominal p=0.013), and the group of genes involved in premature ovarian failure with age at menopause (nominal p=0.025). Our results suggest polymorphic variants in candidate genes of biologically-relevant pathways and related phenotypes are associated with age at menarche and age at natural menopause.

2922/T

Variability in heritability estimates as a confounding effect for association studies in nonsyndromic cleft lip and palate in Brazilian populations. *M.R.S. Passos-Bueno[1,2], L.A. Brito[1,2], L.A. Cruz[1,2], M. Aguena[1,2], L.B. Kobayashi[1,2], D.F. Bueno[1,2], D. Franco[4], A. Mendonça[5], N. Alonso[3], D. Bertola[3], P.A. Otto[1,2].* 1) Dept Gen & Evol Biol, Univ De Sao Paulo, Sao Paulo SP, Brazil; 2) Human Genome Research Center, University of São Paulo, São Paulo-SP, Brazil; 3) School of Medicine, University of São Paulo, São Paulo-SP, Brazil; 4) School of Medicine, Federal University Of Rio de Janeiro-RJ, Brazil; 5) School of Medicine, Federal University Of Rio de Alagoas-AL, Brazil.

Nonsyndromic cleft lip and palate (NSCLP) is a complex multifactorial disorder with average prevalence of 1:1000 live births, varying according to ethnicity, geographic origin and socioeconomic level. A wide range of heritability (30%-85%) for NSCLP has also been estimated in different populations. Several candidate genes have been emerged, but few have been replicated. These controversial results can be partly attributed to differences of the genetic contribution to NSCLP in each population, heterogeneity or its ethnic constitution. Considering the high level of ethnic admixture and the lack of heritability estimates in Brazilian population, we have evaluated these aspects in a large sample of NSCLP patients, from 1042 families ascertained in 5 regions of Brazil (Fortaleza-n=331; Barbalha-n=86, Santarem-n=121, Maceio-n=188, Rio de Janeiro-n=316). Analyzing 40 insertion-deletion ancestry informative markers, we observed that except for the patients from Santarém, the European (~70%), African (~20%) and Amerindian (~10%) contributions were similar among the studied groups of patients, which in turn did not differ from the local control population. In contrast, in Santarem, a larger contribution of Amerindians (42%) was identified and it is apparently higher compared to controls (~20%). Our heritability estimates, based on number of affected relatives of proband, varied among the 5 ascertained samples, with the highest value in Barbalha (85%). Santarém (71%), Rio de Janeiro (70%) and Fortaleza (64%) presented intermediate genetic contributions, whereas NSCLP in Maceio had the lowest heritability (45%). Rate of consanguinity among parents of the probands was significantly different among the 5 studied regions (p=0.001),with higher values in Fortaleza and Barbalha. These results suggest that the genetic contribution varies according to geographic region and inbreeding is one potential explanation for this finding. Ethnicity does not seem to have a major contribution for variability of the heritability estimates; as except for the sample of Santarem, the studied patients' groups were constituted with similar contribution of European, African and Ameridian ancestries. Our results suggest that the proportion of genetic factors contributing to the etiology of NSCLP might vary according to the studied population, a factor that can mask positive associations in case-control studies. Availability of this data in a population is important to interpret GWAS studies.

Follow-up of regions linked to tuberculosis in a Ugandan genome scan. *C.M. Stein[1,2], A.R. Baker[1], S. Zalwango[4], R.P. Igo[1], L.L. Malone[2], M.D. Adams[2,3], H. Mayanja-Kizza[4], W.H. Boom[2].* 1) Dept of Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Tuberculosis Research Unit, Case Western Reserve Univ, Cleveland, OH; 3) Dept of Genetics, Case Western Reserve Univ, Cleveland, OH; 4) Uganda - CWRU Research Collaboration, Kampala, Uganda.

Tuberculosis (TB) is a significant public health problem globally, particularly in the face of the HIV epidemic. Several studies, including genome-wide linkage scans, have suggested a role for human genetics in susceptibility to developing TB. Previously, we conducted a genome-wide linkage scan for TB as part of our ongoing household contact study in Kampala, Uganda; in this study, we identified regions on chromosomes 7 and 20 linked to TB. We have followed up those regions by analyzing specific candidate genes - IL6 and CARD11 on chromosome 7, and CTSZ and MC3R on chromosome 20 - and fine mapping a 1-LOD drop region on chromosome 7p22-7p21. We analyzed 564 individuals from 243 households identified through an index case with culture-confirmed TB, and we genotyped 1536 SNPs on the Illumina platform. In addition to these genotyped SNPs, we also imputed SNPs using MaCH, using three African HapMap populations as our reference sample (Yoruba, Maasai, and Luhya). Though we did not observe association with any single SNPs in CTSZ or MC3R, we detected association between two CTSZ haplotypes and TB (p=0.047 and p=0.0964, respectively); this suggests that there may be an untyped risk variant in the region, or the sequence of SNPs may be associated with TB risk. This association with CTSZ replicates a finding in a South African population. We did not observe association with IL6 or CARD11. In addition, preliminary analysis of imputed markers suggests association with numerous SNPs, including the SDK1 gene (p-values between 0.0063 and 0.044), which has been associated with HIV nephropathy, and FOXK1 (p=0.031), which is associated with lung function; these results warrant confirmation with newly genotyped markers.

2924/T

Domain-dependent clustering and phenotype association of LGI1 gene mutations in autosomal dominant partial epilepsy with auditory features (ADPEAF). *Y. Ho[1,2,3], I. Ionita-Laza[1], R. Ottman[4,5].* 1) Division of Statistical Genetics; 2) Department of Biostatistics; 3) Department of Psychiatry; 4) Department of Epidemiology; 5) G.H. Sergievsky Center, Columbia University, New York, NY 10032, USA.

Introduction: The leucine-rich, glioma inactivated 1 gene (LGI1) encodes a secretory protein with two major functional domains: the N-terminal leucine-rich repeats (LRR) and the C-terminal epitempin repeats (EPTP). Mutations in LGI1 cause autosomal dominant partial epilepsy with auditory symptoms (ADPEAF) (OMIM600512), a focal epilepsy syndrome with auditory symptoms as prominent ictal manifestations, with an estimated penetrance of 67%. Hypotheses: 1. The distribution of ADPEAF-causing mutations is not uniform within the LGI1 gene. 2. Phenotypic features in affected individuals differ depending on the coding domain in which mutations are found. Materials and Methods: Clustering of mutations within the gene was analyzed for all 30 previously reported ADPEAF-causing mutations using a sliding window approach. Phenotypic and genetic information were analyzed on 52 patients with idiopathic focal unprovoked seizures from 11 ADPEAF families with LGI1 mutations. Bivariate analysis was performed using general estimating equations to test for association between mutation site and auditory symptoms. 95% confidence intervals (CI) for the odds ratios (OR) were calculated by the logit method. Results: ADPEAF-causing mutations clustered significantly in the LRR domain (exons 3-5) of LGI1 ($p = 0.001$). The coding domain in which mutations were located was not associated with disease penetrance. Auditory symptoms were present in 91% of patients with mutations in the LRR domain and 73% of patients with mutations in the EPTP domain (OR=3.7; 95% CI=1.1-12.5, $p = 0.038$). Conclusion: ADPEAF-causing mutations cluster significantly within the LRR region of the LGI1 gene, and mutations in this region are also associated with an increased likelihood of manifesting auditory symptoms in ADPEAF. Large-scale meta-analysis identifies more than 40 ulcerative colitis risk loci. *C.A. Anderson[1], G. Boucher[2], R.H. Duerr[3], C.W. Lees[4], G. Radford-Smith[5], J.D. Rioux[2], S. Vermeire[6], R.K. Weersma[7], The International IBD Genetics Consortium.* 1) Statistical Genetics, Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Department of Medicine, Université de Montréal and Montreal Heart Institute, Research Center, Montreal, Québec, Canada; 3) University of Pittsburgh, School of Medicine, Department of Medicine, Division of Gastroenterology, Hepatology and Nutrition, University of Pittsburgh Medical Center, Presbyterian, Pittsburgh, USA; 4) Gastrointestinal Unit, Molecular Medicine Centre, University of Edinburgh, Western General Hospital, Edinburgh, UK; 5) Inflammatory Bowel Diseases Laboratory, Royal Brisbane and Women's Research Foundation, Brisbane, Queensland, Australia; 6) Department of Nephrology, University Hospital Gasthuisberg, Leuven, Belgium; 7) Department of Gastroenterology and Hepatology, University Medical Centre Groningen, University of Groningen, Groningen, The Netherlands.

Several genome-wide association studies (GWAS) of ulcerative colitis (UC), a common form of inflammatory bowel disease (IBD), have been published to date. These studies identified 18 UC susceptibility loci, and highlighted the importance of the epithelial barrier, cell-specific innate response, adaptive immunity and resolution of inflammation in disease pathogenesis. Interestingly, 8 of these loci were previously associated with Crohn's disease, the other common form of IBD, indicating that T-cell differentiation and the innate immune response are broadly involved in IBD pathogenesis. In the current study, data from 6,433 patients with UC and 20,099 population controls, collected from 6 GWAS of North American and European samples, were combined across 1.2 million SNPs using genotype imputation. In total, 75 independent genomic regions were associated at $P<1\times10^{-5}$, including all previously confirmed UC associations. We selected 52 potentially novel UC risk loci for follow-up in an additional set of around 10,000 UC cases and 10,000 population controls of European descent. Of these, 24 loci had a $P<0.05$ in the replication study and $P<5\times10^{-8}$ in the combined analysis and thus represent novel UC loci. Interestingly, 10 of these loci have previously been associated with CD (including *IL12B*, *PTGER4*, *CARD9*, *STAT3* and *JAK2*). Loci associated with other autoimmune diseases (such as multiple sclerosis, celiac disease and systemic lupus erythematosus) were also identified (e.g. *IL7R* and *ETS1*). The association with *ETS1*, which is expressed in all Th subsets and is required for optimal production of inflammatory cytokines (and the suppression of IL10), further implicates the Th17 pathway in disease pathogenesis. The central role of the epithelial barrier in disease risk is further highlighted by the novel, UC specific, association with *GNA12*, which regulates protein interactions within (and inhibits the assembly of) tight junctions. In an expression quantitative trait meta-analysis of 1,469 whole blood samples, 17 of 42 UC associated loci were correlated ($P<0.0028$, FDR 5%) with cis gene expression. In aggregate, known UC risk loci now account for around 10% of phenotypic variance in disease risk. This work has greatly increased the number of known UC loci and has significantly increased our understanding of disease pathogenesis relating to both shared and UC-specific inflammatory pathways.

2926/T

Estimating genetic effects under multistage sampling design of family data. *Y. Choi[1], L. Briollais[2].* 1) Epidemiology and Biostatistics, Univ Western Ontario, London, ON, Canada; 2) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, ON, Canada.

In family-based genetic studies, multistage sampling permits the allocation of resources to families that are most informative for a given objective while allowing population-based inference. The objective of this study is to provide population-based estimates of the relative risk of both major gene and unknown gene mutations and the age-specific cumulative risk of a disease associated with a mutated gene based on the family data collected from a multistage sampling design. A major problem in this study design is to deal with partially or completely missing genetic information among family members. To analyze multistage family designs, we propose a composite likelihood approach and further extend it to account for missing genetic information using an Expectation-Maximization (EM) algorithm. We infer the missing genetic information by its conditional expectation given their phenotype information and known mutation statuses of the other family members. Our approach is developed for time-to-event data to handle missing genetic covariates by using an EM algorithm. We also investigate the role of an unknown major genetic effect that could segregate within families. Assuming the presence of a second gene associated with disease but its genotypes are unknown i.e., all missing, the EM algorithm is used to infer the unknown genetic effect besides the segregation of major gene muations. Our simulation studies have demonstrated the good properties of our approach in terms of consistency and efficiency of the genetic relative risk estimate under different multistage sampling designs in the presence of missing genotypes. In addition, an application to a family study of early-onset breast cancer demonstrates the interest of our approach. The family data are collected from several population-based breast cancer family registries (Ontario, California and Australia), as a part of the NCI-funded Cancer Families Registries initiatives based on a two-stage sampling design. It confirms the important effects of the genes BRCA1 and BRCA2 in these families, while it shows that a wrong inference can be made about this effect if the sampling design is not properly taken into account.

2927/T

A critical assessment of *CIITA* variation and risk for SLE, lupus nephritis and other related clinical outcomes.

P.G. Bronson[1], B.A. Goldstein[2], S.L. May[1], P.P. Ramsay[1], K.B. Beckman[3,4], J.A. Noble[4], J.A. Lane[4], M.F. Seldin[5], J.A. Kelly[6], J.B. Harley[6], K.L. Moser[6], P.M. Gaffney[6], T.W. Behrens[7], L.A. Criswell[8], L.F. Barcellos[1]. 1) Division of Epidemiology, School of Public Health, University of California, Berkeley, CA; 2) Division of Biostatistics, School of Public Health, University of California, Berkeley, CA; 3) Biomedical Genomics Center, University of Minnesota, Minneapolis, MN; 4) Children's Hospital Oakland Research Institute, Oakland, CA; 5) Department of Biochemistry and Molecular Medicine, School of Medicine, University of California, Davis, CA; 6) Oklahoma Medical Research Foundation, Oklahoma City, OK; 7) Immunology Diagnostics and Biomarkers, Genentech, South San Francisco, CA; 8) Rosalind Russell Medical Research Center for Arthritis, Department of Medicine, University of California, San Francisco, CA).

The major histocompatibility complex (MHC) class II transactivator gene (*CIITA*) is an important transcription factor regulating gene required for human leukocyte antigen (HLA) class II MHC-restricted antigen presentation. Association with HLA class II variation, particularly *DRB1*1501* and **0301*, has been well-established for systemic lupus erythematosus (SLE). However, MHC genes only account for a portion of the genetic risk. Several non-MHC genes have recently been associated with risk for SLE, including *PTPN22*, *STAT4* and *TNFAIP3*. In addition, studies suggest that genes regulating initiation of the most serious SLE complication, lupus nephritis (LN), may differ from genes involved in SLE risk. Thus, we investigated *CIITA* variation, *DRB1*1501*, **0301* and important primary and secondary outcomes in SLE. We tested 18 *CIITA* SNPs in 637 SLE trio families and 826 unrelated SLE cases (n=2,737) of European ancestry. Family-based association tests were conducted to compare transmitted vs. nontransmitted alleles. Case-control, case-only and novel genic association tests were conducted in the combined trios and unrelated cases, utilizing nontransmitted parental alleles as controls. Analyses were stratified by *DRB1*1501*, **0301*, LN, arthritis, serositis, neurological involvement, Sm and Ro autoantibody production in cases. No evidence for association was observed between *CIITA* and SLE in family-based and case-control analyses after correcting for multiple testing. Modest evidence for association between the intronic rs11074938**G* variant and the presence of either *DRB1*1501* or **0301* (OR= 1.27, 95% CI=1.11-1.47, *P*=2x10-3), and the UTR-3' rs45617532**C* variant and neurological involvement (OR=4.07, 95% CI=1.83-9.06, *P*=1.2x10-3) were observed in case-only analyses. The genic test did not reveal evidence for association. This is the first comprehensive and well-powered study of *CIITA* and SLE, including examination of clinical phenotypes and influence of known HLA risk alleles. Recent studies have reported evidence for association between *CIITA* and multiple sclerosis, ulcerative colitis and celiac disease. Although the majority of common genetic variation (MAF $\geq$ 0.01) in *CIITA* and its promoter region was fully captured in the current study, results do not provide evidence to support a role for this locus in SLE.

Genetic Data Suggest a Novel Association Between the Vitamin D Pathway and Development of Age-related Macular Degeneration.

M. DeAngelis[1], M.A. Morrison[1], A.C. Silveira[1], S.M. Adams[1], M.G. Kotoula[2], E.E. Tsironi[2], F. Zacharaki[2], I.K. Kim[3], J.W. Miller[3], N.B. Haider[4], A. Jelcick[4], B.W. Hollis[5], R. Chen[6], G.S. Hageman[7], D.A. Schaumberg[8]. 1) Ocular Molecular Genetics Institute, Harvard Medical School, Massachusetts Eye and Ear, Boston, MA; 2) Department of Ophthalmology, University of Thessaly School of Medicine, Larissa, Greece; 3) Retina Service and Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear, Boston, MA; 4) Department of Genetics, Cell Biology, and Anatomy, University of Nebraska Medical Center, Omaha, NE; 5) Medical University of South Carolina, Charleston, SC; 6) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 7) Ophthalmology and Visual Sciences, John A. Moran Eye Center, University of Utah, Salt Lake City, UT; 8) Division of Preventive Medicine, Brigham and Women's Hospital, Boston, MA.

Data from our laboratory suggest a protective role for lifetime UV exposure in susceptibility to age-related macular degeneration (AMD). Thus, we evaluated the genetic contribution of variation in vitamin D pathway genes and serum vitamin D levels to AMD. Using 135 extremely phenotypically discordant sibling pairs, we evaluated 59 SNPs within the vitamin D pathway genes VDR, CYP27B1, CYP24A1, and CYP27A1. Additionally, 50 pairs from this cohort were ascertained for serum vitamin D levels. Single SNPs, haplotypes, and gene-gene interaction were tested for association using the model for sibships in UNPHASED. Initial findings were then evaluated in an extended family cohort, an unrelated case control cohort from central Greece, and a prospective based cohort derived from the Nurses' Health Study (NHS) and Health Professionals Follow-up Study (HPFS), which included patients with various types of AMD (2,528 individuals). Sera analyses showed a slight trend of higher vitamin D levels in unaffected siblings. After controlling for covariates, only variation in CYP24A1 influenced AMD risk. Specifically, rs2181874 was modestly associated with decreased risk of all types of AMD in both the extended sibpair cohort and the Greeks (p= .04 for both). In Greek and NHS/HPFS cohorts, this SNP was significant as part of a haplotype with rs1570669 (overall p = .007 and .009 respectively). Meta-analysis showed that rs1570669, rs1570670, rs2274130, and rs2296239 were more significant for risk of all AMD subtypes in meta-analysis than in any one cohort alone ($p < .01$ for all). While the VDR SNP rs2189480 was significant in the extended family based cohort, it was not significantly associated with AMD in the other cohorts. However, significant gene-gene interaction was shown between CYP24A1 and VDR in all cohorts examined ($p < .05$). Haplotypes and SNPs in CYP24A1 were demonstrated to influence AMD risk after controlling for smoking, sex, and age in all populations both separately and in meta-analysis. This is the first report demonstrating a genetic association between vitamin D metabolism and AMD risk. These data not only extend previous epidemiological and biological studies in AMD, but further relate to common antecedents among several diseases with an inflammatory/immunogenic component including cardiovascular disease and AMD and cancer and AMD.

2929/T

Platelet endothelial cell adhesion molecule-1 gene polymorphisms are associated with coronary artery lesions in chronic stage of Kawasaki Disease.

L.P. Ger[1, 2], S.C. Huang[1, 2], W.H. Lu[3, 4], K.P. Weng[3], T.J. Lai[1, 4], K.S. Hsieh[3]. 1) Department of Medical Education and Research, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan; 2) Institute of Biomedical Sciences, National SunYat-Sen University, Kaohsiung, Taiwan; 3) Department of Paediatrics, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan; 4) Institute of Clinical Medicine, National Yang-Ming University, Taipei, Taiwan.

Kawasaki disease (KD) is the most common cause of pediatric acquired heart disease. Platelet endothelial cell adhesion molecule-1 (PECAM-1) plays an important role in platelet activation modulation, which may be associated with coronary artery lesions (CALs) of KD. We tested the hypothesis that three common single nucleotide polymorphisms (SNPs), Leu125Val, Ser563Asn, and Arg670Gly, of PECAM-1 gene may be associated with coronary artery lesions (CALs) of KD in the acute and chronic stage. The genotyping of SNPs in PECAM-1 using the TaqMan assay was conducted in a case-control study of 299 KD patients with or without CALs. We found that no association between genotypic and allelic types of these three SNPs and CALs of KD. As compared with non-Leu-Ser-Arg haplotype, Leu-Ser-Arg haplotype was with a significantly increased risk for CALs in chronic stage (AOR 2.42, 95% CI 1.02-5.75, P=0.045), but not for CALs in acute stage. Analyses based on the diplotypes of PECAM-1 also showed that KD patients with one or two alleles of Leu-Ser-Arg had a significantly increased risk of CALs in chronic stage (AOR 2.85, 95% CI 1.12-7.30, P=0.029) and increased counts of platelet (×1000/Cumm) (672.6±207.6 VS. 563.1±196.8; P=0.027), as compared to those with other diplotypes. In conclusion, haplotype and diplotype of PECAM-1 might be associated with the increased counts of platelet and the following risk of chronic CALs, which needs further validation in other independent cohort.

2930/T

Replication and generalization of genetic risk factors for depression, anxiety and panic attack in European, African, and Mexican Americans from the National Health and Nutrition Examination Surveys. *K. Glenn, K. Gentry-Brown, M. Allen, P. Mayo, N. Schnetz-Boutaud, D.C. Crawford, T.A. Thornton-Wells.* Ctr Hum Genet Res, Vanderbilt Univ, Nashville, TN.

Anxiety and mood disorders are two of the most common psychiatric disorders, with lifetime prevalence estimates above 20% and heritability estimates of 35-50%, despite clear environmental stressors and risk factors. Many functional candidate genes have been implicated in anxiety, stress and mood; however, investigation within non-European populations is incomplete. As part of the Epidemiologic Architecture for Genes Linked to Environment (EAGLE), we conducted an association study of previously-reported genetic risk variants for anxiety or depression in the ethnically diverse population-based cohort, the National Health and Nutrition Examination Survey (NHANES) ascertained and maintained by the Centers for Disease Control and Prevention (CDC). For this study, we accessed NHANES 1999-2002, which includes psychological survey data for 596 non-Hispanic whites (NHWs), 231 non-Hispanic blacks (NHBs), and 354 Mexican Americans (MAs). We selected 35 SNPs in 23 candidate genes previously implicated in anxiety, mood or personality disorders or the hypothalamic-pituitary-adrenal (HPA) axis. We performed genotyping using the Sequenom and Taqman OpenArray platforms and tested for association using logistic regression with an additive allelic model. The G allele of rs6269 in COMT was associated with decreased anxiety in MAs (OR=0.447, CI=[0.262 - 0.763], p=0.0031), consistent with previous reports that the G allele is associated with higher COMT activity and lower pain sensitivity. The T allele of rs6999100 in TRIM55, downstream of CRH, was associated with decreased rates of anxiety in non-Hispanic whites (OR=0.633, CI=[0.426 - 0.941], p= 0.0236), consistent with a previous report that the T allele is under-transmitted to individuals with behavioral inhibition to the unfamiliar, with is an intermediate phenotype and risk factor for panic disorder and social phobia. The G allele of rs4570625 in the upstream regulatory region of TPH was associated with decreased rates of depression in non-Hispanic blacks (OR = 0.453, CI = [0.234 - 0.876], p = 0.0187), consistent with previous reports that the T allele is associated with amygdala responsivity, panic disorder, anxiety-related disorders and affective disorders. Despite being underpowered, we were able to replicate and characterize genetic associations for anxiety, depression and panic attack. Larger, diverse studies are required to characterize other associations with small genetic effect sizes.

2931/T

Life-span influences of Apolipoprotein E and association with longevity in a large sample. *G.J. McKay, AMD APOE Consortia.* Centre for Public Health, Queen's University Belfast, Belfast, United Kingdom.

The human Apolipoprotein E (*APOE*, MIM 107741) locus located on chromosome 19q13.2 is central to the metabolism of low-density lipoprotein cholesterol and triglycerides and has been associated with increased risk of a variety of complex and age-related disorders. Several reports on human longevity have shown that *APOE E4* allele frequency is lower in older age groups such as octogenarians, nonagenarians and centenarians than younger or middle-aged subjects and that absence of *E4* seems to be a favorable survival factor. In populations of Caucasian descent, an elevated mortality risk has been reported with the *E3/E4* genotype relative to the *E3/E3* genotype with a slightly decreased risk associated with *E2/E3* genotypes. Previously increased frequency of *E2* with advancing age in males only was reported, although follow-up studies have shown inconsistent findings, so whether this effect is specific to males or females is as yet unclear.

This study sought to assess the frequency of *APOE* isoforms in pooled samples from investigations in Caucasian populations. The initial aim was to study the influence of this gene on Age-related Macular Degeneration (AMD) but in this report we examine allele frequency as a function of age and gender in individuals free from the severe form of the disease.

We assessed allelic distribution of *APOE* isoforms, *E2*, *E3* and *E4* in 17,292 non-AMD Caucasian samples from 15 study populations. Following adjustment for center ascertainment, our data demonstrates a significant decreasing frequency of the *E4* isoform from 16.3% to 10.7% between ages of <60 and >85 years (Chi^2= 20.6; *df*=6; P=0.002) with the *E3* isoform increasing from 75.1% to 81.9% as a consequence (Chi^2=17.9; *df*=6; P= 0.006). Assessment for gender bias was found not to be significant following adjustment for center. The age-related effect observed was most prominent in individuals homozygous for the *E4* isoform (ca. 1.84% of sample), the frequency of which decreased by 73% between the ages of 60 and 85 years while the proportion with the *E3/E4* haplotype decreased by 28%. Individuals heterozygous for the *E2/E4* haplotype showed no significant change in frequency within this age range. This study supports the role of *APOE* isoforms in human longevity.

Association of SNPs of the IGF Axis with developmental growth and blood pressure. *P. Parmar[1,2], J.A Marsh[1], N.M. Warrington[2], R. Taal[3], S. Louise[1], J.P. Newnham[2], V.W.V. Jaddoe[3], G.D. Smith[4], L. Briollais[5], S.J. Lye[5,6], L.J. Beilin[7], L.J. Palmer[1], C.E. Pennell[2].* 1) Centre for Genetic Epidemiology and Biostatistics, The University of Western Australia, Perth, Australia; 2) School of Women's and Infants' Health, The University of Western Australia, Perth, Australia; 3) Department of Epidemiology, Erasmus Medical Centre, Rotterdam, the Netherlands; 4) Department of Social Medicine, University of Bristol, Bristol, United Kingdom; 5) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, University of Toronto, Canada; 6) Canadian Institutes of Health Research, Canada; 7) School of Medicine and Pharmacology, Royal Perth Hospital Unit, The University of Western Australia, Perth, Australia.

Purpose: The aim of this study was to investigate the role of polymorphisms in genes within the IGF axis in the relationship between fetal growth trajectories and blood pressure from 1-year to late adolescence. **Methods:** Participants in The Western Australian Pregnancy Cohort (Raine) Study were recruited at 16-18 weeks gestation and followed throughout childhood. Analyses focused on 1,162 singleton-birth Caucasians with complete data in antenatal life and childhood. Genes in the IGF axis (including IGF-1, IGF-2, IGF-receptor-1, IGF-receptor-2 and IGF-binding proteins 1-5) were tagged with 145 single nucleotide polymorphisms (SNPs). Associations were investigated between these SNPs and fetal growth trajectories, anthropometric measures at birth and both BMI and blood pressure trajectories throughout childhood. All analyses were stratified by sex. Replication analyses are currently underway and will be presented for GenR (The Generation R Study) and ALSPAC (Avon Longitudinal Study of Parents and Children) for antenatal and postnatal findings respectively. **Results:** All effects described here were significant to p<0.05 ***Males:*** RS4966015 (IGF1R) was found to be significantly associated with increased head circumference (HC), reduced ponderal index (PI) and increased average SBP throughout childhood. Conversely RS8041224 (IGF1R) was associated with reduced antenatal growth (abdominal circumference (AC) and HC) and reduced SBP. ***Females:*** Both RS3213221 (IGF2) and RS2670504 (IGF1R) were associated with increased fetal growth (AC and PI; AC respectively). During postnatal life RS3213221 (IGF2) was associated with reduced SBP whereas RS2670504 (IGF1R) was associated with increased BMI. Conversely RS1003737 (IGF2R) was associated with reduced birth weight and PI; increased weight change over the first year of life and increased SBP in childhood. **Conclusion:** Multiple SNPs in genes within the IGF pathways are associated with fetal growth trajectories and adolescent SBP trajectories. These data provide evidence to suggest that the relationship between antenatal growth and postnatal blood pressure measures is in part mediated by genetic variation. Patterns of associations were different in males and females and require detailed evaluation and replication in other pregnancy cohorts. These data support the concept that complex gene-environment interactions underlie the developmental origins of hypertension.

2933/T

Genome-wide Association Studies (GWAS) of Uric Acid in African Americans: the CARe Renal Consortium. *A. Tin[1], W.H. Kao[1], C.T. Liu[2], X. Lu[2], E.L. Akylbekova[3], S. Wyatt[4,5], S.J. Few genome-wide association studies (GWAS) have been conducted in populations of non-European ancestry, where differences in linkage disequilibrium (LD) and potential allelic heterogeneity exist. We conducted a genome-wide association analysis of serum uric acid levels of 5820 Africans Americans (AA) from the Atherosclerosis Risk in Communities, Coronary Artery Risk Development in Young Adults, and Jackson Heart Study, as part of the CARe Consortium, to 1) identify potentially novel loci in African Americans and 2) validate lead SNPs and interrogate regions around each of the loci that were previously reported in studies of European ancestry (EA). A meta-analysis was conducted. For the interrogation of previously discovered loci, alpha level was set at 0.05 for the lead EA SNP and corrected for the number of independent SNPs at the locus for the interrogation of each region. In the GWAS of serum uric acid, we identified SNPs at three loci achieving genome-wide significance: a novel locus on chromosome 6 (rs9321453, p=1.4E-8) and two loci previously identified in EA (SLC2A9 and SLC22A12). Of the previously identified loci among individuals of EA (PDZK1, GCKR, SLC2A9, ABCG2, LRRC16, SLC17A1/ SLC17A3, SLC16A9, SLC22A11, and SLC22A12), 8 of 9 beta coefficients of the lead EA SNP showed direction-consistent association for the same modeled allele in AA. Further, four lead EA SNPs at three distinct loci were statistically significant in our AA cohorts (rs12129861 at PDZK1, p=8.7E-5; rs734553 and rs6449213 at SLC2A9, p=2.7E-24 and 2.8E-14; rs505802 at SLC22A12, p=5.2E-6). Next, we interrogated 50 kb flanking regions around the remaining six EA loci and identified the SNP with the lowest pvalue within each region. This resulted in three loci that contained SNPs with Bonferroni-corrected p<0.05 (rs2869736 near ABCG2, p=1.1E-3; rs9467527 at LRRC16, p=2.7E-4; and rs12294207 at SLC22A11, p=4.5E-5). Finally, two independent SNPs (r2 of 0.16 in AA) in SLC2A9 accounted for 2.4% and 2.1% (combined 3.2%) of the variance in uric acid. In summary, we have identified one novel locus in association with serum uric acid in AA and observed similar genetic associations among African Americans for six loci previously reported in studies of EA. Our data support the importance of multi-ethnic GWAS in fine-mapping and the identification of new loci and potential allelic heterogeneity at known loci. With respect to uric acid, the genetic architecture appears similar in EA and AA.

Validating Risk Prediction Models using Family Registries. *W. Wang[1,2], AP. Klein[3], B. Caffo[4], G. Parmigiani[5].* 1) Stanford Genome Tech Ctr, Stanford Univ, Palo Alto, CA; 2) UC Berkeley Dept of Statistics, Berkeley, CA; 3) Johns Hopkins Univ School of Medicine, Dept of Oncology and Pathology, Baltimore, MD; 4) Johns Hopkins Bloomberg School of Public Health, Dept of Biostatistics; 5) Harvard School of Public Health, Dept of Biostatistics, Boston, MA.

We report a novel design and analysis framework for utilizing family data to validate personalized risk assessment models. It is motivated by applications to genetic diseases, and illustrated in the context of pancreatic cancer risk prediction. It has long been recognized that individuals with a family history of cancer are at higher risk of developing the disease in future. Risk prediction models for cancer are important for guiding decision about prevention. A subset of risk prediction models focus on evaluating the risk of developing cancers for which a known genetic effect or familial segregation exist, but specific genes remain unknown. Validation in independent data is an essential component for the selection, improvement and application of these models. Having realized the importance of family history for diseases such as cancer, researchers have established family registries. We describe a design strategy for defining a prospective cohort of individuals from an existing familial cancer registry, and performing the associated validation analysis. Complicating matters is the fact that it is important to consider multiple prospectively followed individuals in one family. In order to account for the genetic correlation among individuals from the same family, we propose to consider the joint risks for correlated individuals, based on the risk assessment model of interest, and use these to calculate evaluation statistics including the observed versus expected ratio, the receiver operating characteristic curve, the concordance index and the Brier's score, both at the family level and the individual level. We implement this strategy by comparing two different Markov chain Monte Carlo methods and choose the method that is much more computationally efficient. We illustrate our methods using PancPRO, a Mendelian risk prediction model of pancreatic cancer, based on data from the National Familial Pancreatic Tumor Registry.

Cumulative effect of lipids-related variants on hypercholesterolemia in the adult U.S. population: the Third National Health and Nutrition Examination Survey (NHANES III). *A. Yesupriya, M. Chang, R.M. Ned, Q. Yang, N.F. Dowling.* National Office of Public Health Genomics, Centers for Disease Control and Prevention, Atlanta, GA.

Genome-wide association studies (GWAS) have identified a number of SNPs associated with serum lipids level. The contributions of these SNPs on hypercholesterolemia are largely unclear for the U.S. adult population. This study evaluated the individual and joint SNP effects on prevalent hypercholesterolemia [total cholesterol ≥ 5.2 mmol/L (200 mg/dL) or use of cholesterol-lowering medications] in U.S. adults using a large population-based study. We examined associations between prevalent hypercholesterolemia and 22 genetic loci previously found to be associated with lipid levels using data from the second phase (1991-1994) of the Third National Health and Nutrition Examination Survey (NHANES III). Individuals aged 17 years and older that self-reported as non-Hispanic white (NHW, n=2323), non-Hispanic blacks (NHB, n=1742), or Mexican Americans (MA, n=1765) were included in the analysis. Within each race/ethnic group, we used logistic regression to examine single SNP associations, as well as the cumulative effect of multiple SNPs (using a genotype score) on risk of prevalent hypercholesterolemia. These analyses assumed an additive genetic model and were adjusted for a set of conventional risk factors. Allele frequencies for all SNPs varied significantly by race/ethnicity (p<0.02). APOE (rs7412 and rs429358) was significantly associated (p<0.05) with hypercholesterolemia in all three race-ethnic groups. An additional nine GWAS-validated SNPs were significantly associated with hypercholesterolemia in at least one race/ethnic group. A 22-SNP genetic score was associated [OR=1.17, 1.14, and 1.13 in NHW, NHB, and MA, respectively. p< 0.0001 in all three race/ethnic groups) with the prevalence of hypercholesterolemia in all three ethnic groups. The area under the curve (AUC) increased 2-3% when comparing models with and without the genetic score in addition to the set of conventional risk factors. Roughly 10% to 15% of the total variation in hypercholesterolemia could be explained by the genetic variants and conventional risk factors. We conclude that the prevalence of these lipids-associated variants differs significantly across the three U.S. race/ethnic groups. However, the distribution of genetic risk score was similar across the race/ethnicities. The combined genetic variants are associated with the prevalence of hypercholesterolemia.

2936/T

Estimating the known-unknowns from known-knowns in the search for missing heritability. *N. Chatterjee, J.-H. Park.* Division of Cancer Epidemiology and Genetics, NCI, Rockville, MD.

Recent genome-wide association (GWAS) studies have discovered a large number of susceptibility loci for many complex traits, yet for any given trait, much of its heritability remains unexplained. We have rencently developed a set of tools to estimate the number of undiscovered susceptibility loci and the distribution of their effect sizes for a trait based on discoveries from existing studies and then to project statistical power and risk prediction utility for future studies integrating over estimated distributions of effect sizes (Park et al., Nature Genetics, In press). In this report, we will use reported GWAS findings for more than 10 complex traits to illustrate the utility of our methodology in planning future GWAS of common variants. We will present data on validation of these methods and related projections using results from GIANT consortium that have used meta-analysis of more than 100,000 subjects to detect a large number of common susceptibility loci for a number of anthropometric traits such as height and BMI. In addition, we will investigate an approach to association scan for future studies incorporating the estimated effect size distribution as prior for Bayesian analysis.

2937/T

Analysis of Multiple Phenotype Data in Genome-Wide Association Studies. *G. Clarke, A.P. Morris.* Wellcome Trust Centre for Human Genetics, University of Oxford, Roosevelt Drive, Oxford, OX3 7BN, UK.

Traditionally, statistical methods for genome wide association studies have mainly concentrated on univariate trait analyses for association mapping of quantitative trait loci (QTL). However, correlated and uncorrelated phenotypes that may or may not share common genetic or environmental factors are often available. Here we show how the power to detect association between a causal genetic locus and a given phenotype of interest can be affected by the inclusion of additional correlated or uncorrelated phenotypes as covariates in simple multivariate regression analyses. We denote two phenotypes as *dissimilar* if their expected values are not proportional. Using simulations we show that if a phenotype is influenced by a QTL, then, in comparison to separate univariate analyses, the combined analysis of that phenotype and any correlated dissimilar phenotype will increase the power to detect the QTL. This boost in power occurs even if the additional phenotype has a null association with the QTL. If the additional phenotype is uncorrelated, then it is only a useful additional covariate if it has a non-null association with the QTL. Results indicate that the multivariate analysis of correlated traits is a powerful screening tool for the preliminary identification of QTLs. Further steps would then be required to make precise estimates of effect sizes.

2938/T

Genome-wide association identifies more than ten novel primary biliary cirrhosis risk loci. *J.A.B. Floyd[1], G. Mells[2], K.I. Morley[1], H.J. Cordell[3], P. Donaldson[4], M. Heneghan[5], D. Jones[4], J. Neuberger[6], G. Alexander[7], R. Sandford[2], C.A. Anderson[1], The UK PBC Genetics Consortium, The Wellcome Trust Case Control Consortium 3.* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Department of Medical Genetics, Cambridge Institute of Medical Research, Addenbrooke's Hospital, Cambridge, United Kingdom; 3) Institute of Human Genetics, Newcastle University, International Centre for Life, Newcastle-upon-Tyne, United Kingdom; 4) Institute of Cellular Medicine, Medical School, Newcastle University, Newcastle upon Tyne, United Kingdom; 5) Institute of Liver Studies, Kings' College Hospital, London, United Kingdom; 6) Liver Unit, Queen Elizabeth Hospital, Birmingham, United Kingdom; 7) Department of Hepatology, Addenbrooke's Hospital, Cambridge, United Kingdom.

Primary biliary cirrhosis (PBC) is a chronic, cholestatic liver disease characterized by progressive, autoimmune (AI) destruction of the small intrahepatic bile ducts. PBC primarily affects women ≥40 years of age and in this high-risk cohort the prevalence rate is approximately one in 1,000. The cause of PBC is unknown. Approximately 5% of PBC patients have a positive family history and the sibling relative risk (λs) is ~10. Over the last 20 years, a succession of candidate gene association studies has established that PBC is associated with the class II HLA haplotype, DRB1*0801-DQA1*0401-DQB1*0402, in Europeans. More recently, a genome-wide association study (GWAS) of PBC identified two additional, non-HLA susceptibility loci, *IL12A* and *IL12RB2*. Here we report a GWAS of 1,840 PBC cases and 5,163 controls of UK origin genotyped across 507,467 SNPs using the Illumina HumanHap670. We identified ten novel PBC loci ($P < 5\times10^{-8}$), in addition to replicating the two previously reported non-HLA PBC associations (*IL12RB2*: $P = 9.5\times10^{-20}$, OR = 1.52; *IL12A*: $P = 2.3\times10^{-16}$, OR = 1.38) and the HLA association. The most strongly supported novel PBC-associated locus was at 7q32, where seven SNPs exceed genome-wide significance (minimum $P = 8.91\times10^{-19}$, OR = 1.58). This locus contains the *IRF5* gene, which has previously been implicated in both systemic lupus erythematosus and rheumatoid arthritis. Of the ten novel PBC-associated loci found, seven have previously been implicated in other autoimmune diseases (including Crohn's disease, psoriasis and multiple sclerosis). Of the nine loci showing nominal evidence of association (three or more SNPs with $P < 1\times10^{-5}$), five overlap with regions previously found to be associated with another autoimmune disease. Three of the novel PBC-associated loci, on chromosomes 12, 14 and 19, do not overlap with any currently known loci involved in autoimmune disease, and thus may represent PBC specific risk loci. More than 20 loci were selected for follow-up in an additional 1,800 cases and 3,300 controls from North America and the UK. This work has significantly increased the number of known PBC loci and has increased our understanding of disease pathogenesis, in particular how PBC clusters biologically with other autoimmune diseases.

2939/T

Genome-wide meta-analysis for serum calcium identifies significantly associated SNPs near the calcium-sensing receptor (CASR) gene. *K. Kapur[1,2], T. Johnson[1,2,3], N. Beckmann[1], J. Sehmi[4], T. Calcium has a pivotal role in biological functions, and serum calcium levels have been associated with numerous disorders of bone and mineral metabolism as well as with cardiovascular mortality. Here we report results from a genome-wide association study of serum calcium, integrating data from four independent cohorts including a total of 12,865 individuals of European and Indian Asian descent. Our meta-analysis shows that serum calcium is associated with SNPs in or near the calcium-sensing receptor (CASR) gene on 3q13. The top hit with a p-value of 6.3x10-37 is rs1801725, a missense variant, explaining 1.26% of the variance in serum calcium. This SNP had the strongest association in individuals of European descent, while for individuals of Indian Asian descent the top hit was rs17251221 (p = 1.1x10-21), a SNP in strong linkage disequilibrium with rs1801725. The strongest locus in CASR was shown to replicate in an independent Icelandic cohort of 4,126 individuals (p =1.02 x 10-4). This genome-wide meta-analysis shows that common CASR variants modulate serum calcium levels in the adult general population, which confirms previous results in some candidate gene studies of the CASR locus. This study highlights the key role of CASR in calcium regulation.

2940/T

Genome wide association study of lung function measures in the Korean population. *K. Min[1], J. Min[2], S. Cho[3], J. Sung[3].* 1) Ajou University School of Medicine, Suwon, Korea; 2) Institute of Health and Environment, Seoul National University, Seoul, Korea; 3) School of Public Health, Seoul National University,Seoul, Korea.

Objective: Lung function is of major importance in public health. Genetic influence on lung-related phenotypes has highlighted from family, twin, and adoption studies to candidate gene studies. However, most studies have focused on lung disorders or diseases with multifactorial background. Such outcomes are likely to have genetic heterogeneity, when searching for genetic links to lung disease or functional variability in the general population. We investigated genetic contributions to lung function in the Korean population, using a population-based genome-wide association study (GWAS). Methods: Affymetrix 5.0 (~550K) SNP arrays were genotyped in 8842 subjects (4183 men and 4659 women) participating in the Korean Genome Epidemiology Study (KoGES). After applying genetic quality-control (genotypic call rates≥95%, MAF≥10%, HWE P≥1.0x10-6), a total of 352,228 markers were included for this analysis. Lung function is focused on three spirpometric outcomes: % predicted FEV1 (forced expiratory volume in 1 second), % predicted FVC (forced vital capacity), and % predicted FEV1/FVC. All procedures were approved by an institutional review committee. Results: Six previously implicated genes in chromosomes 1, 2, 3, 6, 7, and 9 were significantly associated with % predicted forced expiratory volume in 1 second (FEV1) and % predicted forced vital capacity (FVC): cyclin-dependent kinase 5 (CDK5); fragile histidine triad (FHIT); FYN oncogene related to SRC, FGR, YES (FYN); histamine N-methyltransferase (HNMT); protein tyrosine phosphatase, receptor type, D (PTPRD), and vascular cell adhesion molecule 1 (VCAM1). Of the genes, as the number of minor alleles in PTPRD increased, two parameters, % predicted FEV1 and % predicted FVC, also increased, particularly in men. Conclusion: We replicated six potential lung function genes in a Korean population-based association study. The effect of these genes on lung function might be independent of ethnic origin. Additionally, the PTPRD gene region may be of importance in understanding the pathophysiology of lung function.

2941/T

G6PC2 associated with fasting glucose levels in pregnant women of European ancestry. *J. Morrison[1], A. Pluzhnikov[1], M.G. Hayes[2], H. Lee[2], D. Levine[3], C. McHugh[3], L.P. Lowe[2], M. Urbanek[2], L. Armstrong[2], C. Ackerman[2], D. Mirel[4], A.R. Dyer[2], B.E. Metzger[2], N.J. Cox[1], W.L. Lowe[2], HAPO Study Cooperative Research Group.* 1) University of Chicago, Chicago, IL; 2) Northwestern University, Chicago, IL; 3) University of Washington, Seattle, WA; 4) The Broad Institute, Cambridge, MA.

The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study is an international epidemiologic study which recruited ~25,000 women to identify levels of maternal glycemia, as determined by an oral glucose tolerance test (OGTT), associated with risk of adverse pregnancy outcome. OGTTs were performed at 28 weeks gestation with determination of fasting, 1 hr, and 2 hr glucose and fasting and 1 hr C-peptide. We have conducted a genome wide association study of 1360 HAPO European mothers genotyped on the Illumina 610 quad platform to identify genetic factors influencing glucose tolerance and insulin secretion during pregnancy. We used a linear regression model adjusting for age, body mass index, height, parity and gestational age as well as the first two eigenvectors calculated on an LD pruned SNP set. For fasting glucose we saw a strong association with G6PC2 which encodes a glucose-6-phosphate catalytic protein expressed only in pancreatic islets. G6PC2 has been previously associated with fasting plasma glucose levels in non-diabetic European and Asian adults as well as having been associated in a recent GWAS with development of type 2 diabetes. Our strongest association with fasting glucose was with rs560887 - a SNP located in an intron of G6PC2. Minor alleles for this SNP resulted in a reduction of maternal fasting glucose of 1.39 mg/dl [95%CI 0.85-1.92] with a p-value of 3.97e-7. This finding suggests that maternal glucose intolerance is mediated in part by genetic factors including G6PC2.

2942/T

Genome-wide association study on Anorectal Malformations in the Chinese Population. *E.H.M. WONG[1], C.S.M. TANG[1,2], M.G. BARCELO[2], X.J. ZHANG[4], J.J. LIU[5], S.S. CHERNY[1], P.C. SHAM[1,3], P.K. TAM[2].* 1) Department of Psychiatry, University of Hong Kong, Hong Kong SAR, China, Hong Kong; 2) Department of Surgery, University of Hong Kong, Hong Kong SAR, China; 3) Genome Research Centre, University of Hong Kong, Hong Kong SAR, China; 4) 4Department of Dermatology and Venereology, Anhui Medical University, Hefei, Anhui 230032, P.R. China; 5) 5Department of Human Genetics, Genome Institute of Singapore, Singapore, Singapore.

Anorectal malformations (ARM) represent a complex group of congenital diseases characterized by the obstruction of anal opening. Occurring in 1 out of every 4,000 to 5,000 individuals, ARMs are one of the most common pediatric surgical problems. The spectrum of ARMs ranges from anal stenosis to anal atresia/imperforated anus with/without fistula to persistent cloaca. The etiology of ARMs remains unknown, although there is strong evidence for a genetic component. This is indicated by the very early developmental disruption, its recurrence in families and the high concordance of its existence with some abnormalities. Though several candidate genes e.g. endothelin-β receptor (EDNRB) and sonic hedgehog (Shh) were proposed for their potential roles in the development of ARMs, the causes of ARMs still remain unknown. To explore the genetic contribution to the pathogenesis of ARM, we performed systematic analyses of genetic markers, in 176 Chinese patients and 2986 ethnically matched individuals as controls. The genome-wide association study (GWAS) was performed using the Illumina Human 610-Quad BeadChips with 488, 394 SNPs successfully genotyped. An association peak encompassing two gene members of the solute carrier (SLC) family was observed, with p-value= (odds ratio 1.94, 95% CI: 1.54-2.45 for allele C) for the most associated SNP (rs11045422). To confirm the observed association, those statistically significant SNPs will be genotyped in an independent set of cases and controls. Bioinformatics and experimental analysis will be used to study the biological relevance of SLC genes in ARMs.

2943/T

Substantial risk factor of myeloperoxidase gene Polymorphism with Myopia. *c. Hemabindu.* Biotech, GRIET, Hyderabad, India.

Purpose : Myopia or short sightedness is the most common human eye disorder affecting 30% of world population. Genetic and environmental factors are implicated in the onset of myopia. Environmental causes include mechanical factors, oxidative stress, nutritional factors etc. Oxidative stress can arise due to intrinsic or extrinsic factors. myleoperoxidase is one of the antioxidant enzyme. It catalysis the reaction which produces hypochlorous acid. The lack of enzyme activity might result in accumulation of free radicals contributing to oxidative stress .To find out the association of myeloperoxidase gene polymorphism with myopia by genotyping. Methods : In the present study 320 cases of myopia were analyzed for myeloperoxidase gene polymorphism using PCR.for amplification of the gene and genotyping was done. Results : Results were compared with 320 cases of age and sex matched controls. There is a significant difference in the genotype distribution of AA genotype of myeloperoxidase gene polymorphism between disease(0.94%) and controls(5.63%). When the data on myopia was sub grouped with respect to different parameters, interesting results were obtained. Patients with age at onset in between 41-50 years had very high frequency GG Genotype (83.3%) as compared to other ranges of age at onset. Further myopia patients having refractive error 4-6 diopter have high frequency of GG genotype (95.45.6%) when compared with other with lower than 4 diopter and higher than 6 diopter. There is significant difference in the genotype distribution of GG genotype has been observed between consangunity (85.71%) and Non consangunity(66.89%) in myopia patients. Conclusion : These results indicates that there is an elevation of GG genotype in myopia patients which indicate that inefficient detoxification system to combat the accumulation of free radicals might be responsible for the onset of myopia . There was no association of Myleoperoxidase gene polymorphism with , familial incidence, male and female.

2944/T

The FGF/FGFR gene family and risk of cleft lip with/without cleft palate. *H. Wang[1,9], J. Hetmanski[2], T. Wu[1,2,9], I. Ruczinski[2], H. Schwender[2], K. Liang[2], T. Murray[2], R. Redett[3], G. Raymond[3], S. Jin[2], Y. Wu-Chou[4], P. Chen[4], V. Yeow[5], S. Chong[6], F. Cheah[6], S. Jee[7], R. Ingersoll[3], E. Jabs[3,8], A. Scott[3], T. Beaty[2].* 1) Epidemiology and Biostatistics, Peking University School of Publich Health, Beijing, China; 2) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Johns Hopkins University, School of Medicine, Baltimore, MD; 4) Chang Gung Memorial Hospital, Taoyuan, Taiwan; 5) KK Women's & Children's Hospital, Singapore; 6) National University of Singapore, Singapore; 7) Yonsei University, Graduate School of Epidemiology & Health Promotion, Seoul, Korea; 8) Mount. Sinai School of Medicine, New York, NY; 9) Key Laboratory of Epidemiology, Ministry of Education, China.

Isolated, nonsyndromic cleft lip with or without cleft palate (CL/P) is a common human congenital malformation with a complex and heterogeneous etiology. Both genes, regulatory elements outside genes and environmental risk factors may influence risk to clefts. Genes coding for fibroblast growth factors and their receptors (FGF/FGFR genes) are legitimate candidates for CL/P. As part of an international study, we collected DNA, and environmental exposures on 297 CL/P case-parent trios recruited through treatment centers from four sites (Maryland, Taiwan, Singapore, and Korea) to test the importance of FGF/FGFR genes in controlling risk to CL/P. Ten FGF/FGFR genes included: FGFBP1, FGF2, FGF10, FGF18, FGFR1, FGFR2, FGF19, FGF4, FGF3, FGF9, and 122 single nucleotide polymorphic (SNP) markers were genotyped at the Center of Inherited Disease Research (CIDR) of which 112 SNPs were suitable for analysis. Because Asian trios showed very similar LD patterns, all trios from the three Asian sites were combined into one group. The transmission disequilibrium test (TDT) of 112 SNPs using FBAT confirmed previous evidence of linkage and association to markers in FGFR1. Both individual SNPs and haplotypes of multiple markers in FGF19 also showed suggestive evidence of linkage and association with CL/P, giving odds ratios (OR) between 1.31 and 1.87. Haplotypes of three SNPs in the FGFR1 gene (rs6987534, rs6474354 and rs10958700) gave suggestive significance (p=0.04) among Asian trios and one particular haplotype appeared strongly protective, yielding an estimated OR=0.51 (p= 0.0058). We also found suggestive evidence of maternal effects for markers in FGF2 and FGF10 among Asian trios. We used PBAT to scan for gene-environment (GxE) interaction and statistical significance was seen between certain markers in FGFR2 gene and environmental maternal exposures, particularly multivitamin supplementation. Tests of gene-gene (GxG) interaction using Cordell's method yielded significant interaction between SNPs in FGF9 and FGF18. These results raise the possibility that several genes in the FGF/FGFR family may influence risk to oral clefts through distinct biological mechanisms.

2945/T

Evidence of gene-environment interaction for the IRF6 gene and maternal multivitamin supplementation in controlling the risk of cleft lip with/without cleft palate. *T. Wu[1,2,9], K. Liang[1], J. Hetmanski[1], I. Ruczinski[1], M. Fallin[1], R. Ingersoll[1,3], H. Wang[2,9], S. Huang[4], X. Ye[5,6], Y. Wu-Chou[7], P. Chen[7], E. Jabs[3,5], B. Shi[8], R. Redett[3], A. Scott[3], T. Beaty[1].* 1) Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Beijing University School of Public Health, Beijing, China; 3) Johns Hopkins School of Medicine, Baltimore, MD; 4) Peking Union Medical College, Beijing, China; 5) Mount. Sinai School of Medicine, New York, NY; 6) Key Laboratory for Oral Biomedical Engineering of Ministry of Education, Hospital and School of Stomatology, Wuhan University, Wuhan, China; 7) Chang Gung Memorial Hospital, Taoyuan, Taiwan; 8) West China College of Stomatology, Sichuan University, Sichuan, China; 9) Key Laboratory of Epidemiology, Ministry of Education, China.

Although multiple genes have been identified as genetic risk factors for isolated, non-syndromic cleft lip with/without cleft palate (CL/P), a complex and heterogeneous birth defect, interferon regulatory factor 6 gene (*IRF6*) is one of the best documented genetic risk factors. In this study, we tested for association between markers in *IRF6* and CL/P in 326 Chinese case-parent trios, considering gene-environment (GxE) interaction for two common maternal exposures, and for parent-of-origin effects. CL/P case-parent trios from three sites in mainland China and Taiwan were genotyped for 22 single nucleotide polymorphisms (SNPs) in *IRF6*. The transmission disequilibrium test (TDT) was used to test for marginal effects of individual SNPs using Clayton's extension in Stata 10. We used PBAT to screen the SNPs and haplotypes for GxE interaction and conditional logistic regression models to quantify effect sizes for SNP-environment interaction. After Bonferroni correction, fourteen SNPs showed statistically significant association with CL/P ($0.018 < \text{corrected } P < 2.1 \times 10^{-5}$). Evidence of GxE interaction was found for both maternal exposures, multivitamin supplementation and environmental tobacco smoke (ETS). Two SNPs showed evidence of interaction with multivitamin supplementation in conditional logistic regression models [*rs2076153*: odds ratio (OR) =1.28, 95%CI =1.01-1.63, nominal P =0.020; *rs17015218*: OR=0.13, 95%CI=0.02-0.99, nominal P =0.012]. In addition, *rs1044516* yielded evidence for interaction with maternal ETS (OR=1.96, 95%CI =1.38-2.78, nominal P =0.041). Haplotype analysis using PBAT also suggested interaction between SNPs in *IRF6* and both multivitamin supplementation and ETS. However, no evidence for maternal genotypic effects or significant parent-of-origin effects was seen in these data. These results suggest *IRF6* gene may influence risk of CL/P through interaction with multivitamin supplementation and ETS in the Chinese population.

Heritability of Ocular Phenotypes in the Genetic Isolate of Norfolk Island. *E. Matovinovic[1], R. Lea[1], H. Cox[1], J. Herruer[1, 3], M. Hanna[1], J.C. Sherwin[4], A.W. Hewitt[4], L.S. Kearns[4], J. Kelly[5], Y. Ma[4], D.A. Mackey[2,4,6], L. Griffiths[1].* 1) Genomics Research Centre, Griffith Institute for Health and Medical Research, Griffith University, Gold Coast, Queensland, Australia; 2) Lions Eye Institute Centre for Ophthalmology and Visual Science, University of Western Australia, Nedlands, WA; 3) Vrije Universiteit, 1081 HV, Amsterdam, The Netherlands; 4) Centre for Eye Research Australia, Dept of Ophthalmology, University of Melbourne, East Melbourne, Victoria, Australia; 5) Norfolk Optical, Norfolk Island, South Pacific; 6) Dept Ophthalmology, Royal Hobart Hospital, University of Tasmania, Hobart, Tasmania, Australia.

Glaucoma is the leading cause of irreversible blindness worldwide. Chronic glaucoma prevalence in the US population 40 years and older is 1.86%. With an aging population, this prevalence is projected to increase by 50% in 2020. We derived heritability estimates for various ocular phenotypes in the Norfolk Island "Mutiny on the Bounty" population. This well documented pedigree has mean European and Polynesian ancestry of 88% and 12% respectively. Glaucoma incidence on Norfolk Island is high despite uncommon prevalence in Polynesian populations suggesting that one of the European founders may carry a glaucoma related genotype. Eight hundred Norfolk Island participants received exams consisting of several ocular measurements. Of these, 153 participants were identified within the core Norfolk Island pedigree. Ocular phenotype heritability estimates for the Norfolk Island pedigree were generated in this subset using SOLAR. Heritability estimates were determined for several quantitative metrics in both eyes. In the right eye, corneal thickness was the most heritable measure (h2 0.66 p=0.001) followed by intraocular pressure (h2 0.61 p=0.021) and anterior chamber depth (h2 0.54 p=0.008). Similar results were obtained for left eye. Age was a significant covariate for axial length and cup: disc area ratio measures. Hence, several ocular phenotypes are highly heritable in the Norfolk Island population providing opportunities for further genetic research. We are currently conducting linkage studies using microsatellite markers in order to identify genetic loci for these heritable metrics which may be involved in glaucoma and other eye diseases.

2947/T

Multiple sclerosis susceptibility alleles modulate levels of RNA expression involved in lymphocyte activation pathways. *P. De Jager[1], L. Ottoboni[1], F. Esposito[2], N. Patsopoulos[1], F. Martinelli-Boneschi[2], G. Comi[2], P. de Bakker[1], D. Hafler[3].* 1) Brigham & Women's Hospital, Boston, MA; 2) Institute San Raffaele, Milan, Italy; 3) Yale University, New Haven CT.

Background and goals: Multiple Sclerosis (MS) is an inflammatory disease for which 17 susceptibility loci have been identified. The goal of the project is to explore the functional consequences of these susceptibility loci in genome-wide RNA expression data generated from peripheral Blood mononuclear cells (PBMCs) of subjects with MS. Methods and results: We assessed our data for Cis and Trans effects on RNA expression by each of 17 validated MS loci variants. The dataset consists of genome wide RNA expression data on PBMCs from 255 MS subjects. They were either untreated (n=83) or treated with immunomodulatory drugs (n=105 interferon-beta; n=67 glatiramer acetate). Analyses were performed using linear regression and additive model for each SNP as an independent variable and adjusting for SNP-treatment interactions. We have identified: (1) a robust Cis association of MPHOSPH9 RNA expression with the MPHOSPH9 variant rs1790100 (p=1.04x10-6), (2) using pathway analyses (IPA, Ingenuity Systems), we find that 7 different loci (CD6, TNFR1, IL12A, CD226, CLEC16A, IRF8, IL2RA, and RGS1) affect RNA expression of multiple genes in the same 4 signaling pathways: CD28 signaling, TCR signaling, iCOS_iCOS-Ligand and IL2 signature. For example, rs2760524 on RGS1 affects the expression of multiple genes in the CD28 pathway (P=1.479x10-9). Conclusion: We show a remarkable level of interconnectedness among a subset of MS susceptibility loci: some of these loci affect RNA expression within other susceptibility loci and, more striking, multiple different loci have a broad effect on signaling pathways that are critical for T cell function and proliferation. These observations provide a strong bridge between the recent genetic discoveries in MS and the wealth of immunological data that has been accumulated in this disease.

2948/T

Common Genetic Polymorphisms and Risk of Serious Neurological Complications of West Nile Virus Infection. *M. Loeb[1], S. Eskandarian[1], M. Rupp[2], N. Fishman[3], L. Gasink[4], J. Patterson[5], J. Bramson[1], T. Hudson[6], M. Lemire[6].* 1) Dept Pathology & Molec Med, McMaster Univ, Hamilton, ON, Canada; 2) University of Nebraska Medical Center, Omaha, NE; 3) University of Pennsylvania Medical Center, Philadelphia, PA; 4) Hospital of the University of Pennsylvania, Philadelphia, PA; 5) University of Texas Health Science Center San Antonio and South Texas VA, San Antonia, TX; 6) Ontario Institute for Cancer Research, Toronto, ON, Canada.

Background: The relationship between common genetic polymorphisms and susceptibility to neurological complications in West Nile virus (WNV) infected individuals is not well understood. Methods: From 2003 to 2008 patients meeting case definitions for severe WNV disease (meningitis, encephalitis, or acute flaccid paralysis) from Canada and U.S were compared to WNV infected patients without severe disease. Whole blood samples were collected for genotyping using whole genome screening with the Illumina HumanNS-12 Infinium assay. This included 13,371 single nucleotide polymorphisms (SNPs) which were mostly non-synonymous variants but also included synonymous, UTR, and tag-SNPs. To validate association results from the primary analysis, a panel of 34 SNPs was designed using Sequenom MassARRAY IPLEX Gold including tag SNPs from the primary gene of interest, top 12 SNPs from the primary analysis. Results: 445 neuroinvasive cases and 813 controls were compared in the primary analysis. SNPs of importance based on statistical significance and biological plausibility included RFC1 (replication factor) (rs2066786) p= 1.67 x 10-6, OR 1.5 (95%CI 1.21 to 1.86); SCN1A (sodium channel, neuronal type 1 alpha subunit) (rs2298771), p= 1.73 x 10-6, OR 1.50 (1.21 to 1.86); and ANPEP (ananyl aminopeptidase) (rs25651) p = 1.73 x 10-4. Replication samples from 617 patients (277 cases and 340 controls) were obtained. Although there was an overall lack of significance in the replication cohort (p > 0.5 for all three SNPs), RFC1- rs2066786 did replicate in the cohort from one state (Nebraska). Joint analysis showed for RFC1 -rs2066786 p= 3.0 x 10 10-5; SCN1A- rs2298771 p= 1.4 x 10-3; and ANPEP- rs25651 p= 3.1 x 10-3. SNPs in other candidate genes (OAS, TLR3) were not significant. Conclusion: Novel genetic variants may play a role in susceptibility to severe WNV disease.

GRACE Network of Excellence: Genetic Susceptibility to Lower Respiratory Tract Infections. *A. Rautanen, T.C. Mills, S.J. Chapman, A.V.S. Hill, GRACE study group.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

GRACE (Genomics to combat Resistance against Antibiotics in Community-acquired LRTI in Europe) is a Network of Excellence focusing on community-acquired Lower Respiratory Tract Infections (LRTI); one of the leading reasons for seeking medical care. The overall objective of GRACE is to combat antimicrobial resistance by integrating microbial and human genetics with health sciences research. 3000 patients with LRTI and 3000 matched controls were recruited by 14 primary care research networks in 12 European countries, making this the largest prospective study of LRTI ever undertaken in primary medical care. Adult patients with acute cough or clinically suspected LRTI as the main presenting symptom were eligible. Based on our earlier candidate gene and genome-wide association findings with severe LRTI cases suffering from invasive pneumococcal disease, we have selected and genotyped 27 SNPs in 19 genes with Sequenom's iPLEX technology. In the initial case-control analysis where half of the GRACE individuals were genotyped, we were able to replicate associations in the genes PTPN22 (Arg620Trp:p=0.037, OR 2.0) and NFKBIZ (rs616597:p=0.022, OR 0.87; rs600718: p=0.028, OR 0.87). PTPN22 belongs to a family of lymphoid specific protein tyrosine phosphatases and regulates the immune response through the T-cell signaling. NFKBIZ is one of the NFκB inhibitors and thereby affects the transcription of pro-inflammatory genes. For more informative analyses, we will subdivide our patients based on the microbiological cause of their LRTI, namely between bacterial and viral infection, and further to specific pathogens. To enable this subdivision, interpretation of a vast amount of microbiological and clinical data is ongoing. Surprisingly it seems that the majority of the GRACE LRTIs have a viral cause instead of bacterial. Therefore, more candidate SNPs will be genotyped based on their possible involvement in the host immune response to viral infections. The second set of SNPs to be genotyped, however, will be mainly selected based on our currently ongoing meta-analysis of genome-wide screens of invasive pneumococcal disease and community-acquired pneumonia with sepsis. Although the identification of host genetic factors cannot be directly applied to combat antimicrobial resistance, it will provide valuable information about disease pathogenesis and host defence mechanisms. This information could be used to detect, treat, and prevent LRTI in a more individualised manner.

Admixture mapping analysis of blood pressure and BMI in Family Blood Pressure Program (FBPP). *F. Zakharia[1], K. Sunjung[2], Y. SongGon[2], T. Bamidele[3], A. Morrison[4], C. Hanis[4], D.C. Rao[5], R.S. Cooper[3], H. Tang[1], X. Zhu[2], N. Risch[6].* 1) Department of Genetics, Stanford University School of Medicine, 300 Pasteur Drive, Stanford, CA; 2) Department of Biostatistics and Epidemiology , Case Western Reserve University, Cleveland, OH; 3) Department of Preventive Medicine and Epidemiology, Loyola University Chicago Stritch School of Medicine, Maywood, IL; 4) Division of Epidemiology and Disease Control, School of Public Health, University of Texas at Houston Health Science Center, Houston, TX; 5) Division of Biostatistics, Washington University in St. Louis, MO; 6) Institute for Human Genetics, University of California, San Francisco, 513 Parnassus Ave., San Francisco, CA.

African Americans are, on average, at higher risk for hypertension and obesity, compared to European Americans. Previously we have used admixture mapping to identify candidate regions, which both contribute to disease risk and to disparity between populations. Using genotype data at 2,593 ancestry informative SNPs in 2,005 African-American subjects from three networks in the FBPP project, we performed admixture mapping analysis for hypertension related traits and BMI. We observed 5 genomic regions showing strong evidence (P<0.01) of potentially harboring genetic variants contributing to the variation in hypertension related phenotypes, including chromosome 6 and 21 genomic regions reported previously. We were able to refine these two regions by typing additional SNPs. The association evidence in admixture mapping analysis was improved for all hypertension related traits (P<0.001). In single marker analysis we observed SNP rs9490191 is significantly associated with diastolic blood pressure after adjusting for multiple comparisons (P=5.64E-06). For BMI, the most significant region in admixture mapping analysis is at SNP rs8134809 (P=2.3E-04). We did not observe any SNPs significantly associated with BMI after adjusting for multiple comparisons. In summary our analysis suggests that admixture mapping can be a useful method to detect genetic variants underlying complex diseases.

Quantification of DNA instability in the inherited neuromuscular disease myotonic dystrophy using a hierarchical Bayesian approach. *C.F. Higham, C. Cobbold, D.T. Haydon, D.G. Monckton.* University of Glasgow, Glasgow, Scotland, United Kingdom.

Myotonic dystrophy type 1 is caused by inheriting an unstable expanded CTG repeat on chromosome 19 in the 3' untranslated region of the DMPK gene. Expansion of the disease allele during the lifetime of patients and variation in the level of mutation between somatic tissues of an individual are thought to account for the tissue specificity and progressive nature of the symptoms. Clinical diagnosis is currently based on a measure of repeat length from blood cells, but variance in length only accounts for about 25% of the variance in age of onset and, therefore, is not predictive. This low correlation arises because modal length is dependent on age and so confounds the analysis. But also, age of onset is linked to tissues other than blood, such as muscle, which can have greater levels of instability. A more reliable measure for patients would therefore be an indication of the length of their inherited disease allele, otherwise known as the progenitor allele length.

We have developed a new mathematical model to describe the evolution of repeat length in individuals over their lifetime. The model is based on the assumption that the repeat length in each cell changes independently according to a stochastic process that has biologically relevant parameters. By calibrating the parameters in this mathematical model to recent data which quantify, at a fine resolution, the variation in blood DNA from myotonic dystrophy patients, we are able to infer an individual's progenitor allele length and level of mutation. However, applying the model to each patient does not provide a basis for inference about the population, so we will present new work that investigates the distribution of DNA instability within the population using a hierarchical Bayesian approach. This rich statistical framework allows us to provide robust prognostic information for patients. DNA instability is also a quantitative trait that could be assessed in terms of its heritability and used as a biomarker to identify any trans-acting genetic, epigenetic or environmental effects. Our expectation is that these trans-acting genetic modifiers will also apply in the general population where they will affect ageing, cancer, inherited disease and human genetic variation.

Comparison of Methods for Evaluating the Ability of Genetic and Clinical Information to Predict Prostate Cancer Risk. *B.H. Reck[1], P.J. Newcombe[2], J. Sun[4,5], G.T. Platek[1], A.K. Kader[4,6], S-T. Kim[4,5], T. Jin[4,5], Z. Zhang[4,5], S.L. Zheng[4,5], L.D. Condreay[1], J.C. Whittaker[2], C.F. Spraggs[2], V.E. Mooser[3], R.S. Rittmaster[1], J. Xu[4,5,6].* 1) GlaxoSmithKline Research and Development, Research Triangle Park, NC, USA; 2) GlaxoSmithKline Research and Development, Harlow, UK; 3) GlaxoSmithKline Research and Development, King of Prussia, PA, USA; 4) Center for Cancer Genomics, Wake Forest University School of Medicine, Winston-Salem, NC, USA; 5) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC, USA; 6) Departments of Urology, Wake Forest University School of Medicine, Winston-Salem, NC, USA.

Prostate cancer (PCa) is the most common solid organ malignancy affecting American men and the second leading cause of cancer related death in men. The ability of clinical parameters to predict PCa is limited with only a quarter of biopsies resulting in a diagnosis of PCa. Recently, more than 30 PCa risk-associated single nucleotide polymorphisms (SNPs) have been discovered in genome-wide association studies and replicated in multiple populations of European descent. We compared three statistical methods for constructing predictors of PCa based on 33 risk SNPs and clinical variables using genetic samples obtained from 1608 Caucasian men who consented to genetic analyses for prostatic indications and were randomized to receive placebo in the 4 year PCa risk reduction study, The REduction by DUtasteride of prostate Cancer Events (REDUCE®), evaluating the safety and efficacy of Avodart®. Patients participating in this study were required to have a prostate biopsy showing no evidence of PCa at recruitment, elevated PSA levels (2.5 - 10 ng/mL), and agree to having 10-core biopsies after 2 and 4 years of study. The first method was a standard logistic regression model which included separate terms for the clinical covariates and 33 genetic markers. In the second method, PCa effect estimates for the 33 SNPs obtained from external meta-analyses were used to construct a PCa risk "score" for each subject. The score and clinical covariates were subsequently evaluated in a logistic regression model. The third method utilized a Bayesian approach to incorporate PCa effect estimates from the external meta-analysis into a logistic regression model via informative priors. PCa prediction was evaluated using 10-fold cross-validation for all 3 scores. For all three scores, genetic information incorporated alongside the clinical variables significantly improved model fit, leading to a marginal improvement in cross-validated predictive ability. Incorporation of external information, whether via a weighted score (method 2) or informative priors (method 3), led to an apparent but modest improvement in PCa prediction.

2953/T

ASSOCIATION STUDY OF THE 5HTT-LPR AND VNTR-5HTT POLYMORPHISMS OF THE *SLC6A4* GENE AND BIPOLAR DISORDER. *V. Peralta[1], E. Leal[1], JP. Meza[1], J. Duran[2], VL. Lozano[1], M. Gutierrez[3], IP. Davalos[4], CT. Hernandez[5], A. Garcia[5], LJ. Rodriguez[5], HG. Torres[1], M. Partida[6], JG. Perales[1], JC. Moterrubio[1], V. Garcia[1], LA. Cruz[1], KG. Martinez[1].* 1) Genetica Humana, Universidad Autonoma de Tamaulipas, Matamoros, Tamaulipas, Mexico; 2) Biology dept, University of Texas at Brownsville, TX 78520; 3) CU-ALTOS UdeG; 4) CIBO/ CUCS UdeG; 5) Hosp. Gral. Subzona No. 33, Deleg.Ver-Norte del IMSS; 6) Instituto de Genética Humana CUCS.

Polymorphism in the serotonin transporter gene (SLC6A4) has been associated with depressive disorders in some populations in recent publications (1). The aim of this study was analyze the presence of the polymorphism in the SLC6A4 gene and risk of suffering bipolar disorder. The SLC6A4 gene its located at 17q11.2 and shows two common allele variations, one at the promoter region (a 44 base pair deletion/insertion or 5HTT-LPR) related with low mRNA and other inside the second intron (a 9,10 or 12 tandem repeats of 16-17 base pairs or 5HTT-VNTR) (2,3). Methods: From Mexican-Mestizo population, 163 healthy controls and 17 patients with bipolar disorder were analyzed. Bipolar disorder diagnose was made using the DSM-IV criteria. Genomic DNA was extracted from peripheral blood by the phenol-chloroform method. Genotyping was performed by PCR with primers previously described (3). Visualization and determination of the genotypes was made by electrophoresis using polyacrylamide and agarose gels stained in silver nitrate and sybr-safe respectively. Results: The studied polymorphisms are in Hardy-Weinberg equilibrium, the VNTR-5HTT allele shows an X2=0.80, p=0.36974, and the LPR-5HTT an X2=2.98, p=0.08429. This preliminary result shows non statistical association between the presence of the polymorphism and bipolar disorder risk, however, the number of patients was small, and future analysis in Mexican-mestizo population with a bigger number of patients can give results with more statistical accuracy. 2954/T

Association study between polymorphisms in PPARγ, CRP, HSD11B1and ADIPOQ genes and obesity in a young Mexican-American population from S.Texas. *J. Duran[1], I. Ortiz[1], N. Ruiz[1], B.N. Newton[1], G. Zavala[1], M. Ortiz[1], A. Gonzalez[1], E.K. Sanchez[1], S. Fisher-Hoch[2], A. Rentrefo[1], S. Nair[1].* 1) Biology, University of Texas at Brownsville, Brownsville, TX; 2) Division of Epidemiology, University of Texas School of Public Health, Brownsville Campus, Brownsville, TX.

In US, the prevalence of obesity in people 20 years or older is 33.9%, but this statistic varies according to the ethnicity. Mexican-American populations in the US have increased risk for the development of obesity with a prevalence of 39.3% in the same age group. This suggests that in addition to environmental influences, susceptibility to obesity may have a strong genetic component in the Mexican-American population. In this study we analyzed single nucleotide polymorphisms (SNP) rs1205(G>A), rs1801282(C>G), rs846910(A>G) and rs1501299(G>T) of the CRP, PPARγ, HSD11B1 and ADIPOQ genes respectively because of their well documented roles in regulation of insulin sensitivity and homeostatic levels of glucose. The study population (n= 446) including 323 adolescent children from Brownsville schools and 123 college going students from University of Texas at Brownsville (UTB) at South Texas consented to participate. First degree familiars were excluded from statistical analysis. Height, weight, body mass index (BMI) (kg/m2) and waist circumference (WC) were obtained using standard procedures. WHO and CDC classification values were applied for obesity diagnosis. Genomic DNA was extracted with QIAamp DNA kit (Qiagen, Alameda, CA). Genotyping was performed with Assays on demand allelic discrimination assays (Applied Biosystems, Carlsbad, CA). Hardy Weinberg equilibrium and $\chi 2$ test was used to examine differences among categorical variables. The allelic and genotypic frequencies are show in table 1. All the alleles were found in Hardy Weinberg equilibrium. No statistical differences were found in the association of the alleles for any of the analyzed SNPs with obesity (table-2). Study population has an average age of 17.5 years old (range from 14 to 30 years, 283 less than 17 years and 165 between18 and 30) and the obese population represents 22.4% of the individuals. Although NHANES III revealed a 11.5% frequency in the prevalence of obesity in adolescents, a more recent report shows that the frequency of obesity in this age group was 22.1% in South Texas. A similar frequency is reported in the present study in at young Mexican American population from S.Texas. Although we did not observe associations between the investigated polymorphisms and obesity measures, we cannot rule out that these associations do not exist in larger samples of the population.

The rapid and continuing progress in gene discovery for complex diseases is fuelling interest in the potential implications of this knowledge for clinical and public health practice. An essential prerequisite for many genome-based health care applications is the predictive ability of the genetic risk model. The number of studies assessing the predictive performance of genetic risk models is steadily increasing, with widely variable completeness of reporting and apparent quality. Transparent reporting of the strengths and weaknesses of empirical studies is important to facilitate the accumulation of evidence on genetic risk prediction. A multidisciplinary panel developed a checklist of 25 items recommended for strengthening the reporting of Genetic RIsk Prediction Studies (GRIPS), building on the STREGA, REMARK and STARD reporting guidelines. The recommendations do not prescribe or dictate how genetic risk prediction studies should be conducted, but offer consensus guidelines to enhance the transparency of their reporting, and thereby to improve the process of synthesizing information from multiple studies with different strategies regarding design, conduct or analysis.

2956/T

Harnessing hidden relatedness to incorporate missing heritability into genetic risk prediction. *H.M. Kang[1], S. Sanna[2], C. Sidore[2], A. Mulas[2], R. Nagaraja[3], M. Uda[2], D. Schlessinger[3], G.R. Abecasis[1].* 1) Department of Biostatistics, Univ Michigan, Ann Arbor, Ann Arbor, MI; 2) Istituto di Neurogenetica e Neurofarmacologia del CNR, Cagliari, Italy; 3) Laboratory of Genetics, National Institute on Aging, Baltimore, MD, USA.

Genome-wide association studies have identified a number of markers robustly associated with various complex traits. Even in aggregate, these markers account for only small changes in individual genetic risk, and only account for a fraction of heritability in most complex traits. Recently, several studies have demonstrated improved genetic risk prediction utilizing large numbers of markers that are only tentatively associated with a trait of interest, but it remains unclear how to interpret the underlying prediction model. Here we propose a model-based approach for predicting complex trait outcomes using a variance component model. Our model explicitly models robustly associated loci as fixed effects, while cumulative effects from additional small effect loci are modeled as polygenic random effects by leveraging hidden relatedness. Our approach uses available genotype data to estimate this "hidden" kinship matrix. For nearly all complex traits, individual trait values can be better predicted when phenotypes of close family members are available, in addition to genotype of the sample individual of interest. Our variance component model extends this observation to settings where a large number of distantly related individuals are studied and can be used to aid prediction in lieu of closer relatives can substantially improve the predictions. Our approach in effect combines Common-Disease-Common-Variants (CDCV) hypothesis and Multiple-Rare-Variants (MRV) hypothesis in the context of phenotype prediction. We applied our method to 6,000 Sardinian individuals genotyped at >150,000 SNPs. With a set of known loci explaining 2.8% of variance in height under linear model when cross-predicted across different families, our prediction results explain 10.7% of phenotypic variance, and it increases up to 28.6% when close relatives are included in the reference sample. We demonstrate that our method substantially increases the predictive power across multiple complex traits such as serum lipid levels and body mass index.

Genetic Risk Modeling using Genome-wide Association Studies for Psoriasis. *D.I. Perera[1], J.J Liu[1], X.J. Zhang[2,3,4], G.T.H. Keong[1], A. Thalamuthu[1].* 1) Human Genetics, Genome Institute of Singapore, Singapore, Singapore; 2) 2. Institute of Dermatology and Department of Dermatology at No.1 Hospital, Anhui Medical University, Hefei, Anhui 230022, China; 3) 3. The Key Laboratory of Gene Resource Utilization for Severe Diseases, Ministry of Education and Anhui Province, Hefei, Anhui 230032,China; 4) 4. Department of Dermatology and Venereology , Anhui Medical University, Hefei, Anhui 230032, China.

Medical and bio-statistical researchers have used clinically measurable markers for disease classification and prediction for a long time. The successful completion of the HapMap project and development of new and efficient genotyping technologies have given rise to numerous genome-wide association studies which in turn have infused several new markers that bring in a genetic component to the disease classification and risk prediction models. Using Genome-wide Association Studies (GWAS) we attempt to identify a set of Single Nucleotide Polymorphisms (SNPs) for predicting the risk of psoriasis. The data set comprise of 2505 controls and 2488 cases from Caucasian and Chinese populations. We use simple logistic regression and Support Vector Machine (SVM) to obtain Receiver Operating Characteristic (ROC) curve and the estimate of area under the ROC curve (AUC) to measure the predictive power of the SNPs. The set of SNPs for the joint risk modeling is selected based on the predictive power of individual SNPs. Individual SNPs can be selected based on its association p-value. But to have a good predictive power, say AUC, a SNP should have high Odds Ratio (OR), be highly polymorphic and the allele frequency difference between cases and controls should be high. Therefore instead of choosing SNPs based on p-values, we directly choose the SNPs based on its AUC value. Many SNPs in the major histocompatibility (MHC) locus are associated with psoriasis. Therefore we perform the analysis focusing separately on MHC and non-MHC SNPs. To estimate the AUC we perform a 5-fold cross validation based on the combined data set of the two cohorts. Using the top SNPs that give 80% AUC in each cross validation, we obtain 115 common SNPs for the non-MHC region with mean AUC estimates of 0.79 and 0.76 for the training set and a test set respectively. Similarly for the MHC region, we find 30 common SNPs with mean AUC values of 0.79 and 0.78 for the training and test set respectively. We will also be extending the study to identify a set of SNPs common for other auto-immune diseases and to multiple cohorts.

Association of IL-23 receptor pathway genes with rheumatoid arthritis. *M. Seddighzadeh[1], B. Ding[2], L. Klareskog[1], L. Alfredsson[2], K. Dunussi-Joannopoupos[3], JD. Clark[3], L. Padyukov[1].* 1) Dept Medicine, Karolinska Inst & Hosp, Stockholm, Sweden; 2) Institute for Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 3) Inflammation and Immunology, Pfizer Research, 200 CambridgePark Drive, Cambridge, MA 02140.

Background: The activation of IL-23 receptor launches, directed by TYK2 (non-receptor tyrosine-protein kinase), the phosphorylation of STAT (signal transducer and activator of transcription) 3 and 4. These molecules are critical in development of the Th17-dependent autoimmune disorders. No previous association study has investigated these genes in relation to RA subgroups with different autoantibody production, although previous data demonstrated divergence in genetic background for these subgroups for other genetic risk factors. Objectives: We investigated the contribution to association with rheumatoid arthritis (RA) of the TYK2, STAT3 and STAT4 gene polymorphisms with regards to the serologic characteristics of the disease. Methods: Genome-wide association studies (GWAS) data for 2260 RA cases and 898 healthy controls included in the Swedish Epidemiological Investigation of Rheumatoid Arthritis (EIRA) study population was examined for the variants within TYK2, STAT3 and STAT4 genes and their flanking regions (*RAVER1*, *ICAM3* and *STAT1*). The regions of interest were additionally fine-mapped with 64 SNPs using the iPLEX Gold platform and/or TaqMan to define LD-blocks in each gene that have a higher association with RA subgroups. Results: We could demonstrate that *TYK2* (rs12720253), *RAVER1* (rs3181049) and *ICAM3* (rs2304237) are in association with RA and these associations are not RA subgroup specific (OR 1.38 [95% CI 1.11-1.71], OR 1.22 [95% CI 1.07-1.38] and OR 1.25 [95% CI 1.10-1.42] respectively). Furthermore, *STAT3* (rs9891119), *STAT4* (rs3024935) and *STAT1* (rs12693591) demonstrated associations that are stronger in the anti-citrullinated peptide antibody (ACPA) negative group of patients compared to the ACPA positive group of patients (OR 1.27 [95% CI 1.11-1.47],OR 1.48 [95% CI 1.15-1.92] and OR 1.40 [95% CI 1.15-1.71] respectively). Conclusion: Our study confirmed the importance of IL-23 pathway for RA susceptibility. We identified new genetic risk factors for RA with an indication that some of them are more characteristic for autoantibody negative subgroup of patients. The latter one is of particular interest since up till now very few genetic risk genes have been found for this subgroup of RA.

Prospective Assessment of Different Genetic Effects on Progression to Intermediate or Large Drusen and Advanced Stages of Age-related Macular Degeneration. *Y. Yu[1], R. Reynolds[1], J. Fagerness[2], MJ. Daly[2], JM. Seddon[1,3].* 1) Ophthalmic Epidemiology and Genetics Service, Department of Ophthalmology, Tufts Medical Center, Boston, MA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Program in Medical and Population Genetics, 185 Cambridge St. 6th Floor, Boston, MA; 3) Tufts University School of Medicine, Boston, MA.

Accumulation of drusen is seen in early and intermediate stages of age-related macular degeneration (AMD) and can progress to advanced AMD. Genetic variants in the complement, lipid and other pathways are associated with advanced AMD. Understanding roles of different genes in AMD progression may lead to prevention and treatments of this disease in its early stages. Eyes of 3,006 subjects in the Age-Related Eye Disease Study were graded as no drusen or small drusen (<63μm), intermediate drusen (63-124μm), large drusen (≥125μm), GA, or NV based on data from longitudinal ocular examinations and fundus photography. SNPs in the CFH, C2, C3, CFB, CFI, ARMS2/HTRA1, and novel LIPC, CETP, ABCA1 genes/regions were genotyped. Effects of SNPs on progression of each eye to intermediate drusen, large drusen, or advanced AMD, were assessed by Cox proportional hazards models with robust estimates of variance controlling for baseline status including age, gender, smoking, body mass index (BMI), education, antioxidant treatment, baseline drusen size in each eye, and SNPs of interest. The T allele of rs10490924 (ARMS2/HTRA1) increased hazard of intermediate drusen (hazard ratio [HR] = 1.2 [1.05-1.36], p=6.7E-03), large drusen (HR=1.48 [1.28-1.71], p=1.6E-07) and advanced AMD (HR = 1.34 [1.18-1.52], p=4.3E-06). The T allele of rs2230199 in C3 was associated with increased incidence of intermediate drusen (hazard ratio [HR] = 1.21 [1.06-1.37], p=4.2E-03), large drusen (HR=1.33 [1.14-1.55], p=2.8E-04) and advanced AMD (HR = 1.24 [1.09-1.42], p=1.1E-03). Two independent SNPs in CFH were also associated with progression to advanced AMD and large drusen (p<0.05). Decreased incidence of advanced AMD was associated with the TT genotype of LIPC (rs10468017, p=0.01, HR=0.66[0.47-0.92]). The T allele of rs1883025 in ABCA1 was associated with decreased risk of development of intermediate drusen (HR= 0.84[0.73-0.96], p=0.01) and large drusen (HR=0.85[0.73-1.0], p=0.05). Genes in different pathways influence AMD progression in different stages.

CYP2R1 is a Potential Candidate for Predicting Serum 25(OH)D Variation as Suggested by Genetic and Epigenetic Studies. *Y. Zhou, F. Bu, J. Lappe, L. Armas, R. Recker, L. Zhao.* Creighton University Medical Center, Omaha, NE.

Achieving and maintaining an optimal level of serum 25-hydroxyvitmain D [25(OH)D] are important for preventing rickets, osteoporosis and osteoporotic fracture. Oral vitamin D3 supplementation is the best approach to increase serum 25(OH)D levels. However, high variability of serum 25(OH)D in response to a given dose of vitamin D supplementation is widely observed. Factors contributing to the wide variability in serum 25(OH)D are largely unknown. We first conducted a genetic epidemiology study to identify genes important for prevalent serum 25(OH)D variation. Nine candidate genes (ALPL, CYP24A1, CYP27A1, CYP27B1, CYP2R1, CYP3A4, GC, VDR, and PTH) important for vitamin D metabolism were comprehensively screened using 49 tag SNPs in 156 unrelated healthy Caucasian subjects. Evidence of association was observed at six SNPs in the CYP2R1 and GC gene. We further conducted a replication study for these six SNPs in an independent cohort with 340 unrelated healthy Caucasian subjects. Two SNPs in the promoter region of the CYP2R1 gene, rs10766197 (Pdiscovery = 0.007, Preplication = 0.019) and rs12794714 (Pdiscovery = 0.001, Preplication = 0.016), were confirmed to be significantly associated with prevalent serum 25(OH)D levels. CYP2R1 was first identified in 2003 as a key vitamin D 25-hydroxylase that converts vitamin D into 25(OH)D. In order to test whether the gene contributes to serum 25(OH)D variability in response to vitamin D3 supplementation, we conducted an epigenetic study. In total, 446 non-Hispanic white postmenopausal women were treated with calcium (1500 mg/day) and vitamin D3 (1100 IU/day) for 12-months. We selected 18 responders and 18 non-responders from the 446 subjects, at the two extreme tails of the distribution of dose-adjusted 12-month increase of serum 25(OH)D. For each subject, genomic DNA before and after 12-month vitamin D3 intervention was extracted from frozen serum. The average methylation ratio of the CYP2R1 promoter in the non-responder group (30%) was significantly higher than that in the responder group (8%) (p=0.004). In both groups, the DNA methylation ratio was unaffected by vitamin D3 intervention. The hypermetylation in the non-responder group may contribute to gene silencing of CYP2R1, leading to lower increase of serum 25(OH)D levels. These data suggest that CYP2R1 is a strong candidate for the variability in prevalent serum 25(OH)D, and variability in its response to vitamin D supplementation.

Assessing Batch effects for BRLMM-P using the Affymetrix Axiom Platform. *R.W. Davies[1], A.F.R. Stewart[2], S. Shah[3], W.E. Kraus[3], E.R. Hauser[3], C.B. Granger[3], C.H. Haynes[3], R. McPherson[4], R. Roberts[3], G.A. Wells[1].* 1) Cardiovascular Research Methods Centre, University of Ottawa Heart Institute, Ottawa ON, Canada; 2) John and Jennifer Ruddy Canadian Cardiovascular Genetics Centre, University of Ottawa Heart Institute, Ottawa ON, Canada; 3) Department of Medicine, Duke University Medical Center, Durham NC, USA; 4) Atherogenomics Laboratory, University of Ottawa Heart Institute, Ottawa ON, Canada.

Introduction: The generation of genotypes from DNA microarrays involves the processing of batches of samples using genotype calling algorithms (GCA). These algorithms often borrow methodology from the field of machine learning, such that inference of genotypes depends on the samples included in the same batch. The extent to which various configurations of batches affect genotypes for the new Affymetrix Axiom genotyping platform using the default BRLMM-P GCA is as of yet unknown. Objective: To determine whether batch configuration plays a significant role in samples genotyped using BRLMM-P on the Axiom array. Methods: We genotyped 2081 samples from the Duke CATHGEN study, a coronary artery disease GWAS, for which 1942 CEL files which passed QC were generated. Splitting the data into four batches of equal size, we genotyped the samples and used principal-components analysis to remove samples of non-Caucasian ancestry. For the subsequent 1858 samples, we considered 5 different batch configurations, under the premise that while processing by plate, a common practice is to wait until at least X samples are available before genotyping (where X was 100, 200, 500, 1000 and all samples), genotype these samples, and then to wait until at least X samples are available before genotyping the next batch. We considered a dual-pass genotyping method, where on the second pass any sample which failed a 95% call rate on the first pass was excluded and genotyping re-performed. SNPs were deemed to pass QC if (HWE>1e-6 & ((CR>99% & 0.5%< MAF <5%) or (CR>95% & 5%< MAF <50%))). Analyses were conducted using apt-1.12.0 on a 4xE7440 computer with 16GB of RAM running RHEL5. Results: Call rates and sample exclusion by call rate in the first pass of genotyping were relatively consistent across batch configurations, so the number of samples available for each configuration was quite similar (>1843). The number of SNPs passing SNP-wise QC was also consistent at about 500,000. However, the genome-wide inflation factor lambda (logistic regression case versus control adjusted for sex only) was 1.040, 1.033, 1.026, 1.024, and 1.023 across the 5 methods as listed above, respectively. Run times were naturally longer for the configuration with all samples, but all analyses took less than 24 hours. Conclusions: The decrease in lambda with only a marginal increase in computational requirements and negligible loss of call rate suggests running BRLMM-P with as many samples as possible.

The distribution of signal and noise in high throughput SNP arrays: application for IBD mapping. *B. Markus[1], O.S. Birk[1,2].* 1) The Morris Kahn Laboratory of Human Genetics at the National Institute for Biotechnology in the Negev, Beer-Sheva, Israel; 2) Institute of Genetics at Soroka Medical Center, Ben-Gurion University, Beer-Sheva, Israel.

High throughput SNP arrays have become the standard platform in genetic mapping of Mendelian and more complex traits. These dense arrays provide a convenient and practical way to compare the genomes of individuals and search for common regions indicating candidate loci for common phenotypes. Traditionally, methods have been developed to detect Identical By Descent (IBD) regions using low coverage markers and assuming no errors in the data. However, errors are intrinsic to high throughput technologies and have been shown to seriously hinder the ability to detect relatedness signals. A common practice is to try and eliminate as much as possible the errors prior to downstream statistical analyses. While this approach works very well within pedigrees, between pedigrees there is little information that facilitates error detection. Hence, IBD methods for unrelated individuals should incorporate a model for errors within the calculation of IBD probabilities. In this study we examined the distribution of mistyping in Affymetrix 250K arrays and suggested a model for incorporating this information in pair-wise IBD methods that use the Lander-Green algorithm. We demonstrate using real data the efficacy of incorporating errors within pair-wise IBD analyses which allows the recovery of IBD signals even in very low quality and noisy measurements. We discuss implication for IBD mapping in isolated population under unknown or hidden relatedness with examples of recessive traits from the Bedouin population.

Quality Control Pipeline for Genome-Wide Association Studies in the eMERGE Network: Comparing Single Site QC to a Merged QC Approach. *M. Ritchie[1], L. Armstrong[2], Y. Bradford[1], C. Carlson[3,4], D. Crawford[1], A. Crenshaw[5], M. de Andrade[6], K. Doheny[7], J. Haines[1], G. Hayes[2], G. Jarvik[3,4], L. Jiang[1], H. Ling[7], I. Kullo[6], R. Li[8], T. Manolio[8], M. Matsumoto[6], C. McCarty[9], A. McDavid[3,4], D. Mirel[5], L. Olson[1], J. Paschall[10], E. Pugh[7], L. Rasmussen[9], R. Wilke[1], R. Zuvich[1], S. Turner[1].* 1) Molec Physiology & Biophysics, Vanderbilt Univ, Nashville, TN; 2) Northwestern University, Chicago, IL; 3) University of Washington, Seattle, WA; 4) Group Health Cooperative, Seattle, WA; 5) Broad Institute of MIT and Harvard, Cambridge, MA; 6) Mayo Clinic, Rochester, MN; 7) Center for Inherited Disease Research (CIDR), John Hopkins University, Baltimore, MD; 8) National Human Genome Research Institute (NHGRI), Bethesda, MD; 9) Marshfield Clinic, Marshfield, WI; 10) national Center for Biotechnology Information (NCBI).

Genome-wide association studies (GWAS) are being conducted at an unprecedented rate in disease-based cohorts and have increased our understanding of the pathophysiology of complex disease. Regardless of context, the practical utility of this information will ultimately depend upon the quality of the original data. Quality control (QC) procedures for GWAS are computationally intensive, operationally challenging, under constant evolution, and critically important. What has not yet been explored in detail are the challenges that emerge when multiple GWAS datasets, genotyped in different labs, are merged for downstream GWAS analysis; a scenario that is likely to increase in frequency with the advent of dbGaP. The genomics workgroup of the NHGRI funded electronic Medical Records and Genomics (eMERGE) network has spent a considerable amount of effort developing strategies for quality control of these data. eMERGE consists of five sites, each with DNA databanks linked to electronic health information. Approximately 17,000 samples have been genotyped (~15000 European Americans using Illumina 660W half performed at each (Broad and CIDR) and ~2000 African Americans using Illumina 1M performed at Broad), and phenotypes have been enumerated for ~20 diseases and traits. The lessons learned by this group of investigators will be valuable for the genomics community also dealing with the combining of large scale genomic datasets. We compare the characteristics of various quality control measures between each of the five eMERGE sites, and the merged dataset. Here we enumerate some of the challenges in QC of merged GWAS datasets, including population substructure, merging data from 2 genotyping centers, strand orientation, and other errors inherent from merging ~17000 samples GWAS data, and describe the approaches that the eMERGE network uses to guarantee quality assurance in GWAS data, thereby minimizing potential bias and error in GWAS results. Finally, we describe the best practices that we have decided upon, such as having 2 sites duplicate efforts to eliminate errors early on in the process, and discuss areas of ongoing and future research.

2964/F

On data normalization and pre-processing of family-based association studies of copy number variations. *J. Chu[1], I. Ionita-Laza[2], A. Rogers[1], K. Darvishi[3], N. Laird[4], C. Lee[3], B.A. Raby[1].* 1) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) Columbia University, New York, NY; 3) Department of Pathology, Brigham and Women's Hospital, Boston MA; 4) Department of Biostatistics, Harvard School of Public Health, Boston MA.

The task of normalizing and preprocessing data from copy-number variation (CNV) experiments is a challenging problem. While many methods have been considered to improve the CNV calling and data quality, none have leveraged family-based data. Here we describe a normalization method for family-based CNV studies which applies a simple linear regression model for continuous CNV measurements from parents and children. This approach is advantageous because the normalization of an individual array is informed by intensity distributions generated from three related, yet semi-independent arrays. The method is computationally efficient. We demonstrate our method by its application to a family-based CNV data set of 385 trios from a CNV genome-wide association study of asthma patients, using a custom 180k Agilent CGH CNV genotyping array which characterizes ~20,000 known CNV regions. We compare the results of FBAT (family-based association test) and eQTL analysis with expression data from peripheral blood CD4+ lymphocytes, using various combinations of preprocessing and normalization methods, including quantile normalization, PCA (principle component analysis) and our new method for intra-family adjustment. We show that the family adjustment improves upon more standard normalization methods. It can facilitate the identification of poor quality arrays, sample mix up, and outliers. Importantly, this approach results in more self-consistent signals within the family in ~95% of the trios, and when used in conjunction with other normalizing methods, can improve identification of disease-relevant CNVs. In our applied example - a genome-wide CNV association study of asthma - implementation of our method resulted in much stronger associations as compared to more traditional normalization methods, resulting in the identification of several novel asthma-susceptibility candidates.

Description of transmission distortion in two family-based GWAS. *H. Ling[1], JR. Shaffer[2], TH. Beaty[3], ML. Marazita[2], I. Ruczinski[3], E. Feingold[2], CC. Laurie[4], D. Crosslin[4], AF. Scott[4], KF. Doheny[1], EW. Pugh[1].* 1) IGM, Johns Hopkins University SOM, Baltimore, MD; 2) University of Pittsburgh, Pittsburgh, PA; 3) Johns Hopkins University, School of Public Health, Baltimore, MD; 4) University of Washington, Seattle, WA.

Transmission equilibrium, defined as equal transmission probabilities for each of the two alleles at a genetic locus passed from parent to child, is a fundamental assumption for many genetic analyses. However, distortion of the overall transmission ratio has been reported in a variety of studies for both humans and model organisms. Two NIDCR supported GWAS genotyped at CIDR and also part of GENEVA, one of the programs of the trans-NIH Genes, Environment and Health Initiative, included family data (1) a parent-offspring trio study of oral cleft where families were ascertained through an affected child and (2) a nuclear family cohort study of dental caries where ascertainment was independent of phenotype. Both were genotyped on the Illumina 610Quad array. These two studies contain a large number of trios, ~2000 and 752 for cleft and dental caries studies respectively, allowing us to investigate the transmission ratio for high density arrays of SNPs on a genome wide scale. We examined the transmission rate for autosomal SNPs overall, and by direction and degree of difference from expectation in both studies. For the cleft study we also looked at results after excluding regions associated with the trait. Overall, the transmission ratio for the minor alleles was less than 0.5 more often than it was greater. For most SNPs, the deviation from 0.5 was small. SNPs with low minor allele frequency were more likely to have large departures from 0.5 in both directions. Applying SNP quality control (QC) filters developed by the GENEVA coordinating center remarkably reduced the number of SNPs showing significant evidence of transmission distortion. Among these QC filters, the most important one for removing apparent transmission distortion was call rate. Review of the clustering plots for selected SNPs found a variety of clustering problems for many, but not all SNPs showing extreme transmission distortion. Thus, the statistical evidence for true transmission distortion in humans based on genome wide marker panels is tenuous and may be driven by genotyping errors. NIH grants U01DE004425 and U01DE018903, U01DE018993, NIH Contract HHSN268200782096C, U01HG004446.

DNA Fingerprinting: Utilizing the OpenArray® Platform for Genetic Barcoding of Research Samples. *P.L. Whitehead[1], G.W. Beecham[1], S. Slifer[1], I. Konidari[1], W.F. Hulme[1], K. Hayashibara[2], M.A. Pericak-Vance[1], J.M. Vance[1], J.R. Gilbert[1], D.J. Hedges[1], J.L. McCauley[1].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Applied Biosystems (a part of Life Technologies), 850 Lincoln Centre Drive, Foster City CA.

We have defined a panel of single nucleotide polymorphisms (SNPs) to obtain a “genetic barcode” or “fingerprint” of DNA samples. The primary purpose of this panel is to aid in the quality control of biological research sample storage and experimental processing. The need for this panel stems from the continued expansion of biological repository collections (so-called Biobanks). Rapid progress in genomic technology has allowed for large numbers of loci to be rapidly assayed within individuals (e.g. GWAS arrays & Next Generation Sequencing). While powerful, these experiments are costly, and handling errors can both confound downstream analysis as well as waste financial resources. As the number of samples stored and processed in the course of biological research expands by orders of magnitude, it becomes imperative that increased rigor is devoted to the tracking and confirmation of sample identity. To this end, we have created a genetic barcode panel with markers selected based on a number of criteria, including: high minor allele frequency in multiple ethnic populations, representation on high throughput genotyping, and robust genotyping performance via the Applied Biosystem’s TaqMan® assays using the OpenArray® platform. A set of 32 markers were selected to allow unique identification of individuals within the context of a large biorepository setting. This panel takes into account as much diversity as possible to provide both current and future utility as sample collections grow. This barcoding system allows us to uniquely identify individuals throughout each stage of the handling and experimental process. It provides both sample identity and gender checks in the event of sample mix-ups or labeling mistakes. Finally, it serves as a thorough and robust internal control for the expensive genome-wide association studies that have become common place in the field of complex disease research. As our panel contains markers from these large arrays as a primary criterion for inclusion, we now have the ability to match sample genotypes directly from the panel to the GWAS array. This in turn reduces overall experimental error and provides increased assurances and reliability of matching the data to the correct sample. Our primary panel of 32 (along with our extended set of an additional 32 markers) has the potential to be incorporated into a host of genotyping and next generation sequencing platforms, serving the needs of current Biobanks and genomics centers.

2967/F

Haplotype Phasing from Signal Intensity Data. *Z. Yu, Y. He.* Dept Statistics, Univ California, Irvine, CA.

Genotype calling and imputation of missing genotype data are traditionally conducted in two separated steps. In the genotype calling step, although different statistical strategies have been applied, when the allele signal of a marker is not perfectly separated, missing values are generated. Missing data are then imputed based on called genotypes and underlying linkage disequilibrium (LD) structure of SNPs. Recently we proposed a unified approach that simultaneously makes genotype calls and imputes missing genotypes; using empirical data from Wellcome Trust Case-Control Consortium (WTCCC), we showed that it improves genotype calling of other alternatives. To quantify its performance on haplotype phasing, we first simulated signal data using parameters estimated from WTCCC data, and then compared the new approach and the traditional two-stage approach on phasing. Our results show that the unified approach reduces haplotype phasing error substantially. For simulated trio data, we found that incorporating family structure further reduces genotyping and phasing errors.

2968/F

Comparison of genotype calling algorithms for accuracy and missingness at rare SNPs in a genome-wide association study. *C.S. Franklin[1], P. Williams[2], S. Potter[1], H. Blackburn[1], S. Hunt[1], L. Morgan[2,3], R. McGinnis[1], Wellcome Trust Case Control Consortium 3.* 1) Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, UK; 2) School of Molecular Medical Sciences, University of Nottingham, Nottingham, UK; 3) UK Genetics of Pre-eclampsia Consortium.

Rare SNPs are likely to cause complex human disease but SNPs with minor allele frequency (MAF) below 5% can be difficult to accurately genotype since their genotype classes are small or absent and can be problematic for clustering algorithms. To assess genotype accuracy and missingness of the GenCall (GEN) and Illuminus (ILM) calling algorithms, we compared GEN and ILM genotypes from the Illumina 660 array in 1036 Pre-Eclampsia women who are the first half of expected cases in the Wellcome Trust Case Control Consortium 3 (WTCCC3) Pre-Eclampsia study. To identify SNPs with large MAF differences in genotype calls from the two algorithms, we treated the GEN data as “cases” and the ILM data as “controls” and thereby conducted a pseudo case-control analysis using Fisher’s Exact (FE) test. A subset of SNPs identified as significant (p-value< 0.05) were assessed by visually inspecting cluster plots using EVOKER software to determine which, if either, algorithm was correct. Overall, GEN was more stringent in entirely excluding 31245 out of 580,030 autosomal SNPs which ILM called at a mean call rate of 97.4%. By contrast, ILM entirely excluded only 236 SNPs of which 116 were also excluded by GEN. The pseudo association analysis identified 3033 polymorphic SNPs successfully called by both algorithms and having a FE-test p-value <0.05. The MAF distribution of these SNPs was highly skewed with 63% falling below a MAF of 0.05. These 63% low frequency SNPs were characterised by high call rate in both GEN (0.99) and ILM (0.98) with a mean MAF difference between the two algorithms of 0.022. The 37% higher frequency SNPs had on average lower call rates in one or both algorithms and a larger mean MAF difference of 0.071. Visual inspection of genotype cluster plots from over 1100 SNPs with the largest difference in GEN and ILM MAF found the GEN genotype calls correspond far more accurately to true genotypes especially at low MAF. For SNPs with MAF <0.05, 91.5% were correctly called by GEN, 0.5% by ILM and 8% were poorly called by both algorithms. Our initial results indicate that both ILM and GEN perform well on SNPs with high MAF and, given the higher rate of missingness when using GEN, ILM may be preferable for analysis of common variants. However, our examination of low MAF SNPs with divergent calls for the two algorithms finds that the GEN algorithm is considerably more accurate.

2969/F

False positive associations due to batch effects in a genome-wide association study of brain arteriovenous malformation (BAVM). *H. Kim[1,2,3], L. Pawlikowska[1,2], S.M. Weinsheimer[1], N. Bendjilali[1], P.Y. Kwok[2,4], C.E. McCulloch[3], W.L. Young[1,5,6].* 1) Center for Cerebrovascular Research, Dept Anesthesia, UCSF, San Francisco, CA; 2) Institute for Human Genetics, UCSF, San Francisco, CA; 3) Dept Epidemiology & Biostatistics, UCSF, San Francisco, CA; 4) Cardiovascular Research Institute, UCSF, San Francisco, CA; 5) Dept Neurology, UCSF, San Francisco, CA; 6) Dept Neurological Surgery, UCSF, San Francisco, CA.

Background: Genome-wide association (GWAS) studies of complex phenotypes are an established approach for identifying genetic variants, but require stringent quality control to limit false positive findings. While systematic errors can affect genotyping accuracy and call rates, the effect of batch size is not well studied. The optimal batch size for genotype calling would minimize batch to batch effects while providing reliable calls. Thus, we investigated the effect of batch size on genotype calling using GWAS data from a study of sporadic brain arteriovenous malformations (BAVM), a common cause of hemorrhagic stroke in young adults. **Methods:** DNA samples from 401 cases and 1022 controls were genotyped using Affymetrix SNP Array 6.0, and called using Birdseed v2 algorithm (Affymetrix Power Tools). Genotypes were called in 2 batch sizes: large batch (all samples called together), and small batch (≥42 samples in 9 batches ranging from 42-806). Before allelic association analysis, we excluded SNPs with low genotyping call rates (<95%), out of Hardy-Weinberg equilibrium (P<1e-05), and with low minor allele frequency (MAF<1%). Samples were excluded for low genotyping call rates (<95%), sex mismatches, duplicates, or other disease phenotypes (n=313). **Results:** Batch size influenced the number of samples and SNPs passing QC. Large batch calling resulted in exclusion of more samples (848 vs. 933 remaining) and SNPs (717,335 vs. 743,083 remaining), with similar genotyping call rates (99.2% vs. 99.3%). Allelic association analysis yielded 49 SNPs from large batch calling and 212 SNPs from small batch calling (Bonferroni-adjusted P<0.05). The MAF for cases was much higher in small batch vs. large batch, whereas MAF was similar for controls. SNP cluster graphs for 7 SNPs with large MAF batch differences revealed 1 of 5 case batches incorrectly called each time, resulting in falsely elevated MAF. Technical batch effects were not observed, and case batch size did not correlate with calling error. **Conclusions:** Affymetrix recommends ≥44 samples per batch for genotype calling. However, in our study, call reliability was questionable for smaller batches, even with batch sizes of 100. Genotype calling in a single large batch corrected this inflation at the expense of dropping more cases from analysis. Thus, in our study the inaccuracy of calling in smaller batches was a greater concern than controlling for batch to batch variation.

Genotype concordance between Illumina 1M and Affymetrix 6.0 SNP arrays. *L.C. Kwee[1,2,3], C. Haynes[1,2], J.R. Gibson[1,2,3], A. Stone[4], S.A. Schichman[4], Y. Liu[1,2,3], E.Z. Oddone[2,3], M.A. Hauser[1,2,3], S. Schmidt[1,2,3].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Dept. of Medicine, Duke University Medical Center, Durham, NC; 3) Epidemiology Research and Information Center, VA Medical Center, Durham, NC; 4) Pathology and Laboratory Medicine Service and Research Service, Central Arkansas Veterans Healthcare System, Little Rock, AR.

We genotyped 1539 samples from the GENEVA (Genes and Environmental Exposures in Veterans with ALS) study on the Illumina Human1M-Duo and Affymetrix Genome-Wide Human SNP 6.0 arrays. The substantial number of overlapping SNPs between these arrays allowed us to assess genotype concordance and quality for each platform. Samples were included in the analysis if they produced ≥ 98% call rate on both arrays, were not cryptically related to other samples, and showed agreement between self-reported and genotype-inferred gender. We called Illumina genotypes using Illumina's GenomeStudio software, and included SNPs with call frequency ≥98% that passed several QC filters (cluster separation, heterozygote excess, number of replication errors, AB R mean, AB T mean, and T deviation). We analyzed Affymetrix arrays using Birdseed v2 models and included SNPs with call frequency ≥98%. SNPs were excluded from analysis of both arrays if they were monomorphic, showed differential missingness between cases and controls (p<10-5) or failed a test of HWE in controls (p<10-6). After application of these filters, 1462 samples (95%) remained with genotypes on both arrays. Mean genotype reproducibility of duplicate samples was excellent: >99.99% for Illumina and >99.90% for Affymetrix. Of the 294,666 autosomal SNPs present on both arrays, 264,733 SNPs (89.8%) passed the QC filters for both. An additional 25,313 SNPs (8.6%) passed QC criteria for one array, but not the other. In order to assess genotype concordance, we considered 257,202 non-AT/CG SNPs with genotypes on both chips. The median number of discordant Affymetrix-Illumina genotypes per sample was 113 (0.04%), with a range of 43-6309 discordant genotypes (0.02-2.45%). 115,132 markers (44.8%) produced completely concordant genotypes on the two arrays. The remaining SNPs were discordant for a median of 2 samples (range of 1-1264). We propose using an exact test of genotype frequencies between two chips as an additional SNP QC filter when platforms are merged: for the GENEVA data, such a test (p<.001) identified only 422 additional markers to be removed. We also illustrate the results of applying a similar QC strategy to the publicly available genotypes generated on the WTCCC-Phase 2 control samples with the same two platforms. These results show that when appropriate QC filters are applied, the Affymetrix 6.0 and Illumina Human 1M arrays produce highly-concordant genotypes.

Replication of Genetic Variants associated with Serum Lipids in African Americans. *K. Meilleur, A. Adeyemo, A. Doumatey, D. Shriner, H. Huang, J. Zhou, E. Ramos, G. Chen, C. Rotimi.* Center for Research on Genomics and Global Health, NHGRI, NIH, Bethesda, MD.

Statement of Purpose: Both candidate and genome-wide association studies (GWAS) have identified multiple genetic variants associated with serum lipid parameters including triglycerides, HDL and LDL-cholesterol. However, few of these studies have been conducted in African Americans (AA), who have been reported to display different lipid profiles compared to other US groups. We sought to identify novel susceptibility loci for dyslipidemia in AA and to assess whether observed differences in lipid parameters between AA and other ethnic groups could be explained by differences in genetic background. Methods: In the present study, we tested a set of genetic variants associated with lipid traits in GWAS in a sample of 927 African Americans from the Washington DC metropolitan region. Genotyping was conducted using Affymetric® Genome-wide Human SNP Array 6.0 with genotyping calls determined by Birdseed, v2. Imputation was conducted using MACH and the HapMap reference panels for CEU and YRI. A total of 2,366,856 SNPs were assessed for association with lipid traits using PLINK under the additive model with adjustment for age, sex, BMI, and the first 2 principal components identified in the assessment of population stratification. Results: We identified a significant novel locus (rs1047163; p-value 6.4X10-8) associated with HDL on chromosome 2; this SNP is located in the 3' untranslated region (UTR) of HS1BP3 (hematopoietic-specific protein 1 binding protein 3 gene). An intergenic SNP (rs820042) also on chromosome 2 was identified to be associated with LDL. We replicated previous associations with SNPs in the following genes: LPL, APOB, [APOE, APOC1, APOC4, APOC2], PCSK9, [CELSR2, PSCRC1, SORT1], HMGCR, [NCAN, CILP2, PBX4], CETP, DOCK7, B3GALT4, TRIB1, and TOMM40. Conclusion: Overall, we identified novel susceptibility loci for HDL and LDL cholesterol and replicated several reported GWAS findings in this cohort of African Americans.

Practical Consideration of Genotype Imputation: Sample Size, Window Size, Reference Choice and Untyped Rate. *N. Liu, B. Zhang.* Dept Biostatistics, Univ Alabama at Birmingham, Birmingham, AL.

Imputation offers a promising way to infer the missing and/or untyped genotypes in genetic studies. In practice, however, many factors may affect imputation results. In this study we evaluated the untyped rate, the sizes of the study sample and reference sample, the window size, and reference choice for admixed study samples as the factors affecting the quality of imputation. The results show that in order to have good imputation quality, it is necessary to have an untyped rate less than 50%, reference sample size greater than 50, and a window size of greater than 200 SNPs (roughly 0.4 Mb in base pairs) on a chromosome. Compared with whole-region imputation, piecewise imputation with large enough chunk size performs better, suggesting that a chunk size smaller than the one recommended by IMPUTE may be possible. For an admixed study sample, in order to have good quality of imputation, the external reference panel should include samples from the source populations of admixture. If possible, internal references are strongly recommended. When internal references are limited, however, augmentation by external references should be used very careful. Surprisingly, augmentation should avoid references from the populations other than the source populations of admixture, especially the major source of admixture.

Reconstruction of pedigrees from populations using genotype data. *E. Stevens[1], E. Roberson[1,2], G. Heckenberg[3], T.J. Downey[3], J. Pevsner[1,4,5].* 1) Program in Human Genetics, Johns Hopkins School of Medicine, Baltimore, Maryland, USA; 2) Present address: Dept. of Genetics, Washington University, CB8232, 4566 Scott Avenue, St. Louis, Missouri, MO 63110; 3) Partek Inc., St. Louis, Missouri, USA; 4) Department of Neurology, Hugo Moser Institute at the Kennedy Krieger Institute, Baltimore, Maryland, USA; 5) Department of Neuroscience, Johns Hopkins School of Medicine, Baltimore, Maryland, USA.

Patterns of human genetic diversity can be addressed through genotype studies of geographically distinct groups using single nucleotide polymorphism (SNP) data. Methods such as principal components analysis (PCA) are commonly employed to visualize relationships between samples, often matching the geographic distribution of the cases. Identity-by-state (IBS) methods are also useful to describe genetic relatedness of individuals within large samples. We introduce an IBS-based method that is largely independent of population allele frequencies to identify familial relationships, unrelated individuals, and anomalous heterozygosity rates in large-scale SNP data sets. We applied this method to 1,397 Phase 3 HapMap individuals and reconstructed 34 novel pedigrees. In one group having 30 parent/child trios and 94 nominally unrelated individuals (n=184), we reconstructed a single pedigree containing 178 (MKK) individuals; in three separate HapMap groups we reconstructed pedigrees having 32 (ASW), 29 (LWK), and 25 (MXL) individuals. Other Hapmap groups with unexpected relationships were CEU, CHD, GIH, TSI, and YRI. We applied the method to additional data sets: the Human Variation Panel from Coriell, extended CEPH pedigrees, a large gene environment association study, real data from clinical studies and from a large autism study, and synthetic data. This resulted in the identification of many novel, unexpected relationships. The application of this approach could impact genome-wide association studies, linkage, heterozygosity, and other population genomics studies that rely on SNP genotype data.

2974/F

They are relatives. *C.H. Chen, M.H. Su, T.H. Lu.* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Background: Phase III of HapMap project (HapMap3) comprised genome-wide genotypes of 1184 subjects from 11 ethnicity groups. It was documented that 155 trios and 36 parent-offspring duos existed in the sample. However, not all of the relationships between the HapMap3 subjects were fully assessed. We propose a method using two summary statistics, the average identical by state of genome-wide single nucleotide polymorphisms (gIBS) and the count of zero identical by state (IBS0), to determine the kinship type of two persons in question.

Methods: We simulated pedigree data based on population allele frequencies to obtain cutoffs of gIBS for differentiating major types of kinships. We evaluate the cutoffs by the reported kinships in the HapMap3 sample. We also assess relationships between the preassembly unrelated subjects in HapMap3. We further differentiated between full-sibling pairs and parent-offspring pairs by IBS0.

Results: Our results show (1) the gIBS cutoffs for major types of kinships vary but are similar between the 11 HapMap3 ethnicity groups; (2) all of the 346 previously reported parent-offspring pairs in HapMap3 are correctly categorized by the cutoffs; (3) more than 150 cryptic kinships between the HapMap3 subjects, including 26 full sib pairs and 27 parent-offspring pairs, are uncovered using gIBS and IBS0. The results are confirmed by forensic analysis based on likelihood ratios.

Conclusions: Our method using gIBS and IBS0 was able to accurately recognize the major types of kinships between the HapMap3 subjects. The uncovered cryptic kinships between the HapMap3 subjects may guide the use the HapMap3 data and facilitate the on-going sequencing of the 1000 genomes project.

A quality control algorithm for filtering SNPs in genome-wide association studies. *M. Pongpanich[1], P. Sullivan[2], J. Tzeng[1].* 1) North Carolina State University, Raleigh, NC; 2) University of North Carolina at Chapel Hill, Chapel Hill, NC.

The quality control (QC) filtering of single nucleotide polymorphisms (SNPs) is an important step in genome-wide association studies (GWAS) to minimize potential false findings. SNP QC commonly uses expert-guided filters based on QC variables (e.g., Hardy-Weinberg equilibrium, missing proportion, and minor allele frequency) to remove SNPs with insufficient genotyping quality. The rationale of the expert filters is sensible and concrete, but its implementation requires arbitrary thresholds and does not jointly consider all QC features. We propose an algorithm that is based on principal component analysis and clustering analysis to identify low-quality SNPs. The method minimizes the use of arbitrary cutoff values, allows a collective consideration of the QC features, and provides conditional thresholds contingent on other QC variables (e.g., different missing proportion thresholds for different minor allele frequencies). We apply our method to the seven studies from the Wellcome Trust Case Control Consortium (WTCCC) and the major depressive disorder study from the Genetic Association Information Network (GAIN). We measured the performance of our method compared to the expert filters based on the following criteria: (a) percentage of SNPs excluded due to low quality, (b) inflation factor of the test statistics (λ), (c) number of false associations found in the filtered dataset, and (d) number of true associations missed in the filtered dataset. The results suggest that with the same or fewer SNPs excluded, the proposed algorithm tends to give a similar or lower value of λ, a reduced number of false associations, and retains all true associations.

Software for Generating Linkage-disequilibrium Aware Genotype Calls From Next Generation Sequence Data. *C. Sidore[1,4,5], G. Abecasis[1], H.M. Kang[1], Y. Li[1,2,3], S. Sanna[4], S. Zollner[1,6], Y. Lo[1].* 1) Department of Biostatistics, Center for Statistical Genetics, University of Michigan, Ann Arbor, Michigan, USA; 2) Department of Biostatistics, University of North Carolina, Chapel Hill, North Carolina, USA; 3) Department of Genetics, University of North Carolina, Chapel Hill, North Carolina, USA; 4) Istituto di Neurogenetica e Neurofarmacologia, CNR, Monserrato, 09042 (CA), Italy; 5) Dipartimento di Scienze Biomediche, Università di Sassari, Sassari, Italy; 6) Department of Psychiatry, University of Michigan, Ann Arbor, Michigan, USA.

The analysis of data from large-scale sequencing efforts poses challenges for management of computational resources. A key goal is to accurately identify and genotype variants using millions of short read sequence reads from many individuals. This process typically involves multiple complex steps and requires substantial amount of computational expertise. We have implemented a variant calling pipeline that identifies a set of high quality variants by combining data across individuals and generates genotypes for each individual, taking into account linkage disequilibrium relationships between markers and previous genotype data for the sequenced samples. Our pipeline facilitates variant calling by connecting procedures such as read mapping, read filtering and recalibration, genotype likelihood computation, initial variant calling and filtering, integration with existing array-based genotypes, and improvement of genotype calls using linkage disequilibrium aware hidden-markov models. Our variant calling pipeline can combine data from multiple sources and accommodate various contexts of types of sequencing project, including traditional deep sequencing of a few samples as well as low-coverage whole genome sequencing or targeted sequencing of many samples. Our pipeline uses Python to integrate multiple independent tools and can execute back-end modules in parallel through a cluster system. The entire pipeline requires minimal computational expertise from end-users but can also be fully parameterized to accommodate different software tools or custom settings for intervening steps. We illustrate performance with results from variant calling in the 1000 Genome Samples, in a an ongoing project that is sequencing the genomes of 1,000 Sardinians, and in targeted sequencing project of 200 genes in 15,000 individuals.

A genotype imputation algorithm for allelic dropout in microsatellite data. *C. Wang[1], N.A. Rosenberg[1,2,3].* 1) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI 48109 USA; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI 48109 USA; 3) Life Sciences Institute, University of Michigan, Ann Arbor, MI 48109 USA.

Allelic dropout is a commonly observed source of missing data in microsatellite genotypes, in which one or both allelic copies at a locus fail to be amplified by the polymerase chain reaction. This problem especially affects studies that use noninvasive and forensic samples, for which DNA quality is often poor. A consequence of allelic dropout is a bias in estimates of heterozygosity, due to mistaken classifications of heterozygotes as homozygotes when one of the two copies drops out. In this study, we propose an imputation strategy to correct for allelic dropout when only one set of nonreplicated genotypes is available. First, we use a maximum likelihood approach together with an EM algorithm to jointly estimate allelic dropout rates and allele frequencies. Next, using the estimated parameters and an assumption of Hardy-Weinberg equilibrium, we correct the bias in the estimation of heterozygosity through the use of multiple imputations of alleles in cases where dropout might have occurred. With simulation data, we show that our method can (1) correctly estimate the dropout rates if they are sufficiently small (<15%), and (2) successfully correct the bias in estimating heterozygosity. Because the datasets imputed under our model can be used in additional subsequent analyses, our method will be useful for a variety of population-genetic studies of degraded or limited DNA samples.

Ordered subset analysis identifies loci influencing lung cancer risk on chromosomes 6q and 12q. *S. Fang[1], S. Pinney[2], J. Bailey-Wilson[3], M. Andrade[4], Y. Li[1], E. Kupert[2], M. You[5], A. Schwartz[6], P. Yang[4], M. Anderson[2], C. Amos[1].* 1) Epidemiology, UT M.D Anderson Cancer Cente, Houston, TX; 2) University of Cincinnati, Cincinnati, Ohio; 3) National Human Genome Research Institute, Baltimore, Maryland; 4) Mayo Clinic College of Medicine, Rochester, Minnesota; 5) Washington University, St. Louis, Missouri; 6) Karmanos Cancer Institute, Wayne State University, Detroit, Michigan.

Genetic susceptibility for lung cancer can differ substantially across families. Locus heterogeneity in the familial lung cancer linkage study has not been sufficiently evaluated with respect to family-specific susceptibility. We had previously performed a genome-wide linkage screen in 93 families. Samples and data were collected by the familial lung cancer recruitment sites of the Genetic Epidemiology of Lung Cancer Consortium. We estimated linkage scores for each family by the Markov Chain Monte Carlo procedure using SimWalk2 software. We used ordered subset analysis (OSA) to identify genetically more homogenous families by ordering families based on a disease-associated covariate. Permutation testing was used to determine the significance of the linkage in optimal OSA subsets with the maximum linkage score. A genome-wide screen for lung cancer loci identified strong evidence for linkage to 6q23-25 and nearly significant evidence for linkage to 12q24 using OSA, with peak LOD scores of 4.19 and 2.79, respectively. We found other chromosomes also suggestive for linkages, including 5q31-q33, 14q11, and 16q24. Analyses were conducted ranking the family level of risk for several other cancers and identified subsets of families with significantly increased LOD scores on chromosomes 1q23, 2p11, 6q23-25, 13p12, and 17p11 ($p<0.05$). Our OSA results support 6q as a lung cancer susceptibility locus and provide nearly significant evidence for disease linkage on12q24. Validation studies using large sample size are needed to verify the presence of several other chromosomal regions suggestive of an increased risk for lung cancer and/or other cancers.

2979/F

Extension of the PPL framework to allow Lander-Green based computation. *S. Seok, Y. Huang, V. Vieland.* BCMM, RINCH, Columbus, OH.

The PPL framework is a flexible set of techniques for linkage and linkage disequilibrium (association) analysis in human genetics. The primary software package in which the PPL is implemented, KELVIN [see Huang et al., this meeting], utilizes the Elston-Stewart (ES) algorithm for pedigree calculations. However, for smaller families with dense SNP maps, it becomes important to have recourse to the Lander-Green (LG) algorithm as well. Because the PPL framework involves numerical integration over moderately high-dimensional trait spaces, it requires large numbers of likelihood ratio or LOD calculations at each position, requiring specifically adapted approaches. With the ultimate goal of providing on-the-fly selection of algorithm type based on data structures, we here demonstrate our underlying approach to LG-based PPL calculations by adapting Merlin [Abacasis, 2002], and formulating a hybird LG-ES approach to handling the trait model. Merlin uses binary tree data structures to represent the likelihoods of all possible inheritance patterns for both trait models (trait tree) and markers (marker tree). The LOD score is a function of the average trait likelihood (via a trait tree), the average marker likelihood (via a marker tree), and the average likelihood under the alternative hypothesis of linkage (via the trait and the marker trees) over all possible inheritance patterns. We take advantage of the fact that at marker positions, marker trees tend to be very sparse. Rather than constructing full trait trees via LG at these positions, we use the ES algorithm to compute the trait likelihood, which is faster (since multipoint marker data are not needed for the trait calculation alone) and which involves negligible memory use. For the alternative likelihood, only the partial trait tree with nodes (inheritance pattern) corresponding to nonzero marker likelihood values is needed. The savings in both memory and compute time are proportional to the sparsity of the marker tree. This technique is also well suited for calculations of LOD scores maximized over the trait model, or MOD scores. Additional features to improve the speed of the calculations while minimizing memory requirements are developed, including implementation of an imprinting model that does not increase the tree size.

2980/F

Using Parametric Multipoint LODs and MODs for Linkage Analysis Requires a Shift in Statistical Thinking. *S.E. Hodge[1], Z. Baskurt[2,3], T. Chiang[2], L.J. Strug[2,3].* 1) NYSPI, Unit 24, Columbia Univ, New York, NY; 2) The Hospital for Sick Children, Toronto, ON; 3) University of Toronto, Toronto, ON.

Multipoint (MP) linkage analysis represents a valuable tool for whole-genome studies but suffers from the disadvantage that its limiting distribution is unknown. Moreover, that limiting distribution varies with marker information and density, genetic model, number and structure of pedigrees, and the affection status distribution [Xing & Elston, 2006; Hodge et al., 2008]. This implies that **the MP significance criterion can differ for each marker and each dataset.** One way to circumvent this difficulty is to use simulations or permutation testing. However, a better theoretical understanding is preferable, which we present here: We show how to use the *evidential statistical paradigm* for planning, conducting and interpreting MP linkage studies for LODs and MODs. This involves a) specifying a simple alternative hypothesis (used for planning only), b) formulating the likelihood ratio (LR) between that alternative and the null hypothesis of no linkage to calculate error rates for planning, and c) maximizing the LR and using the magnitude of the maximized LR as a direct measure of evidence strength for or against linkage, compared to a criterion k (k can be 32, 100, or 1,000, etc.) The evidential analog to type I error rate, M, is calculated for the criterion k. We know from Royall [2000] that there is a large-sample bound for M using MP LODs, also that M®0 as n®¥. Moreover, M is naturally low. So set a reasonable value of k, as opposed to setting a fixed value for Type I error (α) as the criterion; then use sample size to control probabilities of weak evidence (it is weak evidence when 1/k<LR<k). We show: (1) Under the alternative hypothesis, error rates also remain low, and we can similarly control them via sample size (shown via simulations); (2) Although error rates under the null are higher for MODs than for LODs, under the alternative hypothesis the opposite is true where power is higher for MODs than for LODs (shown analytically); and (3) M under both null and alternative is greatest at the midpoint between contiguous markers spaced furthest apart, which provides an obvious simple alternative hypothesis to specify for planning MP linkage studies (shown analytically). In conclusion, with α allowed to vary rather than being fixed, the MP LODs and MODs can, themselves, be used to interpret the evidence strength. Moreover, **a common criterion k can be applied at each marker to represent strong evidence favouring linkage.** .

2981/F

Ordered Subset Analyses of Prostate Cancer Susceptibility in Finland Provides Evidence for Replication of *HPCX1* and *HPC10* Loci and Suggestive Evidence for Several Novel Loci. *C.D. Cropp[1], C.S. Simpson[1], T. Wahlfors[2], A. George[1,3], H. Nati[2], T. Tammela[4], J. Schleutker[2], J.E. Bailey-Wilson[1].* 1) Statistical Gen Branch, IDRB/NHGRI/NIH, Baltimore, MD; 2) Institute of Medical Technology, University of Tampere and Tampere University Hospital, Tampere, Finland; 3) Fox Chase Cancer Center, Philadelphia, Pennsylvania; 4) Department of Urology, Tampere University Hospital, University of Tampere, Tampere, Finland.

Prostate cancer is the most common non-cutaneous cancer in men in America and European industrialized countries. It is a complex disorder, with a strong genetic component. Although better treatments and earlier detection have contributed to decreasing mortality rates for many countries, mortality rates are actually increasing in Asian countries such as Japan and Singapore. We recently reported a genome-wide linkage scan in 69 Finnish Hereditary Prostate Cancer (HPC) families, which replicated the *HPC9* locus on 17q21-q22 and identified a locus on 2q37. Using ordered subset analysis (OSA) and conditioning on non-parametric linkage to these loci, we sought to find other loci linked to HPC in subsets of families not detectable in the overall sample. Significance of the change in LOD scores (ΔLOD) due to OSA analysis was determined using permutation tests (empirical p-value). These analyses revealed a significant linkage peak with an OSA LOD score of 4.876 on Xq26.3-q27 (ΔLOD = 3.193, empirical p = 0.009)in a subset of 41 families weakly linked to 2q37. This region overlaps the *HPCX1* locus. Other linked loci were 12q21.1-q23.3 (OSA LOD = 3.67, ΔLOD = 2.526, p = 0.04) in a subset of 17 families unlinked to 2q37, and 8q24.22-q24.3 (OSA LOD = 3.195, ΔLOD = 2.963, p = 0.02) in a subset of 15 families weakly linked to 2q37, overlapping the *HPC10* locus. Another subset of 41 families most strongly linked to 17q21-q22 revealed a significant linkage to Xq25 with a peak OSA LOD score of 3.542 (ΔLOD = 1.484, p = 0.04). This subset contains many of the same families found in the subset linked to Xq26.3-q27 when conditioning on linkage to 2q37. Thus it is likely that these signals represent the same locus. Other strongly linked loci were found at 3q26.31-q27.1 (OSA LOD = 3.492, ΔLOD = 2.39, p = 0.02) in a subset of 47 families unlinked to 17, and 12q14.2-q21.31 (OSA LOD = 3.23, ΔLOD = 2.326, p = 0.02) in a subset of 34 families unlinked to 17. We also used the maximum of the family NPL scores for 2q37 and 17q21-q22 to condition on linkage to either of these loci. Two novel loci were found in this analysis; 18q12.1-q12.2 (OSA LOD = 2.541, ΔLOD = 1.651, p = 0.03) and 22q11.1-q11.21 (OSA LOD = 2.395, ΔLOD = 2.36, p = 0.006), which is close to *HPC6.* Using ordered subset analysis allows us to find additional loci linked to HPC in subsets of families, which would not otherwise be detectable, thus contributing to the effort to untangle the complex genetic heterogeneity of HPC.

Genetic Heterogeneity of Myopia Susceptibility in an Ashkenazi Jewish Population. *C. Simpson[1], R. Wojciechowski[1], D. Stambolian[2], J.E. Bailey-Wilson[1].* 1) Inherited Disease Res Branch, NHGRI, NIH, Baltimore, MD; 2) Department of Ophthalmology, University of Pennsylvania.

Myopia affects at least one third of most populations, is a complex disorder, with both genetic and environmental etiological influences. It has a significant impact on the lives of affected individuals and carries high economic costs associated with treatment and with loss of productivity and co-morbidity from vision impairment. Despite many years of research, most of the factors contributing to myopia development remain unknown. Genetic studies have pointed to a strong inherited component, but although many loci have been found, few genes have been positively identified as causal agents. We have previously reported 2 genomewide linkage scans in a population of 49 highly aggregated Ashkenazi Jewish families which identified a locus on chromosome 22. Here we have used ordered subset analysis, conditioned on non-parametric linkage to chromosome 22 to detect other loci which also had evidence of linkage to myopia in subsets of the families, but not the overall sample. Similar analyses using parametric LOD scores in OSA are ongoing and may increase power. Suggestive linkage to a 25-cM linkage interval with a peak OSA nonparametric allele-sharing LOD score of 2.622 on 20p12.1-q11.23 (ΔLOD = 2.193, empirical P = 0.034) was identified in a subset of 15 families with strong evidence of linkage to chromosome 22, which represents 31% of the total dataset (15/49 families). Seven other loci also presented with suggestive LOD scores > 2.0 on chromosome 2q34-q35, 3p11.1-q24, 5q21.1-q23.3, 6q22.31-q24.2, 7p22.3-21.3, 9q31.1-q33.3 and 14q31.3-q32.3. However, none of the ΔLOD scores were significant by permutation testing. Results using model-based parametric LOD scores in OSA will also be presented. The chromosome 20 locus is entirely novel and appears only in a subset of families already known to be strongly linked to chromosome 22. Using ordered subset analysis allows us to find additional loci linked to myopia in subsets of families, and underlines the complex genetic heterogeneity of myopia even in highly aggregated families and genetically isolated populations such as the Ashkenazi Jews.

2983/F

Getting More from Your Dense SNP Data: EAGLET Increases Power and Precision. *E. Drill, W. Stewart.* Biostatistics, Columbia Univ Sch Pub Hlth, New York, NY.

The correlation between genetic markers (a.k.a. linkage disequilibrium (LD)) can be a serious problem for the analysis of dense SNP linkage data, especially when the genotypes of founders are unavailable and families are enriched for affected members (e.g. affected sib-pair (ASP) designs). If completely ignored, LD can bias estimates of trait location, inflate the Type I error, and reduce the power to detect linkage. However, by considering the full spectrum of LD, we show that the power to detect linkage and the precision to localize traits are dramatically improved. In particular, we have extended EAGLET (Efficient Analysis of Genetic Linkage: Estimation and Testing)---our freely available linkage and association software package, in the following ways: (1) unlike most competing methods which force the user to specify unknown tuning parameters, EAGLET finds the optimal value of the LD-tuning parameter for you; (2) our minimum variance, bias-corrected estimates of location yield candidate gene regions with increased precision while maintaining nominal coverage; and (3) the quality of the Monte Carlo sampling is assessed internally, and simple guidelines are given to help optimize program performance. RESULTS: Using dense SNP data simulated with LD and linkage, we show that our estimate of the LD tuning parameter is consistent, irrespective of the underlying pattern of LD, genetic model, or family structure. Furthermore, we show that (on average) the length of our minimum variance, bias-corrected 95% confidence interval (CI) is shorter than or equal to the length of the original EAGLET CI, and that both have approximate 95% coverage. Lastly, we illustrate the utility of the internal Monte Carlo assessments when optimizing program performance. CONCLUSIONS: By increasing both the power to detect, and the precision to localize disease susceptibility genes, our new and improved software package should greatly reduce the cost of sequencing efforts in candidate gene regions. This, in turn, will finally give researchers the ability to realize the full potential of dense SNP linkage analysis. In addition, the algorithmic improvements have significantly increased the speed of all bootstrap-related features, and the user-friendly documentation and tutorials make EAGLET very easy to use.

Handling Hierarchical Phenotypes in the PPL Framework. *K.A. Walters, V.J. Vieland.* Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital, Columbus, OH.

The use of hierarchical phenotypes (HPs), such as "strict," "intermediate," and "broad" classifications commonly used in psychiatric genetic diagnosis, pose a dilemma for standard statistical genetic methods. The usual approach is to create a series of increasingly inclusive binary phenotypes, to analyze the data once under each phenotypic model, and to select the strongest linkage or association result across the multiple tests (the maximizing phenotype, or MP, method). This is a form of maximizing over the phenotype, which is known to inflate Type I error rates. The PPL framework offers an alternative approach, in which HPs are taken into consideration within a single analysis using liability classes (LCs). Individuals classified as affected under any level of the HP are coded as affected, but assigned to a LC based on HP level. As with all forms of the PPL, penetrances are then integrated out of the resulting linkage or association statistic separately within each LC, allowing for the possibility of different penetrance vectors in the different classes. In principle, this method should properly allow for increasing "phenocopy" rates as the HP level increases in inclusiveness, while maintaining its robustness even when these rates are the same across classes, all without the need for multiple analyses. Here we compare the sampling behavior of the LC and MP methods in application to linkage data generated under a broad range of HP models. We find that when at least 30% of families contain exclusively cases at the narrowest trait level, the LC model is robust and preferable to the MP approach. Under other circumstances, simply including all HP levels in a single "affectedness" category proves to be equally robust, probably because the technique of integrating over the penetrance vector is intrinsically insensitive to a small amount of diagnostic misclassification. Thus without any modifications to the PPL (and PPLD) framework or software [see Huang et al., this meeting] we are able to make use of hierarchical diagnostic information without the need for multiple testing over HP classes.

Sex-Specific Regulation of the mitochondrial DNA (mtDNA) content: Genome-wide Linkage Analysis for Identifying Quantitative Trait Loci. *S. Lopez[1], A. Buil[1], J.C. Souto[2], J. Casademont[3], J. Blangero[4], A. Martinez-Perez[1], L. Rib[1], J. Fontcuberta[2], L. Almasy[4], J.M. Soria[1].* 1) Unit of Genomics of Complex Diseases, Research Institute Hospital de la Santa Creu i Sant Pau, Barcelona, Spain; 2) Department of Haematology, Hospital de la Santa Creu i Sant Pau. Universitat Autònoma de Barcelona, Barcelona, Spain; 3) Internal Medicine Department, Hospital de la Santa Creu i Sant Pau. Universitat Autònoma de Barcelona, Barcelona, Spain; 4) Department of Population Genetics. Southwest Foundation for Biomedical Research. San Antonio, TX, USA.

Mitochondrial DNA (mtDNA) is the key for the maintenance of mitochondrial integrity and function, which indeed influence cell survival. Alteration of the mtDNA quantity has been associated with common diseases and oxidative damage. The aim of the study was to delineate the genomic regions that influence the mtDNA content by a genome-wide linkage analysis in families from the Genetic Analysis of Idiopathic Thrombophilia (GAIT) Project. Mitochondrial DNA levels were measured by quantitative real time PCR in 387 individuals belonging to 21 extended Spanish families. A total of 485 DNA microsatellite markers were genotyped to provide a 7.1 cM genetic map. Genetic heritability (h2) of mtDNA content was estimated in the GAIT sample. A variance component linkage method was conducted to evaluate linkage and to detect quantitative trait loci (QTLs). A first linkage analysis was carried out taking individuals altogether. Further linkage analyses were performed separating the individuals according to the gender. According to our results, mtDNA content is highly heritable (h2=0.334; p=1.82E-05). First linkage analysis showed a QTL suggestive of linkage with mtDNA content on Chromosome 2 (LOD score=2.21; p=7.09E-04). Interestingly, three different strong QTLs influencing mtDNA content were detected when men and women were analysed separated. Women showed a QTL on Chromosome 2 (LOD score=3.09; p=8.11E-05) and another one on Chromosome 3 (LOD score=2.67; p=2.27E-04). Men showed a QTL on Chromosome 1 (LOD score=2.81; p=1.57E-04). Our study clearly reports great evidence of sex specific differences in the genetic determinants involved in the control of the mtDNA content. We report three novel QTLs involved in the quantitative variation of the mtDNA levels. All the regions of linkage contain potential candidate genes that are involved in replication processes, mitochondrial transport, and mitochondrial protein translation. Thus, further genetic and functional analyses are warranted.

Complex segregation analysis reveals a major gene effect controlling dental decay resistance in an isolated population from north of Brazil. *M.T. Mira[1], R.I. Werneck[1], F.P. Lazaro[1], A. Cobat[3,4], A.V. Grant[3,4], M.B. Xavier[2], L. Abel[3,4,5], P.C. Trevilatto[1], A. Alcais[3,4,5].* 1) Graduate Program in Health Sciences, Center for Biological and Health Sciences, Pontifical Catholic University of Paraná, Curitiba, Paraná, Brazil; 2) Tropical Medicine Core, Federal University of Pará, Belém, Pará, Brazil; 3) Laboratoire de Génétique Humaine des Maladies Infectieuses, Institut National de la Santé et de la Recherche Médicale, INSERM U550, Paris, France; 4) Université Paris René Descartes, Faculté Médecine Necker, Paris, France; 5) Laboratory of Human Genetics of Infectious Diseases, Rockefeller Branch, Rockefeller University, New York, New York.

Caries is a chronic, complex and one of the most common diseases affecting humans. It is widely accepted that the occurrence of dental decay depends on environmental and host-related factors, such as diet, biofilm composition, host susceptibility and time of exposure. Over the last years, studies using experimental animal models, as well as human observational (familial aggregation and twin studies), linkage and association analysis were conducted aiming to demonstrate the existence of genetic factors influencing dental decay. However, due to the complex characteristic of the trait, questions such as the model of inheritance and parameters as the frequency and penetrance of the deleterious allele are yet to be addressed. We conducted a Complex Segregation Analysis (CSA) using as phenotype both the quantitative Decayed, Missing and Filled Teeth index (DMFT) and the number of Decayed Teeth (DT) in a sample of 11 extended multiplex families (451 individuals) from an isolated population from Amazonic state of Pará, north of Brazil. Complex Segregation Analysis was conducted by using the regressive model, which specifies a regression relationship between each individual phenotype and a set of explanatory variables, including major gene, phenotype of preceding relatives, and other covariates. A major gene effect controlling resistance to both phenotypes was detected, with the best-fit model being co-dominant for DMFT and dominant for DT. For DT, the frequency of the resistance allele "A" was 0.63 and mean DT was 1.53 and 9.53 for genoptypes AA/AB and BB respectively. Our data indicates that the genetic model detected for DMFT is likely the result of a combination of independent genetic mechanisms controlling the components of the index. The CSA is the first step towards a comprehensive description of the exact nature of the genetic risk factors controlling human susceptibility to dental decay. A deeper understanding of the genetic aspects of dental decay pathogenesis will ultimately lead to new strategies for prevention of such prevalent disease worldwide.

Comparisons of next-generation sequencing alignment programs. *S. Sun[1,2], X. Yu[2].* 1) Case Cancer Center, Case Western Reserve University, Cleveland, Ohio 44106; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, Ohio 44106.

Next-generation sequencing (NGS) technology in a single run produces a 2-3 GB's of data, which usually includes millions of sequencing reads. In order to map sequencing reads onto a reference genome, several alignment programs, including ELAND, SOAP, and BOWTIE, have been developed. However, it is unclear how well each existing program performs on real sequencing data that have different low quality issues. In order to determine the strengths and weaknesses of each alignment program, at analyzing data with low quality issues, we have compared different mapping programs using both simulated sequencing data and real NGS data. Our preliminary result shows that SOAP and BOWTIE alignment results have a relatively small percent of agreement, but ELAND and SOAP results have a relatively larger percent of agreement than ELAND and BOWTIE. We also find that the alignment results of using one single alignment program can be significantly different with various parameter settings. These results suggest that significant opportunities for further improving alignment algorithms.

2988/F

How do sequencing quality issues affect SNP calling results? *X. Yu[1], K. Guda[3], J. Willis[5], M. Veigl[2], S. Markowitz[3,4], S. Sun[1,2].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, Ohio, 44106; 2) Case Comprehensive Cancer Center, Case Western Reserve University, Cleveland, Ohio, 44106; 3) Department of Medicine, Case Western Reserve University, Cleveland, OH 44106; 4) Howard Hughes Medical Institute, Cleveland, OH 44106; 5) Department of Pathology , Case Western Reserve University, Cleveland, Ohio, 44106.

Next-generation sequencing (NGS) technology provides a powerful way to identify both novel and known single nucleotide polymorphisms (SNPs) in a genome. However, there are different sequencing quality issues in the NGS data: for example, 1) some sequencing reads may be aligned to multiple locations in a genome; 2) a single run may have a very large amount of replicated reads at certain genomic positions; and 3) the 3' end of raw reads may have very low qualities. Currently, how to handle these different quality issues is not clear. We may use different strategies such as trimming reads at 3' end and discarding "problematic" reads. Our preliminary results show that the alignment results vary significantly when different methods are used to handle sequencing quality issues. However, it is unknown how these different alignment strategies and results will affect the downstream SNP calling results. In order to determine the effects of various alignment strategies on downstream SNP calling results, we align NGS data using different methods to handle quality issues and then compare the SNP calling results. In particular, we use known dbSNP to address the false positive and negative rates.

2989/F

A Likelihood Based Flexible Threshold Test for Detecting Associations with Rare Variants. *H. Zhong[1], C. Kooperberg[2].* 1) SAGE Bionetworks, Seattle, WA; 2) Fred Hutch Cancer Research Center, Seattle, WA.

Deep sequencing technology will soon generate comprehensive sequence information in large human samples. However, the potential for discovery of genes associated with a complex disease trait by deep sequencing human exom remains unknown. Although power to detect association with an individual rare variant is limited, pooling variants by gene provides an alternative strategy for identifying susceptibility genes. Here we used a rigorous population-genetic simulation framework to characterize the allele frequency spectrum of rare variants involved in complex traits and to motivate statistical strategies to identify such variants. We developed a likelihood based flexible p-value threshold test that can effectively combine evidence of association over different variants. This method optimizes the gene-specific threshold by an efficient permutation algorithm, making it robust with respect to various properties of individual genes. The proposed methods were extensively evaluated using population genetic simulations and trait simulations inspired by the Women's Health Initiative Sequencing Project. Compared to several existing methods, the proposed test showed higher power and robustness under various trait properties and the presence of mis-genotyping errors.

Haplotype Specific Amplification in High Throughput Tumor Sequence Data. *N. Dewal[1], M. Freedman[2,3], T. LaFramboise[4,5], I. Pe'er[6].* 1) Department of Biomedical Informatics, Columbia University, New York, NY; 2) Department of Medical Oncology, Dana-Farber Cancer Institute, Boston, MA; 3) Medical and Population Genetics Program, The Broad Institute of Harvard and MIT, Cambridge, MA; 4) Department of Genetics, Case Western Reserve University School of Medicine, Cleveland, OH; 5) Genomic Medicine Institute, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH; 6) Department of Computer Science, Columbia University, New York, NY.

During tumor progression, culprit genes and variants confer selective advantage to progenitor cancer cells via allowing them to bypass normal growth control mechanisms. Both regions of somatic amplification as well as germline DNA sequence represent variants that are selected for along the tumor genome. High throughput sequencing of tumor and normal tissues identify such somatically amplified regions and hold the potential to reveal the specific gene variants being amplified. We propose a novel Hidden Markov Model-based method -- Haplotype Amplification in Tumor Sequences (HATS) -- that analyzes tumor and normal sequence data to infer amplified alleles and haplotypes in regions of copy number gain. HATS also utilizes existing information from public repositories (e.g. 1000 Genomes Project) in order to infer haplotypes. Our method is designed to handle biases in read data as well as accomodate rare variants. We assess the performance of HATS using simulated amplified regions generated from varying copy number and coverage levels. We demonstrate that HATS infers amplified haplotypes more accurately than naive haplotype construction that is based on allelic read counts alone, especially at lower coverage levels. We thus believe our method will help further the integration of variant types in sequence data and aid the cancer community in identifying causal variants.

Detection and Characterization of Novel Sequences in Next-Generation Sequencing Data from Diverse Populations. *M.W. Snyder, G.R. Abecasis, H.M. Kang.* Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

Ongoing efforts to sequence whole genomes, which are expected to generate hundreds of sequenced genomes this year, are rapidly increasing our catalog of DNA sequence variation, including structural variants, in humans. As the number of sequenced genomes increases, we expect to discover many sequences that are not represented in the current human reference sequence but are present in many or all of these newly sequenced individuals. Some of these newly discovered sequences may include new genes and other functional sequences and could thus contribute to human disease and phenotypic variation. Recent efforts towards novel sequence discovery have focused on de novo genomic assembly, which presents computational challenges when scaled to high-coverage next-generation sequencing data. We evaluate a series of tools designed to identify novel sequences from resequencing data and to describe the presence of such sequences in different populations. We further suggest a method to validate such sequences.

Enriching Targeted Sequencing Experiments for Rare Disease Alleles. *T. Edwards[1], Z. Song[2], C. Li[3].* 1) Vanderbilt Epidemiology Center, Division of Epidemiology, Department of Medicine, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics Research, Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN 37212; 3) Center for Human Genetics Research, Department of Biostatistics, Vanderbilt University, Nashville, TN 37212.

Next-generation targeted resequencing of GWAS-associated genomic regions is a standard approach for discovering rare disease alleles, with the intent to genotype candidate SNPs captured by resequencing. This approach is reasonable, but may be inefficient for rare alleles if samples are not carefully selected for the resequencing experiment. We have developed an approach, SampleSeq, to estimate the expected count of captured rare disease alleles for each subject at each considered locus, and to select samples to maximize the chance of detecting rare alleles in a targeted resequencing experiment. SampleSeq requires specification of prevalence and a target rare disease allele frequency range, and assumes genotypes are available at previously associated SNPs. SampleSeq was compared to selecting random cases or controls, or selecting subjects for burden of high-risk alleles at previously associated SNPs. We used the coalescent simulator Cosi, calibrated to produce haplotypes of sequence-level variation with the LD profile of the original 3 HapMap populations (CEU, YRI, JPT/CHB). We simulated 1000 replicates of 2000 cases and 2000 controls for 15 regions with disease allele frequencies 0.001-0.01 and prevalences 0.01-0.2. SampleSeq provided >35% higher yields of rare disease alleles, acquired >35% more samples with at least 1 disease allele, and required >33% less samples to capture the same number of disease alleles in all scenarios compared to the best alternative. This allows for smaller sample sizes in resequencing experiments, or captures rarer risk alleles. SampleSeq can also calculate required sample size to capture rare alleles. If controls are selected for the experiment by SampleSeq, tests of association are also possible.

2993/F

Variant calling from low-pass next generation sequence data in families. *B. Li, W. Chen, G. Abecasis.* Biostatistics, Univ Michigan, Ann Arbor, MI.

Next generation sequencing is currently being employed to uncover rare variants associated with human complex traits after successful genome wide association studies (GWAS). It becomes challenging due to high error rates of next-gen sequencing technologies. Although population based studies are powerful for GWAS to identify common variants, family designs offer an efficient approach for association studies of rare variants. By utilizing transmission constraints within families, accuracy can be greatly increased by jointly calling variants within families. In addition, if families with multiple affected individuals are collected, rare variants are greatly enriched, making variant calling more accurate and association studies more powerful. Family designs also offer an effective approach for follow-up studies by recruiting family members once a significant rare variant is identified in an individual. Here we developed a likelihood framework and implemented it in software for calling variants from low-pass next-gen sequencing data in families, based on likelihood information encoded in Genotype Likelihood Format (GLF) and rigorous population genetics theories. Simulations using different error rates (0.01 ~ 0.001) and sequence coverage (2X ~ 8X) showed that more variants can be called with higher accuracy in families than in unrelated individuals, especially when the error rate is high and coverage is low. For different frequency categories, except for the extremely rare variants, family designs have higher sensitivity and specificity of variant calling. For the situation when only polymorphic sites in a sample are considered, family designs always have better detection rate and accuracy. One additional advantage of this framework is that imputation is inherent in the variant calling which makes it appealing for increasing the power of association studies. We are currently sequencing families in the SardiNIA project and the new software will be applied to the sequencing data for variant calling and association studies.

2994/F

Alternative Grouping Strategies Improve Association Power of Detecting Rare Variants for Complex Diseases. *YF. Pei[1,2], L. Zhang[1,2], C.J. Papasian[1], HW. Deng[1,3,4].* 1) Univ Missouri - Kansas City, Kansas City, MO; 2) Key Laboratory of Biomedical Information Engineering, Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, 710049, P. R. China; 3) Center of System Biomedical Sciences, Shanghai University of Science and Technology, Shanghai 200093, P. R. China; 4) College of Life Sciences and Engineering, Beijing Jiao Tong University, Beijing 100044, P. R. China.

When detecting rare variants for diseases, an efficient analytical approach involves grouping all variants in a genomic region together for examining the association. One factor complicating this approach is that the vast majority of rare variants are actually neutral to diseases, even when only non-synonymous variants in gene expressing regions are considered. Here, we propose two alternative grouping strategies in order to improve the statistical power of tests of association. In the first exhaustive grouping strategy, we group and test all possible groups formed by subsets of rare variants. In the second selective grouping strategy, we group and test variants that are overrepresented in case and control populations separately. When the proportion of neutral variants is moderate to large we show, by simulation, that both of these alternative grouping approaches can improve the statistical power of association compared to the total grouping method. When applied to the sequencing datasets produced by the ENCODE3 project, the proposed grouping strategies clearly outperform their competitors by several fold, demonstrating the feasibility of the proposed methods.

2995/F

Power of selective sequencing strategies in next-generation whole genome sequencing studies. *S. Su, E. Jorgenson.* Ernest Gallo Clinic and Research Center, UCSF, Emeryville, CA.

Next-generation DNA sequencing enables the comprehensive analysis of genomes, including the identification of rare variants that may influence human diseases and traits. Currently, the cost of whole genome sequencing of large numbers of individuals for genetic association studies is prohibitive, necessitating efficient sample selection strategies to maximize statistical power with limited resources. The selective sequencing approach is a cost-efficient way for detecting genetic variants by selecting individuals with extreme phenotypes. While it is clear that selecting subjects with the most extreme values from a quantitative distribution provides the greatest power to detect genetic variants, most large studies measure multiple traits, and optimal selection strategies for multiple phenotypes and multiple causal variants have not been fully investigated. We conducted a simulation study to examine the power to detect disease association between rare genetic variants and multiple quantitative traits after phenotypic selection. The results encompass several selection strategies (various percentages of samples selected from subjects with the most extreme phenotypes) given different genetic models, including models with one QTL (quantitative trait locus) underlying one phenotype, one QTL underlying multiple phenotypes, and multiple QTLs underlying multiple phenotypes. We show the power of detecting disease association under each selection scheme for each genetic model. Our results can be used as a guideline for selecting samples for genotyping to optimize the power of the study given limited research funds.

2996/F

Improved Detection of Rare Genetic Variants for Diseases. *L. Zhang[1,2], YF. Pei[1,2], J. Li[1], C.J. Papasian[1], HW. Deng[1,3,4].* 1) Basic Med Sci, UMKC Sch Med, Kansas city, MO; 2) Key Laboratory of Biomedical Information Engineering, Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, 710049, P. R. China; 3) Center of System Biomedical Sciences, Shanghai University of Science and Technology, Shanghai 200093, P. R. China; 4) College of Life Sciences and Engineering, Beijing Jiao Tong University, Beijing 100044, P. R. China.

Technology advances have promoted gene-based sequencing studies with the aim of identifying rare mutations responsible for complex diseases. A complication in this type of association studies is that the vast majority of non-synonymous mutations are believed to be neutral to phenotypes. It is thus critical to distinguish potential causative variants from neutral variation before performing association tests to increase their power. In this study, we used existing predicting algorithms in order to predict functional amino acid substitutions, and incorporated that information into association tests. Using simulations, we comprehensively studied the effects of several influential factors, including the sensitivity and specificity of functional variant predictions, number of variants, and proportion of causative variants, on the performance of association tests. Our results showed that incorporating information regarding functional variants obtained from existing prediction algorithms improves statistical power under certain conditions, particularly when the proportion of causative variants is moderate. The application of the proposed tests to a real sequencing study confirms our conclusions. Our work may help investigators who are planning to pursue gene-based association studies.

2997/F

Leveraging the added coverage of exome sequencing with the larger sample size of genomewide association data in the Lung Health Study. *R. Mathias, National Heart, Lung, and Blood Institute's Exome Sequencing Program — and Lung Project Team.* Medicine, Johns Hopkins University, Baltimore, MD.

The utility of massively parallel sequencing for identifying causal mutations underlying rare, monogenic diseases has recently achieved much success. We conducted a genomewide association study (GWAS) using the Illumina 660W to identify markers associated with lung function decline on >4,000 subjects with a minimum of 3 time-points where lung function was measured over a 5-year time frame as part of the NHLBI-supported Lung Health Study (LHS). Approximately 1M SNPs were imputed for up to 2.5M SNPs using MACH and tests for association have been performed using a linear model for lung function decline for each SNP. As part of the NHLBI Exome Sequencing Program, a subset of the LHS samples have undergone exome sequencing using in-solution hybridization probes against a CCDS (2008) target, comprising of about 28Mb over 160,000 exons, to an average of 56X. LHS samples were selected from the phenotypic extremes of lung function decline (i.e. from the upper and lower quartiles), a design which optimizes statistical power to detect rare variants controlling lung function decline. Unequal-variance t-tests will be used to test for association against the rare variants identified through sequencing, an approach that may decrease statistical power but prevent inflated type I error for low frequency variants. We will contrast association signals detected throughout the exome via the two data sources and approaches: the lower coverage larger sample GWAS vs. the higher coverage exome sequencing sample of much smaller size. We anticipate that in this population of European ancestry, we will find additional signals and/or narrow the region of association by leveraging both these strategies.

2998/F

Fine-mapping of classical HLA associations in HIV-1 host control and celiac disease reveals key amino acid residues involved in epitope presentation. *X. Jia[1,2], P.J. McLaren[2,3], S. Ripke[3,4], F. Pereyra[2,9], D.W. Haas[5], D. Heckerman[6], M. Carrington[7], C. Wijmenga[8], B.D. Walker[9], P.I.W. de Bakker[2,3], International HIV Controllers Study.* 1) Harvard-MIT Health Sciences and Technology, Boston, MA; 2) Brigham and Women's Hospital, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) Massachusetts General Hospital, Boston, MA; 5) Vanderbilt University School of Medicine, Nashville, TN; 6) Microsoft Research, Los Angeles, CA; 7) National Cancer Institute-SAIC, Frederick, MD; 8) University Medical Center Groningen, The Netherlands; 9) Ragon Institute of MGH, MIT and Harvard, Charlestown, MA.

Background: DNA sequence variation in the major histocompatibilty complex (MHC) influences the heritable risk for autoimmune disease and the host response to pathogenic infections. Many significant associations have been identified within the MHC, but identification of causal variants is confounded due to linkage disequilibrium across the MHC. **Methods**: We developed an automated pipeline to impute classical HLA alleles as well as all polymorphic amino acids in HLA proteins using a reference panel from the Type 1 Diabetes Genetics Consortium with SNP data and 4-digit HLA types at class I and class II loci. We applied this method to two genome-wide SNP data sets in two diseases with MHC associations: host control of HIV-1 (n=1712) and celiac disease (n=2689). Both case-control data sets contain samples of European ancestry. We tested the imputed amino acids for association, and used stepwise regression to identify independent variants. **Results**: In total, we imputed 263 HLA alleles and 372 amino acid positions in class I and II HLA proteins, and validated with experimental HLA types that imputation accuracy is excellent for HLA alleles with frequency >2%. Stepwise regression revealed 7 HLA alleles associated with host control of HIV-1 (B*5701, B*2705, Cw*0802/B*14, B*35, Cw*07, B*52, A*25). Stepwise regression of amino acids identified four independent residues (positions 67, 63, 62, and 97) within the peptide-binding pocket of HLA-B, one residue (77) in HLA-A, and one residue (304) in HLA-C that together explain the classical associations of protective and risk HLA alleles with host control of HIV-1. In celiac disease, we identified HLA alleles associated with risk (DQA1*05, DQB1*02, DQB1*0302), and found that the DQ2.5 heterodimer produced the most significant association (OR=19, P=2E-167), consistent with previous findings. We were able to resolve these associations down to a pair of perfectly correlated residues (74, 71) within HLA-DQB1, one residue (52) in HLA-DQA1 that line the binding pocket of the HLA-DQ molecule, and another residue (9) of HLA-DQB1. **Conclusions**: Imputation and association testing of individual amino acid positions within HLA molecules can help interpret known HLA signals in infectious and autoimmune disease. In two very different diseases, we demonstrate a key role for discrete polymorphisms within the peptide-binding pockets in the presentation of viral or gluten peptides.

Estimation of allele frequencies and association mapping using next-generation sequencing data. *SY. Kim[1], A. Albrechtsen[2], Y. Li[3], T. Corneliussen[2], G. Tian[4, 5], N. Grarup[6], T. Jiang[3], T. Sparso[6], G. Andersen[6], D. Witte[7], T. Jorgensen[8], T. Hansen[6], O. Pedersen[6, 9, 10], J. Wang[2, 3], R. Nielsen[2], the LuCamp Consortium.* 1) Department of Integrative Biology/Stats, UC Berkeley, Berkeley CA 94720, USA; 2) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 3) Beijing Genomics Institute, Shenzhen 518000, China; 4) Beijing Institute of Genomics, Chinese Academy of Science, Beijing 101300, China; 5) The Graduate University of Chinese Academy of Sciences, Beijing 100062, China; 6) Hagedorn Research Institute, Copenhagen, Denmark; 7) Steno Diabetes Center, Gentofte, Denmark; 8) Research Centre for Prevention and Health, Glostrup University Hospital, Glostrup, Denmark; 9) Faculty of Health Sciences, University of Aarhus, Aarhus, Denmark; 10) Institute of Biomedical Sciences, University of Copenhagen, Copenhagen, Denmark.

Estimation of allele frequencies is of fundamental importance in population genetic analyses and in association mapping. In most studies using next-generation sequencing, a cost effective approach is to use medium or low-coverage data (e.g., <15X). However, SNP calling and allele frequency estimation in such studies is associated with substantial statistical uncertainty because of varying coverage, high error rates, etc. We present a new maximum likelihood method for estimating the allele frequencies in low and medium coverage next-generation sequencing data, based on integrating over uncertainty in the data for each individual rather than calling genotypes. This method can be directly applied to detect associations in case/control studies. We compare our method to methods based on genotype calling using simulations, and show that the likelihood method outperforms the genotype calling methods in terms of: (1) accuracy of allele frequency estimation, (2) distribution of allele frequencies across neutrally evolving sites, and (3) statistical power in association mapping studies. Using real re-sequencing data from 200 individuals obtained using exon-capturing, we show that the patterns observed in the simulations in fact also can be found in real data . In particular, the null distribution of the test statistic computed based on called genotypes shows a significant departure from the chi-square(1) distribution expected using classical asymptotic theory. However, the test statistic calculated using the full likelihood method closely follows the expected distribution. Overall, our results suggest that association mapping and estimation of allele frequencies should not be based on genotype calling in low to medium coverage data. Furthermore, if genotype calling is used, it is better not to filter individuals based on call confidence score.

3000/F

QCALL: SNP detection and genotyping from low coverage sequencing data on multiple diploid samples. *Q.S. Le, R. Durbin.* Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge. CB10 1SA UK.

An efficient approach is to detect SNPs from diploid samples is to sequence many samples at low coverage then to combine data across samples to detect shared variants. Here we present methods to discover and genotype single-nucleotide polymorphism (SNP) sites from low coverage sequencing data, making use of shared haplotype (linkage disequilibrium) information. We first collect SNP candidates based on independent sequence calls at the site with 0.01 posterior probability. We then use MARGARITA with genotype or phased haplotype data from the same samples to collect 20 ancestral recombination graphs (ARGs). We refine the posterior probability of SNP candidates by considering possible mutations at internal branches of the 40 marginal ancestral trees inferred from the 20 ARGs at the left and right flanking genotype sites. Using a population genetic prior on tree branch length and Bayesian inference we determine a posterior probability of the SNP being real, and also the most probable phased genotype call for each individual. We present experiments on both simulation data and real data from the 1000 Genomes Project to prove the applicability of the methods. The current method is limited to samples with available genotypes data. To overcome this limitation, we are developing an approach to place probabilistically new sample with sequencing data in existing ARGs and include the prior probability in Bayesian inference. Consequence, we can analyze any samples as long as we have starting reference ARGs for a related population for examples from HapMap3. Software to implement the methods is available in the QCALL package from www.sanger.ac.uk/software/QCALL/.

GWAStoolbox: an R-package which standardizes and accelerates quality control and data handling of multiple GWAS data files. *C. Fuchsberger[1], D. Taliun[2], P.P. Pramstaller[2], C. Pattaro[2] on behalf of the CKDGen consortium.* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Institute of Genetic Medicine, European Academy, Bolzano, Italy.

Large-scale meta-analyses of genome-wide association studies (GWAS) have led to the discovery of numerous novel loci for a variety of complex traits. Despite the methodological challenges in combining a large number of studies, standardization and in depth quality control of all the data sets involved in the meta-analysis is of crucial importance for the reliability of final findings. Results from a single GWAS typically consist of large files (~250Mb) and the number of SNPs that are currently being analyzed is typically >2.5M and will increase rapidly with imputation based on the 1000 Genome Project. Recently published meta-analyses of GWAS were often composed of 10s of studies. Future collaborative efforts, such as the Metabochip project, will include even more. Therefore, problems must be quickly identified to avoid delays of the entire meta-analysis process and to prevent spurious results. We have developed the GWAStoolbox, an R-package which standardizes and accelerates quality control (QC) of individual-study result files undergoing meta-analysis. After setting up a simple configuration file, GWAStoolbox is capable to process any number of GWAS files, and to produce a full QC report for each study, typically in a matter of minutes. Each QC report comprises three parts: (1) formal checking to assess if all files meet given formatting guidelines; (2) quality checking at the individual study level, including the identification of unexpected values for the main statistics and assessment of p-value inflation; (3) global checking to uncover systematically different studies, which might be caused for example by improper phenotype transformation. Moreover, the package contains functions to facilitate data handling and annotation, and graphical tools to support the interpretation of results. We illustrate GWAStoolbox based on a recent meta-analysis of kidney related GWAS as part of the CKDGen consortium. In brief, the computational time for processing 20 studies on a desktop pc was ~36 min (<2min per file) and required in total ~600Mb of memory. Many different kinds of file formatting problems were quickly uncovered. Checks on the distribution of the main parameters and systematic across-study comparisons enabled us to identify studies with systematic biases in the analysis process. Finally, the fast QC process enabled a quick turn-around so that individual-study analysts could fix the problems without causing major delays to the whole consortium.

An algorithm to infer haplotypes of copy number variations from noisy high-throughput data. *M. Kato[1], S. Yoon[1], N. Hosono[2], A. Leotta[1], J. Sebat[3], T. Tsunoda[2], M.Q. Zhang[1,4].* 1) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) Center for Genomic Medicine, RIKEN, Yokohama, Japan; 3) Department of Psychiatry, University of California, San Diego, CA; 4) Center for Systems Biology, University of Texas, Dallas, TX.

Accurate and complete information on haplotypes and individuals' diplotypes is required for population-genetic analyses; however, microarrays do not provide data on a phased diplotype (e.g., 1 copy in one haplotype and 2 copies in the other) at a copy number variation (CNV) locus, but only provide data on a diploid number, which is the total number of copies/bases over a diplotype (3 copies in the above example). We previously developed algorithms to infer CNV haplotypes from diploid numbers (Kato et al, Am J Hum Genet, 2008; Kato et al, Bioinformatics, 2008); however, these algorithms cannot correctly handle microarray data in which the signal intensities deriving from different diploid numbers are not clearly separated due to noise.

Here we report an algorithm and computational tool to infer CNV haplotypes and individuals' diplotypes from noisy microarray data, incorporating uncertainty due to noise into the expectation-maximization procedure. The uncertainty is represented by likelihoods that a given observed signal intensity may be derived from different underlying diploid numbers. This tool can handle a combination of integer copy numbers, single nucleotide variations in CNV regions (e.g., AAB, unlike AB of single nucleotide polymorphism), and single nucleotide polymorphisms.

We performed simulation studies based on the known diplotypes of 600 individuals in a European population as well as an error model obtained from real microarray data. The new algorithm outperformed the previous algorithms: the error rate of haplotype frequency estimation was 1-2% in the new one compared with 12-18% in the previous ones. In addition, the new algorithm also corrected diploid numbers wrongly determined due to noise in a customary method: the rate of wrong diploid numbers was 4-5% in the new one compared with 21-34% in the customary one. Encouraged by this success, we applied this algorithm to real microarray data and obtained phased CNV genotypes along the genome for the CEU population. These phased genotypes will be basic information for various analyses in population genetics of CNVs.

ParaHaplo 2.0: A Program Package for Haplotype-estimation and Haplotype-based Whole-genome Association Study using Parallel Computing. *K. Misawa[1], N. Kamatani[1,2].* 1) Research Program for Computational Science, Research and Development Group for Next-Generation Integrated Living Matter Simulation, and Fusion of Data and Analysis Research and Development Team; 2) Laboratory for Statistical Analysis, RIKEN Center for Genomic Medicine.

Background: The use of haplotype-based association tests can improve the power of genome-wide association studies. Since the observed genotypes are unordered pairs of alleles, haplotype phase must be inferred. However, estimating haplotype phase is time consuming. When millions of single-nucleotide polymorphisms (SNPs) are analyzed in genome-wide association study, faster methods for haplotype estimation are required.

Methods: We developed a program package for parallel computation of haplotype estimation. Our program package, ParaHaplo 2.0, is intended for use in workstation clusters using the Intel Message Passing Interface (MPI). We compared the performance of our algorithm to that of the regular permutation test on both Japanese in Tokyo, Japan and Han Chinese in Beijing, China of the HapMap dataset.

Results: Parallel version of ParaHaplo 2.0 can estimate haplotypes 100 times faster than a non-parallel version of the ParaHaplo.

Conclusion: ParaHaplo 2.0 is an invaluable tool for conducting haplotype-based genome-wide association studies (GWAS). The need for fast haplotype estimation using parallel computing will become increasingly important as the data sizes of such projects continue to increase. The executable binaries and program sources of ParaHaplo are available at the following address: http://en.sourceforge.jp/projects/parallelgwas/releases/.

LocusZoom: Regional visualization of genome-wide association scan results. *R.P. Welch[1,2], R.J. Pruim[3], S. Sanna[4], T.M. Teslovich[2], P.S. Chines[5], T.P. Gliedt[2], M. Boehnke[2], G.R. Abecasis[2], C.J. Willer[2].* 1) Bioinformatics Graduate Program, University of Michigan Medical School, Ann Arbor, MI 48109; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI 48109; 3) Department of Mathematics and Statistics, Calvin College, Grand Rapids, MI 49546; 4) Istituto di Neurogenetica e Neurofarmacologia (INN), Consiglio Nazionale delle Ricerche, c/o Cittadella Universitaria di Monserrato, Monserrato, Cagliari, Italy 09042; 5) National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland.

Genome-wide association studies (GWAS) are a recently developed strategy whereby a large number of samples are genotyped for millions of single nucleotide polymorphisms (SNPs), which are then tested for association with a particular disease or trait of interest. GWAS have reported hundreds of SNPs associated with disease. Many of these SNPs are in linkage disequilibrium with others nearby, implicating large genomic regions that may contain the causal disease variant(s). Each region contains a number of important features for understanding the association signal, including the association p-values, linkage disequilibrium patterns in various populations, recombination hotspots, the position of genes, and genomic annotations such as regulatory regions, conserved sequences, and transcription factor binding sites. To visualize all of this information simultaneously, we developed LocusZoom (http://csg.sph.umich.edu/locuszoom), a web tool that creates regional plots for genome-wide association results or similar types of data such as candidate gene studies. LocusZoom plots contain all of the features listed above, and can be extended to include user-defined annotations. We support plotting not only a user's association results, but those from other publicly available datasets such as the Kathiresan et al. 2009 GWAS scan on lipid traits. Users can generate single plots interactively, or by using our batch mode that creates plots for each SNP provided in a specification file. We support SNPs in rsid or 1000G naming format, which allows plotting of SNPs from the 1000 Genomes Project or newly discovered SNPs from sequencing experiments. Our software has been used to produce publication-quality plots for multiple complex disease traits, including type 2 diabetes (DIAGRAM), BMI (GIANT), and lipid levels (GLGC). LocusZoom is available via a web interface and as a stand alone application which can run on most Linux/Unix platforms. In both cases, we use the lattice graphics package in R to render plots. Source code is also available for download. Since LocusZoom was released in February 2010, we have created over 1,000 plots per month for external users.

3005/F

Genetic analysis of biological pathway data through genomic randomization. *B. Yaspan[1,2], W. Bush[2,3], E. Torstenson[1,2,3], C. McMunn[2,4], D. Ma[5], M. Pericak-Vance[5], M. Ritchie[1,2,3], J. Sutcliffe[1,2,6,7], J. Haines[2].* 1) Department of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 3) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN; 4) Computational Genomics Core, Vanderbilt University Medical Center, Nashville, TN; 5) The John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 6) Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN; 7) Department of Molecular Neuroscience, Vanderbilt University Medical Center, Nashville, TN.

Genome Wide Association Studies (GWAS) have become a standard approach for large-scale common variation characterization and for identification of single genes of even modest effect size predisposing to disease. However, due to issues of moderate sample sizes and particularly multiple testing correction, many variants of smaller effect size are not detected within a single allele analysis framework. Thus, small main effects and potential epistatic effects are likely not consistently detected by GWAS using standard analytical approaches that consider only single SNP alleles. Here we propose unique methodology that aggregates variants of interest (for example, genes in a biological pathway) using GWAS results. Multiple testing and type I error concerns are minimized using genomic randomization, an empirical approach, to estimate significance. Biologic pathways are parsed into independently inherited “features”, linkage disequilibrium (LD) blocks or SNPs in linkage equilibrium, based on the genes within counting the number which are empirically significant. A randomized set of features of similar size (in terms of SNPs tested and LD structure) is generated and significance is compared to the features in the biologic pathway. Randomization corrects for common pathway-based analysis biases such as SNP coverage and density, LD, gene size and pathway size. PARIS (Pathway Analysis by Randomization Incorporating Structure) applies this randomization and directly accounts for linkage disequilibrium effects. Whereas most pathway-based analytical methods require reanalysis of the raw genotype data, PARIS is independent of association analysis method and is thus applicable to GWAS datasets of all study designs. Using the KEGG database we apply PARIS to the publicly available Autism Genetic Resource Exchange (AGRE) GWA dataset, revealing several pathways with significant enrichment (top hits p<0.001: pentose and glucuronate interconversions, ubiquitin mediated proteolysis, synthesis and degradation of ketone bodies, riboflavin metabolism).

3006/F

DiNAMIC: A Method for Assessing the Statistical Significance of DNA Copy Number Aberrations. *V. Walter[1, 3], A.B. Nobel[1, 2, 3], F.A. Wright[1, 3].* 1) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 2) Department of Statistics, University of North Carolina, Chapel Hill, NC; 3) Lineberger Comprehensive Cancer Center, Chapel Hill, NC.

DNA copy number gains and losses are commonly found in tumor tissue, and some of these aberrations play a role in tumor genesis and development. Although high resolution DNA copy number data can be obtained using array-based techniques, no single method is widely used to distinguish between recurrent and sporadic copy number aberrations. Here we introduce Discovering Copy Number Aberrations Manifested In Cancer (DiNAMIC), a novel method for assessing the statistical significance of recurrent copy number aberrations. DiNAMIC largely preserves the correlation structure found in the underlying DNA copy number data, which may yield additional power to detect recurrent aberrations. Moreover, extensive simulation studies show that DiNAMIC controls false positive discoveries in a variety of realistic scenarios. We use DiNAMIC to analyze two publicly available tumor datasets, and our results show that DiNAMIC detects multiple loci that have biological relevance. DiNAMIC is a useful tool for researchers interested in detecting recurrent DNA copy number aberrations.

3007/F

IntRapid: software for rapid testing of gene-gene interactions in genome-wide association studies. *K. Bhattacharya, R. Magi, A.P. Morris.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK.

Genome-wide association (GWA) studies have established themselves as the most successful approach to mapping the genetic determinants of complex traits. However, the primary analyses of GWA studies focus on the marginal effects of single SNPs, and have helped to understand only a small proportion of the genetic component of phenotypic variation. There is increasing evidence from model organisms that complex traits may be influenced by interplay between genes, so that the effect of a causal SNP at one locus is modified by genotypes at other loci. GWA interaction studies may thus help to map additional causal loci, providing a better understanding of the genetic architecture underlying complex traits.

One of the key challenges in performing GWA interaction studies is computational burden. To address this challenge we have developed the IntRapid software to perform rapid testing of gene-gene (GxG) interactions in GWA studies of dichotomous or continuous traits. To achieve this, we undertake a two-stage interaction testing strategy. In the first stage, all pairs of SNPs are tested using a rapid GxG interaction test. For a dichotomous trait, this is equivalent to the PLINK “fast epistasis” analysis. For a continuous trait, the distribution is dichotomised at the median, with half the sample treated as “cases” and half as “controls”. In the second stage, all pairs of SNPs with rapid interaction *p*-values meeting a pre-defined significance threshold are carried forward for testing in a traditional generalised linear modelling framework. Within this framework, we can assess the significance of interaction effects, adjusting for potential non-genetic risk factors, which cannot be fully assessed in the first stage. The open source IntRapid software is freely available for download from www.well.ox.ac.uk/IntRapid, together with documentation and examples, and scripts for converting standard PLINK and SNPTEST format input data files.

We have applied IntRapid to GWA studies of seven common diseases undertaken by the Wellcome Trust Case Control Consortium. Using a rapid interaction threshold of $p<10^{-4}$, analysis of each disease cohort (~2000 cases, ~3000 controls) takes ~20 days on a single processor. Our results highlight interactions between loci that suggest novel mechanisms and pathways underlying disease susceptibility, and warrant follow-up in independent cohorts for confirmation.

3008/F

A library and tools for manipulating and analysing next generation sequence data. *M. Trost, H.M. Kang, P. Anderson, B. Li, W. Chen, C. Fuchsberger, X. Zhan, G.R. Abecasis.* University of Michigan, Ann Arbor, MI.

As the volume of next generation sequencing and genotyping data increases, there is great demand for high quality, high performance data processing and analysis tools. We are actively developing a set of open source tools and libraries to meet this need. Our C++ library and tools facilitate interaction with common data structures used in the analysis of genetic data, including family information stored in pedigree files, raw sequence data stored in FASTA and FASTQ files, and alignment information stored in SAM, Sequence Alignment and Mapping, and BAM, Binary Sequence Alignment and Mapping Format, files. Our library robustly reads and writes each of these file types, providing rapid, validated access to the information they contain. The library is designed to provide a clear, easy to use interface to a variety of file formats and facilitate the development of data analysis tools.

We illustrate a variety of freely available tools that build upon the underlying library to facilitate file format checking, editing of annotation tags, file merging, duplicate marking and removal, base quality recalibration, variant calling and filtering (including family-structure aware variant callers), checking of sample identities, and various quality assessments. The implementation is memory efficient enough that recalibration or duplicate removal of an ~10 GB BAM file with 70 million reads can typically be accomplished within a gigabyte of memory consumption. Our library and software are publicly available from: http://genome.sph.umich.edu/wiki/Software.

3009/F

Copy Number Variation Accuracy in Genome Wide Studies. *P. Lin, S. Hartz, L. Bierut, J. Rice, COGA Collaborators, COGEND Collaborators, GENEVA.* Department of Psychiatry, Washington University , St. Louis, Missouri, USA.

Copy Number Variations (CNVs) are a major source of variation between individuals and are a potential risk factor in many diseases. Numerous diseases have been linked to deletions and duplications of these chromosomal segments. Data from genome-wide association studies (GWAS) and other microarrays may be used to identify CNVs by several different programs, although the reliability of the results has been questioned. However, no study has tested the reliability of CNV identification in a genome-wide scale. In this study, we estimated the sensitivity and positive predicted rate for CNV calling using a mathematical model based on duplicates in our samples. We found that the positive predictive rate increases with number of probes in the CNV and the size of the CNV, with the highest positive predicted rates in CNVs of at least 500kb and at least100 probes. Our analysis also indicates that identifying CNVs reported by multiple programs can greatly improve the positive predicted rate. These tools can be used by investigators to identify CNVs in genome-wide data with greater reliability.

3010/F

Robust Relationship Inference In Genome Wide Association Studies. *W.M. Chen[1,2], A. Manichaikul[1,2], J. Mychaleckyj[1], S.S. Rich[1], K. Daly[3], M. Sale[1,4,5].* 1) Center for Public Health Genomics, Univ Virginia, Charlottesville, VA; 2) Dept of Public Health Sciences Division of Biostatistics and Epidemiology, Univ Virginia, Charlottesville, VA; 3) Dept of Otolaryngology, Univ Minnesota, Minneapolis, MN; 4) Dept of Medicine, Univ Virginia, Charlottesville, VA; 5) Dept of Biochemistry and Molecular Genetics, Univ Virginia, Charlottesville, VA.

Genome-wide association studies (GWAS) have been widely used to map loci contributing to variation in complex traits and risk of diseases in humans. Accurate specification of familial relationships is crucial for family-based GWAS, as well as in population-based GWAS with unknown (or unrecognized) family structure. The family structure in a GWAS should be routinely investigated using the SNP data prior to the analysis of population structure or phenotype. Existing algorithms for relationship inference have a major weakness of estimating allele frequencies at each SNP from the entire sample, under a strong assumption of homogeneous population structure. This assumption is often untenable. Here, we present a rapid algorithm for relationship inference using high-throughput genotype data typical of GWAS that allows the presence of unknown population substructure. The relationship of any pair of individuals can be precisely inferred by robust estimation of their kinship coefficient, independent of sample composition or population structure (sample invariance). We present simulation experiments to demonstrate the algorithm has sufficient power to provide reliable inference on millions of unrelated pairs and thousands of relative pairs (up to the 3rd-degree relationships). Application of our robust algorithm to HapMap and GWAS datasets demonstrates it performs properly even under extreme population stratification, while algorithms assuming a homogeneous population give systematically biased results. Our extremely efficient implementation performs relationship inference on millions of pairs of individuals in a matter of minutes, dozens of times faster than the most efficient existing algorithm known to us (e.g., as implemented in PLINK). Our robust relationship inference algorithm is implemented in a freely available software package, KING.

3011/F

GenAMap: An integrated analytic and visualization software platform for structured GWA and eQTL analysis. *R.E. Curtis[1,2], E.P. Xing[2,3].* 1) Joint Carnegie Mellon-University of Pittsburgh PhD Program in Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 2) Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 3) School of Computer Science, Carnegie Mellon University, Pittsburgh, PA.

GenAMap is a software project that integrates the power of structured GWA with a usable interface and novel visualizations. GenAMap is specifically designed for large-scale association analysis, especially for analyses that take advantage of structure in a genome-wide collection of markers and thousands of traits or gene expression data structured as a network, time-series, or hierarchy. GenAMap provides novel ways of exploring these kinds of data through human-computer interaction. GenAMap currently supports algorithms based both on classical methods and novel structured sparse regression techniques, such as the GFlasso. GenAMap enhances performance of these algorithms with a complex parallel-computing system that runs all algorithms on a remote cluster. Once results for the association analysis have been obtained, GenAMap provides users with natural visualization schemes that enhance discovery by enabling researchers to visualize the structure of the data while exploring the association results. We consider one or two association studies which highlight the usefulness of GenAMap's visualization techniques.

3012/F

Enrichment analysis of gene-sets and gene-centric SNP-sets reveals evidences of potential shared mechanisms underlying hypertension across race groups. *L. de las Fuentes[1], W. Yang[2], A. Morrison[4], M. Fornage[4], J. Chu[2], V.G. Dávila-Román[1], E. Boerwinkle[4], C.C. Gu[2,3].* 1) Department of Medicine, Cardiovascular Division, Washington University, St. Louis, MO; 2) Division of Biostatistics, Washington University, St. Louis, MO; 3) Department of Genetics, Washington University, St. Louis, MO; 4) Human Genetics Center, University of Texas School of Public Health, Houston, TX.

Shared mechanisms likely underlie complex diseases such as hypertension (HT) despite GWAS studies that typically identify SNPs with little overlap between races. We hypothesize that actions of shared mechanisms vary in different populations and/or under different environmental pressure, resulting in different signal strengths for components missed by conventional single-SNP scans. A customized gene-set enrichment analysis method called VSEA (variable set enrichment analysis) was applied to evaluate aggregated effects of GWA for mean arterial blood pressure (MAP) in the Atherosclerosis Risk in Communities (ARIC) Study. The dataset consisted of 3132 African Americans (AA; 832,077 SNPs after QC) and 9315 Caucasians (CA; 828,744 SNPs). VSEA evaluated enrichment of MAP association in 1376 known pathways (from GO, KEGG & BioCarta), 3872 novel networks (self-curated), and 1252 single genes (402 CVD candidate gene, plus top/bottom 2000 MAP-associated SNPs). Analyses were performed within race and agreement between races was examined for empirical evidence of shared mechanisms for HT. Briefly, (1) in both races, significant enrichment (adjusted $p<0.05$) was discovered in multiple known pathways, many previously implicated in HT (e.g., "NF-kB signaling", "Regulation of PGC1α"); (2) 21 gene-sets were common to both races, with the "mitosis" pathway figuring prominently, interesting since this process was recently associated with HT; (3) gene-based analyses found enrichment for 139 and 67 genes in CA and AA, respectively, but only 8 shared to both races (IL21, ACADL and others); 402 CVD candidate genes fared well with a typical inflation factor of ~1.12; (4) significant enrichment was found in 218 and 315 novel networks in CA and AA, respectively, with 16 enriched networks common to both races. The most prominently enriched novel network involves methyltransferase (METTL7A), iron absorption (SLC11A2), and taste receptor (TAS1R2); (5) cross-validation with the results from an independent CA sample (n=592) confirmed 10~30 commonly enriched known pathways. In summary, our analyses provide strong evidence for shared mechanisms of HT across races. More commonality between races was found as the unit of analysis changed from single SNPs to genes to gene-sets. Thus, analyses of aggregated effects are needed to detect relevant components of putative shared mechanisms of HT even if the factors contribute to varying signal strength between populations remain to be identified.

3013/F

KELVIN 2.1: A tool for modeling genetic architecture for complex disorders. *Y. Huang[1], S. Seok[1], W. Valentine-Cooper[1], J. Burian[1], L. Mangin[1], B. Nouanesengsy[1], A. Modi[1], V. Vieland[1,2].* 1) Battelle Ctr Math Med, Res Inst at Nationwide Children's Hospital, Columbus, OH; 2) Dept Pediatrics, Ohio State University, Columbus, OH.

KELVIN (v2.1) is a comprehensive statistical genetics software package developed under the PPL framework. It currently supports more than 20 different types of analyses, including marker-to-marker or trait-to-marker analysis; dichotomous trait, quantitative trait, and QT threshold models; linkage and trait-marker linkage disequilibrium (association) analysis; and gene x gene interaction models. Using an accurate and efficient numerical integration method, values of the unknown trait parameters are integrated out of the likelihood, rather than fixed at arbitrary values. Through Bayesian sequential updating, evidence is accumulated in a mathematically rigorous manner across multiple sets of data, while allowing for heterogeneity both within and between data sets. All statistics under the PPL framework are on the probability scale, they converge to 0 with evidence against and to 1 with evidence in favor of linkage and/or association, and their interpretation is direct and straightforward. Recent upgrades to KELVIN provide unique flexibility, allowing simultaneous analysis of different data structures, from case-control data to extended pedigrees, and allowing different marker maps and/or pedigree peeling algorithms to be used for different pedigrees within a single analysis. Analyses can be done on a single node or can be distributed across a cluster. KELVIN can be run on multiple platforms (Linux, Mac OS X, Windows XP/Vista/7), and a newly implemented version provides a web interface allowing users to upload data, set up and submit analyses, and to download results, through a user-friendly interface. KELVIN also includes tools for graphing results, including a utiliy specifically designed for plotting genome-wide association or linkage scans (not restricted to PPL analyses) with zoom in/out functionality, plot overlays, and flexible annotation features. KELVIN is continuously being updated and polished as a tool for modeling genetic architecture for complex disorders.

3014/F

Evaluation of 1000Genomes data for imputation in genome-wide association studies: analysis of Fasting Glucose in 5,402 individuals from the NFBC66 cohort. *V. Lagou[1,2], R. Mägi[1], M.I. McCarthy[1,2], A.P. Morris[1], I. Prokopenko[1,2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism (OCDEM), University of Oxford, Oxford, UK.

In the past few years, genome-wide association studies (GWAS) have significantly contributed to unravelling the genetic architecture of phenotypes of biomedical importance. Genotype imputation is a widely used procedure in the analysis of GWAS and their large-scale meta-analyses. Availability of novel data from the 1000Genomes project and HapMap III, and development of new imputation tools can enable us to improve the quantity and quality of GWAS data. Our study has three key aims. First, we explore properties of the reference panels available for imputation, namely 1000Genomes (112 CEU, August 2009 release, Sanger alignment of haplotypes)/HapMap III CEU (1KG+HM3) in comparison to HapMap II CEU (HM2), respectively. Second, we compare the performance of IMPUTE v1 and IMPUTE v2 software, in genome-wide imputation for the population-based Northern Finland Birth Cohort 1966 (NFBC66), 5,546 subjects genotyped in Illumina HumanCNV-370DUO array. Third, we investigate the quality of imputed data on in the analysis of association for Fasting Glucose (FG) quantitative phenotype. We performed genome-wide imputation using NFBC66 ~328K genotyped SNPs and 5,402 subjects available after genotyping quality control. We were able to impute successfully ~2.2M and ~7.2M additional SNPs from HM2 and 1KG+HM3, respectively, on a Linux environment. It took ~198 hours and ~1410 hours of CPU time for whole-genome imputation using IMPUTE v1 (HM2) and IMPUTE v2 (1KG+HM3), respectively. We have performed GWA analysis of FG using an additive genetic model implemented in SNPTEST. We investigated the accuracy of imputation for both sets of reference panels. We evaluated the performance of IMPUTE v1 and v2 for common and rare variants in comparison with directly genotyped SNPs in a specific chromosomal region. The false positive rates (FPR) and false negative rates (FNR) were lower in IMPUTE v2 (FPR= 1.75%, FNR=1.4%) than IMPUTE v1 (FPR=2.3%, FNR=21.8%). Our results highlight that imputation from multiple reference panels with high density of polymorphic variants (1KG+HM3) increases the accuracy and quantity of imputed data, although it requires 7-fold increase in computing time in comparison to HM2 panel. IMPUTE v2 with larger and denser reference panels performs better than IMPUTE v1 at predicting the genotypes for common and rare SNPs. Accurate imputation of rare SNPs is of great importance in GWAs, as these markers may be involved in complex diseases pathophysiological pathways.

3015/F

Efficient haplotype reconstruction for pedigree data with zero individual genotype mismatches. *Q. Li[1], M. Fallin[2], J. Bailey-Wilson[1].* 1) Inherited Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, MD; 2) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD.

Haplotype phase imputation is useful for most haplotype based association tests and for missing genotype imputation. However, phase imputation in extended pedigrees is not trivial. For large haplotype blocks, the number of possible diplotype configurations grows exponentially with the number of markers in the block. There are several haplotype phase estimation or reconstruction algorithms, and a few recent methods handle extended pedigree data. However, haplotypes with rare frequencies are often left out in reconstruction. In application, this can result in misclassification of imputed genotypes. These erroneous genotype assignments are considered particular to individuals, and are usually ignored. Based on population haplotype frequencies, we developed an efficient algorithm to impute phases (and therefore genotypes) for haplotype blocks of up to 8 SNPs, in trios as well as in extended pedigrees. To ensure no individual genotype assignment errors, we consider all possible haplotypes, even those with extremely rare frequencies. We evaluated our phase imputation method using simulated data with masked genotypes within pedigrees. We examined the misclassification proportions of imputed genotypes when rare haplotypes are left out, and compared our methods with other methods: PHASE, HAPLORE, PedPhase, and PhyloPed.

3016/F

Haploscope: a graphical tool for the display and investigation of haplotypes in populations. *F.A. San Lucas[1], N.A. Rosenberg[2], P. Scheet[1].* 1) Dept. of Epidemiology, University of Texas M.D. Anderson Cancer Center, Houston, TX; 2) Dept. of Human Genetics, University of Michigan, Ann Arbor, MI.

Haplotype structure is often depicted pictorially by using tools that rely on visualizations of raw data or pairwise linkage disequilibrium patterns. We propose an alternative that provides a novel graphical representation of haplotype frequencies and that enables natural comparisons of haplotype structure across subgroups of a population (e.g. cases and controls, or separate subpopulations). In particular, we provide a tool for visualization of the haplotype cluster frequencies that are produced by a statistical model of haplotype structure across a genome.

Haploscope is a graphics program that generates visual representations of population haplotype variation. It is based on output from the specific statistical model for population haplotype variation used in the software fastPHASE (P. Scheet & M. Stephens, AJHG 78:629-644, 2006), though it can also be applied to other cluster-based models for haplotypes. The program displays summaries of population-specific haplotype frequencies and aids direct comparisons of haplotype composition among subgroups. Haploscope is an extension the program Distruct, which generates graphical images of clustering patterns within populations from cluster data. In a Distruct image, each vertical line corresponds to an individual, and is partitioned into K colored components that represent membership in K distinct clusters. Haploscope generates similar images where the clusters represent haplotype -- rather than population -- structure. Haplotype clusters are represented as colors, and genomic markers are depicted as vertical bars partitioned into colored segments that correspond to membership coefficients in the clusters. An example of Haploscope output can be found in M. Jakobsson et al. (Nature 451:998-1003, 2008). Various options for generating the images enable the user to control the range of marker positions to include in the cluster image, as well as the order of clusters. Cluster colors and other graphical labels and features are also configurable. Thus, the flexibility offered by Haploscope in the graphical representation provides investigators with the ability to report visually appealing and informative plots of haplotype structure.

Coordinated New Versions of the Pedigree Simulation Packages SLINK and SUP. *A.A. Schaffer[1], M. Lemire[2], J. Ott[3,4], G.M. Lathrop[5], D.E. Weeks[6].* 1) NCBI/NIH/DHHS, Bethesda, MD, USA; 2) Ontario Institute for Cancer Research, Toronto, Ontario, CANADA; 3) Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing, CHINA; 4) Laboratory of Statistical Genetics, Rockefeller University, New York, NY USA; 5) Centre National de Genotypage, Evry, FRANCE; 6) Departments of Human Genetics and Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA.

Simulation of replicates of pedigrees with genotypes filled in at random is an important tool to evaluate the power of a linkage study and to assess the empirical significance of linkage as well as association study results. SLINK (J. Ott PNAS 86(1989), 4175-4178; D. E. Weeks et al. AJHG 47(1990), A204) is one widely-used package for pedigree simulations. Over 15 years ago, SLINK was modified to incorporate faster algorithms from early versions of FASTLINK (Cottingham et al. AJHG 53 (1993), 252-263). One limitation of SLINK, as with most methods based on the Elston-Stewart pedigree likelihood algorithm, is the small number of markers that can be generated. The software package SUP (M. Lemire BMC Genetics 7(2006):40) is an elegant wrapper for SLINK that circumvents the limitation on number of markers by using pseudomarkers generated by SLINK to simulate a much larger number of markers on the same chromosome. Initial versions of SUP were limited in their functionality due to a limit on the number of alleles in SLINK and contorted in their design because SLINK did not output some internal variables needed by SUP. We have released new coordinated versions of SLINK (3.0; available from http://watson.hgen.pitt.edu) and SUP (v090804; available from mlemire.freeshell.org/software or http://watson.hgen.pitt.edu) that integrate the two software packages and remove the previous limitations on SUP. SLINK v3.0 includes improvements from later versions of FASTLINK that make it faster and simplify the set-up procedure. There is no restrictive limit on the number of alleles and the simulated genotypes at the trait locus can be output directly. SUP v090804 has been rewritten to handle pedigrees of arbitrary size and the typical usage is substantially streamlined, as compared to previous versions. Both new releases include new documentation and examples.

Genetic Map Interpolator. *N. Mukhopadhyay[1], X. Tang[2], D.E. Weeks[1,2].* 1) Dept Human Genetics, Univ Pittsburgh/Sch Pub Hlth, Pittsburgh, PA; 2) Dept Biostatistics, Univ Pittsburgh/Sch Pub Hlth, Pittsburgh, PA.

Many statistical algorithms for analyzing genetic data require genetic maps of the markers, which specify the recombination rates between adjacent markers. However, while it is relatively easy to extract physical map positions from the on-line databases, it is more difficult to extract genetic map positions. Furthermore, some of the genetic map tools require that one input not only the marker ID, but also the marker's physical position in a specified older build of the genome. The Genetic Map Interpolator (GMI) package is designed to create interpolated genetic maps of single nucleotide polymorphism (SNP) markers. Starting from a list of SNP names, GMI uses the R packages biomaRt and RMySQL to fetch the most up-to-date SNP and microsatellite physical positions from Ensembl, and then combines these with the Rutgers combined genetic and physical map to estimate the corresponding Kosambi genetic positions by linear interpolation for these SNPs. The resulting information is then output in map files formatted to be read in by our data-reformatting program, Mega2. GMI has a number of useful features: (1) It automatically looks up and uses the physical positions for each marker from the most recent Ensembl build. (2) For each SNP that is not initially found in Ensembl, GMI automatically checks to see if that SNP has been assigned a different rs number. (3) GMI automatically figures out which chromosome each marker is on, so knowledge of a marker's chromosome is not required to run GMI. (4) For each of these database queries, the list of SNPs being queried is broken up into smaller chunks so that each individual query can be completed within a few seconds. This has been done to prevent premature timing out of web connections, and in order to obey the limit guidelines required for Entrez queries. GMI is a Unix-based program written in Perl and R, and is portable over most Unix platforms. We have used and tested it extensively on both Intel and PPC-based Macs. Both GMI and Mega2 are available for free from (http://watson.hgen.pitt.edu/register/). This reasearch is supported under NIH grant R01GM076667 (Weeks, Daniel E).

A statistical approach for the identification of inter-population variation in recombination rates. *Q. Fan[1], SM. Saw[1,2], YY. Teo[1,3].* 1) Department of Epidemiology and Public Health, National University of Singapore, Singapore; 2) Singapore Eye Research Institute, Singapore; 3) Department of Statistics and Applied Probability, National University of Singapore, Singapore.

Context: Recombination is a driving force for linkage disequilibrium (LD) decay and it tends to cluster in highly localized regions named 'hotspots'. Using population-based recombination rate estimation method, several studies suggested that the recombination hotspots were evolutionarily conserved over broad scales among human populations, but not at the local level. However, the pattern of the fine-scale recombination rate variation due to hotspots across human populations is not well characterized partially because of the hotspot detection method is complicated and not generally consistent. Objective: The goal of the current study is to quantify the fine-scale variation in recombination rates from different well-defined human populations, especially in the locations and intensities of recombination hotspots. We further explore the association of those top-ranked regions with variation between population-specific patterns of LD, local positive selection and potential gene inversion, which has implication on the identification of genetic variants across populations. Methods: We propose a statistical method for the assessment of recombination rate variations between two populations, identifying the top regions in the human genome that exhibit these inter-population differences. Simulations were performed in various scenarios in terms of the hotspot peak strength and locations to test the sensitivity and specificity of this method. We apply this method to analyze the recombination rate data of 1.6 million SNPs from Chinese, Asian Indian and Malays in Singapore, and from Phase 2 of the HapMap. Results: Simulation indicates this method has high power (> 80%) to detect the existence of strong or moderate recombination rate peaks in one population but no hotspot peak or non-overlapping peak in another population; and it is not influenced by SNP density.The false discovery rate is generally below 20%. We observe this approach can be used to identify fine-scale variation in recombination rates between populations, and correlates with genomic regions exhibiting evidence of LD variations. The success of this approach also suggests the potential for prioritizing regions undergoing positive natural selection and gene inversion. Conclusion: The results demonstrate that our proposed method could lead to the location of the extent of the inter-population recombination rates variation.

Synthesis-View: visualization and interpretation of SNP association results for multi-cohort, multi-phenotype data and meta-analysis. *S.M. Dudek, S.A. Pendergrass, D.C. Crawford, M.D. Ritchie.* Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN.

Significant GWAS findings are being further investigated for replication and characterization, both in the populations in which the initial GWAS findings were discovered (such as European-Americans) as well as in new cohorts and populations. To increase sample size, meta-analysis is often used to combine results from multiple research sites. In addition, multiple independent and correlated phenotypic measurements may be included in the analyses, such as cardiovascular disease and related biomarkers (lipids, inflammation, etc). Visualization of these data, including p-values or other metrics of significance, allele frequencies, sample sizes, effect size, and direction of effect is integral to being able to interpret as well as share the complex and multi-layered results of these follow-up studies. The software "Synthesis View" has been developed to visually synthesize multiple pieces of information of interest from these studies with the flexibility to perform multiple types of data comparisons. Synthesis View was extended from the previous software "LD-Plus" which also uses a flexible data display format of multiple data "tracks" that can be viewed (Bush, et al., 2010). Through the use of stacked data-tracks information on SNP genomic locations, presence of the SNP in a specific study or analysis, as well as related information such as genetic effect size and summary phenotype information, is plotted according to user preference. With Synthesis view, trends from many different kinds of information can be visualized in a more integrated way than by using tabular data alone. This is important to understanding in greater depth the relationships between SNPs, strata, sample size, and phenotype differences, with the increasing complexity of emerging datasets. Synthesis-View is freely available for non-commercial research institutions, for full details see https://chgr.mc.vanderbilt.edu/synthesisview.

Imputation of Untyped Markers for HyperGEN African American Population. *Y.J. Sung[1], C.C. Gu[1], H. Tiwari[2], D.K. Arnett[2], U. Broeckel[3], D.C. Rao[1].* 1) Div Biostatistics, Washington Univ, St Louis, St Louis, MO; 2) School of Public Health, University of Alabama at Birmingham; 3) Department of Medicine, Medical College of Wisconsin, Milwaukee.

Genetic imputation methods impute SNPs that are not genotyped in a study but are present on a reference panel such as the HapMap. They are popular for increasing statistical power and also for comparisons across studies using different platforms. However, the choice of reference panels for an admixed study sample is less straightforward. For African Americans (AA), the commonly used approach is "cosmopolitan" approach that combines HapMap Phase II CEU and YRI haplotypes into a single reference panel. We evaluated 3 strategies (http://www.sph.umich.edu/csg/abecasis) using MACH for imputing in 1,258 HyperGEN AAs who were genotyped with Affymetrix 6.0. The first strategy used the common "cosmopolitan" approach that consists of SNPs polymorphic in both CEU and YRI data. The second strategy used also "cosmopolitan" approach, but consists of SNPs polymorphic in either CEU or YRI data. The third strategy involved imputing twice with CEU and YRI separately and then merging the imputed data sets. These three strategies imputed 2.20 million, 3.01million, and 3.19 million SNPs, respectively. Based on results for chromosme 22 alone, the third strategy, imputation with CEU and YRI separately yielded discrepancy of 19.6%. For these discrepant calls, imputation with YRI was chosen for the merged data set based on HyperGEN AA' higher admixture proportion with YRI. The first and second strategy yielded concordance of 97.8%, whereas the first and third strategy yielded concordance of 94.9%. The accuracy rate was 99.4% for the first and second and 98.8% for the third strategy. Results from genome-wide imputations will be presented. We advocate using the second strategy because it is as accurate as the commonly-used (first) strategy and able to impute an additional 0.8 million SNPs that are ancestry-informative.

3022/F

KSNaP: A New Tool for Integrating SNP, Gene and Biomolecular Pathway Information. *N. Nock[1], R. Shields[2], C. Gray-McGuire[1,3].* 1) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, Ohio, 44106, USA; 2) Department of Computer Science, Case Western Reserve University, Cleveland, Ohio, 44106, USA; 3) Department of Arthritis and Immunology, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma, 73104, USA.

The widespread use of high-throughput single nucleotide polymorphism (SNP) chip arrays has created an imminent need to efficiently identify common biological pathways from genomewide and large-scale custom SNP data sets. We have developed a software program called "KSNaP", which interfaces with widely utilized pathway (e.g., Kyoto Encyclopedia of Genes and Genomes, KEGG) and SNP (e.g., The Single Nucleotide Polymorphism National Center for Biotechnology Information (NCBI) database, dbSNP) databases to: 1) identify common biological pathways from user-provided SNP (and/or gene) data sets; and, 2) facilitate the integration of publicly available annotation information for SNPs (e.g., type, quality, allele frequency) in a given biological pathway. We will describe the features of KSNaP and illustrate its utility in analyzing SNP data from a systemic lupus erythematous study of 20,000 candidate genes and, in performing a pathway-level analysis of SNPs in the adipocytokine signaling pathway.

3023/F

Visualizing multidimensional support intervals for genetic models. *B. Nouanesengsy[1,2], S. Seok[1], V. Vieland[1].* 1) Nationwide Children's Hosp, Columbus, OH; 2) The Ohio State University, Columbus, OH.

Many genetic analyses involve log likelihoods (LogLs) written as functions of underlying genetic parameters such as gene frequencies, penetrances, etc. While maximum likelihood (ML) can be used to obtain the vector of parameter values "best" supported by the data, it is also frequently of interest to explore the multidimensional support interval (MDSI) itself. For instance, the ML model might support dominant inheritance with a specific penetrance, but dominant models with penetrances across a broad range, or even some recessive models, might also fall within an n-unit support interval of the maximum, particular as functions of variable disease allele frequencies or other parameters. Visualization offers an intuitive approach to exploring such multidimensional features of likelihood surfaces, which are otherwise difficult to capture. We have developed a visualization software program which creates groups of 2D plots (one for each genetic parameter) giving an overview of how each parameter affects the LogL. Each of these 2D plots displays the projection of the LogL space onto a two dimensional subspace, formed by the LogL and one parameter. An additional "overview" 2D plot is created by using the distance of each sampled point to a point of interest. This overview plot provides a high-level visual summary of the multidimensional space. The user can then define a support threshold, which defines the rectangular space MDSI, containing all portions of the parameter space for which the LogL exceeds the threshold. Multiple tools for exploration of the MDSI are provided. Regions of interest can be highlighted in one 2D plot, resulting in automatic highlighting of the corresponding regions in the other 2D plots. Additional 2D plots displaying pair-wise correlations among parameters are also available. 3D distance and correlation plots are currently under development to facilitate simultaneous viewing of 3 parameters at a time (say, three penetrances). Together, these visualization tools can provide information about the shape and size of LogL peaks and the correlations among parameters within regions of maximum support.

Many Genome Wide Association Studies (GWAS) into psychiatric disorders use alternative phenotypes to the clinical manifestation of the disorder. For example, reaction time (RT) variability, has been strongly associated with attention deficit hyperactivity disorder behaviors (ADHD) at the phenotypic and genetic levels. It is hoped that this is more proximal to the biological etiology of ADHD than the diagnosis and so a truer representation of the underlying genetic liability for ADHD. Despite potential advantages, intermediate phenotypes can be more expensive and time consuming to collect than questionnaire data, and so prohibitive to large sample sizes, highlighting a need for collaborative research strategies. However, genetic heterogeneity across samples may decrease power in GWAS. We aimed to use full information maximum likelihood estimation to examine if there is justification for combining data across two different measures, where no participants had data across both task measures. Data were collected from ADHD probands, their siblings and control sibling pairs on IQ and measures of mean RT, RT variability, and omission and commission errors. RT and error data were collected across three tasks: 'fast task' 'go/no-go task' and 'stop task'. All participants had IQ data; 685 families only had error and RT data from the 'fast task' and 'go/no-go task'. A further 385 families only had error and RT data from the 'stop task'. Prior theory suggested that only the RT variables may be similar across tasks. Multivariate structural equation modeling (SEM) was employed, using all variables, in a familial model using the known correlations of latent familial and individual-specific etiological factors between members of a sibling pair. Mean RT across the two different tasks showed a familial correlation (rF) =.70 (95% confidence interval (CI): -.06 -1.00). The estimates for RT variability were rF= .81 (.81-.100). This indicated, for the first time, that RT variability data could be combined across different tasks and different samples for future GWAS studies. Additionally, bootstrapping methods were calculated in R and used with the SEM for a simulated sample size of 5,000. This gave similar point estimates, but much tighter CIs, with both forms of RT data showing significant rF across samples. This confirms the suitability of aggregating RT variability data and highlights the need to investigate methods for examining the genetic heterogeneity across samples.

3025/F

A small number of candidate gene SNPs reveal geographical ancestry. *N. KODAMAN[1], J.R. SMITH[2], L.B. SIGNORELLO[2,3], K. BRADLEY[2], J. BREYER[2], S. COHEN[2], J. LONG[2], Q. CAI[2], W.J. BLOT[2,3], C. MATTHEWS[2], S.M. WILLIAMS[1].* 1) CENTER FOR HUMAN GENETICS RESEARCH, VANDERBILT UNIVERSITY, NASHVILLE, TN; 2) DEPARTMENT OF MEDICINE, VANDERBILT UNIVERSITY, NASHVILLE TN; 3) INTERNATIONAL EPIDEMIOLOGY INSTITUTE, ROCKVILLE, MD.

Ancestry Informative Markers (AIMs) are genetic variants that differ substantially in frequency among geographical populations. They are frequently used in conjunction with PCA or STRUCTURE to infer ancestry and subsequently to control for stratification in genetic epidemiological studies. The number of AIMs necessary to infer ancestry and provide adequate information to control for stratification is not clear. Original estimates suggested as many as 300 AIMs were necessary, but more recently, Allocco et al. (2007) found that as few as 50 SNPs chosen randomly from the HapMap database predicted ancestral continent of origin with an average accuracy of 95%. This observation raises the question of whether AIMs are necessary to estimate ancestry in candidate gene studies if the study has a sufficient number of markers. Here, using genomic data from an obesity-related candidate gene study on 2547 African-American and Caucasian participants, we assessed the proportion of African/European ancestry in individuals by running STRUCTURE (k=2) with 276 AIMs, and then compared the results to analyses using randomly chosen subsets of 100, 50, and 25 AIMS, as well as 100, 50, and 25 SNPs chosen randomly from 1144 SNPs in 44 obesity candidate genes. Each subset of AIMs and SNPs was chosen randomly 100 times, and each randomized sample was analyzed with STRUCTURE 25 times. We found that all of the subsets of AIMs and SNPs generated reliable estimates of ancestry. For example, the correlation between quantitative ancestry estimates using 276 AIMs and only 50 random SNPs chosen from among the candidate genes was approximately 0.95. Our results confirm Allocco et al's conclusion on the informativeness of random SNPs, while further showing that even SNPs randomly chosen from a small number of hand-picked genes can accurately place individuals to their continent of origin and be used to estimate the degree of admixture in mixed-race individuals. Our findings suggest that future candidate gene studies on African-American and Caucasian populations could be conducted more cost-effectively by forgoing the use of AIMs to control for population stratification and just using SNPs from the candidate genes.

3026/F

More efficient experimental designs for copy number variation (CNV) studies utilizing aCGH technology. *S.K. McDonnell[1], S.M. Riska[1], E.C. Thorland[2], E.W. Klee[1], N.E. Kay[3], S.N. Thibodeau[2], J.E. Eckel-Passow[1].* 1) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Department of Laboratory Medicine and Pathology, Mayo Clinic College of Medicine, Rochester, MN; 3) Division of Hematology, Mayo Clinic, Rochester, MN.

Introduction: Most CNV detection methods use microarray based technologies that output relative intensity values rather than absolute copy number (CN), necessitating the use of a baseline sample to estimate relative CN. In most studies utilizing aCGH technology, a common reference sample is co-hybridized to every array using the same dye to provide the baseline for CN estimation (reference design). Copy number is then calculated as the ratio of the intensity of the experimental sample relative to the same-array reference sample at each probe. Because the reference sample is often not of biological interest and is only used to estimate CN, we hypothesized that more cost-efficient designs exist that do not require a reference sample be co-hybridized on every array. These cost-efficient designs construct and utilize an average baseline for estimating CN. Here, we evaluate the effectiveness of an average baseline and how many reference samples are necessary to construct the average. Methods: We constructed multiple average baseline samples by averaging 2,...,n reference samples and used the average intensity at each probe as the baseline for estimating CN (average baseline design). We evaluated both the variability and sensitivity of the estimated CN associated with each average baseline sample and compared it with the reference design using empirical data. The median absolute deviation (MAD) of the CN estimates across all probes for a given subject was used as a robust measure of variability. Sensitivity was defined as the probability that the average baseline design detected a segment that was identified using the reference design. Data from a chronic lymphocytic leukemia (CLL) cohort study (n=50) run on the Agilent aCGH 1M array and data from a prostate cancer (PC) case-control study (40 cases, 20 controls) run on a custom Agilent aCGH array targeting chromosome 22 (105k probes) were used to test our hypotheses. Results: The distribution of MAD values stabilizes when the average baseline sample consisted of ≥10 (~ 25% of total study subjects) reference samples and is close to (PC data) or better than (CLL data) than the MAD values obtained from a reference design. With respect to sensitivity, most segments identified for a patient sample using the reference design were also identified for an average baseline consisting of 10 reference samples. Future work will evaluate the effect of competitive binding when co-hybridizing two experimental samples.

3027/F

A statistical approach to the adaptive design of optimal replication studies. *G. Rudolf, E. van den Oord, J. Bukszar.* Center for Biomarker Research and Personalized Medicine, School of Pharmacy, Virginia Commonwealth University, Richmond, VA.

Although replication studies are generally assumed to be critical for following up results from large scale genetic studies, they are often designed intuitively and in an ad hoc fashion. We developed a general statistical approach to design optimal replication studies. Our framework can be used to 1) minimize the costs of replication studies, 2) provide statistically motivated decision rules for declaring significance in replication studies (e.g. as opposed to arbitrary rules such as p-values smaller than 0.05 suggest replication), and 3) design replication studies "adaptively" by using the initial findings. This latter property avoids that replication studies are entirely based on assumptions that may be incorrect potentially leading to goals not being achieved or goals which could have been achieved at much lower costs. Our methods are developed in the context of two-stage GWAS studies, but can be readily adapted to different scenarios. Study design is a multi-objective problem, where we aim to simultaneously achieve a low false discovery rate (FDR), high average power (APW), and low cost. Design decisions include marker selection, sample selection, and critical value selection. We concentrate on the problem of minimizing the cost of the study while maintaining prescribed levels of FDR and APW. However, our optimization framework is sufficiently flexible to allow handling different requirements, such as maximizing the APW of a study with a fixed budget while controlling the FDR. An important additional concern is that in order to obtain estimates for FDR and APW we need information about the fraction of markers with no real effect (p0), and the distribution of the test statistic under both the null and the alternative hypothesis. This leads to the use of parameter estimation methods for p0 and the (average) effect size. A benefit of adaptively designing the followup stage of the study after the first stage results are observed is the opportunity to replace initial assumptions on parameter values with estimators before the follow-up stage is performed. Another advantage is that first-stage test statistics can be used to estimate the fraction of markers with effect in the second stage. We present simulation-based computational results comparing our methods with existing non-adaptive two-stage designs, demonstrating significant advantages including lower costs as well as avoiding underpowered study designs.

3028/F

A Method to Prioritize Quantitative Traits for Sequencing in Family-Based Studies. *K.P. Shah, J.A. Douglas.* Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Genome-wide association studies have been used to examine the role of common variants in complex quantitative traits, however, the impact of rare variants on these traits has been largely unexplored. One strategy to identify rare variants associated with quantitative traits is to sequence unrelated individuals in the tails of the trait distribution using high-throughput sequencing technologies. We present a new method that leverages the relatedness of individuals in the context of family-based studies to prioritize quantitative traits that are most likely to be influenced by rare variation and therefore are good candidates for such sequencing studies. The hypothesis underlying our method is that phenotypically extreme individuals will be more closely related if the trait is influenced by a rare variant of strong effect as opposed to being purely polygenic (null hypothesis). To test this hypothesis, we condition on the observed pedigrees and derive the distribution of mean pairwise kinship coefficients through repeated simulation of a purely polygenic quantitative trait with heritability equal to that of the trait of interest. If the observed mean pair-wise kinship coefficient of individuals in the tails of the quantitative trait distribution is significantly larger than that under our simulated polygenic model, then there is evidence for a rare variant carried by phenotypically extreme individuals. Through simulation, we evaluated the power to detect the presence of an associated rare variant in a sample of 1,481 women from 178 extended Amish families from our genetic study of breast density. Conditional on our observed pedigrees, we have ≥50% power for quantitative traits ranging in heritability from 20-80% when the underlying variant explains ≥10% of the phenotypic variance and has a minor allele frequency (MAF) <5%. In general, the most powerful tail size corresponds to the expected number of carriers of the rare variant given the sample size and MAF. As proof of principle, we apply this test to a quantitative trait for which a previous sequencing study has identified a rare variant of strong effect. Using SNP data, we are also evaluating the strategy of estimating regions of the genome shared identical by descent by phenotypically extreme individuals to localize the associated variant. Application of these methods may be useful in prioritizing and mapping quantitative traits in family-based sequencing studies.

A comparison of multiple testing correction methods using 2.5M imputed SNPs. *X. Gao.* Div Statistical Genomics, Washington Univ, St Louis, MO.

Multiple testing corrections are an active research topic in genetic association studies, especially for genome-wide association (GWA) studies, where tests of association with traits are conducted at hundreds of thousands single nucleotide polymorphisms (SNPs). Failure to address multiple comparisons appropriately can introduce excess false positive results and make subsequent studies following up those results inefficient. Permutation tests are considered the gold standard in multiple testing adjustment; however, this procedure is computationally demanding, especially for GWA studies where imputation has been conducted. Notably, the permutation thresholds for this huge amount of SNPs in real data sets have not been reported. Many researchers have recently developed algorithms to rapidly approximate the permutation thresholds with similar accuracy to the permutation test. In this study, we compare recently published multiple testing correction methods and measure their performance using 2.5M SNPs. We also derived permutation thresholds based on 10,000 permutations of GWA studies using 2.5M imputed SNPs and simulated phenotypes. Our results show that simpleM gives the closest approximation to the permutation threshold while requiring the least computation time. The thresholds derived in this study can provide multiple testing guidelines to current GWA studies using imputed SNPs.

Effects of ignoring relatedness among study subjects in genotype imputation analyses. *S. Nelson[1], C.C. Laurie[1], D. Crosslin[1], B.L. Browning[2], M.L. Marazita[3].* 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Department of Statistics, University of Auckland, Auckland, NZ; 3) Department of Human Genetics, University of Pittsburgh, Pittsburg, PA.

Genotype imputation is the process of inferring unobserved genotypes in a study sample based on the haplotypes observed in a more densely genotyped reference sample, allowing for both improved power in individual genome-wide association studies (GWAS) and for meta-analysis of studies assayed on different platforms. We used BEAGLE software (Browning and Browning 2009) and a HapMap3 reference to perform genotype imputation in a dataset of 3,520 individuals of genetically-defined European ancestry, containing an assortment of duos, trios, and other nuclear and extended families. We ignored these family relationships in this imputation analysis, despite the violation of assumptions in the BEAGLE imputation method. To assess the impact of ignoring relatedness, we generated two additional sets of chromosome 1 imputation results in: (1) a maximal subset of 1,960 unrelated subjects run with a default seed and (2) the same subset of unrelated subjects run with a non-default seed. We then compared the estimated allele dosages among the three sets of results at 77,104 imputed SNPs across all 1,960 subjects from the unrelated subset. The mean correlation between allelic dosages from the primary approach and comparison set (1) was 0.998. The mean correlation between comparisons set (1) and (2) was also 0.998, indicating that ignoring relatedness in our primary analysis had minimal impact on imputation results. Furthermore, the distribution of dosage correlations across all imputed SNPs in the comparison of the primary approach and set (1) was very similar to the distribution when comparing sets (1) and (2). We also found high concordance rates in the maximal set of unrelated samples when comparing most likely imputed genotypes from the primary approach and set (1). When imputed SNPs were binned by minor allele frequency (MAF), the mean concordance ranged from 99.93% (MAF<2%) to 97.95% (MAF>20%). These findings indicate that the differences between imputation into the entire sample of related individuals and imputation into the maximal subsample of unrelated individuals are mostly attributable to the sequence of pseudorandom numbers generated during the imputation process. Our results suggest that, for large data sets, ignoring relatedness during imputation yields imputed genotype probabilities that are similar in quality to those obtained from imputation into unrelated individuals. NIH grant DE-018903, DE-014899, NIH contract HHSN268200782096C.

A test for cryptic relatedness to map disease genes in as few as two affected individuals. *W. Wu[1], C. Huff[1], J. Xing[1], D. Witherspoon[1], T. Tuohy[3], D. Neklason[3], R. Burt[3], S. Guthery[2], L. Jorde[1].* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Department of Pediatrics, University of Utah, Salt Lake City, UT; 3) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT.

Traditional gene-mapping approaches usually require either extended families or large sample sizes. New methods have been recently introduced to identify disease genes with much smaller sample sizes using exome or whole-genome data, although these data are still expensive to obtain and computationally challenging to analyze. Here, we present an inexpensive alternative that relies solely on high-density SNP microarray data and is appropriate for sample sizes as small as two affected individuals. From microarray data, we first use GERMLINE 1.4 to identify chromosomal segments that are identical-by-descent (IBD) between pairs of affected individuals who are not known to be related. The expected length of an IBD segment depends primarily on the number of generations since the common ancestor. When a rare disease-causing mutation is present on the segment, the expected length of the segment is increased due to ascertainment on disease status. Therefore, the size of an IBD segment is a powerful statistic for detecting a disease-causing mutation inherited from a relatively recent common ancestor. Using the empirical distribution of IBD segments from a population with matching genetic background, we can assess the statistical significance of the length of the largest IBD segment shared among cases. For two individuals with European ancestry, when a dominant disease-causing allele was inherited from a common ancestor five generations ago, the power to identify the disease-causing locus is approximately 0.88 at the 0.05 level; at 10 generations ago the power is about 0.66. The power improves substantially with either an increase in sample size or with a recessive mode of inheritance. We tested this method with 13 individuals with attenuated familial adenomatous polyposis resulting from an identical disease-causing mutation. This sample allows us to evaluate our method with pairs of individuals in a real world example where the number of generations to the common ancestor is unknown. Among the 62 pairs of individuals that were not known to be related, the test for cryptic relatedness was significant at the known disease-causing locus (APC gene) in 27 pairs. Therefore, the disease region could have been successfully mapped 44% of the time with just two individuals from this sample. In summary, this approach provides a powerful, inexpensive alternative for mapping rare genetic diseases without any family information, and with as few as two affected individuals.

Comparison of affection status classification using less affected eye versus severe affected eye in Age Related Macular Degeneration. *L.M. Olson[1], K.L. Spencer[1], J.D. Hoffman[1], N.C. Schnetz-Boutaud[1], A. Agarwal[2], J.L. Kovach[4], S.G. Schwartz[4], P. Gallins[3], G. Wang[3], W.K. Scott[3], M.A. Pericak-Vance[3], J.L. Haines[1].* 1) Ctr of Human Genetics Research, Vanderbilt Univ Med Ctr, Nashville, TN; 2) Department of Ophthalmolgy, Vanderbilt Univ Med Ctr, Nashville, TN; 3) Hussman Insitute of Human Genetics, University of Miami - Miller School of Medicine, Miami, FL; 4) Bascom Palmer Eye Institute, University of Miami - Miller School of Medicine, Miami, FL.

Age-Related Macular Degeneration (AMD) is one of the leading causes of central vision loss among the aging Caucasian population in the United States. Previously published work has shown that genetics play a significant role in risk of AMD disease development. In these studies affection status classification is often reported based on the more severely affected eye. We propose that looking at the less severely affected eye does not change the risk for developing AMD. We created a case/control population with the following characteristics: Age of Exam (AOE) reported, genotyping for known risk factors: rs1061170 (CFH Y402H), rs10490924 (ARMS2 A69S), rs2230199 (C3 R102G) and mtDNA 4917 as well as protective factor rs641153 (CFB R32Q), smoking status (ever/never smoked/unknown) and OD (right eye) & OS (left eye) grades for both eyes. Our final dataset had a total of 988 individuals. First, affection status classification was determined based on the more severely affected eye (Affected=676, Unaffected=312), then univariate and multivariate analysis was completed to give us a baseline for comparisons as this method of affection status classifications is the current standard operating procedure. After reclassifying individuals based on their less affected eye (Affected=590, Unaffected=398), we ran univariate and multivariate analysis and compared the results. No significant deviations were found between the two classification with respect to the risk and protective factors when comparing both the univariate and multivariate odds-ratios.

Selective sequencing for efficient fine-mapping of disease loci. *E. Marchani[1], E. Wijsman[1,2,3].* 1) Div Med Gen, University of Washington, Seattle, WA; 2) Dept Biostat, University of Washington, Seattle, WA; 3) Dept Genome Sci, University of Washington, Seattle, WA.

Sequence data is a vital, but expensive, tool for identifying the genetic causes of disease segregating within families. Linkage signals and genome-scan data in families can be used to target the most informative individuals and genomic regions for sequence data collection. These sequences are then used to identify candidate variants to be genotyped in the rest of the family with a less expensive protocol, or a subset of candidate genes for follow-up functional analyses.

We assume genome-scan marker data within a family and a region of interest, defined by candidate genes, associated alleles, or linkage signals. Under the hypothesis that a disease-risk allele is segregating within the family, affected individuals are expected to have inherited the genetic region surrounding that allele from the same ancestor (IBD) with high probability. The exact value of that probability depends on the number and penetrance of segregating risk alleles.

We estimate expected and observed kinship coefficients between pairs of affected relatives, excluding subjects unavailable for sequencing. Expected kinship may be estimated using pedigree structure without marker data or using the complete set of genome-scan markers, while observed kinship is estimated using pedigree data and multipoint marker information within the region of interest (*e.g.*, using MCMC methods). The ratio of observed-to-expected kinship is then used to rank pairs of affected individuals for sequencing, prioritizing pairs of distant relatives who have high IBD probability within the region of interest. This prioritization shortens the chromosomal segments shared IBD, reducing the number of shared variants and the amount time and money investigating these candidates.

Our approach excels when applied to extended pedigrees or genetically heterogeneous traits. Extended pedigrees offer more distant relationships, and therefore the greatest narrowing of IBD regions between prioritized subjects. In the case of genetic heterogeneity within a family, our approach allows investigators to target only pairs of affected relatives who share IBD in the region of interest and to avoid pairs that do not.

Selection of rare variants by enrichment in familial samples and functional annotation: a data-oriented approach. *W. Yang[1], S. Wang[1], S. Hunt[3], A. Chakravarti[4], D.C. Rao[1,2], E. Boerwinkle[5], D. Arnett[6], U. Broeckel[7], C. Jaquish C[8], H. Tiwari[9], G. Stormo[2], C.C. Gu[1,2].* 1) Division of Biostatistics, Washington Univ in St Louis, St Louis, MO; 2) Department of Genetics, Washington Univ in St Louis, St Louis, MO; 3) Department of Internal Medicine, University of Utah, Salk Lake City, UT; 4) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 5) Human Genetics Center, University of Texas School of Public Health, Houston, TX; 6) Department of Epidemiology, University of Alabama at Birmingham, Birmingham, AL; 7) Department of Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 8) Division of Cardiovascular Sciences, NHLBI, Bethesda, MD; 9) Department of Biostatistics, University of Alabama at Birmingham, Birmingham, AL.

Backgrounds: Genome-wide studies of rare variants have revealed that “small effect” variants can strongly affect those few who possess them. Methods were developed to “collapse” clusters of rare variants to produce detectable aggregate effects. A key to success is to include only “relevant” mutations in the clusters. We hypothesize that disease-associated variants are enriched in ascertained familial samples particularly for rare variants, and this information can be used to select promising rare SNPs for downstream analysis. Methods: Allele frequencies of 369,623 autosomal SNPs (shared on 2 platforms) in 1270 Caucasians from the family-based HyperGEN (Hypertension Genetic Epidemiology Network) study are compared to those in 9345 Caucasians from the population-based ARIC (Atherosclerosis Risk in Communities) Study. Enrichment of a SNP is measured by significantly elevated minor allele frequency (MAF). These are divided into 4 groups according to MAF: 0.001~0.01 (SNP Set 1), 0.01~0.05 (Set 2), 0.05~0.1 (Set 3), and ≥0.1 (Set 4). In each group, we calculated proportions of SNPs with functional annotation in public databases and the mean imputed functional score (IFS, estimated from cross-species conservation and transcription factor binding capacity of flanking sequences) using an in-house database; and compared the results with those derived from randomly selected SNP sets of equal sizes. Results: A total of 40,329 SNPs had significantly elevated MAF in HyperGEN: (1) SNPs in Sets 1-3 were slightly more likely to be proximal to a known gene, but not for those in Set4. (2) Compared with random SNP sets, SNPs in Set 1 (MAF<0.01) are more likely to contain exonic splicing enhancers (ESE, 0.90% vs 0), exonic splicing silencers (ESS, 0.01% vs 0), and non-synonymous mutations (NS, 0.42% vs 0). The trend holds true for Sets 2&3, but not for the more common SNPs in Set 4. (3) SNPs in Sets 2&3 have the highest probability to be ESE (0.13, 0.12, respectively), ESS (0.009, 0.018) and NS (0.043, 0.04). (4) The mean IFS scores in all 4 sets are substantially higher than those in the random SNP sets (0.39-0.44 vs 0.33-0.34). Moreover, the mean IFS values decrease as SNP MAF increases (0.44, 0.43, 0.42, 0.39 for Sets 1-4, respectively). Conclusion: The analyses provide strong empirical evidence for enrichment of rare variants in ascertained familial samples. It is a simple but potentially very useful way to enhance power of aggregate effects of rare variants.

Improving genotype imputation in African populations. *L. Huang[1], M. Jakobsson[2], T.J. Pemberton[3], J.K. Pritchard[4,5], S.A. Tishkoff[6], N.A. Rosenberg[1,3].* 1) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 4) Department of Human Genetics, University of Chicago, Chicago, IL; 5) Howard Hughes Medical Institute; 6) Departments of Biology and Genetics, University of Pennsylvania, Philadelphia, PA.

In human populations, Sub-Saharan Africa has consistently been identified as the part of the world with the greatest genetic diversity. This high level of diversity causes difficulties for genome-wide association studies in African populations - for example, by substantially reducing the accuracy of genotype imputation in African populations compared to non-African populations. Here, we perform a detailed investigation of imputation in Africa, using genotypes at 1,272 SNPs in 253 unrelated individuals from 15 Sub-Saharan African populations. We identify the populations that provide the greatest potential for serving as reference panels for imputing genotypes in the remaining groups. Considering reference panels comprised of samples of recent African descent in Phase III of the HapMap Project, we identify mixtures of HapMap reference groups that produce the maximal imputation accuracy in each of the sampled populations. In many of the populations, the optimal mixture of reference groups for imputation can be predicted by using a simple model that relates imputation accuracy to the extent of haplotype sharing between study samples and potential reference samples. Our results suggest strategies that can be used to increase the accuracy of imputation in populations from Sub-Saharan Africa, thereby assisting in the extension of GWA techniques for use in these populations.

Non-replication of genome-wide association studies: Winner's Curse or Survival Bias? *L.B. Chibnik[1], P. Kraft[2].* 1) Program in Translational NeuroPsychiatric Genomics, Department of Neurology, Brigham & Women's Hospital, Boston, MA; 2) Department of Epidemiology, Harvard, School of Public Health.

Purpose. Some risk loci discovered using Genome Wide Association (GWA) studies have not been replicated in other studies. One potential reason for non-replication is differential survival bias. We quantify this bias and its effect on the power to replicate an association found in a prospective cohort study (which is not affected by survival bias) within a case-control study (which is). Methods. The odds ratio (OR) expected from a case-control study can be estimated from the OR from a cohort study multiplied by an inflation factor, ψ, where ψ is the relative probability of ascertainment into a case control study for those with the risk allele versus those without. This probability depends on the relative hazard of mortality for the risk allele (HRg), the genotypic frequency, and the time from disease diagnosis to case ascertainment. We calculate the power to replicate an association observed in a cohort study across a range of these parameters in two scenarios, motivated by pancreatic cancer (5-year survival rate of 5%) and ovarian cancer (5-year survival rate of 45%) Results. The inflation factor ψ depends on median survival for the population and time from diagnosis to ascertainment into a case control study. It is inversely related to HRg such that for large HRg the OR in a case control study will be inverted relative to the OR from the cohort study. Starting with a cohort OR of 1.3 and time to ascertainment of 1 year post-diagnosis, for pancreatic cancer we observe a U-shaped relationship between power and HRg. The power to replicate the association decreases before an HRg of 1.5 and increases with larger HRg, reflecting increased power to detect the inverted association. For ovarian cancer, with a higher 5-year survival rate, power slowly decreases as mortality hazard increases. Conclusion. Survival bias has the potential to affect the power to replicate significant findings from a cohort study in a case control study. However, only very specific values of average survival, the relative mortality hazard, time to enrollment, and the association in the cohort study may significantly bias results.

Exact Tests of Hardy-Weinberg Equilibrium - A Markov Base Approach. *M. Rao, S. Venkatesan.* Environmental Hlth, Univ Cincinnati, Cincinnati, OH.

The focus of the presentation is on exact tests of Hardy-Weinberg Equilibrium in multi-allelic problems. The exact test that is commonly used is the one developed by Guo and Thompson (1992). The key idea of the test is to fix the allele frequencies and enumerate all possible data sets with the same allele frequencies. Even for moderate number of alleles, the enumeration is a gargatuan task. Borrowing ideas from 'algebraic statistics,' we develop an exact test built upon Markov Bases and Metropolis-Hastings algorithm. This test is an alternative to Guo and Thompson's. A comparison of the proposed new test and Guo and Thompson's test is made.

Comparative analyses of different algorithms for copy number variation identified by Affymetrix SNP 6.0 chips. *H. Wang[1, 2], X. Zhang[1], X. Gong[1], S. Li[1,2], F. Zhang[1], Y. Sun[1], Y. Shen[4], S. Xu[3], B. Wu[2,4], L. Jin[1,2,3].* 1) School of Life Sciences, Fudan Univ, Shanghai, China; 2) Institute of Biomedical Research, Fudan U, Shanghai, China; 3) Inst of Computational Biology, Chinese Academy of Sciences, Shanghai, China; 4) Boston Children's Hospital, Harvard Medical School, Boston, USA.

Copy number variation (CNV) is a new logo of disease susceptibility polymorphism in genomic DNA. Although there are many mature and widely used softwares for CNV analysis based on raw data calling, a gold standard is still absent. In order to validate the effectiveness of various software for CNV calling and analysis, we did the following comparison. First, we collected the SNP6.0 chip data from the total 325 samples which contain three pairs of duplicate samples to test for the different software's reproducibility on data analysis. Then Penncnv, Cnag, Birdsuite and Dchip were run to analyze the sample sets and generate CNV data. In terms of the identified CNV number, Dchip generated the most (36568), while CNAG called the least (6481). Birdsuite's and Penncnv's call were close to 22494 and 17594 respectively. Penncnv's Gain-Loss ratios were always under the isoline; CNAG close to the isoline; Dchip and Birdsuite were above the isoline. Analysis of CNV lengths shows that Dchip's CNV call mainly were below 100K, CNAG above 100K, and Birdsuite's and Penncnv's distributions were similar and uniform. The verification of these four algorisms' consistency reveal that nearly 1/3 of the CNV call by Penncnv's and Birdsuite were similar to that called by the other software, while CNAG is about 2/5. Penncnv verified 87%, CNAG 74%, Dchip 49%, and Birdsuite 53% through the three pairs of duplicate samples reproducibility test. Finally, the CNVs with the Q-PCR verification results were also sent to a DGV-like self-developed database. By comparison analysis, Cnag is the most conservative in CNV calling with the lowest false positive rate and the highest false negative rate. Cnag was the most effective algorithm of CNV detection for the known loci. Dchip's algorithm is the least conservative, which generated the most results. Both Birdsuite and Penncnv have very low false positive and false negative rates. The overall performance of Penncnv is the best calling, but the software has no visual interface because of running under Dos. In summary, the most optimized method is to use Penncnv for Raw data analysis, Birdsuite for visualized analysis, CNAG for exporting SNP signal for the association analysis and then Dchip for LOH analysis. With this combination, we imported all reliable CNV and LOH call into the DGV and our own database for the subsequent data mining.

CNVineta: A data mining tool for large case-control copy number variation data sets. *M. Wittig[1], I. Helbig[2], S. Schreiber[1], A. Franke[1].* 1) Christian Albrechts University, Institute of Clinical Molecualr Biology, Kiel, Germany; 2) Department of Neuropediatrics, University Clinic Schleswig-Holstein, Campus Kiel, Arnold-Heller-Strasse 3, Building 9, 24105 Kiel, Germany.

Copy number variation (CNV), a major contributor to human genetic variation, comprises 1 kb or longer genomic deletions and insertions. Yet, the identification of CNVs from microarray data is still hampered by high false negative and positive prediction rates due to the noisy nature of the raw data. Here, we present CNVineta, an R package for rapid data mining and visualization of CNVs in large case-control data sets genotyped with single-nucleotide polymorphism oligonucleotide arrays. CNVineta is compatible with various established CNV prediction algorithms, can be used for genome-wide association analysis of rare and common CNVs and enables rapid and serial display of log2 of raw data ratios (LRR) as well as B-allele frequencies (BAF) for visual quality inspection. In summary, CNVineta aides in the interpretation of large-scale CNV data sets and prioritization of target regions for follow-up experiments. CNVineta is available as an R package and can be downloaded from http://www.ikmb.uni-kiel.de/CNVineta/; the package contains a tutorial outlining a typical workflow. The CNVineta compatible HapMap (International HapMap Consortium 2003) data set can also be downloaded from the link above.

Identification of Copy Number Variations associated with Hepatitis B Virus Infection in Hepatocellular Carcinoma Families and Chronic Liver Diseases. *K.Y. Chang[1], S.W. Chang[1], D.I. Tai[2], C.L. Hsu[1], C.S.J. Fann[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Liver Research Unit, Chang Gung Memorial Hospital, Chang Gung University College of Medicine, Taipei, Taiwan.

Hepatitis B is a major health problem worldwide and a potentially life-endangering liver infection. Previous studies have shown that male was a significant factor for hepatitis severity. In this study, we conducted a genome-wide survey of copy number variations (CNVs) with 625 male Taiwanese. To our knowledge, this is the first CNV study on HBV infection: 321 HBsAg positive cases and 304 HBsAg negative controls were included and genotyped by Illumina HumanHap beadchips. A total of 456,262 SNPs was used in the analysis after quality control filters with an average call rate of 99.95%. To detect CNVs with intensity data of 456,262 SNPs, PennCNV was applied. 52 CNV gains and 390 losses were identified that were different between the case and control groups (Fisher's exact test P < 10-6). The case and control groups showed significantly different patterns of CNV gains on chromosomes 6, 9, 11, 14, 15, 16, and 19 and different patterns of CNV losses on chromosomes 6, 8, 11, 14, 15, and 19. We found that one deleted region (P < 10-21) and one amplified region (P < 10-8) covered HLA-B locus on chromosome 6 that might be associated with persistent HBV infection.

3041/F

Relationship between obesity, diabetes and admixture in African American and Hispanic American Women. *R. Nassir[1], L. Qi[2], R. Kosoy[1], L. Garcia[2], J.A. Robbins[3], M.F. Seldin[1].* 1) Rowe Program Gen, Univ California, Davis, Davis, CA; 2) Public Health Sciences, Univ California, Davis, Davis, CA; 3) UCD Health System, General Medicine, UCDMC, Sacramento, CA.

Different ethnic groups have different propensities for obesity and type 2 diabetes. To further assess the relationship between ethnicity and these phenotypes we examined whether differences in continental admixture in a cross-sectional analysis of both African American and Hispanic American adult women in the Women's Health Initiative were associated with these traits. The proportion of European, sub-Saharan African and Amerindian admixture was estimated for each individual participant using a Bayesian clustering method (STRUCTURE) and 92 SNP ancestry informative markers (AIMs). In self-identified African American women (n= 11821) there was a significant positive association between BMI and African admixture (p < 10-4). This relationship had a substantial effect size (estimate = 0.42 +/- 0.08 expressed as a fraction of the trait standard deviation) when BMI was considered as a continuous variable, and age, education, exercise, parity, income and smoking were included as covariates. A dichotomous model (upper and lower BMI quartiles) showed that a unit increase in African admixture was associated with a high odds ratio [OR = 3.25, 2.07 - 5.12, 95% confidence interval (CI)]. In contrast, for the self-identified Hispanic group (n = 5133) there was no association between BMI and admixture. When waste to hip ratio (WHR) was used as an alternate measurement of obesity, very different results were obtained. There was no significant association in the self-identified African American group but there was a strong association in the Hispanic group (estimate = 0.65 +/- 0.08, p<10-4; dichotomous model OR Amerindian admixture = 5.81, CI = 3.60 - 9.37). Finally, diabetes prevalence showed a positive association with both African [Hazard Ratio (HR) = 1.98, p < 10-4] and Amerindian admixture (HR = 2.00, p <10-4) in African American and Hispanic American groups, respectively. In the African American group the HR decreased significantly when BMI was used as a covariate. For Hispanic Americans, WHR but not BMI significantly decreased the HR of the diabetes association with Amerindian admixture. These studies show that 1) African admixture is associated with both obesity (BMI) and diabetes in African American women; 2) Amerindian ancestry is associated with both obesity (WHR) and diabetes in Hispanic American women; and 3) it may be critically important to consider different indices of obesity in different ethnic population groups.

Gene mapping study of constitutive skin color in a genetically isolated population. *H-J. Kim[1,4], SH. Paik[2], H-Y. Son[3], SB. Lee[1,4], YS. Ju[3,4], JH. Yeon[2], SJ. Jo[2], J-S. Seo[1,3,4], OS. Kwon[2,6], J-I. Kim[3,4,5].* 1) Department of Biomedical Sciences, Seoul National University Graduate School; 2) Departments of Dermatology, Seoul National University College of Medicine; 3) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine; 4) Genomic Medicine Institute (GMI), Medical Research Center, Seoul National University; 5) Psoma Therapeutics, Inc., Seoul; 6) Laboratory of Cutaneous Aging and Hair Research, Institute of Dermatological Science, Seoul National University.

To elucidate the responsible genes governing constitutive skin color, we measured the extent of skin pigmentation in buttock, the sun-unexposed area for the life time, and conducted a gene mapping study on skin color in genetically isolated population composed of 344 individuals from 59 families who live in Dashbalbar, Dornod Province, Mongolia. Through the linkage analysis of 1039 short tandem repeat (STR) microsatellite markers, we found novel genomic region regulating constitutive skin color on 11q24.2 with an LOD score of 3.39. Moreover, we found other five candidate regions controlling intrinsic skin color. To test further association in regions of linkage, we selected chromosome 11, 17, and 6 (maximum LOD score > 2.5), and in each chromosome, high linkage peak regions (LOD score >1.5) were analyzed. On linkage region of chromosome 11, we identified 19 significant SNPs (p < 9.29 × 10-6). Further we found two (p =9.74 × 10-7) and one (p=2.00×10-6) significant SNPs on linkage regions of chromosome 17 and chromosome 6, respectively. In that the strongest locus of linkage on 11q24.2 harbors and significant SNP is located adjacent to ST3GAL4, we suggest ST3GAL4 as the novel candidate gene responsible for controlling constitutive skin color. Taken together with our linkage analysis and association study, other candidate genes are DRD2, MPZL3, BRIP1 and ZBTB17.

3043/F

Genome-wide detection and characterization of mating asymmetry in human populations. *M. Bourgey[1], J. Healy[1], P. Saint-Onge[1], H. Massé[1], D. Sinnett[1, 2], M-H. Roy-gagnon[1, 3].* 1) Hemotologie-Oncologie, CHU Sainte-Justine, Montreal, PQ, Canada1Sainte-Justine Hospital Research Center, University of Montreal, 3175 chemin de la Côte-Sainte-Catherine, Montreal, Quebec, H3T 1C5, Canada; 2) Department of Pediatrics, Faculty of Medicine, University of Montreal, 3175 chemin de la Côte-Sainte-Catherine, Room 7955, Montreal, Quebec, H3T 1C5, Canada; 3) Department of Social and Preventive Medicine, Faculty of Medicine, University of Montreal, PO Box 6128, Station Centre-Ville, Montreal, Quebec, H3C 3J7, Canada.

The mother can play an important role in shaping disease susceptibility in her offspring through the effects of her genes acting directly on the intrauterine milieu or indirectly through feto-maternal gene-gene interactions. An important source of bias in feto-maternal genetic association studies however is the possibility of confounding due to mating asymmetry (MA). Departures from mating symmetry between parental mating pairs can lead to distortions in the distribution of alleles among case-mothers and create spurious maternal associations. The evaluation of the effects of asymmetry on feto-maternal association testing has been limited by our meager understanding of the dynamics of MA in human populations. We propose a new quantification estimator for mating asymmetry (ChA) along with its related test to determine the significance of asymmetry at a given locus. To achieve a fuller understanding of the dynamics of mating asymmetry in human populations we carried out a genome-wide evaluation of MA using mate-pairs of European and African ancestry from the International HapMap Project. We measured MA for ~1.2 million SNPs from all autosomes of the CEU and YRI population samples and investigated MA variation both within and across populations. Our results show that specific genomic regions are subject to MA among human populations and we show how the levels of MA observed in human population can incur important bias in feto-maternal association testing and significantly inflate false-positive rates.

3044/F

Genome-Wide Association Scan of Osteoporotic Fracture Rate among African American Women in the Women's Health Initiative. *K. Taylor[1], K. North[1], N. Franceschini[1], R. Jackson[2], A. LaCroix[3], J. Robbins[4], B. Lewis[5], M. Stefanick[6], J. Cauley[7].* 1) Epidemiology Dept, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Ohio State University, Columbus, OH; 3) Fred Hutchinson Cancer Research Center, Seattle, WA; 4) University of California at Davis Medical Center, Sacramento, CA; 5) University of Alabama, Tuscaloosa, AL; 6) Stanford Prevention Research Center, Stanford University, Stanford, CA; 7) University of Pittsburgh, Pittsburgh, PA.

Background. Osteoporosis is a major public health problem that over a lifetime results in fractures in 40% of aging women, resulting in disability and death. Osteoporosis has a strong genetic component, with 25-85% of the variation in osteoporosis-related traits being attributable to genetic factors. However, most of these data are from Caucasian populations. We used GWAS data in the Women's Health Initiative (WHI) as part of the SNP Health Association Resource (SHARe) program to study genetic determinants of fracture among African American (AA) women. Methods. Data on incident fractures, except fingers, toes, face, skull or sternum, were analyzed for 8155 unrelated AA clinical trial (CT) and observational study (OS) participants in the WHI. Hip fractures were centrally adjudicated in all arms of the WHI. Other fractures were only adjudicated in the CTs, and in select OS centers. The Affymetrix 6.0 GWAS panel was used for genotyping, and YRI and CEU individuals from HapMap were pooled and used as the reference sample for imputation. Individual ancestry estimates, divided into Caucasian, East Asian, Native American, and African ancestry proportions, were calculated using FRAPPE and were used to adjust for population stratification. We used Cox proportional hazard models to evaluate the effect of ~2.5 million SNPs on incident fracture rate, adjusting for ancestry, age, and region (4 geographical regions in the U.S.). Results. No SNPs reached genome-wide significance (P £ 5.0 E-8). For self-reported fractures (874 events, 304 of which were adjudicated), one intronic SNP in MOGAT2, involved in dietary fat absorption, approached significance (rs12284314, P=7.9 E-8; minor allele frequency, 0.21) (hazard ratio: 1.37; 95% CI: 1.22, 1.53). The same SNP was the most significant locus when restricting the analysis to adjudicated fractures (P=2.4 E-7). This novel finding was not reported in any previous osteoporosis-related GWA studies. Given that dietary fat is important for bone health, replication of our findings in other African American populations is warranted.

Test of independence in contingency tables of large dimension with ordered categories and its application in population genetics. *J. Ge[1,2], R. Chakraborty[1,2], B. Budowle[1,2].* 1) Inst of Investigative Genetics, Univ North Texas, Health Science Center, Fort Worth, TX; 2) Department of Forensic and Investigative Genetics, University of North Texas Health Science Center, Fort Worth, Texas.

Classic tests of independence of two categorical variables generally use chi-square or likelihood ratio statistics by summarizing data in a two-way contingency table. However, at times the sample size is not large enough to populate the cells of the contingency table, such as when analyzing Y chromosome short tandem repeat (STR) haplotypes that often are observed only once in a sample population database. In this situation, the classic tests yield degenerate distributions (or nearly so). In this study, a new permutation test was developed based on the number and distribution of mismatches between profiles from unrelated individuals. This test is statistically powerful even when the sample size is smaller than the number of categories of either variable. Independence among autosomal STRs, Y chromosome STR and mitochondria DNA (mtDNA) were tested with empirical data, and independence among them was confirmed. The power of the mismatch-based test was calculated. The dependence between autosomal and Y chromosome markers due to population substructure can be detected with greater than 90% accuracy if the subpopulations have similar proportions and at least 800 samples are typed.

Reference samples in imputation and its implications in association analysis results. *M. de Andrade[1], M.E. Matsumoto[1], S. Maharjan[1], E.J. Atkinson[1], S.L.R. Kardia[2].* 1) Div Biomed Statistics Informat, Mayo Clinic, Rochester, MN; 2) Dep Epidemiology, Un Michigan, Ann Arbor, MI.

Imputation of untyped genetic markers has been shown to increase genome coverage in genome wide association studies with minimal added cost. However, there are still some questions about which reference samples to use when imputing and how much the reference influences association analysis results. Our evaluation is two-fold. First, we used four reference panels and evaluated the overall quality and accuracy of the imputed markers. Second, we compared association analysis results using known markers and imputed versions of the same markers. To compare the four reference panels, we used two populations from the GENOA cohort: 1385 European Ancestry (EA) sibships and 1535 African Ancestry (AA) sibships. We used MACH (version 1.0) software for the imputation and four reference panels all pulled from the HapMap Phase II data: 1) 60 CEU samples; 2) 60 YRI samples; 3) combination of the 1st and 2nd panels; 4) combination of panel 3 with 90 JPT/CHB samples. For each study population we applied a two-step procedure. Step 1 was run using a set of unrelated subjects (510 for AA and 379 for EA) and one of the 4 panels to infer haplotype phase and recombination rates. In step 2, 2.5 million markers were imputed for subjects using the first stage estimates. To evaluate imputation quality and accuracy we examined the minor allele frequency of the imputed dosage, the average recombination rates, the quality measures and the accuracy of masked genotypes. To compare the association analysis results, we first evaluated the familial relationship implied by the genotype data since our samples consist of related individuals and the imputation was performed assuming unrelated samples. This was done using identity-by-descent calculations based on the known genotypes and on the 4 versions of imputed genotypes. Next, we performed association analysis using the known genotypes and using the imputed genotypes of selected known markers. Our preliminary results show that panel 1 is a good reference for the GENOA EA sibships, panel 3 is a good reference for the GENOA AA sibships, and the association analysis results are not affected if a good reference panel was used.

Genome-wide association study of Ankylosing Spondylitis identifies four new loci, a tag SNP for HLA-B27, and an interaction between HLA-B27 and variants in ERAP1. *DM. Evans, WTCCC2 and TASC.* Social Medicine, Univeristy Bristol, Bristol, United Kingdom.

Ankylosing Spondylitis (AS) is a common inflammatory arthritis, which can lead to fusion of the spine and other affected joints. In order to identify genetic variants predisposing to risk of AS, we performed a genome-wide association study of 1782 British cases fulfilling modified New York Criteria and 5167 historical controls from the Wellcome Trust Case Control Consortium 2 (WTCCC2). After imputing to Hapmap, the study was combined with existing results from the TASC Consortium using inverse variance meta-analysis and subsequently replicated in 2109 cases and 4410 controls from the UK and Canada. As well as confirming known associations at HLA, IL23R, ERAP1, 2p15 and 21q22 we identified and subsequently replicated risk predisposing variants in RUNX3 (combined p = 3.3 x 10-12), KIF21B (p = 1.1 x 10-11), IL12B (p = 1.8 x 10-8), and LTBR (p = 4.5 x 10-10), and found suggestive association at ANTXR2 (p = 3.8 x 10-7), PTGER4 (p = 7.8 x 10-8), CARD9 (p = 1.2 x 10-6), TRADD (p = 4.1 x 10-6) and TBKBP1-TBX21 (p = 5.9 x 10-8). We identified a single SNP, rs4349859 near the gene MICA, which tagged HLA-B27 with near perfect sensitivity (98%) and specificity (99%) in 531 cases and 729 controls of UK origin. These findings were confirmed in an independent set of 251 Sardinians and also showed that whilst rs4349859 tagged the non-AS associated HLA-B2709 subtype, it did not tag the AS associated HLA-B2707 subtype, indicating that rs4349859 is not AS causative. Finally, we identified an interaction between HLA-B27 and variants within ERAP1 in the WTCCC2 (p = 0.008), TASC (p = 0.004) and replication datasets (p = 0.004). Specifically, risk variants in ERAP1 increased odds of disease in individuals who were positive for HLA-B27, but not those who were B27-ve (combined interaction p = 1.4 x 10-6). This result implies that B27+ve and B27-ve forms of disease have substantially different aetiologies and that ERAP1 contributes to disease risk through its action in trimming peptides prior to loading into nascent HLA class I molecules, rather than by cleaving pro-inflammatory cytokine receptors on the cell membrane. In summary, we have identified four new loci at genome-wide significant levels that affect risk of AS, a single SNP variant that tags HLA-B27 which may be used in the future as a cheap alternative to expensive B27 typing, and have discovered one of the first convincingly replicated examples of a genetic interaction affecting risk of a complex disease.

3048/F

Genes influencing the high sensitivity C-reactive Protein (hs-CRP) levels by the obesity status: The Healthy Twin Study, Korea. *D.E. Kim[1], J. Sung[1], Y.M. Song[2], K. Lee[3], D.H. Lee[1], M.K. Lee[1].* 1) Department of Epidemiology, Seoul National University of Public Health; 2) Department of Family Medicine, Samsung Medical Center, SungKyunKwan University School of Medicine; 3) Department of Family Medicine, Busan Paik Hospital, School of Medicine, Inje University.

Recently, growing body of evidence indicates the role of inflammatory process in the etiology of coronary heart disease(CHD) and carcinogenesis. It is also well known that obesity increase the inflammation status, and increased inflammation may bridge obesity and its sequels. C-Reactive Protein(CRP) is a general marker released during inflammation process. CRP level showed genetic contributions and recent genome-wide association studies revealed several genetic variants regulating CRP levels. The specific goal of the study is to identify the genes accounting for the serum CRP concentration, and comparing the CRP-associated genes with genes showing association after considering the obesity level. overall genetic contribution of CRP level was analyzed by variance component methods (SOLAR) and specific genes were identified by the Family Based Association Test(FBAT). 3445 individuals of Korean twins and their families, including 1239 twins in the Healthy Twin study in Korea were analyzed. Affymetrix Genome-wide Human SNP Array 6.0 Genechip was used for genotyping the subjects. The average CRP concentration of objects is 0.154mg/L(1487 for men, 1958 for women). With solar, estimated heritability is 0.350(±0.031) and after adjusting age, sex, and BMI, heritability estimated about 0.325((± 0.032). In genome-wide association test, SNP A-1993164 and flanking SNPs (in chromosome 8) showed genome-wide significance SNP (p-value : 1.70E-0.05) adjusting age, sex or smoking. The analyses were repeated after adjusting BMI levels. It is assumed that chromosome 8 has a significant role on hsCRP level. As a conclusion, Genetic factors associated with many other environmental factors to determine CRP level.

A powerful truncated tail strength method for testing an overall hypothesis in a dataset. *B. Jiang[1], X. Zhang[1], Y. Zuo[2], G. Kang[1,3].* 1) The University of Alabama at Birmingham, Birmingham, AL; 2) Michigan State University, East Lansing, MI 48824; 3) School of Medicine, University of Pennsylvania, Pennsylvania, PA 19104.

In microarray analysis, medical imaging analysis and functional magnetic resonance imaging, we often need to test a large number of single hypotheses (usually larger than 1,000) in one data set. To measure an overall significance for a set of a large number of m (≥ 1,000) independent single hypothesis tests under the overall null hypothesis that all m single hypotheses are true, a tail strength statistic (Taylor and Tibshirani, 2006) and Fisher's probability method are useful and can be applied. Here, we propose a new method that improves the tail strength statistic by only considering the values whose corresponding p-values are less than some pre-specified cutoff. We call it truncated tail strength statistic. Then, we propose a Monte Carlo method to estimate the empirical p-value of the truncated tail strength statistic. Simulation studies show that the truncated tail strength statistic not only controls type one error rate quite well and but also it has significantly higher power than the tail strength method and Fisher's method with a cutoff value of 0.005 in most cases. We applied the truncated tail strength method to two genome-wide data sets by chromosome. Result showed that our truncated tail strength method with a cutoff of 0.005 identified more significant chromosomes than the tail strength method.

APOBEC3B gene polymorphism among patients with chronic Hepatitis B Virus infection. *S. SUBODH[1], S. Datta[2], K. MADAN[3], S. PARIHAR[1], K. NARAYANASAMY[1].* 1) THE CENTRE FOR GENOMIC APPLICATION, AN IGIB-IMM CO, NEW DELHI; 2) INDIAN STATISTICAL INSTITUTE, KOLKATA; 3) ALL INDIA INSTITUTE OF MEDICAL SCIENCES, NEW DELHI.

A large number of chronic liver diseases and hepatocellular carcinoma cases in India are attributed to Hepatitis B virus infections. The disease progression may be due to an inter play of viral and host factors. It is imperative to understand these factors to direct our understanding of disease outcomes and therapeutic targets. One such host factor is the APOBEC3B gene (A3B) which is believed to play an important role in innate immunity by posing barrier to viruses such as HBV and HIV. A deletion polymorphism of this gene can seriously alter the functioning of A3B and would be preferentially selected if this variant offered the individual with greater resistance to specific pathogens. To test this hypothesis we analyzed the A3B deletion frequency in 152 patients chronically infected with HBV and those who were carriers. These individuals did not clear the virus and were assumed to have a high A3B deletion allele frequency. Chi-square analysis revealed that the frequency of insertion homozygous individuals (II) was much higher among HBV patients than among controls. On the other hand the deletion homozygous individuals (DD) comprised only 2% of the HBV patient population as compared to 6% in the control population. Additionally, the frequency of the insertion allele (I) was significantly higher among HBV patients. It is possible that A3B be acting in conjunction with other proteins by alternate mechanisms and may not be the major determinant of viral clearance.

Statistical Prediction of Classical HLA Typing Using Unphased SNP Data. *X. Zheng[1], J. Shen[2], M. Ehm[2], M. Nelson[2], B. Weir[1], J. Wakefield[1,3].* 1) Departments of Biostatistics, University of Washington, Box 357232, Seattle, Washington 98195-7232, USA; 2) GlaxoSmithKline, Research Triangle Park, NC 27709, USA; 3) Departments of Statistics, University of Washington, Box 357232, Seattle, Washington 98195-7232, USA.

Genetic variation in the Human Leukocyte Antigen (HLA) region, located on chromosome 6p21.3, is known to be highly polymorphic, and typing at classical HLA loci has been an essential tool for basic as well as clinical immunology research. High-resolution HLA typing is limited by the cost of genotyping technologies. A hidden Markov model (HMM) has been developed to predict HLA alleles based on haplotype inference from genotypic data in a recent study (Leslie et al, 2008). Their approach does not take into account the different probabilities of the estimated individual haplotypes from the phasing procedure, and does not allow missing values in the SNP predictors. Here, we introduce a novel statistical method for predicting HLA alleles, which computes the posterior probability from all possible haplotypes in the training data under the model assumptions of Markov property. Our method allows missing SNP genotypes in the training and validation data, and is computationally efficient because no haplotypes are estimated for each individual. Leave-one-out cross-validation is used to demonstrate the performance of our method on prediction accuracy, compared to the previous approach (HMM), for the four HapMap populations. Two additional datasets, 1958 birth cohort data of Welcome Trust Case Control Consortium (n = ~1800), and data for 1564 subjects from several racioethnic groups of GlaxoSmithKline collections, are used to validate the accuracy of our approach. Our results indicate that a panel of 50 ~ 100 SNPs typed at specific loci is sufficient to predict classical HLA alleles with ~90% accuracy in European samples. Finally, our SNP-based method provides an efficient and low-cost way to predict HLA alleles using genome-wide association data, which is useful in many experimental and clinical settings. Our study is supported in parts by NIH grant GM 75091.

The story of chromosome 16 rewritten in relation to susceptibility to Crohn's Disease. *D.M. Swallow, W. Lau, N. Maniatis.* Research Department of Genetics, Evolution & Environment, University College London, London, United Kingdom.

Crohn's Disease (CD) is one of two main kinds of Inflammatory Bowel Disease (IBD) with an estimated heritability of approximately 50-60%. Although a Meta-analysis on three genome-wide association studies has detected 32 loci, these account for only 20% of the genetic risk of the disease. In this study we employ a novel association method based on linkage disequilibrium mapping and utilising a multilocus approach to identify new regions associated with CD. We focused on chromosome 16, which has been reported to show significant linkage over a very extensive region, and which cannot fully be accounted for by the one chromosome 16 gene (NOD2) that has been identified. The chromosome was divided into non-overlapping windows measured in LD units, for which the significance of association with disease status was calculated. We detected significant associations between CD and several novel regions implicating multiple genes, some previously reported for ulcerative colitis (CADH1, CADH3), or multiple sclerosis (IRF8), which also has features of an immune dysregulation condition. Introduction of this approach will accelerate the identification of genes and pathways for CD, and will be useful for other complex traits.

3053/F

Association of Polymorphisms in Novel Innate Immune Genes with Gram Negative Sepsis. *I.V. Yang, L.A. Warg, S.D. Alper, D.A. Schwartz.* Center for Genes, Environment, and Health, Departments of Medicine and Immunology, National Jewish Health, Denver, CO 80206.

The role of host susceptibility in the initiation and severity of infections caused by Gram negative (GN) bacteria is incompletely understood. Our project aims to further understand why some individuals develop infection, and of those with infection, why only some go on to have adverse outcomes. We have previously shown that polymorphisms in TLR4 predispose humans to GN sepsis. However, our previous findings also demonstrate that sequence variants of TLR4 account for only a portion of the LPS phenotype in either mice or humans and that other genes are involved in regulating the response to LPS. In this study, we used a combination of genetic and genomic techniques following a challenge with lypopolysaccharide (LPS), an outer membrane component of GN bacteria, in model systems (mice, *C. elegans*, and cell culture) to identify genes other than TLR4 that may regulate the pathophysiologic response to innate immune stimuli in humans. To translate these findings to humans, we performed an association study in patients with GN bacteremia. Tagging SNPs were selected for 35 high priority candidate genes and three 96-plex Illumina Veracode GoldenGate genotyping assays were designed. Genotyping was performed in 300 individuals with GN bacteremia (family Enterobacteriaceae) and 300 control subjects with no signs of infection. Association analysis was performed using standard logistic or linear regression with adjustment for gender, sex, and race. Tests of association were independently performed for several variables, including GN bacteremia, Acute Physiology and Chronic Health Evaluation II (APACHE II) score that is indicative of disease severity, acute lung injury/acute respiratory distress syndrome (ALI/ARDS), disseminated intravascular coagulation (DIC), septic shock, and outcome. Significant associations will be presented.

3054/F

Heritability of serological measures of common infections in participants of the San Antonio Family Heart Study. *R. Rubicz[1], C.T. Leach[2], E. Kraig[3], N. Dhurandhar[4], J. Blangero[1], R. Yolken[5], H.H.H. Göring[1].* 1) Dept. of Genetics, SFBR, San Antonio, TX; 2) Dept. of Pediatrics, University of Texas Health Science Center at San Antonio, San Antonio, TX; 3) Dept. of Cellular and Structural Biology, University of Texas Health Science Center at San Antonio, San Antonio, TX; 4) Pennington Biomedical Research Center, Baton Rouge, LA; 5) Dept. of Pediatrics, Johns Hopkins School of Medicine, Baltimore, MD.

Variation in susceptibility to infectious disease has been documented among individuals and between populations and is attributable to different environmental and genetic factors. Here we test the hypothesis that variation in antibody titer, as well as the overall number of infections, is partly due to genetics. Participants were >1300 Mexican Americans in the San Antonio Family Heart Study. Antibody titers and seroprevalence were determined by ELISA (except Ad-36, which was quantified using a published serum neutralization test) for 13 common infections: *Chlamydophila pneumoniae*; *Helicobacter pylori*; *Toxoplasma gondii*; Adenovirus 36 (Ad-36); hepatitis A; influenza A; influenza B; cytomegalovirus; Epstein-Barr virus; herpes simplex I virus (HSV-1); herpes simplex II virus (HSV-2); human herpesvirus 6; and varicella zoster virus (VZV). Both quantitative antibody titers and discrete serostatus phenotypes (seropositivity/seronegativity) were analyzed. Additive genetic heritability (h^2) was calculated using variance component (VC) pedigree analysis with the computer program SOLAR. To assess the influence of shared environmental factors, a household component was included in the VC model. All but two pathogens (HSV-2, which is sexually transmitted, and VZV) were found to have a significant heritable component at p£0.05, with h^2 ranging from 9.0% (Ad-36) to 45.7% (hepatitis A) for quantitative titers, and 18.4% (Ad-36) to 70.4% (*C. pneumoniae*) for seropositive/seronegative status. However, fewer pathogens were significantly heritable when simultaneously accounting for household. Household was significant for approximately half the pathogens, the largest contribution being 32.4% ($p=7.2x10^{-03}$) for influenza A, possibly due to the infection being passed among relatives. Most participants (80%) had between 6 and 9 infections, and pathogen load was significantly heritable for all pathogens (h^2=37.6% and 27.2%, for the quantitative and discrete traits, respectively), as well as for the herpesviruses (h^2=32.0% and 18.1%). These results demonstrate that individual genetic differences do contribute to serological phenotypes, and that identifying the underlying genetic factors may help illuminate how the immune system functions and our understanding of the variation in disease susceptibility, potentially leading to novel approaches for the treatment of patients suffering from infectious disease.

3055/F

Estimation of the contribution of rare causal variants to complex diseases. *W. Guan[1], M. Boehnke[2], L.J. Scott[2].* 1) Division of Biostatistics, Univ of Minnesota, Minneapolis, MN; 2) Department of Biostatistics and Center for Statistical Genetics, Univ of Michigan, Ann Arbor, MI.

Rapid advances in next-generation sequencing technologies are providing ever more complete surveys of genomic regions of interest and even whole genomes, and these advances are facilitating genetic association studies of an increasingly wide array of common and rare variants. As we plan re-sequencing studies, it is interesting to consider constraints on the range of plausible genetic models based on results of previous genetic studies of complex traits. In particular, results of genome-wide association (GWA) studies and previous linkage studies provide information on the range of causal variant risk allele frequencies (RAF) and effect sizes (genotype relative risk, or GRR) that might underlie common GWA signals and might, more broadly, exist in a given genomic region. In this study, we use power calculations to evaluate the range of models that would result in little evidence for linkage in a linkage scan (a typical finding) and different degrees of evidence for association at genotyped markers in an association study, assuming a multiplicative model of disease risk. We find that prior negative linkage or association results can help to restrict the plausible range of GRR, and little evidence for linkage and significant evidence for association can reduce the plausible ranges of both GRR and RAF in the corresponding region. We apply our approach to large-scale linkage and GWA meta-analyses for type 2 diabetes. Our results suggest that several association signals can only be explained by relatively common causal variants (RAF > .01), while other signals are consistent with a wide range of RAF and GRR.

3056/F

Allelic Heterogeneity in a Genome-wide Association Study of Body Mass Index in 123,000 Individuals. *R. Weyant[1], C. Willer[1], H. Lango Allan[2], M. Weedon[2], T. Ferreira[3], C. Lindgren[3,4], E. Speliotes[5,6], S. Berndt[7], K. Monda[8], G. Abecasis[1], G. Thorleifsson[9], M. Boehnke[1], K. Stefansson[9,10], K. North[8,11], M. McCarthy[3,4,12], J. Hirschhorn[5,14,13], E. Ingelsson[15], R. Genome-wide association studies have identified variants that are associated with many complex traits. Typically, initial analyses focus on a single variant in each identified locus. This variant is then examined in additional samples and discussed in the context of nearby genes and eQTL signals. Although it is known that many GWAS signals overlap with previously (or subsequently) identified Mendelian loci, the extent to which identified loci harbor multiple associated variants has not been fully explored. The GIANT consortium identified 32 loci associated with BMI in an initial analysis of ~123,000 individuals and subsequent follow-up in ~125,000 individuals. At least three of the 32 loci (near POMC, SH2B1 and MC4R) are known to also harbor variants associated with morbid obesity. To explore allelic heterogeneity for common variants in the 32 novel loci, we repeated genome-wide analyses after conditioning on lead variants for each of the 32 loci. The analysis identified a non-synonymous SNP (rs2229616, minor allele frequency (MAF) = 0.017, effect size -0.33 kg/m2 per minor allele) in MC4R that shows association with BMI (p = 6 x 10-6) and is also independent of the previously reported variant at that locus (rs571312, MAF = 0.283, effect size 0.23 kg/m2 per minor allele). The minor allele at this SNP, V103I (rs2229616) was previously reported to be associated with reduced risk of obesity. There is no evidence of linkage disequilibrium between these two SNPs (r2=0.004) which are ~200kb apart from each other, potentially representing different mechanisms of altering gene function. While our results do not provide evidence for widespread allelic heterogeneity at BMI associated loci, they do illustrate that common variants at the same locus can point to different functional subunits.

Genetic and Non-Genetic Risk Estimation in the Coriell Personalized Medicine Collaborative. *C.B. Stack, N. Gharani, E.S. Gordon, T.J. Schmidlen, M.F. Christman, M.A. Keller.* Coriell Institute for Medical Research, Camden, NJ.

Recent genome wide-association studies have identified hundreds of single nucleotide polymorphisms associated with common complex diseases. With the momentum of these discoveries comes a need to communicate this information to individuals. The Coriell Personalized Medicine Collaborative(CPMC®) is an observational research study designed to evaluate the utility of genetics knowledge in medicine. Participants provide saliva samples for genotyping and complete extensive on-line medical history, family history, and lifestyle questionnaires. Only results for selected genetic variants associated with diseases deemed potentially actionable by an independent advisory board are reported. Results for non-genetic risk factors are also provided to convey the multi-factorial nature of reported diseases. We present our methodology for developing risk reports for CPMC® participants. Risk estimates are given as relative risk, derived or reported from valid and representative peer-reviewed publications. Studies used for risk reporting are selected based upon the strength of the design and study quality. Use of relative risk allows for consistent reporting across genetic and non-genetic factors, and across multiple diseases. Also, relative risks are applicable to most individuals, as measures of relative effect are generally stable across populations. Importantly, this approach to risk reporting does not require estimates of population lifetime disease risks, which have been shown to vary substantially across populations. Because communicating risk in relative terms to a lay audience is more challenging, we include detailed descriptions for the risk estimates within our reports. Risk reports are accompanied by information on disease prevalence, heritability and ethnic-specific genotype frequency. The delivery of risk reports is supported by web-based educational material and access to genetic counseling and educational seminars. In developing our reporting methods, we acknowledge some trade of conceptual simplicity for accuracy and transparency. CPMC® risk reports demonstrate an approach to communicating risk of complex disease via the web that encompasses risks due to genetic variants along with risks due to family history and lifestyle factors. This approach can be applied to multigenic risk models, as they are developed and validated. The report format is amenable to integration into an electronic health record (eHR) or personal health record (pHR).

Modulation of alternative splicing using morpholino oligonucleotides. *S. Tantzer[1], K. Sperle[1], J. Taube[2], G.M. Hobson[1,2].* 1) Nemours Biomedical Research, Alfred I. duPont Hospital for Children, Wilmington, DE; 2) Department of Biological Sciences, University of Delaware, Newark, DE.

Pelizaeus-Merzbacher Disease (PMD) is a neurological disease often caused by duplication of the proteolipid protein 1 gene (*PLP1*) on the X-chromosome. However, PMD is also caused by small deletions, insertions and single base mutations that affect the coding sequence of the protein or the splicing of the gene. *PLP1* has two major splice isoforms due to alternative 5' splice donor sites for intron 3 leading to either PLP1 or *DM20* mRNA transcripts. Tight regulation of the PLP1/DM20 alternative splice is critically important for central nervous system function; a developmental switch in the isoform ratio from *DM20* toward the *PLP1* isoform occurs during myelination in the central nervous system. We showed that patient mutations within exon 3 or intron 3 that reduce the ratio of *PLP1* to *DM20*, without resulting in amino acid changes, cause PMD. Although there are currently no therapeutic interventions or cures for PMD or for the many other diseases that can be caused by disruption of alternative splicing, molecules that modulate aberrantly spliced products toward a more normal ratio are currently being tested as a therapeutic intervention. We have designed morpholino oligomers (MO) to target the *DM20* 5' splice site to increase the *PLP1* to *DM20* transcript isoform ratio. An oligodendrocyte cell line, Oli-neu was treated with MO and the resulting endogenous *PLP1* to *DM20* ratio was found to be significantly increased. *PLP1* mini-gene splicing constructs containing different patient mutations that affect *PLP1* splicing also showed a significant increase in the *PLP1* to *DM20* ratio after transfection into Oli-neu cells and treatment with MO. Our studies indicate that MOs can be used to alter *PLP1* splice site selection both endogenously and in mutant transfected constructs, suggesting that MOs may be a therapeutic option for PMD caused by aberrant alternative splicing. The results of these studies have implications for other diseases caused by misregulation of alternative splicing.

3059/W

Viral vector tropism for supporting cells in the developing murine cochlea. *A.M. Sheffield[1], S.P. Gubbels[2], M.S. Hildebrand[1], J.A. Chiorini[3], G. Di Pasquale[3], R.J.H. Smith[1].* 1) Department of Otolaryngology—Head and Neck Surgery, University of Iowa, Iowa City, IA; 2) Division of Otolaryngology—Head and Neck Surgery, University of Wisconsin, Madison, WI; 3) National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda, MD.

Gene therapies are currently being developed to provide novel treatments for genetic hearing loss. Many genetic forms of deafness are congenital and gene transfer-based therapies for these forms of deafness would require initiating treatment prior to the onset of significant hearing loss. Recently, Bedrosian and colleagues developed a safe and effective method for in utero transfer of therapeutic agents to progenitor cells in the embryonic murine otocyst. In this study, we recapitulated this approach to investigate viral tropism in the developing inner ear. The cellular heterogeneity that exists within the cochlea makes viral tropism an important consideration for effective inner ear gene therapy. For the first time we have characterized viral tropism for cochlear supporting cells following in utero delivery to their progenitor cells. Supporting cells are the primary site of connexin 26 gap junction proteins that are mutated in the most common form of congenital genetic deafness (DFNB1). We examined the inner ear tropism of three previously untested vectors: AV5-CMV-GFP (first-generation adenovirus), Adf.11d (late-generation adenovirus) and BAAV-CMV-GFP (bovine adeno-associated virus). Adult mice underwent timed matings to generate embryos for transuterine microinjection. Injection of GFP-expressing viral vectors into the left otocyst of mouse embryos was performed via transuterine microinjection at embryonic day 12.5 (E12.5). Auditory brainstem response (ABR) testing was performed at 5 weeks of age on injected mice and littermates to assess for potential hearing loss associated with virus administration. Subsequently, cochleas were analyzed for GFP expression using fluorescence microscopy to assess cellular tropism of each viral vector. Both first- and late-generation adenovectors (AV5-CMV-GFP and Adf.11d) showed robust tropism for organ of Corti supporting cells throughout the cochlea. However, both adenovectors resulted in markedly increased ABR thresholds in the injected cochleas indicating toxicity to normal hearing. Bovine adeno-associated virus also showed tropism for organ of Corti supporting cells, with preferential transduction toward the cochlear apex. BAAV-injected cochleas showed normal hearing at 5 weeks of age when compared to non-injected cochleas. These results suggest BAAV as a promising vector for safe targeting of supporting cell progenitors in the developing murine cochlea.

Transduction of choroid plexus epithelia is crucial for gene therapy rescue of a murine model of Menkes disease. *A. Donsante[1], L. Brinster[2], P. Zerfas[2], D. Goldstein[3], J. Prohaska[4], J. Centeno[5], S. Kaler[1].* 1) Unit on Human Copper Metab., NIH,NICHD, Bethesda, MD; 2) Division of Veterinary Resources, NIH, Bethesda, MD; 3) Clinical Neurocardiology Section, NINDS, NIH, Bethesda, MD; 4) Dept of Biochemistry and Molecular Biology, U. of Minnesota, Duluth, MN; 5) Armed Forces Institute of Pathology, Washington, D.C.

The *mottled-brindled* (*mo-br*) mouse manifests a lethal abnormality in copper transport to the brain caused by a mutation in *atp7a*, a P-type ATPase, and is a model for Menkes disease. We treated neonatal *mo-br* mice with either intracerebroventricular recombinant adeno-associated virus serotype 5 (AAV) harboring an atp7a homolog, intracerebroventricular copper, or both treatments. As we previously noted, only AAV+Cu treatment rescued *mo-br* mice. Transduction by AAV occurred primarily in the choroid plexus epithelia at the viral titers ($5x10^8$ vector genomes) employed. Survival was associated with higher brain copper levels and improved activity of dopamine-β-hydroxylase, a copper enzyme metallated in the *trans*-Golgi compartment. In contrast, the activities of cytosolic and mitochondrial copper enzymes did not differ notably among treatment groups. Serial neurobehavioral testing in long-surviving *mo-br* mice using the constant speed rotarod (balance and coordination) and wire hang (neuromuscular strength) was performed weekly beginning at 25d of age and up to 300d of age (3 trials per time point, 60s maximum). AAV+Cu *mo-br* mice were similar to wild type controls on the rotarod at 25d of age [*mo-br* (N=10) 56s, wild type (N=9) 60s]. However, they exhibited significant impairment in later weeks, averaging 15-20s on the rod. Surprisingly, three AAV+Cu *mo-br* mice regained the ability to remain on the rotarod for the full 60s beginning at ages 95d, 144d, and 173d. On the wire hang test, AAV+Cu mice were abnormal at 25d of age (30s vs. wild type 60s; $p<10^{-4}$) but showed improvement with age. At 116d, *mo-br* mice (N=6) stayed on the wire for a mean duration of 54s versus 60s in wild type (N=10). 67% of AAV+Cu *mo-br* mice completed the full 60s at this time point as compared to 10% at 25d of age. At 300 days of age, electron micrographs showed no overt ultrastructural abnormalities and myelin staining appeared similar between treated *mo-br* brain and normal controls.

Our findings suggest that 1) rescue of the *mo-br* mouse is dependent upon improved copper retention in the brain due to transduction of choroid plexus epithelia, 2) copper enzymes metallated in the *trans*-Golgi network are responsible for improved life span in AAV+Cu *mo-br* mice, and 3) recovery of motor function in the rotarod and wire hang test long after administration of therapy may be explained by slower than normal rates of myelination and axonal growth/development.

Elucidation of Mechanism and Therapy for Loeys-Dietz Syndrome Using an Allelic Series of Mutant Mice. *D. Loch[1], E. Gallo[1,2], H. Dietz[1,2].* 1) Johns Hopkins University School of Medicine, Baltimore, MD; 2) Howard Hughes Medical Institute.

Loeys-Dietz syndrome (LDS) is a systemic connective tissue disorder with significant phenotypic overlap with Marfan syndrome (MFS). Unlike MFS, LDS carries a strong risk of aneurysm and dissection throughout the arterial tree that is often difficult or impossible to manage surgically, highlighting the need to elucidate pathogenesis and develop medical therapies. LDS is caused by heterozygous missense mutations in the kinase domain of the type I or type II subunits of the transforming growth factor-beta receptor (TβRI or TβRII, respectively). Expression of mutant receptor subunits in cells naïve for the corresponding receptor fails to support TGFβ signaling, yet analysis of LDS patient aortic tissue has shown paradoxically enhanced TGFβ signaling, like MFS. The angiotensin II type 1 receptor blocker losartan has shown the ability to attenuate both TGFβ signaling and aneurysm progression in mouse models of MFS and is often prescribed for LDS patients on a theoretic rather than empiric basis. To address the issue of mechanism, we have created three mutant mouse models of LDS; two knock-in strains with missense mutations in TβRI (M318R) or TβRII (G357W) and a transgenic strain that ubiquitously over-expresses TβRII mutant G357W. Strains haploinsufficient for the TβRI or TβRII gene have also been analyzed. Both knock-in strains fully recapitulate the LDS vascular phenotype, with widespread arterial disease including arterial tortuosity, aneurysm and dissection. G357W transgenic mice also develop vascular disease, with increased severity seen in homozygosity, despite full TGFβ signaling capacity in cultured cells, arguing against a dominant-negative mechanism. In contrast, both haploinsufficient mouse strains show normal longevity and no evidence of vascular disease. LDS knock-in mice show increased canonical TGFβ signaling in aortic tissue (phosphorylated Smad2 and PAI1 expression) and activation of noncanonical TGFβ signaling cascades (ERK1/2), suggesting a gain-of-function mechanism. A blinded and placebo-controlled trial of losartan in LDS mice demonstrated prevention of aortic root dilatation with reduced canonical and noncanonical TGFβ signaling, in accordance with previous findings in MFS. This study highlights the utility of studying pathogenesis in models that recapitulate the physiologic complexity of the human system and suggests that therapeutic strategies developed for MFS may find broader application in disorders of vessel wall homeostasis.

The Link between innate immunity and Gaucher disease: Implications for therapy. *A. Farwah[1], O. Alpan[4], P. Mistry[3], D. Unutmaz[2], O. Goker-Alpan[1].* 1) LSD Research and Treatment Unit, Center for Clinical Trials, Springfield, VA; 2) NYU School of Medicine, Departments of Microbiology and Pathology, New York, NY; 3) Yale University School of Medicine, New Haven CT; 4) Laboratory of Immunopathogenesis, O & O Alpan, LLC, Springfield VA.

Lipid engorged macrophages are the hallmark for Gaucher disease (GD), which are not metabolically inert, but strongly express markers of macrophage activation. Similarly, the plasma of GD patients shows more than 1000 fold increase of chitotriosidase, a chitinase secreted from activated macrophages. While these markers respond to therapy, they are not specific for different organ involvement. In GD, the mechanisms of macrophage activation remain unclear, but non-specific inflammatory response, poor wound healing and insulin resistance may indicate that there are multiple pathways involved. Activation of macrophages could impact other innate immune system components such as NK cells, and adaptive immunity through modifying T cell and B cell function. Therefore, understanding the mechanisms of macrophage activation could provide mechanistic insights in GD. We hypothesized that in GD macrophage activation could occur both through an alternative pathway, such as CCL18-mediated activation and by more direct effects of lipid metabolites. We then assessed the effects of macrophage activation on NK function modulation, macrophage function and response to therapy. NK cell numbers and activity were evaluated in peripheral blood mononuclear cells. NK cells have the ability to induce cell death in tumor cells. K562, human erythroleukemia cell line was loaded chromium and lysis of the K562 targets by NK was measured by the amount of chromium in the supernatant. NK and T cell subsets were evaluated by flow cytometry. Chitotrisidase levels were followed as a marker of alternative macrophage activation. Although the number of circulating NK cells was normal, there was a significant decrease in target killing in vitro. Despite normalization of chitotriosidase and other GD biochemical markers with enzyme replacement therapy, inflammatory markers in peripheral blood remained elevated. In GD, pathways leading to macrophage activation are heterogeneous. NK cell dysfunction contributes to secondary macrophage activation, which may alter the expected outcomes and response to therapy in some patients with GD. Therapeutic interventions that suppress macrophage activation may control the inflammatory component of GD, which in turn could alleviate the development or progression of bone, pulmonary and neurological complications.

Protocol for early initiation of growth hormone therapy in Prader-Willi Syndrome yields good clinical results. *J. Atkin[1], A. Dye[2], D. Hardin[3], D. Repaske[2], K. Anglin[2].* 1) Molecular/Human Genetics, Nationwide Children's Hospital/Ohio State University, Columbus, OH; 2) Endocrinology, Nationwide Children's Hospital/Ohio State University, Columbus, OH; 3) Ohio State University, Columbus, OH.

Growth Hormone (GH) therapy in children with Prader-Willi Syndrome (PWS) has been shown to be beneficial in decreasing body fat percentage, improving lean body mass, and increasing linear growth and resting energy expenditure. However, earlier initiation of growth hormone therapy could have direct benefits on psychomotor and cognitive development. Thus, although GH therapy seems beneficial for children with PWS, it is unclear at what age to safely initiate this therapy. We therefore report a protocol for early initiation of growth hormone therapy in infants with PWS. Our multidisciplinary PWS team involves a collaboration of genetics, pediatric endocrinology, and nutrition specialists who see patients every three months. Our PWS clinic has been successfully using a protocol for early initiation (ages 3-4 months) of growth hormone therapy with good clinical results. Developmental milestones are monitored at each visit and patients with early initiation of GH therapy demonstrate earlier acquisition of developmental milestones. All patients undergo polysomnography assessments to evaluate for central apnea and sleep disordered breathing prior to the initiation of growth hormone. Low-dose growth hormone is started and gradually increased with careful attention to subsequent sleep studies and side effect profiles with close follow-up. Conclusion: Introduction of growth hormone therapy as early as 3-4 months of age in the Prader-Willi population can be safe and effective when closely monitoring for obstructive/central apnea with repeated polysomnography assessments and side effect evaluations. Growth hormone is beneficial for improving body composition and motor development which may impact cognitive development and should be considered in early infancy.

3064/W

Everolimus for subependymal giant-cell astrocytomas (SEGAs) in patients with tuberous sclerosis (TS). *D.A. Krueger[1], M.M. Care[1], K. Holland-Bouley[1], K. Agricola[1], C. Tudor[1], P. Mangeshkar[1], A. Weber Byars[1], T. Sahmoud[2], D.N. Franz[1].* 1) Division of Neurology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Novartis Pharmaceuticals Corporation, Florham Park, NJ.

Objective: TS is a potentially devastating disorder caused by mutations in *TSC1* or *TSC2* and characterized by hamartoma formation in multiple organ systems, including the brain. SEGAs develop in 5-15% of TS patients and represent a significant medical risk, including the potential for sudden death secondary to acute hydrocephalus. Neurosurgical resection, the standard treatment of SEGAs, carries a significant risk of peri- and postoperative complications, and incomplete resection, which invariably occurs, necessitates repeat procedures. However, no effective alternative currently is available. This open-label, phase-II study evaluated the effect of treatment with the mTOR inhibitor everolimus on SEGA volume in patients with TS. **Methods:** Patients aged ≥3 years with a definitive TS diagnosis and serial SEGA growth based on evidence from magnetic resonance imaging (MRI) scans received oral everolimus (starting dose, 3 mg/m^2 daily) titrated to trough concentrations of 5-15 ng/mL. The primary endpoint was change from baseline in SEGA volume after 6 months of treatment as assessed by central radiological review of MRI scans. Seizure frequency was assessed by 24-hour video electroencephalograms (EEGs). **Results:** Median treatment duration for 28 patients enrolled between 1/07 and 12/08 was 21.5 months (range 4.7-34.4). Everolimus was associated with clinically meaningful reductions in SEGA volume ($p<0.001$). Twenty-one patients (75.0%) experienced reductions in SEGA volume ≥30% during the first 6 months. Mean reduction in left and right ventricular volume was 3.22 and 3.15 cm^3, respectively, from baseline to month 6. No new lesions, worsening hydrocephalus, or symptoms attributable to increased intracranial pressure developed. No surgical resection or other SEGA treatment was required. Grade 3 adverse drug reactions were single cases of sinusitis, pneumonia, viral bronchitis, tooth infection, stomatitis, and leukopenia; no grade 4 events occurred. Clinically relevant reductions in overall clinical and subclinical seizure frequency ($p=0.022$) also were observed. Of 16 patients with evaluable EEG data, 9 experienced a decrease from baseline in seizure frequency, 6 reported no change (5 of whom were event-free at baseline), and 1 patient experienced an increase (median change 1.0, $p=0.012$). **Conclusions:** Everolimus offers a viable alternative to surgical resection and appears to be well tolerated.

Novel Enzyme Replacement Therapy for Gaucher Disease: Clinical program with Plant Cell Expressed Recombinant Glucocerebrosidase (prGCD) - taliglucerase alfa. *E. Almon-Brill[1], R. Chertkoff[1], M. Maas[2], M. Petakov[3], E. Terreros Muñoz[4], S.E. Solorio-Meza[5], D. Amato[6], G.S. Duran[7], F. Giona[8], R. Heitner[9], H. Rosenbaum[10], P. Giraldo[11], A. Mehta[12], A. Zimran[13].* 1) Protalix Biotherapeutics, Carmiel, Israel; 2) Academic Medical Centre Department of Diagnostic Radiology, Amsterdam, The Netherlands; 3) Belgrade University Medical School Institute of Endocrinology, Diabetes and Diseases of Metabolism, Belgrade, Serbia; 4) Centro Médico Nacional Siglo XXI Departamento Clínico de Hematología México, D.F. México; 5) Hospital de Especialidades No. 1 del Centro Médico Nacional del Bajío Unidad de Investigación en Epidemiología, León, Gto Mexico; 6) Mount Sinai Hospital Department of Medicine Mount Sinai Hospital, Toronto, Ontario, Canada; 7) Pontificia Universidad Católica de Chile , Departamento de Pediatría, Santiago, Chile; 8) Ematologia, Dipartimento di Biotecnologie Cellulari ed Ematologia, Università La Sapienza, Roma, Italy; 9) Department of Pediatrics, Johannesburg Hospital and University of Witwatersrand, Johannesburg, South Africa; 10) Hematologic department, Rambam Medical Center, Haifa , Israel; 11) Haematology Department, Miguel Servet University Hospital, Zaragoza; 12) Department of Hematology, Royal Free Hospital and University College London , London, UK; 13) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel.

Taliglucerase alfa is a carrot-cell-expressed recombinant human β-glucocerebrosidase for treating Gaucher disease developed and produced by Protalix Biotherapeutics. A Phase III double-blind, randomized, parallel dose groups (60units/kg /infusion and 30units/kg /infusion) clinical trial was completed. The 9-month,Pivotal trial treated-naïve adult symptomatic patients. Safety endpoints were drug-related adverse events and antibody formation. Primary efficacy endpoint was reduction in spleen volume. Secondary endpoints were: change from baseline of: hemoglobin levels, liver volume, and platelet count. Exploratory parameters included biomarkers and Quantitative Chemical Shift Imaging Patients from 11 centers worldwide were enrolled and equally randomized to each dose group. No serious adverse events were reported; drug-related adverse events were mild/moderate and transient. Two patients (6%) developed IgG, none of which presenting neutralizing activity, two other patients developed hypersensitivity reactions. There was a statistically significant difference from baseline for the primary efficacy measures, i.e splenic reduction ($p<0.0001$) in both 60 U/kg dose and 30 U/kg dose treatment groups. The primary endpoint was already achieved after six months of treatment in both treatment groups. Statistically significant improvements compared with baselines were observed in the secondary endpoints, including increase in hemoglobin level, decrease in liver size and increase in platelet count at the 60 U/kg dose. Statistically significant improvements compared with baselines were observed in hemoglobin level and liver size and significant nominal elevation in platelet count in the lower dose of 30 U/kg. Taliglucerase alfa 30 and 60 units/kg administered by intravenous infusion for 9 months in 31 patients with moderate to severe Gaucher disease was found to be safe and efficacious in a clinically relevant and statistically robust manner. Additional clinical trials including an extension study, switch over study from imiglucerase to taliglucerase, early access program and pediatric study are currently on-going and will be addressed.

3066/W

Preliminary Analysis of Cervical Cord Involvement in Mucopolysaccharidosis VI Patients Aged <6-Years Old Before and After Enzyme Replacement Therapy with Naglazyme® (galsulfase). *C. Hendriksz[1], P. Harmatz[2], R. Giugliani[3], H. Nicely[4], A. Waite[4], MPS VI Clinical Surveillance Program Investigators.* 1) Clinical Department, Birmingham Children's, Birmingham, B4 6NH, United Kingdom; 2) Children's Hospital and Research Center Oakland, Oakland, CA 94609; 3) Medical Genetics Service/HCPA, Department of Genetics/UFRGS and INAGEMP, Porto Alegre, RS, Brazil; 4) BioMarin Pharmaceutical Inc., Novato, CA 94949.

OBJECTIVES: Deficiency of N-acetylgalactosamine 4-sulfatase leads to accumulation of undigested glycosaminoglycans (GAG) dermatan sulfate/chondroitin 4-sulfate in untreated patients. GAG storage leads to skeletal dysplasia and dural thickening, accentuated in rapidly progressing patients. This retrospective analysis assesses incidence of cervical cord involvement in patients with mucopolysaccharidosis VI (MPS VI) <6 years of age, relative to enzyme replacement therapy (ERT). METHODS: Baseline and routine data were examined from 141 patients (54 USA; 87 EU) collected to date in the BioMarin Pharmaceutical MPS VI Clinical Surveillance Program (CSP). Analyses selected <6-yr old patients on ERT and included magnetic resonance imaging (MRI) describing cervical cord compression (CCC) as "present" or "absent" and rating MRI as "stable", "worse" or "improved" since last examination. PRELIMINARY RESULTS: Twenty-seven patients (27/141; 19%) <6 yr of age were identified, all of whom had received at least one ERT infusion. Of these patients, 14/27 (52%) had MRI at any time; 10/27 (37%) had "baseline" MRI anytime prior to ERT and up to 6 months post-ERT treatment. Of these patients, 2 (20%) had compression at baseline; 8 patients (80%) did not. Of the 8 patients without compression at baseline, 2 patients (25%) remained unchanged, while 6 patients (75%) developed compression at different lengths of follow-up. CONCLUSION: Thirty-seven percent (10/27) of <6 yr old patients in the CSP had cervical compression documented by MRI regardless of treatment time, suggesting comorbidity in this patient population. In those with sufficient follow-up, no observable trend was determined between ERT and CCC, although sample size was limited. MRI assessments at diagnosis, baseline and follow-up are necessary to understand the prevalence and natural history of cervical cord compression as well as the impact of surgery and ERT on this condition. Caution should be used in generalizing these data to the entire MPS VI patient population.

3067/W

Clinical and immunological response in patients with type 1 Gaucher disease transitioning from imiglucerase to velaglucerase alfa: ongoing extension of study TKT034. *R. Mardach-Verdon[1], G. Pastores[2], A. Zimran[3], A. Tylki-Szymanska[4], A. Mehta[5], M. Heisel-Kurth[6], C. Eng[7], L. Smith[8], P. Harmatz[9], J. Charrow[10], D. Elstein[3], D. Zahrieh[11], E. Crombez[11], G. Grabowski[12].* 1) Dept Genetics, S CA Kaiser Permanente, Los Angeles, CA; 2) NYU School of Medicine, New York, NY; 3) Shaare Zedek Medical Center, Jerusalem, Israel; 4) Children's Memorial Health Institute, Warszawa, Poland; 5) Royal Free Hospital, London, UK,; 6) Children's Hospitals of Minnesota, Minneapolis, MN; 7) Baylor College of Medicine, Houston, TX; 8) Children's Mercy Hospital, Kansas City, MO; 9) Children's Hospital & Research Center Oakland, Oakland, CA; 10) Children's Memorial Hospital, Chicago, IL; 11) Shire Human Genetic Therapies, Cambridge, MA; 12) Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Purpose: To assess long-term enzyme replacement therapy with velaglucerase alfa in patients with type 1 Gaucher disease who were clinically stable on imiglucerase therapy. **Methods:** Study TKT034 was a 1-year, open-label, multicenter trial in which patients with type 1 Gaucher disease aged ≥2 years with stable hemoglobin concentrations and platelet counts while receiving imiglucerase (for ≥30 consecutive months, at a dose unchanged for ≥6 months) transitioned to the same number of units of velaglucerase alfa (15-60 U/kg every other week by 1-hour intravenous infusion). After 1 year, patients were offered enrollment in an ongoing extension study. The primary endpoint was safety; secondary endpoints evaluated efficacy. Adverse events, hematology, and anti-velaglucerase alfa antibodies were measured at baseline and throughout the study (anti-imiglucerase antibodies were assayed at baseline). Liver and spleen MRI were done at baseline, 6 months, and 1 year in TKT034, and annually during the extension. **Results:** In study TKT034, 40 patients were enrolled and received ≥1 dose of velaglucerase alfa (median age, 37 [range 9-71 years], median prior imiglucerase use, 67 months [range 22-192 months]). At baseline, median hemoglobin concentration was 13.8 g/dL (range 10.4-16.5 g/dL) and median platelet count 162 x10^9/L (range 29-399 x10^9/L). Three patients were anti-imiglucerase positive at baseline. However, none of these patients developed antibodies to velaglucerase alfa during the trial, nor did patients who were antibody-negative at baseline. Velaglucerase alfa was generally well tolerated with most reported AEs of mild or moderate severity; no patient experienced a life-threatening AE; one patient experienced an SAE (hypersensitivity reaction) that led to discontinuation. Clinical parameters remained stable over the first year of treatment, and 38 patients continued into the extension. To date (18 months), mean changes for hemoglobin concentration and platelet counts are negligible; liver and spleen volumes will be recorded at Month 24.

Conclusion: In study TKT034, patients with type 1 Gaucher disease successfully transitioned from imiglucerase to velaglucerase alfa, maintaining clinical parameters over the long-term. Velaglucerase alfa was generally well tolerated, and appeared to show a favorable immunogenicity profile.

3068/W

A multicenter, randomized, double-blind, head-to-head, phase III study of velaglucerase alfa enzyme replacement therapy compared with imiglucerase in patients with type 1 Gaucher disease. *A. Mehta[10], M-F. Ben Dridi[1], DE. Gonzalez[2], A. Zimran[3], M. Kabra[4], EA. Lukina[5], P. Giraldo[6], I. Kisinovsky[7], A. Bavdekar[8], H. Ben Turkia[1], N. Wang[9], E. Crombez[9], K. Bhirangi[9].* 1) La Rabta Hospital, Tunis, Tunisia; 2) Sanatorio Español, Asunción, Paraguay; 3) Shaare Zedek Medical Center, Jerusalem, Israel; 4) All India Institute of Medical Sciences, New Delhi, India; 5) National Research Center for Haematology, Moscow, Russia; 6) Hospital Universitario Miguel Servet, Zaragoza, Spain; 7) Your Health S. A., Buenos Aires, Argentina;; 8) KEM Hospital Research Centre, Pune, India;; 9) Shire Human Genetic Therapies, Cambridge, MA, USA; 10) Dept Hematology, Royal Free Hosp, London, United Kingdom.

Purpose: Enzyme replacement therapy (ERT) with recombinant glucocerebrosidase (imiglucerase) has been the standard of care for Gaucher disease since the early 1990s. This study compared efficacy and safety of velaglucerase alfa (recently approved in the US) with imiglucerase in patients with type 1 Gaucher disease. Methods: Study 039 was a 9-month, global, randomized, double-blind, non-inferiority study comparing velaglucerase alfa with imiglucerase (60 U/kg every other week) in treatment-naïve patients aged ≥2 years, with anemia and either thrombocytopenia or organomegaly. The primary endpoint was the difference between the groups in mean change from baseline to 9 months in hemoglobin concentration (performed in intent-to-treat [ITT] and per-protocol [PP] populations). Results: 35 patients in 9 countries were randomized; 34 received study drug (ITT population: 17 velaglucerase alfa; 17 imiglucerase). Baseline characteristics were similar in the 2 groups; overall, 18/34 (53%) were female, the age range was 3-73 years (9/34 [27%] were <18 years), and 20/34 (59%) were splenectomized. The PP population included 15 patients in each arm. After 9 months, the estimated mean treatment difference for hemoglobin concentration from baseline between velaglucerase alfa and imiglucerase was 0.14 and 0.16 g/dL in the ITT and PP populations, respectively, with a lower bound of the 97.5% 1-sided confidence interval of -0.60 g/dL in both populations, greater than the pre-defined non-inferiority margin of -1.0 g/dL. These results indicate that the primary endpoint was met. There were no statistically significant differences in the secondary endpoints, including platelet counts, or spleen and liver volumes. The majority of AEs were mild or moderate in severity; no patient discontinued due to an AE. One treatment-emergent SAE was considered probably related to study drug (allergic skin dermatitis in a patient in the velaglucerase alfa group). No patient treated with velaglucerase alfa developed antibodies to velaglucerase alfa; 4 patients (23.5%) treated with imiglucerase developed antibodies to imiglucerase. Conclusion: This head-to-head study demonstrates the efficacy of velaglucerase alfa compared with imiglucerase in adult and pediatric patients with type 1 Gaucher disease, with velaglucerase alfa meeting the primary and all secondary efficacy endpoints. In addition, the results suggest possible differences in antigenicity between velaglucerase alfa and imiglucerase.

3069/W

SBC-102, a recombinant enzyme replacement therapy, corrects key abnormalities due to lysosomal acid lipase deficiency. *A.G. Quinn[1], A. Harvey[1], M. Chen[1], L. Christmann[1], M. Leavitt[1], W. Hu[1], T. Nagy[2], A. Lents[1], R. Richards[1].* 1) Synageva BioPharma Corp., Lexington, MA; 2) Dept of Pathology, College of Veterinary Medicine, University of Georgia, Athens, GA.

Lysosomal acid lipase (LAL) deficiency is a rare disease associated with significant morbidity and mortality, which affects individuals from infancy through adulthood. In infants LAL deficiency, sometimes called Wolman's disease, is a rapidly progressive and fatal condition characterized by malabsorption, growth failure and significant weight loss. In other patients the disease manifests with marked hepatomegaly, liver fibrosis, type II hyperlipidemia and accelerated atherosclerosis. The profound clinical effects of LAL deficiency are due to a failure to break-down cholesteryl esters and triglycerides in lysosomes, which leads to massive accumulation of lipid in many organs and a marked disturbance in cholesterol and lipid homeostatic mechanisms. We have developed methodologies for the production of recombinant therapeutic proteins in egg white (EW), including lysosomal enzymes, which have substantial advantages over cell culture based systems. We have expressed recombinant human LAL protein using this approach and demonstrated that the purified protein, SBC-102, is highly effective in correcting LAL deficiency in vitro and in an in vivo model. SBC-102 has N-glycans with terminal GlcNAc and mannose structures as well as mannose-6-phosphate moieties. In vitro studies with fluorescently labeled SBC-102 show cellular uptake into macrophages and fibroblasts via mannose and mannose-6-phosphate receptors respectively. Lysosomal localization was confirmed using confocal microscopy and LysoTracker. Incubation of fibroblasts from a patient with LAL deficiency demonstrated normalization of LAL enzymatic activity. Studies in a preclinical animal model of LAL deficiency have shown that IV injections of SBC-102 correct abnormalities associated with LAL deficiency including: 1) a reduction in liver, spleen and gut size relative to body weight; 2) normalization of gross pathology and histo-pathological abnormalities; and 3) decreases in tissue lipid content. **Conclusions:** 1. SBC-102, a rhLAL produced in EW has properties which allow effective lysosomal targeting to key target cells. 2. Enzyme replacement with rhLAL in an in vivo preclinical model demonstrates that this protein reduces lipid substrate levels in diseased tissues and corrects abnormalities associated with enzyme deficiency. These studies indicate that SBC-102 warrants further investigation as a therapy for LAL deficiency in patients.

Hypophosphatasia in Children: Enzyme Replacement Therapy Using Bone-Targeted, Tissue-Nonspecific Alkaline Phosphatase. *M.P. Whyte[1], C.R. Greenberg[2], D. Wenkert[1], W.H. McAlister[3], K.L. Madson[1], A.L. Reeves[1], K.E. Mack[1], L. Bourrier[4], J.E. Mayhew[5], A.M. Skrinar[5], H. Landy[5].* 1) Center for Metabolic Bone Disease & Molecular Research, Shriners Hospital for Children, St Louis, MO; 2) University of Manitoba, Winnipeg, Canada; 3) Mallinckrodt Institute of Radiology, St. Louis, MO; 4) Clinical Research Unit, Manitoba Institute of Child Health, Winnipeg, Canada; 5) Enobia Pharma, Montreal, Canada.

Hypophosphatasia (HPP) features low serum alkaline phosphatase (ALP) activity caused by deactivating mutation(s) within the gene that encodes the tissue-nonspecific isoenzyme of ALP (TNSALP). The natural substrates for TNSALP that accumulate extracellularly include inorganic pyrophosphate (PPi), an inhibitor of mineralization, and pyridoxal 5'-phosphate (PLP), the principal form of vitamin B6. Rickets occurs because PPi blocks hydroxyapatite crystal growth within the skeletal matrix. HPP severity spans stillbirth from profound skeletal hypomineralization to osteomalacia late in adult life. There is no established medical treatment. ENB-0040 is a bone-targeted, human recombinant, TNSALP fusion protein that preserved skeletal mineralization and survival in a TNSALP knockout mouse model of severe HPP (J Bone Miner Res 23:777, 2008). Patient trials began in 2008. In a 6-mo, open-label study initially of 6 pts (£ 3 yrs) with life-threatening HPP, substantial skeletal remineralization, weaning from respiratory support, and improved motor development occurred with ENB-0040 (2 mg/kg IV followed by 1-3 mg/kg SC 3x/wk). Now, we report a phase II, open-label assessment of ENB-0040 in 13 children with HPP, ages 5-12 yr (2 girls, 11 boys), randomized to receive either 2 or 3 mg/kg SC 3x/wk for 6 mo. One pt awaiting scoliosis surgery was withdrawn, and 12 finished Wk 12. The complete (24-week) study will be reported. Transient injection site erythema was common, but there were no drug-related SAEs. Serum PPi and PLP levels, significantly elevated in all patients at baseline, declined in all and were normal in 8 and 10, respectively, at Wk 12. Increases in circulating parathyroid hormone from enhanced skeletal mineralization occurred in most pts, but without symptomatic hypocalcemia from "hungry bones". Skeletal radiographic improvement was present in nearly all pts by Wk 12; in some as early as Wk 6. All pts reported increased strength, endurance, and mobility within several weeks of ENB-0040 treatment. There was a mean increase in walking distance of 84 meters on a 6-minute walk test at Wk 12 (baseline of 325 m was subnormal), and mean strength and agility composite scores increased from the 3rd to the 10th percentile on the BOT-2. This change accompanied the appearance of running, jumping, and hopping skills. Pain troubled 7 pts at baseline, and only 3 at Wk 12. ENB-0040 is a promising enzyme replacement therapy for children with hypophosphatasia.

Arbaclofen Treatment Is Associated with Global Behavioral Improvement in Fragile X Syndrome (FXS): Results of a Randomized, Controlled Phase 2 Trial. *W.T. Brown[1], R. Hagerman[2], B. Rathmell[3], P. Wang[3], R. Carpenter[3], M. Bear[4], E. Berry-Kravis[5].* 1) Dept Human Gen, NYS Inst Basic Res, Staten Island, NY; 2) UC Davis, Sacramento, CA; 3) Seaside Therapeutics, Cambridge, MA; 4) HHMI & MIT, Cambridge, MA; 5) Rush Univ Med Ctr, Chicago, IL.

Background: Arbaclofen is a GABA-B agonist, and is one of the first targeted treatments for a genetic disorder resulting in neurodevelopmental impairment. The rationale for testing arbaclofen in FXS includes data from mouse and drosophila models of FXS, and from the anecdotal use of racemic balcofen in patients with FXS. Arbaclofen's mechanism is relevant to the mGluR theory of FXS, as pre-synaptic GABA-B stimulation inhibits glutamate release. This study was designed to explore the safety and efficacy of arbaclofen for the treatment of behavioral symptoms in FXS. Methods: A double-blind, placebo-controlled, crossover trial was performed at 12 sites in the United States. 63 subjects (55 male, 8 female) with a full mutation of FMR1, and who met severity criteria on the Aberrant Behavior Checklist - Irritability (ABC-I) subscale, were enrolled. Up to 3 concomitant psychoactive medications were allowed. In each treatment period, study drug was flexibly titrated, then continued at the optimal titrated dose for 4 weeks total. Multiple behavioral and cognitive assessment were performed at baseline, 2 weeks, and 4 weeks in each treatment period. Results: 49 subjects completed the study and had no major protocol deviations. In this group, clinicians ($p= 0.05$) and parents ($p<0.10$) both reported a blinded preference for arbaclofen vs. placebo. These results were more robust among subjects who met criteria for autism ($p<0.01$) or who had higher baseline severity (ABC-I score ≥ 18, $p<0.01$). Similarly, significantly more subjects were "responders" on the Clinician Global Impression - Improvement scale when receiving arbaclofen vs. placebo (35% vs 18% overall, 50% vs. 6% in the autism group, 44% vs. 11% in the high severity group). The ABC-I scale was not sensitive to these effects. However, a post-hoc analysis showed that subjects with higher ABC-Social Withdrawal baseline scores had significant improvement on that scale, consistent with parent reports of improved socialization and communication. Arbaclofen was very well-tolerated and showed no notable weight gain or metabolic side effects. A majority of subjects enrolled in an open-label extension study, and some have withdrawn from their concomitant medications, including from antipsychotics. Conclusions: Arbaclofen shows significant potential for the treatment of behavioral symptoms in FXS, and possibly for the treatment of core social symptoms in autism.

3072/W

Testing the metabotropic glutamate receptor theory in fragile X syndrome: a randomized, placebo-controlled, proof-of-concept study of AFQ056, a novel, sub-type selective mGluR5 inhibitor. *S. Jacquemont[1,8], A. Curie[2,8], Y. He[3], C. Paulding[3], M.G. Torrioli[4], F. Chen[1,5], N. Hadjikhani[5], D. Martinet[1], J. Meyer[3], J.S. Beckmann[1], G. Neri[6], F. Gasparini[7], T. Hilse[7], A. Floesser[7], J. Branson[7], D. Johns[7], V. des Portes[2], B. Gomez-Mancilla[7].* 1) Service de Génétique Médicale, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 2) Service de Neurologie Pediatrique, HFME, Hospices Civils de Lyon - Université Lyon 1, Lyon, France; 3) Biomarker Development, Novartis Institutes for Biomedical Research; 4) Università Cattolica del Sacro Cuore, Cattedra di Neuropsichiatria Infantile, Rome, Italy; 5) Brain Mind Institute, EPFL, Lausanne, Switzerland; 6) Università Cattolica del Sacro Cuore, Istituto di Genetica Medica, Rome, Italy; 7) Neuroscience Discovery, Novartis Pharma AG, Basel, Switzerland; 8) Both authors contributed equally to the study.

Fragile X syndrome (FXS) is the most common cause of inherited mental retardation and is associated with behavioral problems including hyperactivity, attention deficit disorder and autism. It is caused by the expansion of a CGG repeat in the FMR1 gene, leading to hypermethylation, transcriptional silencing of FMR1 and absence or reduced levels of the translational repressor FMR1 protein (FMRP). The metabotropic glutamate receptor (mGluR) theory hypothesizes that without FMRP, uncontrolled protein synthesis occurs in response to activation of synaptic Group I mGluRs and may be the underlying cause of some of the clinical symptoms of FXS. Research in animal models of FXS suggests that mGluR5 may be a valid target for a therapeutic intervention in FXS treatments. The aim of this study was to assess the efficacy of AFQ056, a novel, sub-type selective inhibitor of mGluR5, to improve the behavioral symptoms in people with FXS, and test the validity of the mGluR hypothesis. This was a multicenter, randomized, double-blind, placebo-controlled, two-treatment, two-period cross-over study of AFQ056 in 30 men aged between 18 and 35 years with FXS (NCT00718341). Patients were randomly assigned to receive either AFQ056 then placebo, or placebo then AFQ056. Each treatment period lasted 28 days and the two periods were separated by a wash-out period of at least one week. Patients received 50 mg AFQ056 bid on Days 1-4, 100 mg bid on Days 5-8, 150 mg bid on Days 9-20, 100 mg bid on Days 21-24 and 50 mg bid on Days 25-28. The primary efficacy assessment of behavior was the Aberrant Behavior Checklist - Community (ABC-C) score at Day 19/20. Secondary efficacy assessments included the Clinical Global Impression (CGI) scale, Vineland Adaptive Behavior Scale (VABS), Repetitive Behavior Scale - Revised (RBS-R), Social Responsiveness Scale - Adult Research Version (SRS), Visual Analog Scale of behavior (VAS), KITAP test battery and the Peabody Picture Vocabulary Test - Revised (PPVT-R) scores. This proof-of-concept study was designed to test the effect of inhibiting mGluR5 with AFQ056 on the behavioral symptoms of FXS, and assess the safety of 50-150 mg bid AFQ056 in a population with FXS. A biomarker was shown to distinguish between responders and non-responders to AFQ056 treatment on the behavioral symptoms of FXS. We would like to acknowledge the patients who participated in this study and the Clinical Investigation Center, Hospices Civils de Lyon, Lyon, France.

In utero gene-environment interactions influence asthma susceptibility phenotype in rat models of atopy and airway hyperresponsiveness. *N. Carpe[1,2], I. Mandeville[1], F. Kaplan[1,2].* 1) Montreal Children's Hospital Research Institute, Montreal, Quebec, Canada; 2) Department of Human Genetics, McGill University, Montreal, Canada.

Rationale. Asthma, affecting 6.8 million children in the US, is a leading cause of childhood morbidity. Existing evidence suggests that increased prevalence of asthma derives from early exposures acting on pre-existing asthma-susceptible genotypes. Abnormalities of the lung already exist in infants who subsequently develop asthma. We showed previously that diverse transcriptome signatures are associated with distinct developmental respiratory phenotypes in rat strains that model the traits of airway hyperresponsiveness (AHR, Fisher)and atopy (Brown Norway, BN). Hypothesis. We hypothesized that, in these models, in utero allergen exposure would amplify individual variation in asthma risk and perturb innate patterns of lung gene expression. Methods. Fisher, BN and Lewis (control) rats were sensitized to ovalbumin(OVA) or saline 14 days prior to mating. Pregnant dams were challenged with aerosolized OVA or saline and pups were collected at postnatal days (PN)1, 7 or 14. Outcome assessments included lung function (PN14), bronchoalveolar lavage (BAL) cell differentials (PN1-14), and serum IgE levels(PN14). Expression of genes previously implicated in asthma and/or with strain specific expression patterns were assessed by Real-Time PCR. Results. Fisher pups of saline exposed dams displayed elevated airway resistance following methacholine challenge compared to Lewis and BN. All pups exposed to OVA in utero showed increased lung resistance. This increase was most pronounced in Fisher pups. Fisher pups of saline exposed dams consistently exhibited elevated BAL neutrophils compared to Lewis and BN (PN1-14). In utero OVA-exposed Fisher pups also showed a significant increase in BAL neutrophils when compared to saline-exposed Fisher pups at PN7. Maternal OVA exposure led to a significant increase in BAL eosinophil levels in BN pups compared to saline-exposed BN pups and to OVA-exposed Lewis and Fisher pups. There was also a trend towards increased serum IgE levels in in utero OVA-exposed BN pups. In utero OVA exposure amplified differences in lung gene expression of Serpina1 and Ficolin B(Fisher) and Ly-6B and Egfr(BN)compared to Lewis pups. Conclusion. In utero exposures that interact with pre-existing respiratory genotypes in the developing lung influence asthma susceptibility traits. The delineation of specific molecular and environmental determinants of respiratory susceptibility has implications for both pediatric and adult pulmonary health.

Development of Neocentromere-based minichromosome gene delivery system. *Y. Inaba[1, 2], L.H. Wong[1], K.H.A. Choo[1].* 1) Chromosome and Chromatin Research Laboratory, Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 2) Department of Paediatrics, The University of Melbourne, Parkville, Victoria, Australia.

Human engineered chromosomes (HECs) have been generated to overcome many of the hurdles presented by other gene delivery systems such as viral vector system. They are fully functional chromosomes containing the minimal genomic content compatible with correct mitotic function, and have the capacity to carry large transgene or gene clusters (> 300 kb). The neocentromere of marker chromosome Mardel 10, derived from chromosome 10 provides a highly desirable source for HEC construction. Mardel 10 neocentromere-based minichromosomes (NC-MiCs) were generated as a therapeutic gene vector, by truncation of the chromosome arms and successful incorporation of a loxP site specific sequence. The availability of purified NC-MiC is essential to achieving successful HEC delivery. Currently Flow cytometry is the most efficient method for sorting single chromosomes at a high level of purity. NC-MiC1 (3.5Mb in size) was successfully isolated with high purity confirmed by reverse chromosome painting. The same approach was applied to sort NC-MiC6 (1.4Mb) and the use of multiple gates lead to 20-40 times enrichment in the sorted samples. Such levels of purification of minichromosomes less than 2Mb in size has not been previously reported and opens the way for the use minichromosome preparations carrying less background genetic material. While comparing the NC-MiC6 quantity in each sorted samples, we developed a new DNA quantification method. It is relatively simple and quick, and importantly more sensitive (with a confirmed threshold up to 0.12pg) than currently available DNA quantification methods. The next phase of our approach will focus on the integration of therapeutic genes into NC-MiC and its delivery into various cell lines.

Long-term phenotypic correction of a lethal mouse model of methylmalonic acidemia using rAAV9-mediated gene therapy and metabolic improvement after re-boosting at 1 year. *J.S. Sénac, R.J. Chandler, C.P. Venditti.* Genetics and Molecular Biology Branch, NHGRI, NIH, Bethesda, MD.

Methylmalonic acidemia (MMA) is an inherited metabolic disorder most commonly caused by the deficient activity of methylmalonyl-CoA mutase (MUT). The disorder carries a poor prognosis for long-term survival. We have recently demonstrated that gene therapy with an adeno-associated virus serotype 8 (rAAV8) vector can both rescue $Mut^{-/-}$ mice from neonatal lethality and provide long-term phenotypic correction. Over time, hepatic Mut RNA levels and Mut protein significantly decreased in the rAAV8 treated $Mut^{-/-}$ mice, suggesting that translation to human subjects may require multiple rounds of gene delivery throughout life. Our goal was to develop a new gene therapy vector using an alternative AAV serotype. We engineered an rAAV9 vector to express the murine Mut cDNA under the control of an enhanced chicken beta actin promoter (rAAV9-CBA-mMut). rAAV9-CBA-mMut was delivered directly into the liver of newborn $Mut^{-/-}$ mice at a dose of $1x10^{10}$ GC (N=9). A small group (N=5) of older treated $Mut^{-/-}$ mice were re-injected via the intraorbital route after 1 year with $2x10^{9}$ GC per gram. Effects on survival, growth, metabolites, in vivo propionate oxidative capacity were used to determine the efficacy of rAAV9 gene therapy. Untreated $Mut^{-/-}$ mice (N=58) uniformly perish, with most dying during the newborn period. However, rAAV9 treated $Mut^{-/-}$ mice survived for more than 1 year. On an unrestricted mouse diet, the treated $Mut^{-/-}$ mice displayed elevated methylmalonic acid levels in the plasma yet were vigorous and have maintained 80% of the weight of age, sex and diet matched controls. Expression of the Mut transgene, as early as 24 hours post injection, appears to correlate with early phenotypic correction. rAAV9 treated mice that received a second dose at one year showed metabolic improvements as early as 72 hours post injection and experienced a full correction of propionate oxidative capacity 2 weeks post injection. These experiments demonstrate that rAAV9 is an efficient gene therapy vector for the treatment of MMA in a mouse model that faithfully replicates a severe form of the disorder, even at lower dose than that used in previous studies with rAAV8. Re-treating older $Mut^{-/-}$ mice with a dose of rAAV9 similar to that used in human clinical trials produced a measurable effect, rapidly. Our data support the use of rAAV9 as a vector with potential human translation in the treatment of MMA.

CELL AND GENE THERAPY FOR ANTIGEN-SPECIFIC TOLERANCE INDUCTION AGAINST THERAPEUTIC PROTEINS. *G. Sule[1], M. Suzuki[1], R. Cela[1], J. Rodgers[3], B. Lee[1,2].* 1) Baylor College of Medicine , Department of Molecular and Human Genetics, Houston, TX; 2) Howard Hughes Medical Institute; 3) Baylor College of Medicine, Department of Pathology & Immunology Houston, TX.

Immune reaction towards a particular therapeutic protein leads to alleviation of the beneficial effects of the protein. This is particularly seen in Hemophilia A patients, where about a third of them develop inhibitory antibodies to recombinant protein as a consequence of the repeated protein infusions. Induction of tolerance towards therapeutic protein would prevent such an antibody response and hence prolong the efficacy of the therapeutic protein. Tolerogenic dendritic cells (DCs) have the unique ability to initiate and direct the host immune response towards peripheral tolerance. Cytokines such as IL-10 and TGF-β1 have been identified as key mediators of tolerogenic response. Thus, we hypothesize that the genetic modification of DCs to produce immune modulatory cytokines such as TGF-β1 and IL-10 will enable us to generate antigen specific immune tolerance. Our in vitro studies show, transducing DCs by helper-dependent adenovirus to express hTGF-β1 and vIL-10 renders them semi-mature. These DCs demonstrate tolerogenic characteristics by, preventing T cell proliferation, and increasing the frequency of regulatory T cells. Adoptive transfer of antigen-loaded, transduced DC to mice prior to protein treatment induced suppression of the immune response towards the protein. These mice also show a decrease in protein specific antibody formation. This report demonstrates that autologous cell therapy for antigen-targeted immune suppression may be developed to facilitate long-term therapy. Additionally, this study would have broader implications in solid organ transplantation, immune response to protein replacement therapies, and auto-immune diseases like diabetes and inflammatory bowel disease where proinflammatory responses are undesirable.

Characterization of host sensing mechanism of helper-dependent adenovirus for gene therapy of Hemophilia A. *M. Suzuki[1], V. Cerullo[1,4], T. Bertin[1], C. Racel[1], C. Clarke[1], R. John[2], B. Lee[1,3].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Immunology, Baylor College Med, Houston, TX; 3) Howard Hughes Medical Institute; 4) University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland.

Hemophilia A is a common inherited coagulopathy caused by deficiency of factor VIII (FVIII) activity. Previously, we focused on gene therapy of hemophilia A using helper dependent adenovirus (HDAd) encoding FVIII in both dog and mouse models. However, host antibody response to hFVIII has been a limitation of these therapies. We hypothesized that the innate immune response to HDAd may correlate with the induction of adaptive immune response to transgene product delivered with these vectors. Recently we demonstrated that TLR/MyD88 signaling is required for maximal innate and acquired (Th1) immune responses following systemic administration of helper-dependent adenoviral vectors (HDAds). However, MyD88-deficient mice injected with HDAdLacZ exhibited only partial reduction of innate immune cytokine expression compared with that of wild-type (WT) mice, suggesting MyD88-independent pathways also respond to HDAds. Our results indicate that NOD2, a NOD-like receptor known to detect muramyl dipeptides in bacterial peptidoglycans, also contributes to innate responses to HDAds and empty adenoviral particles lacking vector DNA, but does not mediate humoral or Th1 immune responses. Indeed, NOD2-deficient mice exhibited significantly higher transgene expression than did WT mice. Macrophages, especially Kupffer cells, play an important limit for adenovirus gene therapy in vivo. Bone marrow-derived macrophages from NOD2-deficient mice also exhibit lower innate response and higher transgene expression in vitro compared to WT. These results indicate that the intracellular sensor NOD2 is required for innate responses to adenovirus protein and limiting transgene expression. Our results suggest that the use of HDAd still faces hurdles, especially induction of acute toxicity through pathogen-recognition receptors. We need to understand better the molecular mechanisms of how host cells recognize HDAd and induce innate responses to improve the therapeutic index of these vectors.

Identification of triplet repeat disease-causing alleles by a novel pull-down method and disease-causing allele specific silencing by RNAi. *M. Takahashi[1], S. Watanabe[1], M. Murata[1,2], H. Furuya[3], I. Kanazawa[1,2], K. Wada[1], H. Hohjoh[1].* 1) National Institute of Neuroscience, NCNP, Kodaira, Tokyo, Japan; 2) National Center Hospital, NCNP, Kodaira, Tokyo, Japan; 3) Neuro-Muscular Center, National Omuta Hospital, Fukuoka, Japan.

Nucleotide variations including single nucleotide polymorphisms (SNPs) in the coding region of disease genes are essential as targets for a potential tailor-made RNA interference (RNAi) treatment, which is promising for intractable diseases such as triplet repeat diseases, and for which it is vital to find such nucleotide variations linked to diseases. Here we show rapid determination of coding SNPs (cSNPs) haplotypes in triplet repeat disease-causing alleles by a novel and easy-to-use pull-down method, followed by SNP typing. The method is based on the hybridization and fractionation techniques using biotinylated CAG ribonucleotide repeat probe (biotin CAG RNA probe). The cDNAs synthesized from total RNAs prepared from Huntington's disease (HD) patients' specimens were treated by the pull-down method, and the resultant cDNAs were examined by conventional PCR analysis for expansion of CAG trinucleotide repeats. As a result, abundant PCR amplicons derived from aberrantly expanded CAG repeats were markedly detected, suggesting that biased collection of the mutant *HTT* cDNAs was performed by the method. The subsequent SNP typing using the cDNAs further revealed the SNP haplotypes of the mutant *HTT* alleles; and then, based on the haplotypes, we demonstrated disease-causing *HTT* allele specific silencing by RNA interference targeting the determined allelic nucleotides at the SNP sites. The current procedure has also achieved a great deal of reduction of processing time to determine the disease-causing alleles: it takes about 6 hours for the determination, whereas conventional procedures usually take at least one week. We further indicate that the procedure may be available for other triplet repeat disease genes, for example, *ATXN3*, *CACNA1A*, and *ATN1*, to identify their disease-causing alleles. Taken together, our current procedures may contribute to achievement of a tailor-made RNAi treatment for intractable triplet repeat diseases.

3079/W

Adeno-Associated Virus Serotype 8 (AAV8) Gene Transfer Rescues a Neonatal Lethal Murine Model of Propionic Acidemia. *R.J. Chandler[1, 2], S. Chandrasekaran[1], T.M. Cowan[3], C.P. Venditti[1].* 1) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Institute for Biomedical Sciences, The George Washington University, Washington, DC; 3) Department of Pathology, Stanford School of Medicine, Stanford, CA.

Propionic Acidemia (PA) is an autosomal recessive inborn error of metabolism caused by a deficiency of the mitochondrial enzyme propionyl-CoA carboxylase, encoded by the *PCCA* and *PCCB* genes. Defects in either the *PCCA* or *PCCB* gene can cause PA. Despite dietary and cofactor therapy, PA patients still suffer from life-threatening metabolic instability as well as numerous chronic disease related complications. A murine model of PA (*Pcca*$^{-/-}$) was created that replicates the severe neonatal manifestations of PA and perishes within the first 48 hours of life. A recent study describes adenoviral gene delivery of the human *PCCA* cDNA to *Pcca*$^{-/-}$ mice and reports a modest increase in life expectancy (maximum increase of less than 40 hours) without demonstrating PCCA expression or metabolic correction. Therefore, whether gene transfer is a potential treatment for PA remains uncertain. To determine the efficacy of AAV gene transfer as a therapy for PA, we engineered an AAV8 vector to express the human *PCCA* cDNA under the control of a combined CMV-enhancer-chicken beta actin promoter and injected 1x10^10 genome-copies of the virus into the liver. Survival effects, phenotypic correction, transgene expression and biochemical parameters were studied in the treated mice to determine the efficacy of gene transfer. We rescued a total of 9 *Pcca*$^{-/-}$ mice from certain death with AAV8 mediated gene transfer. Two treated *Pcca*$^{-/-}$ mice were sacrificed at day 16 of life to confirm PCCA expression. Immunoblots of liver extracts from the treated *Pcca*$^{-/-}$ mice revealed levels of hepatic PCCA protein greater than wild-type mice. No hepatic Pcca protein was detected in the untreated *Pcca*$^{-/-}$ mice. The treated *Pcca*$^{-/-}$ mice also exhibited markedly reduced plasma levels of propionylcarnitine and 2-methylcitrate compared to the untreated *Pcca*$^{-/-}$ mice, which indicates significant levels of propionyl-CoA carboxylase enzymatic activity were achieved after gene transfer. At the time of this report, the oldest treated *Pcca*$^{-/-}$ mice were over one month of age and not discernable from their wild-type littermates. In summary, AAV gene delivery of PCCA effectively rescues *Pcca*$^{-/-}$ mice from neonatal lethality, restores growth and substantially ameliorates metabolic markers of the disease state. These experiments are the first to demonstrate that gene transfer might be used as a treatment for PA, a devastating and often lethal disorder desperately in need of new therapeutic options.

Early intrathecal and intravenous enzyme replacement therapy improves gene expression alterations in cortical neurons in canine mucopolysaccharidosis I. *P.I. Dickson[1], B.L. Tippin[1], N.M. Ellinwood[2], S.Q. Le[1], S. Kan[1], S. Karsten[1].* 1) LA BioMed Harbor-UCLA Med Ctr, Torrance, CA; 2) Department of Animal Science, Iowa State University, Ames, IA.

Introduction: Glycosaminoglycan (GAG) storage in brain normalizes after intrathecal enzyme replacement therapy (IT ERT) for canine mucopolysaccharidosis I (MPS I), but downstream effects on neuronal function are not known. Methods: We studied normal dogs (n=4, age 14-22 m), untreated MPS I dogs (n=4, 17-28 m), and MPS I dogs treated with IT and intravenous (IV) ERT (n=4, 15-18 m). Treated dogs received 0.05 mg/kg IT ERT diluted in artificial spinal fluid delivered into the cistern magna every three months starting from 12-112 d old and weekly 0.58 mg/kg IV ERT starting from 3-23 d old. Treatment continued for 56-80 weeks. Animals were sacrificed 48 hours after the final IT ERT dose and brains removed, quick frozen and stored at -80°C until analysis. Laser capture microdissection was performed by NeuroInDx (Signal Hill, CA) of frontal cortical neurons stained with Cresyl violet. Total RNA extracted from ≥200 neurons per dog underwent a two-round T7-based amplification labeling process and was hybridized onto canine whole genome microarrays (Agilent). Data analysis was performed with the TM4 software suite (http://www.tm4.org/) and DAVID, PANTHER, OMIM and KEGG databases. Results: There were 320, 1380, and 280 differentially regulated genes, respectively in Untreated vs. Normal, Treated vs. Normal, and Untreated vs. Treated dogs. The expression pattern of ~75% of genes with altered expression showed normalization of 15% or more with IT+IV ERT. Thirteen processes showed ≥2-fold enrichment in Untreated MPS I vs. Normal. These included synaptic transmission, transmission of nerve impulse, actin cytoskeleton organization and biogenesis, cellular homeostasis, visual perception, sensory perception of light stimulus, cellular chemical homeostasis, cellular ion homeostasis, proteolysis, actin filament-based process, RNA processing, ion homeostasis, and cell maturation. The majority of genes in these processes showed a normalized expression pattern after IT+IV ERT. Conclusion: Gene expression is altered in frontal cortical neurons of MPS I dogs, affecting critical pathways. Early IT+IV ERT may improve cortical neuronal gene expression in the MPS I dog.

Discovery and Evaluation of a Non-Iminosugar Glucocerebrosidase Inhibitory Series with Chaperone Activity. *O. Motabar[1,2], W. Zheng[2], J. Marugan[2], E. Goldin[1], W. Westbroek[1], N. Southall[2], E. Sidransky[1].* 1) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) NIH Chemical Genomics Center, NHGRI, NIH, Rockville, MD.

Gaucher disease is a lysosomal storage disorder (LSD) caused by a deficiency in the enzyme glucocerebrosidase (GC). Small molecule chaperones have been proposed as a promising therapeutic approach for the treatment of LSDs. Most of the small molecule chaperones described in the literature have iminosugar scaffolds. Here, we present the discovery and evaluation of a new series of GC inhibitors with quinazoline cores. This series was discovered through the quantitative high throughput screening (qHTS) of 326,770 compounds, in which several quinazoline analogues were identified. Structure-activity relationship (SAR) optimization yielded compounds with an IC50 close to 300 nM. These compounds were able to inhibit the hydrolysis of the natural substrate, and were selective for GC when tested against other lysosomal enzymes. Thermal denaturation experiments demonstrated the capacity of this series to stabilize GC. Immunocytochemistry on control and GC deficient fibroblasts with anti-GC and anti-LAMP2 antibodies was performed followed by laser scanning confocal microscopy. Upregulation and colocalization of GC to the lysosomes was seen with some of the compounds from this series. Systematic synthetic modifications enhancing the usefulness of these compounds are presented as part of the SAR. This new class of GC inhibitors may open new avenues for the development of alternative therapies for patients with Gaucher disease.

Global Differential Gene Profiling of Patients with VCP-Associated Myopathy and Paget Disease of Bone. *A. Nalbandian[1], E. Dec[1], S. Ghimbovschi[2], S. Aizik[3], J. Vesa[1], M. Badadani[1], G. Watts[4], C. Smith[5], B. Martin[5], E. Hoffman[2], V. Kimonis[1].* 1) Department of Pediatrics, Division of Genetics and Metabolism, University of California, Irvine, Irvine, CA; 2) Children's National Medical Center, Research Center Genetics Medicine, Washington, DC; 3) Department of Pediatrics, General Clinical Research Center, University of California, Irvine, CA; 4) School of Medicine, Health Policy and Practice, University of East Anglia, Norwich, Norfolk, UK; 5) Department of Neurology, University of Kentucky Medical School, Lexington, KY.

Inclusion body myopathy associated with Paget's disease of the bone and frontotemporal dementia (IBMPFD) is caused by mutations commonly in the ubiquitin binding domain of the Valosin Containing Protein (VCP) gene on 9p12-13. IBMPFD is characterized by progressive, proximal muscle weakness, ubiquitin and TDP-43 inclusions and LC3+ and p62+ vacuoles in muscle fibers, malfunction in the bone remodeling associated with increased osteoclastic activity, and premature frontotemporal dementia. VCP is a ubiquitously expressed member of the type II AAA+ ATPase family and is involved in several cellular processes including post-mitotic nuclear envelope reformation, Golgi reassembly, cell cycle progression, endoplasmic reticulum degradation of defective proteins and DNA damage repair. To elucidate the affected signaling transduction axes in IBMPFD quadriceps samples from 16 patients and unaffected relatives, we determined expression profiles by Affymetrix GeneChip Human Genome Array. Differentially dysregulated genes analyzed by DAVID included the actin cytoskeleton, ubiquitin-mediated proteolysis, lysosomal and MAPK signaling transduction pathways. Statistical analyses of the obtained expression data revealed that 279 genes were differentially expressed in patients' muscle ($p<0.01$). Most of the dysregulated genes were shared with other muscle dystrophies except for the striking downregulation of Platelet-Derived Growth Factor Receptor Alpha (PDGFR-α), Nitric Oxide Synthase 3 (NOS3), and Fibroblast Growth Factor Receptor 2 and upregulation of Cytochrome P450, and family 19, subfamily a, polypeptide 1 (CYP19A), validated by qPCR. Defective PDGFR-α expression is involved in the progression of muscular dystrophies in the promotion of muscle fibrosis as well as in the active stage of tissue destruction. Nitric oxide (NO) mediates fundamental physiological actions on skeletal muscle and NOS3 levels are altered in muscular dystrophy. Additionally, studies have revealed that FGFs/FGFRs levels are tightly regulated and play essential functions in skeletal development and adult homeostasis. Future studies will clarify how PDGFR-α, NOS3 and FGF signaling may result in impaired autophagic degradation, increased apoptosis, defective myotube formation, and associated muscle weakness in IBMPFD patients. Our study is the first to compare gene expression profiling in IBMPFD patients, providing insights into the pathways involved in VCP disease and potential future therapies.

Long-Term Follow-up of Patients with Leber's Optic Neuropathy Treated with Co-enzyme Q or Idebenone. *S.C. Benes[1], D.W. Hauswirth[2], K. Vesper[3], O. Bartlett[4].* 1) Eye Ctr Columbus, Columbus Children's Hosp, Columbus, OH; 2) Columbus Children's Hospital, Ohio State University; 3) Ohio State College of Veterinary Medicine; 4) Salida Hospital, Colorado.

This observational study of 24 affected patients with Leber's optic neuropathy describes the reversibility of central vision loss in patients treated with either co-enzyme Q or idebenone and followed for 18-25 years. Of the 8 with the 11778 mutation, 2 had recovery of vision (in 1 eye and 2 eyes); of the 6 with the 3460 mutation, 1 recovered vision in both eyes; of the 5 with 15257 mutation, 3 recovered vision in both eyes; the 1 patient with both the 13708 and 15257 mutations recovered vision in both eyes. Our patients with other mutations had no improvement with either co-enzyme Q or idebenone (2 with 4917, 1 with only 13708, 1 with 14484). References: Mashima Y, Hiida Y, Oguchi Y. Remission of Leber's hereditary optic neuropathy with idebenone. Lancet. 1992;340:368-369 Mashima Y, Kigasawa K, Wakakura M, Oguchi Y. Do idebenone and vitamin therapy shorten the time to achieve visual recovery in Leber hereditary optic neuropathy? J Neuro-ophthalmol. 2000;20:166-170 Huang cc, Kuo HC, Chu CC, Kao LY. Copper and bezafibrate cooperate to rescue cytochrome c oxidase deficiency in cells of patients with SCO2 mutations. *L. Salviati[1], A. Casarin[1], G. Giorgi[1], E. Trevisson[1], M. Doimo[1], V. Pertegato[1], R. Rizzuto[2], S. DiMauro[3], M.M. Davidson[3], E.A. Schon[3].* 1) Pediatrics, University of Padova, Padova, PD, Italy; 2) Biomedical Sciences, University of Padova, Italy; 3) Neurology, Columbia University, New York, NY.

Cytochrome c oxidase (COX) deficiency is a clinically and genetically heterogenous mitochondrial disoreder usually causes by defect in ancillary factors required for the assembly of the COX holoenzyme, encoded by COX-assembly genes. Mutations in SCO2 present with COX deficiency associated to neonatal-onset, rapidly fatal, cardiomyopathy and encephalomyopathy. SCO2 encodes a protein involved in copper delivery to COX, and it has been shown that supplementation with copper salts can rescue the COX deficiency in cells of patients with mutations in this gene. Recently, it has been also shown that treatment with bezafibrate (BZF), a drug that induces mitochondrial biogenesis by stimulating the PGC1-alpha/PPAR-gamma pathway, may ameliorate the COX deficiency in cells and in mice with mutations in COX10, another COX-assembly gene. We have investigated the effect of BZF on cells with mutations in SCO2. We found that respiratory chain complex displayed different responses to BZF, and COX activity increased of about 40% in all cell lines we tested (both WT and COX-deficient). SCO2 cells reached about 80% COX activity compared to untreated controls. The increase in COX activity was associated with an increase in cellular ATP. The effect was dose dependent with a maximum with BZF concentrations around 400 uM. We did not observe a plateau with higher doses of the drug, but rather there was a relative reduction of COX activity. Combined treatment with 100 uM CuCl2 and 200 uM BZF (which are only marginally effective when administered alone) could achieve complete rescue of COX activity in SCO2 cells. We show that CuCl2 treatment increases the steady-state levels of the mutant Sco2p, suggesting that the mechanism of action involves a stabilization of the mutant protein, which in turn allows a more efficient assembly of COX stimulated by BZF. These data are crucial to design future therapeutic trials with these compounds for this otherwise fatal disorder. In fact, the additive effect of these two compounds will allow to employ lower doses of each drug, avoiding potential toxic effects.

Environmental enrichment modulates phenotypic manifestations of a mouse model of Rett Syndrome trough a non-standard transcriptional program. *P.A. Silva[1], B. Kerr[1], K. Walz[2], J.I. Young[1, 2].* 1) Centro de Estudios Cientificos, Valdivia, Chile; 2) John P. Hussman Institute for Human Genomics. Miller School of Medicine, University of Miami, 1501 NW 10th Ave, Miami, Fl 33136.

Rett syndrome (RTT) is an X-linked disorder characterized by psychomotor retardation, purposeless hand movements, autistic-like behavior, abnormal gait and one of the leading causes of mental retardation in females. RTT is caused by mutations in the gene encoding methyl-CpG binding protein 2 (MeCP2). We here report the effects of environment enrichment (EE) on the phenotypic manifestations of a RTT mouse model that lacks MeCP2 (Mecp2-/y). We observed that EE delayed and attenuated some neurological alterations presented by Mecp2-/y mice and prevented the development of motor discoordination and anxiety-related abnormalities. To define the molecular correlate of these effects of EE on the RTT-like phenotypes, we analyzed the expression of several synaptic marker genes whose expression is increased by EE in several mouse models. We found that EE induced downregulation of several synaptic markers, suggesting that neurons lacking MeCP2 are unable to respond to EE through canonical pathways and that the partial prevention of RTT-associated phenotypes is achieved through a non-conventional transcriptional program. The EE-induced decrease in mRNA levels for synaptic proteins in Mecp2-/y mice suggests a reduction in synapse number. Since our EE program started when mice were of 3 weeks of age, these results could reflect an interference in the process that culminates with synapse number compensation or a loss of synapses during EE. Our data strengthen the hypothesis that alterations in synaptic function underlie the pathophysiology of Rett syndrome.

3086/W

The effect of different levels of dystrophin on muscle function and pathology in mouse models. *M. van Putten, V.D. Nadarajah, E. van Huizen, M.A. Hulsker, T. Messemaker, P.A.C. 't Hoen, G.J.B. van Ommen, J.T. den Dunnen, A.M. Aartsma-Rus.* Human Genetics, Leiden University Medical Center, Leiden, Netherlands.

In patients with Duchenne Muscular Dystrophy (DMD) frame shifting or non sense mutations in the *DMD* gene lead to the synthesis of truncated, non functional dystrophin proteins. Fibers lacking dystrophin are more injury-susceptible, which exhausts the regenerative capacity leading to severe muscle wasting, functional impairment and death in the mid twenties. Several therapeutic approaches currently under investigation aim to restore the synthesis of functional dystrophin to improve the phenotype. It is largely unknown which levels of dystrophin are minimally needed for restoration of muscle function, integrity and protection against exercise induced damage. Similarly, a correlation between dystrophin levels and these parameters has never been studied in detail. To address these issues we have generated a mouse model with varying, low levels of dystrophin. These mice were generated by crossing female mice carrying a mutation in the Xist promoter (coordinating X-inactivation) with dystrophin negative *mdx* males. During embryogenesis, due to the preferential inactivation of the maternal X chromosome the mutant *DMD* gene will be active in 60-90% of the cells resulting in low dystrophin levels. In female offspring (*mdx-xist*) dystrophin levels varied from 5-40%. Dystrophin positive fibers were spread randomly across the muscles. *Mdx-xist*, *mdx* and wildtype females were divided in groups that participated in a 12 week functional test regime, aiming to either assess muscle function (grip strength, rotarod, 2 and 4 limb hanging wire tests), muscle integrity (2x per week horizontal treadmill running) or muscle function after chronic exercise (3x per week horizontal treadmill running directly followed by a functional test). Overall, *mdx-xist* mice outperformed *mdx* mice in the functional tests, had improved histopathology and normalized pro-inflammatory biomarker expression in a dystrophin level dependent manner. Furthermore, body weight and creatine kinase levels were lower in the *mdx-xist* mice. Based on these findings the *mdx-xist* mouse offers great possibilities to study the effect of different levels of dystrophin on different outcome measures.

Stabilization of Transthyretin by Tafamidis in Transthyretin Amyloidosis Patients Across Different Amyloidogenic Variants. *J. Packman[1], R. Labaudinière[1], J. Fleming[1], E. Souther[2], D. Grogan[1].* 1) FoldRx Pharmaceuticals, Inc., Cambridge, MA; 2) Genzyme Genetics Analytical Services, Los Angeles, CA.

Background: Homotetrameric transthyretin (TTR) is one of 20 proteins that form fibrillar deposits in human amyloidoses. There are >100 mutations associated with TTR amyloidosis (ATTR). The two most common are V30M and V122I (associated with polyneuropathy and cardiomyopathy, respectively). Wild-type (wt) and mutated variants are involved in amyloid disease, but a mutation in TTR accelerates fibrillogenesis. The rate determining step is tetramer dissociation leading to monomers that misfold and misassemble into amyloid fibrils. Two trans-suppressor TTR variants (T119M and R104H) confer protective clinical effects by increasing resistance of TTR tetramer to dissociation. Tafamidis, by binding to and stabilizing tetrameric TTR, is a potent inhibitor of TTR dissociation, mimicking the overall stabilization effect shown by the trans-suppressors. The ability of tafamidis to stabilize TTR in ATTR patients with different mutations was evaluated. Methods: Plasma samples were obtained from patients administered 20 mg tafamidis in 3 clinical trials: an 18-month, randomized, double-blind, placebo-controlled trial in V30M ATTR patients (N=125) and two 12-month, open-label trials—one in nonV30M ATTR patients (N=21) and one in V122I or wt ATTR patients (N=35). Using an immunoturbidimetric assay, samples were incubated under urea denaturing conditions and the ratio of tetramer after and before denaturation was determined. The mean and 95% confidence interval (CI) for the percent stabilization were previously determined in healthy volunteers to determine a stabilization cutoff. Values obtained from ATTR patients above this cutoff were deemed to be "stabilized". Results: Nine nonV30M mutations (V122I, Leu58His, Phe64Leu, Thr60Ala, Gly47Ala, Ile70Val, Ser77Tyr, Asp38Ala, Ser77Phe), and wt and V30M were evaluated. At the first assessed time point, stabilization was observed for all TTR mutations in tafamidis-treated patients: V30M (n=63) 98%, nonV30M (not V122I, n=19) 95%, V122I (n=4) 100%, as well as wt (n=31) 97%. Only 7% of V30M placebo-treated patients (n=60) were stabilized. Results were similar at the end of treatment. Conclusions: TTR stabilization during chronic dosing with tafamidis was observed for V30M, nonV30M, and wt genotypes in ATTR patients that should translate clinically to reduced disease progression.

SMA therapy with valproate (VPA): Why do we have Positive- and Non-Responders? *B. Wirth[1], L. Heesen[1], I. Hölker[1], T. Bauer[2], C. Müller[2], J. Dimos[3], R. Heller[1], L. Garbes[1].* 1) Institute of Human Genetics, Institute of Genetics, and Center for Molecular Medicine Cologne, Cologne, Germany; 2) Institute of Pharmacology, Cologne, Germany; 3) iPierian, San Francisco, USA.

Spinal muscular atrophy (SMA) is the most frequent genetic cause of childhood lethality. SMA is caused by functional loss of *SMN1* but all patients retain an almost identical copy gene, *SMN2*. However, *SMN2* is unable to compensate for the loss of *SMN1* since it produces only low amounts of full-length transcripts, while the majority is alternatively spliced. Within the last years a plethora of compounds has been identified that activate transcription and/or restore the correct splicing of *SMN2* or stabilize the SMN2 protein *in vitro* or in SMA-like mice. We showed that valproic acid (VPA), a short-chain fatty acid histon deacetylase (HDAC) inhibitor, significantly increases SMN levels *in vitro*, *ex vivo* and in VPA-treated SMA patients. However, only about 1/3 of SMA patients are such responders, whereas the remaining are non- or even negative responders. To answer the question why only a subset of patients positively responds to VPA, we obtained skin biopsies from all SMA patients included in our previous study and treated them with VPA. We found a strong correlation between both cell systems - fibroblasts and white blood cells. Next, we used fibroblast mRNA from positive- and negative-responders, either mock or VPA-treated to identify transcriptome-wide expression differences. qRT-PCR helped us to confirm four candidate genes - two of them significantly up-regulated and two transcripts down-regulated in positive-responders compared to non-responders. Interestingly, one of the latter genes is involved in fatty acid metabolism suggesting a disturbed VPA turnover in non-responders. To clarify this issue we are currently analyzing VPA metabolism in fibroblasts derived from both groups. In addition, overexpression and knockdown studies showed that the four genes belong to a common pathway and are influencing each other. Lastly, we already succeeded in generating induced pluripotent stem cells (iPS) from fibroblast lines of positive- and non-responders. Differentiating these cells into motoneurons will allow us to verify our fibroblast data in the actual SMA target cells. Understanding the molecular mechanisms and pathways influencing VPA response will have a major impact on therapy of SMA and of other diseases like epilepsy and mood disorders, where VPA is frequently used. Furthermore, pre-therapeutic analysis of candidate gene expression will avoid ineffective drug administration and advance SMA patients' perspective.

Division of Pediatric Genetics, Joe DiMaggio Children's Hospital, Hollywood FL. *P. Benke.* Pediatric Gen, Joe Dimaggio Children's Hosp, Hollywood, FL.

Last year we described preliminary observations of treatment of a boy with Ehlers Danlos Syndrome IV (EDIV) with Losartan. This boy had small size, easy bruisability, hyperextensible joints, thin skin, thin hair, and poor subcutaneous tissue with highly visible veins. A c.3554 G>A mutation in Exon 49 of the Col3A1 gene was shown (Univ. Washington). Losartan (50-75 mg/day) appeared to increase abdominal wall skin thickness, and decrease venous prominence of the abdomen, but did not improve easy bruisability, growth or weight gain. A second child with EDIV has since been treated for 8 months, and again, abdominal skin thickness and abdominal vein appearance showed some improvement, but there was no effect on easy bruisability, growth or weight gain. The first patient suffered a traumatic blow to the lower abdomen, resulting in a large hematoma as the child began year 2 of therapy. The finger tips and skin of the hands became thin and tight. Since the latter may have been a complication of therapy, and the therapy was not having an effect on bruising or growth, it was suggested to the family that the medication be discontinued. They agreed and therapy was withdrawn. The tight, thin finger tip skin did not improve after Losartan therapy was discontinued. For the second child, a dilated subclavian vein was discovered during the course of therapy of Losartan 50 mg/day. It was recommended that Losartan be discontinued in this child as well. Easily measurable findings such as dilated aortic arch are not part of the presentation of EDIV. For the important matters that are, success with Losartan treatment has not been observed.

DEVELOPING A CELLULAR ROADMAP FOR CORRECTORS OF CFTR MISFOLDING. *L.C. Pyle[1], W.E. Balch[2], G. Lukacs[3], I. Braakman[4], W.B. Guggino[5], P.J. Thomas[6], C. Penland[7], H.B. Pollard[8], J.L. Brodsky[9], R.A. Frizzell[10], E.J. Sorscher[1], W.R. Skach[11].* 1) Gregory Fleming James Cystic Fibrosis Research Center, University of Alabama at Birmingham, Birmingham, Alabama; 2) Department of Cell Biology, The Scripps Research Institute, La Jolla, California; 3) Department of Physiology, McGill University, Montreal, Quebec; 4) Department of Chemistry, Utrecht University, Utrecht, Netherlands; 5) Johns Hopkins Cystic Fibrosis Center, Johns Hopkins University, Baltimore, Maryland; 6) Department of Physiology, University of Texas Southwestern Medical Center, Dallas, Texas; 7) Cystic Fibrosis Foundation, Bethesda, Maryland; 8) Department of Anatomy, Physiology and Genetics, Uniformed Services University, Bethesda, Maryland; 9) Department of Biological Sciences, University of Pittsburgh, Pittsburgh, Pennsylvania; 10) Department of Cell Biology and Physiology, University of Pittsburgh, Pittsburgh, Pennsylvania; 11) Department of Biochemistry & Molecular Biology, Oregon Health & Science University, Portland, Oregon.

High throughput screening (HTS) has emerged as a powerful tool to probe large regions of chemical space and identify therapeutic agents with new biological properties. Because HTS is generally based on a rapid, simple, and binary cellular or biochemical phenotype, it does not require a priori knowledge of a precise cellular target. The strategy has proven particularly well suited for diseases with complex cellular physiology such as Cystic Fibrosis in which inherited mutations disrupt intracellular trafficking and target CFTR for rapid degradation. A potential weakness of HTS, however, is that active compounds often lack a known mechanism of action. This limits the ability to predict potential long-term toxicities and more importantly, frustrates attempts to identify and rationally develop alternate molecular scaffolds that act via different cellular pathways. Here we report on the results of an international consortium established to augment HTS efforts aimed at correcting intracellular trafficking of the F508del variant of cystic fibrosis transmembrane conductance regulator (CFTR). Our strategy was to identify intracellular pathway(s) affected by compounds or conditions that correct CFTR trafficking using a diverse array of cell-based and in vitro assays that query distinct aspects of CFTR biology. The assays employed are hierarchically overlaid on a modified scheme of the secretory pathway, which we refer to as the CFTR roadmap. Central nodes of the scheme were designed to direct consortium efforts and define global effects on CFTR function, structure, surface expression/stability, ER associated degradation, intracellular trafficking, and biophysical properties of CFTR folding. Within each major node, specific assays were also developed to more precisely interrogate the corresponding cellular machinery involved. This empirical, data-driven analysis yields a complex cellular 'fingerprint' or 'signature' that provides valuable insight into mechanism and can be used to compare different correction strategies. The approach and assay panel are intended for collaborative access by members of the CF research community and provide a complementary and novel platform to HTS efforts for genetic and acquired disease states. Supported and funded by CFFT.

The Pharmacological Chaperone AT1001 Increases rhα-Gal A-mediated Cellular Uptake and Substrate Reduction in vitro and in a Mouse Model of Fabry Disease. *A.E. Schilling, R. Khanna, B.L. Young, J.J. Flanagan, Y. Lun, L. Pellegrino, M. Frascella, J. Feng, R. Soska, B. Ranes, H. Do, D.J. Lockhart, K.J. Valenzano, E.R. Benjamin.* Amicus Therapeutics, Cranbury, NJ.

Fabry disease is an X-linked lysosomal storage disorder caused by mutations in the gene that encodes α-galactosidase A (α-Gal A), and is characterized by pathological accumulation of globotriaosylceramide (GL-3). Regular infusion of recombinant human α-Gal A (rhα-Gal A; agalsidase beta, Fabrazyme®, Genzyme Corp. or agalsidase alpha, Replagal™, Shire Human Genetic Therapies, Inc.), termed enzyme replacement therapy (ERT), is the primary treatment for Fabry disease. However, rhα-Gal A has low physical stability (especially at neutral pH and body temperature), a short circulating half-life, and variable access and uptake across different tissues. The iminosugar AT1001 (migalastat hydrochloride) is a pharmacological chaperone that selectively binds endogenous α-Gal A (wild-type and mutant forms), increasing physical stability, lysosomal trafficking, and total cellular activity. We hypothesized that AT1001 could also improve the pharmaceutical and pharmacological properties of exogenous rhα-Gal A. In vitro, AT1001 increased the physical stability of rhα-Gal A (agalsidase beta), preventing denaturation and loss of activity at neutral pH and 37 °C. In cultured Fabry fibroblasts, AT1001 co-incubation with the recombinant enzyme increased the amount of rhα-Gal A protein (4- to 5-fold) and enzymatic activity (3-fold) recovered in cell lysates, and importantly, resulted in up to 31% greater GL-3 reduction than that seen after incubation with rhα-Gal A alone. The potencies for rhα-Gal A cellular uptake and GL-3 reduction were increased by 4- and 5-fold, respectively, after co-incubation with AT1001. In wild-type rats, oral administration of AT1001 in combination with intravenous rhα-Gal A led to a 2-fold increase in the circulating half-life of the enzyme. In GLA knockout mice, AT1001 co-administration increased rhα-Gal A enzyme activity in skin, heart, and kidney by as much as 400%, and importantly, reduced tissue GL-3 levels by as much as 30%, over that seen with rhα-Gal A alone. Collectively, these results indicate that AT1001 increases the stability and cellular uptake of rhα-Gal A when co-administered, translating to greater enzyme activity and substrate turnover in situ. As such, AT1001 may also reduce the quantity of ERT required to treat Fabry patients, and thus warrants further clinical investigation.

Developing RNAi therapy for FSHD candidate genes. *S. Garwick[1], L. Wallace[1,2], S. Harper[1,2,3].* 1) Ctr Gene Therapy, Res Inst at Children's Hosp, Columbus, OH; 2) Molecular, Cellular, and Developmental Biology Graduate Program, The Ohio State University, Columbus, OH; 3) Department of Pediatrics, The Ohio State University College of Medicine, Columbus, OH.

Over the last 15 years, muscular dystrophy gene therapy strategies have been primarily aimed at replacing defective or missing genes underlying recessive disorders, such as Duchenne muscular dystrophy (DMD). However, these gene replacement strategies are not feasible for treating dominant diseases. Instead, patients bearing dominant mutations would likely benefit from reduction or elimination of the abnormal allele. Until very recently, there was no feasible mechanism to reduce or eliminate disease genes, and molecular therapy development for dominant muscular dystrophies was largely unexplored. RNA interference (RNAi) has recently emerged as a powerful tool to suppress any gene of interest in a sequence specific manner. As such, RNAi is a leading candidate strategy to silence dominant disease genes, including those involved in muscular dystrophies such as facioscapulohumeral muscular dystrophy (FSHD). FSHD is a dominant genetic disorder caused by contraction of D4Z4 repeats on chromosome 4q35. Current evidence supports that FSHD is an epigenetic disorder. FSHD-associated deletions produce chromatin changes that may aberrantly up-regulate multiple myotoxic genes. Currently, two FSHD-candidate genes, FRG1 and DUX4, have been shown to cause dystrophy-related phenotypes upon over-expression in vivo, suggesting their potential involvement in FSHD pathogenesis. Thus, RNAi therapies targeting FRG1 or DUX4 may offer the first targeted treatment for FSHD. Currently, only mouse models overexpressing FRG1 exist. To establish proof-of-principle for FSHD targeted RNAi therapy, we developed therapeutic microRNAs to reduce toxic FRG1 expression in mice. These microRNAs (miFRG1) caused significant knockdown of FRG1 mRNA and protein in vitro. When delivered via AAV6 viral vectors to FRG1-high mouse muscle, miFRG1, but not control miGFP microRNAs, significantly reduced toxic FRG1 levels, and improved muscle mass, strength and histopathology. Specifically, miFRG1-transduced muscles were normal in size, showed no fibrosis or fat deposition in muscle, and had no evidence of myofiber degeneration or regeneration. Our results provide the first proof-of-principle for RNAi therapy targeting an FSHD candidate gene, and support its feasibility for other dominant muscular dystrophies in general.

Potential of murine bone-marrow mesenchymal stem cells (BM-MSC) in treatment of muscular dystrophy. *P. Onofre-Oliveira, P. Martins-Machado, D. Ayub-Guerrieri, D. Zilbersztajn-Gotlieb, A. Santos, M. Vainzof.* Human Genome Res Ctr, Univ Sao Paulo, Sao Paulo, SP, Brazil.

Human muscular dystrophies (MD) are a heterogeneous group of genetic disorders, with still no efficient treatments. Mouse models for these diseases are important tools for testing putative therapies. Identifying adult stem cells capable of restoring the function of affected muscles is a challenge. Bone-marrow mesenchymal stem cells (BM-MSC) are multipotent and also have immunosuppression and immunomodulation characteristics, which are important to be considered in their use for transplantation. The main objective of this study was to evaluate the therapeutic potential of BM-MSC in 3 different murine models for dystrophy: *Dmd^{mdx}* (dystrophin deficient, mild phenotype), *Lama2^{dy2J}*/J (laminin-α2 deficient, severe phenotype) and *Large^{myd}* (defect in glycosylation of α-DG, severe phenotype in older animals). Normal *C57Black* mice were also injected using the same protocol, to study homing and behavior of these cells under non-dystrophic conditions. BM-MSC were isolated from the femur of FVB/N eGFP mice and characterized by flow cytometry for stem cell markers before injection into dystrophic and control mice. Systemic intravenous injections were repeated at weekly intervals in 18 animals: 3 *C57Black*, 3 *Dmd^{mdx}*, 6 *Large^{myd}* and 6 *Lama2^{dy2J}*/*J*. The presence of donor cells was tracked in the recipient muscles by PCR of eGFP and western blotting. DNA of transplanted BM-MSC was found in 5 out of the 18 injected animals: 1 *C57Black*, 1 *Dmd^{mdx}*, 1 *Large^{myd}* and 2 *Lama2^{dy2J}*/*J*. Our results suggest that no homing problems occurred since these cells were properly engrafted in the target tissue both for hostile dystrophic environment as well as for the normal muscle. Additionally, the BM-MSC can stay and express proteins in the muscle tissue *in vivo*, despite the differences in MHC H2 haplotype of donor and receiver mice. Complementary additional studies with more treated animals and for a longer term are necessary to enhance the number of animals retaining the injected stem cells and to improve the amount of expressed muscle proteins leading to a better therapeutic effect. Financial support: FAPESP-CEPID, CNPq-INCT, FINEP, ABDIM.

3094/W

Cholesterol And The GM_2 Ganglioside Accumulate In Chédiak-Higashi Syndrome Cells And Are Released By A Small Lysosome Corrector Molecule. *AR. Cullinane[1], W. Introne[1], M. Huizing[1], WA. Gahl[1], W. Zheng[2], W. Westbroek[1].* 1) Medical Genetics Branch, NHGRI (NIH), Bethesda, MD; 2) NIH Chemical Genomics Center (NHGRI), National Institutes of Health, Bethesda MD.

Chédiak-Higashi syndrome (CHS; MIM #214500) is a rare autosomal recessive disorder characterized by partial oculocutaneous albinism, immunodeficiency, late onset neurological features and a mild bleeding tendency. Mutations are identified in the LYST/CHS1 gene in approximately 90% of patients, the protein product of which has an unknown function but is thought to be involved in the regulation of lysosomal size and trafficking. Approximately 85% of affected individuals with nonsense or frameshift mutations develop the classic early-onset accelerated phase of lymphoproliferative infiltration of the bone marrow and reticuloendothelial system. Atypical late onset CHS patients who generally have missense mutations, and classic patients who undergo stem cell transplantation develop neurological features in adolescence and early adulthood. These features include low cognitive abilities, balance abnormalities, ataxia, tremor, absent deep-tendon reflexes and motor and sensory neuropathies. The cellular hallmark of CHS is the presence of enlarged lysosomes and lysosome-related organelles in many cell types. Confocal immunofluorescence microscopy of two atypical CHS patients' fibroblasts and melanocytes showed an accumulation of GM_2 gangliosides and cholesterol in enlarged lysosomal structures. GM_1 did not accumulate in these cells. When a small lysosome corrector compound was added to the growth medium of the affected fibroblasts for five days of culture, both the GM_2 and cholesterol accumulation dispersed and the cells appeared to be more like control cells. Using dot blot analysis, the actual amount of GM_2 also decreased after drug treatment in the patient cells similar to that of control cells. The lysosomal size in CHS cells was not corrected by compound treatment. Both GM_2 and cholesterol accumulation has previously been shown to cause failure of neuronal dendrite outgrowth, impaired oligodendrocyte development and myelin biogenesis and neurodegeneration. The identification of these two molecules accumulating in CHS cells correlates with neurological dysfunction and could explain the neurological findings in CHS. Furthermore, the discovery of a small compound that reduces the accumulation of these molecules could potentially be used in the clinical management of the condition.

Parent care-giver administration of home enzyme replacement therapy in the mucopolysaccharidoses (MPS disorders). *K. Kim[1,2], B. Burton[1,2].* 1) Div Genetics, Children's Memorial Hospital, Chicago, IL; 2) Northwestern University, Feinberg School of Medicine, Chicago, IL.

For the past several years, enzyme replacement therapy for MPS I, II and VI has been commercially available and recommended for many affected patients. Given that the enzyme replacement product is generally well tolerated with many patients experiencing minor or no infusion associated reactions, patients at many treatment centers are being transitioned to weekly home infusions. The feasibility of home infusions for the MPS disorders have now been reported in the literature; and, it has been the experience at our center that even severely affected patients are able to safely receive ERT in the home setting. Traditionally, trained infusion nurses are brought into the home to administer the weekly IV infusions. However, some families may experience difficulty finding an appropriate home infusion nurse, may be uncomfortable with a nurse in the home or may experience missed infusions due to the lack of flexibility of the home infusion nurse's schedule. We now report on two families, one with a 5 year old MPS II child and the other with a 12 year old MPS VI child, in which a parent care-giver has been successfully trained to administer the weekly IV infusions of idursulfase (Elaprase®) and galsulfase (Naglazyme®), respectively. The parents report complete comfort with obtaining IV access, following the infusion protocol, obtaining vital signs, and recording the infusion log, which is submitted to our office for review. Both parents report this to be a positive experience for themselves and their child. We, therefore, conclude that in some circumstances, parents can be trained to successfully administer ERT for their child in the home.

Antisense-mediated reading frame restoration is presently the most promising therapeutic approach for Duchenne muscular dystrophy (DMD). In this approach, antisense oligoribonucleotides (AONs) induce specific exon skipping during pre-mRNA splicing to restore the disrupted open reading frame and allow synthesis of internally deleted, partly functional Becker-like dystrophin proteins. The approach is theoretically applicable to over 70% of all patients. Proof of concept has been achieved in cultured muscle cells from patients carrying different mutation types, in the mdx mouse and dog models and recently in patients as well. In a first trial published in 2007 (van Deutekom et al. NEJM) we showed exon 51 skipping and dystrophin restoration in four patients after local intramuscular AON injections. A subsequent systemic trial has recently been successfully completed by Prosensa, as a multicenter one-month dose-finding trial, using subcutaneous administration. This better route for self-administration was previously tested to be efficient in reaching proper muscle AON levels, with a lower peak circulation level as intravenous administration. The 12 patients enrolled showed a clear dose response, both of skipping and dystrophin restoration, without adverse effects. A 6-months follow-up trial using the most effective dosage is underway. Our preclinical further research now focuses on the next steps in developing and improving therapy: the development of more refined readouts for therapeutic success using transcriptomics and proteomics technology, on different systemic delivery methods and long term treatment of dystrophic animal models, and supporting treatments to increase myogenesis. Finally, the success of the exon skipping work in DMD has led us to explore applications to genes affected in other diseases, including Huntington disease. Promising results have been obtained and will be presented.

Familial Dysautonomia (FD; Riley-Day Syndrome) is the best known and most frequent of a group of congenital sensory neuropathies characterized by widespread sensory and variable autonomic dysfunction. FD is a devastating disorder that involves both developmental and progressive neuronal degeneration. We have previously shown that mutations in the *IKBKAP* gene cause FD and that the major mutation results in a unique tissue-specific splicing defect that leads to variable reduction of IKAP protein. During an NINDS sponsored Drug Screening Consortium, we identified kinetin, a plant cytokinin, to be a potent modulator of *IKBKAP* splicing *in vitro*. Our recent *in vivo* mouse studies show that kinetin increases normal message and protein in all tissues tested, including brain. Most importantly, however, we have shown that kinetin improves *IKBKAP* splicing in human FD carriers. Recently, we have generated an *Ikbkap* knock-out model and have demonstrated for the first time that complete loss of *Ikbkap* results in embryonic lethality. We have also created several humanized transgenic lines using both normal and mutant human *IKBKAP* BACs and have shown that the tissue-specific splicing pattern seen in FD patients is modeled perfectly in these mice. Armed with these unique mouse models and the knowledge that we can directly target the splicing defect, we have now shown that increasing the amount of IKAP protein expression using the human transgene can prolong development by altering gene expression. These exciting results suggest that increasing IKAP protein by altering mRNA splicing using kinetin may well prove efficacious in FD patients.

Orally Delivered Synthetic *cis*-Retinoid Therapy (QLT091001) in Subjects with Leber Congenital Amaurosis (LCA): Preliminary Results of a Phase Ib Open Label Clinical Trial. *D.A. Saperstein[1], H.A. Strong[2], J. Racine[3], O. Cuzzani[2], S-A. Crocker[2], E. Esteban[3], A. Omar[3], M. Darvish-Zargar[3], K. Palczewski[4], R.K. Koenekoop[3].* 1) Vitreoretinal Associates of Washington, Seattle, WA; 2) QLT Inc., Vancouver, BC; 3) Montreal Childrens Hospital, Department of Ophthalmology, McGill Univsersity, Montreal QC; 4) Case Western Reserve University, Department of Pharmacology, Cleveland, OH.

Purpose: To assess visual function changes and safety parameters after the oral administration of a synthetic *cis*-retinoid, QLT091001, in subjects with LCA due to mutations in the Lecithin:Retinol Acyltransferase (LRAT) or Retinal Pigment Epithelial 65 Protein (RPE65) genes. There are no proven therapies for this progressive retinal degeneration. QLT091001 has been shown to restore vision in mouse and dog models with LCA. **Methods:** This ongoing, IRB approved, Phase Ib open-label, proof-of-concept clinical trial evaluates the safety and efficacy of QLT091001 in subjects with LCA due to RPE65 or LRAT gene mutations. Subjects are treated daily with oral QLT091001 for 7 days at the Montreal Children's Hospital. Visual function testing (ETDRS visual acuity [VA], Goldmann visual fields [GVF], Full-field stimulus threshold testing [FST], Electroretinograms, and Color Testing), Optical Computed Tomography, complete ophthalmic and physical exams, electrocardiograms and blood testing are completed before and after therapy at predetermined time points. **Results:** 3 subjects with LRAT mutations have been enrolled. The 1st subject was a 10 year old girl with baseline 20/200 VA and 30° GVFs. After 7 days of therapy she regained temporal islands on the GVF, VA increased to 20/80 and retinal sensitivity improved. GVF expanded to 85° by month 1 and both VA and GVF have remained stable for 4 months. The 2nd subject was her 12 year old brother with baseline VA of 20/800 and GVF of 60°. His VA improved 15 letters at Day 6 and has remained stable for 3 months. Both of these patients, and their parents, reported improvements in their activities of daily living (ADLs). The 3rd subject was an unrelated 38 year old woman with baseline VA of hand motion and no response on GVF testing. After 7 days of treatment, her VA was 2 letters on the ETDRS chart and GVF improved. In the 3 subjects, there were no SAEs. Transient headache and photophobia were reported and reversible elevations in triglyceride levels and reduction in HDL were recorded. **Conclusions:** 7 days of oral QLT091001 appears to improve VA, GVF, FST in both eyes and ADLs in these 3 subjects . The effect lasted up to 4 months. Adverse events were mild to moderate, transient and/or reversible. These changes in visual parameters show that an oral synthetic retinoid may rescue vision in subjects with LCA due to LRAT mutations. We intend to complete study enrollment of LCA subjects with RPE65 mutations.
